Abstract: Robust evidence in nutritional psychiatry has highlighted the relationship between healthy dietary patterns and positive mental health throughout the life span. In late childhood and adolescence, eating behavior and social environment of eating change considerably as youth gain autonomy around food choices. This is also a time period wherein a number of mental health problems start emerging. The relationship between diet and mental health has been relatively under-investigated in children and adolescents. Studies have linked higher child behavior checklist (CBCL) scores with lower fruit and vegetable intake and with increased intake of processed foods. Putative mechanisms underlying this association include: 1) fruits/vegetables may provide the folate required for neurotransmitter synthesis critical for mood and emotion regulation 2) processed food has been associated with increased neuroinflammatory markers. However, most of these studies have been limited by small sample size as well as confounding contextualizing factors such as socioeconomic status. The Adolescent Brain Cognitive Development Study ^{SM} (ABCD Study®) a longitudinal, multi-site study has recruited a sociodemographically diverse cohort of more than 11,000 children with the goal of investigating a wide range of factors that influence developmental trajectories across adolescence. Here, we examine the cross-sectional association between dietary pattern and behavioral impairment in the ABCD sample at Year 1 follow-up. Dietary pattern was assessed with child nutrition questionnaire administered to the caregiver asking about frequency of consumption of 14 food categories in the past week. Higher scores indicate healthier dietary patterns. The CBCL was used to assess the mental health and behavior. Generalized additive mixed models, which modelled family nested within site as random effects, were used to examine the statistical relationship between dietary scores and CBCL scores. The following fixed effects covariates were used child's age, child's body mass index (BMI), waist circumference, sex, race, ethnicity, parental higher education, family income and marital status. Our results showed a significant association between dietary scores and CBCL scores such that higher scores on the nutrition questionnaire were associated with lower CBCL scores after controlling for covariates. These results suggest that a healthy diet (more fruits, vegetables and lower fast and processed food) may be associated with better mental health in early adolescence. Thus, modifying dietary behaviors may be a crucial strategy for maintaining optimal mental health in this age group.

Title: Early adolescent inhibition of prefrontal GABAergic activity disrupts the maturation of prefrontal E-I balance in adulthood.

Authors: *E. FLORES-BARRERA, E. ARTUR DE LA VILLARMOIS, A. CABALLERO, K. Y. TSENG;
Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago (UIC), Chicago, IL

Abstract: Understanding the processes that contribute to prefrontal cortex (PFC) maturation are crucial to reveal the neural mechanisms underlying the development and onset of major psychiatric disorders such as affective and substance use disorders, and schizophrenia. A hallmark of PFC maturation is the *re-calibration* of an excitatory-inhibitory (E-I) balance during adolescence. Here we asked the extent by which local GABAergic activity in the PFC during adolescence plays a role in the functional acquisition of an enhanced E-I control of PFC output in adulthood. Towards this goal, we implemented a chemogenetic approach to inhibit PFC GABA interneurons by using an inhibitory DREADD driven by an interneuron-specific DLX promoter. Using *ex-vivo* and *in vivo* electrophysiological measures, we found that transient inhibition of PFC GABAergic interneurons within the early adolescent window prevents the maturation of local GABA function and the normal inhibitory control of afferent drive without altering the level of AMPA-mediated synaptic transmission. As a result of the selective inhibitory disruption, the AMPA/GABA ratio in the PFC remains >1.0 as seen in P35-45 animals. Notably, this period of sensitivity to transient inhibition of PFC GABA interneurons was no longer apparent after P45. Collectively, these results indicate that an activity dependent mechanism contributes to the functional maturation of PFC GABAergic function during adolescence.

Title: Mir-218 as a potential target to regulate prefrontal cortex development in adolescence

Authors: *A. MORGUNOVA[1], M. GIROUX[3], G. A. HERNANDEZ[4], C. FLORES[2];

Abstract: Adolescence is a period of increased vulnerability to psychiatric disorders, including major depressive disorder (MDD), and there is a need for markers to identify individuals at risk. Our studies on male mice found that miR-218 regulates expression of the guidance cue receptor DCC, which controls prefrontal cortex (PFC) maturation in adolescence, and functions as a switch between vulnerability and resilience to depressive-like traits in adult mice. miR-218 is downregulated in the adult PFC of individuals with MDD who died by suicide in comparison to psychiatrically-healthy sudden death controls. Furthermore our rodent findings show that microRNA levels in blood can match expression in the brain, and elevated "adult-like" miR-218 levels in adolescence predict risk to stress-induced behavioral abnormalities in adulthood. Our next objective is to assess the impact of altered miR-218 levels in adolescence via translational non-invasive manipulations, and to begin investigating the role of miR-218 in female rodents. In male mice, we administered anti-sense oligonucleotides (antagomiR-218 or a scrambled sequence) with intranasal spray and characterized behavioral traits. Mice that received intranasal antagomiR-218 in adolescence showed anxiolytic-like behaviors on elevated arms maze as adults ($p=0.033$, $n=20$), consistent with effects observed following adolescent antagomiR-218 intra-PFC microinfusions. We also assessed developmental trajectories of miR-218 expression in the PFC in females and find a rapid rise of expression in early adolescence, reaching adult-like levels by mid adolescence ($F(2, 23)=11.38$, $p=0.0004$, one-way ANOVA). This is in contrast to miR-218 expression in the male PFC, which increases gradually during early and mid adolescence until adulthood. These results suggest that miR-218 administered non-invasively in adolescence can have lasting impact on behavior. The timing and the direction of this effect, however may differ between males and females. Elucidating molecular mechanisms underlying adolescent PFC development and individual differences in susceptibility to stress could provide insight into the discovery of biomarkers of psychiatric risk.

Title: Neuropathological Signatures Connecting Early-Life Trauma to Compulsive Eating Behavior and Obesity

Authors: *P. ONTIVEROS-ANGEL[1], V. E. WILLIAMS[1], T. B. SIMON[1], F. SHARAFEDDIN[1], J. LOU[2], I. DELA PENA[3], C. VIET[4], M. POMPILUS[5], M. FEBO[5], J. D. FIGUEROA[1];

Abstract: Background: Childhood trauma heightens the risk of severe weight gain and adult obesity. However, the neuropathological correlates of increased risk of obesity in individuals exposed to early-life trauma remain poorly understood. Preclinical findings from our laboratory support the notion that alterations to cortical structures that control top-down control of feeding behavior, may account for the added risk of adult obesity in individuals with early life trauma. While anxiety and stress-related disorders are at least twice as prevalent in women as men, the neurobiological basis of this discrepancy has not been well studied. The present study identifies sex-dependent neuroadaptations mediating the elevated risk of obesity, cognitive deficits, and aberrant feeding behaviors in adolescents exposed to an obesogenic diet and early life trauma. **Methods:** Male and female adolescent Lewis's rats (n=96, 48M, 48F) were exposed to a novel two-hit model of predator-based psychosocial stress (PSS) followed by intermittent access to a Western-like high-saturated fat diet (WD). Animals were fed for twelve weeks with Western Diet (WD, 41% kcal from fat) or a matched control diet (CD, 13% kcal from fat) and evaluated longitudinally for molecular and behavioral effects. Subsequently, animals were exposed to three cycles of an intermittent feeding paradigm to evaluate binge eating-like behaviors. In female rats, the estrus cycle was monitored to assess cyclicity. Brains were scanned using MRI techniques to identify microstructural changes due to consumption of WD and challenges to their allostatic load. **Results:** We found that female rats displayed binge eating-like feeding behavior when intermittently exposed to WD over three cycles of binge eating. This phenotype was associated with heightened anxiety-like behaviors in the elevated plus-maze and enhanced background anxiety. Interestingly, in female rats exposed to PSS, estrus cyclicity evaluation revealed dysregulated length and variability in stage frequency. In addition, anatomical changes were found in the brains of the rats that consumed WD and were exposed to PSS. **Conclusions:** Our findings demonstrate that early life stress and consumption of an obesogenic WD during adolescence heightens behavioral vulnerabilities associated with risk for anxiety and stress-

related eating disorders. Furthermore, our model recapitulates sex differences in the traumatic stress response and binge-eating behaviors, identifying sexual dysmorphisms and neuroadaptative links between early-life trauma and compulsive eating behaviors.

Title: Long-term inactivation of sodium channels as a mechanism of adaptation in CA1 pyramidal cells with implications for place cell firing

Authors: *C. UPCHURCH[1], C. L. COMBE[2], C. J. KNOWLTON[3], C. C. CANAVIER[4], S. GASPARINI[5];
[1]Louisiana State Univ. Hlth. Sci. Center-, New Orleans, LA; [2]Neurosci. Ctr., [3]Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [4]Cell Biol. and Anat., LSU Hlth., New Orleans, LA; [5]Neurosci. Ctr. of Excellence, LSU Hlth. - New Orleans, New Orleans, LA

Abstract: The hippocampus is involved in memory and spatial navigation. Many CA1 pyramidal cells function as place cells, increasing their firing rate when an animal traverses a specific place field in its environment. The dependence of CA1 place cell firing on position within the place field is asymmetric as shown by *in vivo* recordings. We investigated this asymmetry by injecting triangular depolarizing current ramps to approximate the spatially-tuned, temporally-diffuse depolarizing synaptic input received by these neurons while traversing a place field. Ramps were applied to rat CA1 pyramidal neurons *in vitro* (slice electrophysiology) and *in silico* (multi-compartmental NEURON model using several biophysically realistic morphologies). Under control conditions, CA1 neurons fired more action potentials at higher frequencies on the up-ramp versus the down-ramp, producing asymmetric, adapting voltage responses. This effect was more pronounced for dendritic compared to somatic ramps. Pharmacological blockers specific for K^+ currents that are known to underlie adaptation (SK, M-type or A-type) did not affect the asymmetry, measured as the ratio between the number of spikes on the up-ramp over those on the down-ramp. We incorporated into our model a five-state Markov scheme for $Na_V1.6$ channels with spatially-dependent parameters, in agreement with the literature showing that long-term inactivation increases along the dendrites with distance from

the soma. This spatial dependence was sufficient to explain the more pronounced adaptation in dendritic versus somatic ramps. Modeling two components of the delayed rectifier (K_v1 and K_v2) separately was essential because of the role of K_v2 channels in the control of the firing frequency. PKC activators like the phorbol ester Phorbol-12, 13 Dibutyrate (PDBu) are known to reduce Na_V channel long-term inactivation in CA1 neurons. *In vitro* application of PDBu removed attenuation in back-propagating spike amplitude during dendritic spike trains, consistent with decreased Na_V long-term inactivation. Moreover, PDBu greatly reduced adaptation, consistent with our hypothesized mechanism. Our synergistic experimental/computational approach shows that long-term inactivation of $Na_V1.6$ is the primary mechanism of adaptation in CA1 pyramidal cells, and it is strongly affected by phosphorylation, and therefore by neuromodulators. Since changes in adaptation control the position of the center of mass of the place field, modulation of $Na_V1.6$ long-term inactivation levels could affect the timing of place cell firing.

Title: On the dynamic modulation of spike threshold and depolarization baseline in mouse hippocampal CA1 pyramidal neurons

Authors: *R. MIGLIORE[1], D. BIANCHI[1], P. VITALE[1], M. GARAD[2], P. A. POUSINHA[3], H. MARIE[3], V. LESSMANN[2], M. MIGLIORE[1];

Abstract: In this work we study an electrophysiological feature often observed in recordings from mouse CA1 pyramidal cells. It consists of a progressive increase in the spike threshold and in the depolarization baseline (i.e. the minimum value of the membrane potential between

successive action potentials, DBL) as a function of the somatic current injection. These effects are potentially important, because they can directly affect neurotransmitter release and, more generally, the efficacy of synaptic transmission. However, they have been ignored so far by experimentalists (probably because of the technical difficulty in measuring fast transient mechanisms during a stimulus) and modelers (because none of the current computational models is able to reproduce them). Here we present a model addressing this point. It suggests that these effects can be an indication of a significant dynamic change of the membrane properties occurring at the input location. The results suggest that the processes responsible for the spike threshold and DBL increase can be a local, stimulus-induced, dynamic alteration of local ion concentrations and permeabilities, and point to potentially important consequences for I/O and dendritic integration properties that should be considered by both modelers and experimentalists, if they occur under normal *in vivo* activity. Modelers implementing detailed computational models of neurons and networks subjected to strong inputs, without taking into consideration the effects, can miss low frequency components (in the θ range in our case) of membrane oscillations both at the soma and at dendritic synaptic locations. The former can alter the frequency content of the signal propagated to the rest of the network, the latter can unpredictably alter the induction of local synaptic plasticity. Experimentalists may want to reconsider the range of input currents used *in vitro* to assess the intrinsic neurons' excitability. Hippocampal CA1 pyramidal neurons of mice fire action potentials at an average frequency that is approximately 5-fold higher than in rats. If this activity can be considered physiologically plausible, it implies that the range of currents used to test neurons of other species needs to be extended to include strengths that allow to fire action potential at the same rate as for the mouse. In this case, and assuming that the mammalian's hippocampus has similar local ionic microenvironment at rest to the mouse, the model predicts that the same phenomena should also be observed for other species during inputs able to generate action potentials above approximately 40 Hz, with an extent of DBL that will depend on the specific neuron properties.

Title: Activation of dopamine D1-like receptors ameliorates decreased intrinsic excitability potentiation of CA1 pyramidal cells induced by neonatal blockade of NMDA receptors

Authors: *E. GRIEGO, E. J. GALVÁN;
CINVESTAV, Mexico City, Mexico

Abstract: Dysregulation of dopaminergic transmission combined with transient hypofunction of N-methyl-D-aspartate receptors (NMDARs) is a key mechanism that may underlie cognitive symptoms of schizophrenia. Therefore, we aimed to identify electrophysiologic alterations in animals neonatally treated with the NMDA receptor antagonist, MK-801 or with saline solution. Patch-clamp whole-cell recordings from MK-801-treated animals revealed altered passive and active electrophysiologic properties compared with CA1 pyramidal cells from saline-treated animals, including upregulation of the K^+ inward-rectifier conductance and fast-inactivating and slow/non-inactivating K^+ currents. Upregulation of these membrane ionic currents reduced the overall excitability and altered the firing properties of CA1 pyramidal cells. We also explored the capability of cells treated with MK-801 to express intrinsic excitability potentiation, a non-synaptic form of hippocampal plasticity associated with cognition and memory formation. CA1 pyramidal cells from animals treated with MK-801 expressed a diminished intrinsic excitability potentiation and had blunted synaptic potentiation. Interestingly, we found that activation of D1-like dopaminergic receptors with the agonist SKF-38, 393, partially restores the plastic capabilities of CA1 PCs. Our results offer a molecular and mechanistic explanation based on dysregulation of glutamatergic in addition to dopaminergic transmission that may contribute to the understanding of the cognitive deterioration associated with schizophrenia.

Title: Plateau-generating and pacemaker neurons have similar ion channel subtypes with different voltage and kinetic properties

Authors: *C. NEVEU, J. H. BYRNE;
Dept. of Neurobio. and Anat., McGovern Med. Sch. of UTHSC at Houston, Houston, TX

Abstract: Some neurons express a plateau of activity greatly outlasting the stimulation, whereas others do not. The difference between these firing patterns is generally believed to be due to the

different expression of specific ion channels (e.g., persistent Na^+, and Ca^{2+}). However, an alternative possibility is that the same channels are expressed but they have different properties. To examine this issue, we compared two different plateau-generating neurons, B51 and B64, with a known pacemaking neuron, B8, in *Aplysia californica.* We found that all three neurons expressed a delayed K^+, A-type K^+, L-type and R-type calcium and preliminary data suggests all express the persistent Na^+ (Napp), and K_{Ca} was expressed in B8 and B51. Suprisingly, several channel properties were similar in neurons with vastly different firing properties. For example, the voltage dependency of activation of L-Type Ca^{2+} and R-Type Ca^{2+} was similar between B51, B64, and B8. The voltage dependency of activation and inactivation of the delayed K^+ was similar in B51, B64, and B8. Whereas other properties were dramatically different in neurons with similar firing properties. For example, a steeper voltage dependency and higher current density in the A-type K^+ in B51 compared to B64 and B8. The activation kinetics of the L-Type Ca^{2+} and R-Type Ca^{2+} was slower in B8 and B51 compared to B64. Conductance-based computational models will help explain how the different firing properties emerge from the unique ion channel properties and provide insights into how channel properties affect computations within a network.

Title: Mechanisms that regulate firing rate set points are cell type-specific

Authors: *N. TROJANOWSKI, G. TURRIGIANO;
Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: To enable robust network stability in the face of dynamic sensory inputs and developmental changes, rodent neocortical pyramidal neurons actively maintain their mean firing rates within a target range. While this target range, or firing rate set point (FRSP), can span several orders of magnitude within a transcriptional cell type, individual pyramidal neurons reliably return to their own specific FRSP during prolonged activity perturbations. Thus, individual FRSPs are actively maintained. High and low FR neurons in rodent frontal cortex and hippocampus are differentially modulated by sleep states, suggesting that they are functionally distinct and may play unique roles in information storage and transmission. However, little is

known about the factors that generate this broad distribution of FRSPs observed across different cell types *in vivo*.
To gain selective access to high and low activity neurons, we used the permanent green-to red Ca^{2+}- and UV-dependent photoconversion of CaMPARI2 to label neurons in rodent visual cortex based on their mean activity levels. Red/green ratios following 30-minute *in vivo* photoconversion were lognormally distributed, mirroring *in vivo* firing rates, and neurons with greater *in vivo* photoconversion had higher firing rates *ex vivo*. During *ex vivo* photoconversion, neurons with higher firing rates underwent greater changes in CaMPARI2 red/green ratio. Thus, CaMPARI2 labeling is sensitive enough to detect differences in mean firing rates and differentiate between neurons with low and high FRSPs.
We next measured intrinsic and synaptic electrophysiological properties in high and low FR neurons in different cell types. Using *in vivo* and *ex vivo* photoconversion protocols, we found that high activity layer 4 (L4) pyramidal neurons had greater intrinsic excitability and received stronger inputs from other L4 pyramidal neurons, although there were no consistent differences in total E/I ratio between these neurons. In contrast, we then found that in L5 TLX-3-positive neurons (a subset of thin-tufted, regular spiking pyramidal neurons), high activity neurons received stronger excitatory input but had no increase in intrinsic excitability. Experiments using RNAseq to identify gene transcripts differentially expressed in high and low activity neurons are ongoing.
Together, our data demonstrate that intrinsic excitability and excitatory synaptic strength can be important contributors to the broad range of FRSPs observed within single cell types *in vivo*, though their relative importance in determining FRSPs of individual neurons differs across cell types.

Title: Increased excitability of pyramidal neurons in the secondary motor cortex mediates cocaine relapse

Authors: *D. HUANG[1], S. IM[2], J. M. CIALDELLA[2], A. V. SALINAS[2], Y. Y. MA[1];
[1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Binghamton University, SUNY, Vestal, NY

Abstract: Drug-induced impairments to the medial prefrontal cortex (mPFC) contribute to persistence of drug craving and relapse. However, the cortical neuronal substrates underlying habitual drug-seeking behaviors remain unclear. Here, we explored the motor cortex, including the primary and secondary motor areas (M1 and M2), as well as the mPFC, including the infralimbic (IL), prelimbic (PrL), and anterior cingulate (AC) cortex. Sprague-Dawley (SD) rats, experienced with intravenous self-administration (IVSA) of saline or cocaine, 1 hour per day for 5 days, were tested *in vivo* or *in vitro* 1 or 45 days after withdrawal (WD1 or WD45). Cocaine-experienced rats showed significant increases of drug seeking behaviors on WD 45 vs. WD1. Whole-cell patch clamp recordings of pyramidal neurons in layer 2/3 (denoted L2) from cocaine-experienced rats demonstrated a transiently decreased excitability in the PrL and M2 on WD1, compared to that in saline rats. Interestingly, only the M2 from cocaine-experienced rats showed an increased excitability on WD45. No differences of excitability between saline vs. cocaine rats were detected in layer 5 (denoted L5) in any of the 5 cortical areas tested. $GABA_A$ receptor agonist, muscimol, dose-dependently (0.1 mM, 0.3 mM and 10.mM) decreased the excitability of L2 pyramidal neurons in the M2 on WD 45. *In vivo* bilateral microinjection of muscimol primarily targeting L2 in the M2 attenuated cocaine-seeking behaviors on WD45. In addition, chemogenetic inhibition by activating Gi-coupled DREADD receptor primarily expressed in L2, but not L5, in the M2 attenuated cocaine-seeking behaviors on WD45. Neither pharmacological nor chemogenetic inhibition approaches altered general locomotor activity. Our results demonstrate that cocaine IVSA induces differential short-term and prolonged excitability changes in the motor cortex and mPFC. Importantly, the increased excitability in the M2, particularly in L2, as a prolonged effect after cocaine IVSA, could be a novel target in preventing drug-relapse during withdrawal.

Title: Sympathetic postganglionic neurons as a potential locus of modulation and plasticity in the sympathetic pathway

Authors: *N. H. CHANG[1], M. L. MCKINNON[1], S. HOCHMAN[2], A. A. PRINZ[1];
[1]Dept. of Biol., [2]Dept. of Physiol., Emory Univ., Atlanta, GA

Abstract: Thoracic sympathetic postganglionic neurons (tSPNs) in paravertebral chain ganglia are the final autonomic output neurons regulating vascular and thermoregulatory systems. tSPNs were long thought to act as relays of the spinal signals, however, we previously used computational modeling to show that tSPNs integrate inputs more effectively than presumed. Important questions are whether tSPN membrane properties: (i) are tuned to optimally process synaptic inputs, (ii) represent a locus for behavioral state-dependent modulation, and (iii) undergo compensatory homeostatic changes in excitability due to long-term alterations in central preganglionic synaptic drive. We address these questions in a tSPN mouse model. Its membrane currents include: a fast sodium current I_{Na}; a low-threshold calcium current I_{CaL}; a delayed-rectifier potassium current I_{Kd}; a fast transient potassium current I_A; a slow and non-inactivating potassium current I_M; and a calcium-dependent potassium current I_{KCa}; a hyperpolarization-activated inward current I_H; and a leak current I_{leak}. To simulate synaptic input from the spinal cord, we provide the tSPN model with excitatory synaptic conductance waveforms that match measurements from mouse tSPNs in number, synapse strength, and presynaptic firing pattern. We find that this synaptic input results in an increase of synaptic gain, confirming that tSPNs may be able to integrate and boost spinal inputs. We next individually vary the maximal conductance for each membrane current from its canonical value and observe that: 1) Varying the conductances for I_{Kd}, I_A, and I_H has little effect on synaptic gain. These currents therefore may not be effective targets for modulation or plasticity. 2) Increasing the conductance for I_{Na} increases synaptic gain, as expected for an inward current. 3) Increasing the conductance for I_M, I_{KCa}, and I_{CaL} reduces synaptic gain. For the I_M and I_{KCa} this occurs because they are outward currents, thus increasing their conductance decreases tSPN excitability. I_{CaL} is an inward current but has a negative effect on synaptic gain because it indirectly reduces excitability via increasing the outward current I_{KCa}. Our simulations implicate the tSPN membrane currents I_{Na}, I_M, I_{KCa}, and I_{CaL} as factors that may determine tSPN excitability and synaptic gain, with I_{Na} as a positive regulator and I_M, I_{KCa}, and I_{CaL} as negative regulators. These currents may be suitable targets for plasticity and modulation of signal integration in the thoracic sympathetic pathway, including in therapeutic approaches that aim to control dysfunction in autonomic drive (e.g. after spinal cord injury).

Abstract: Neural circuits are remarkable in their ability to simultaneously function reliably and flexibly adapt to changes in their environment. In addition, circuits that perform the same physiological function can be built with different underlying parameters. It remains unclear how neural circuits can balance adaptation to perturbation with physiological stability. To study this question, we used the pyloric circuit within the stomatogastric ganglion of the crab *Cancer borealis*, a neural circuit with a long history of both experimental and computational studies. Here we present the effects of one type of perturbation, high extracellular potassium concentration, on both biological neurons and computational models. Pyloric neurons of the crab stomatogastric ganglion (STG) initially become quiescent, then recover spiking activity in high potassium saline (2.5x[K^+], He et al. 2020). The neurons retain this adaptation and recover more rapidly in subsequent high potassium applications, even after hours in control saline (Figure A,B). We constructed a novel activity-dependent computational model that qualitatively captures the main observations in our experiments. In this model, regulation of conductances is gated on and off depending on how far the neuron is from its target activity. This allows the model neuron to retain a memory of past perturbations even after it returns to its target activity in control conditions (Figure C). When these rules are implemented, models of bursting neurons adapt to the high potassium perturbation and maintain this robustness upon subsequent applications. Finally, we show that in biological neurons adaptation to high potassium can be erased by presenting a new challenge such as low potassium saline (0.4x[K^+]). Thus, perturbation, followed by recovery of normal activity, can hide cryptic changes in neuronal properties that are only revealed by subsequent perturbations.

Title: Fast depolarizing events triggered by synaptic inputs suggest activation of intrinsic regenerative currents in axonal spines

Authors: *N. VRIELER[1], Y. LEFLER[2], O. AMSALEM[3], N. MEDVEDEV[4], K. VASO[1], A. GURKAN[4], I. SEGEV[1], M. Y. UUSISAARI[4], Y. YAROM[1];

Abstract: Dendritic spines have received a lot of attention in the context of understanding the structure and plasticity of neuronal processing, while spines on axons are relatively rarely studied even though they are not uncommon (see for example Amaral 1978; Williams, Goldman-Rakic and Leranth 1992; Miller, Chiaia and Rhoades 1990). Spine heads on axons innervated by excitatory inputs - as have been described in the Inferior Olive (IO) of cat (de Zeeuw et al. 1990) - would appear to be in a prime position for activating the neuron's output with high priority. Nevertheless, the possible functional roles of this input-output configuration have not yet been investigated. In this work, we present evidence that excitatory inputs innervating IO neuron axonal spine heads can trigger particularly large and fast sub-threshold depolarizations (with amplitudes up to 30mV and rise-time 0.3 - 1.5ms, comparable to action potentials). Specifically, we hypothesize that these events result from 'amplification' of the incoming inputs by intrinsic regenerative currents located in the axonal spine heads. Large, fast depolarizations occur spontaneously in mouse IO neurons, and are especially intriguing because the amplitude distribution of these events usually shows a distinct grouping while the waveforms of the amplitude-normalized events within a single neuron are identical. Using *in vitro* patch-clamp experiments we show that these events are eliminated by pharmacological blockade of glutamatergic transmission, and that they can be activated by optogenetic stimulation of specific groups of axons that innervate the IO. By simulating various possible sources of these events on a reconstructed IO neuron morphology in NEURON, we show that these properties are best explained by assuming that the events originate as intrinsic regenerative currents in axonal spine heads. This is further supported by electron microscopy data demonstrating the existence of spines on the axons of mouse IO neurons, and by additional anatomical experiments combining immunofluorescence and super-resolution confocal microscopy methods. Taken together, our results indicate that the intrinsic physiological properties of axonal spines may make them especially significant in the study of how spines contribute to neural computation.

Abstract: Genome-Wide Association Studies revealed *Triggering receptor expressed on myeloid cells 2* (*TREM2)* R47H mutation as one of the strongest genetic risk factors for late-onset Alzheimer's Disease (AD). In the brain, TREM2 is a transmembrane receptor expressed exclusively by myeloid cells. Many current TREM2 R47H mouse models have observed evidence of cryptic splicing products of the mutant allele, resulting in artefactually reduced protein product. Model Organism Development & Evaluation for Late-Onset Alzheimer's Disease (MODEL-AD) consortium at University of California - Irvine has developed TREM2*R47H^{em1Aduci} mouse model (TREM2^{R47H}) where *Trem2* ^{em1Aduci} allele is expressed at a level similar to the wild-type *Trem2* allele, with no evidence of cryptic splicing products from the mutant allele. In this experiment, we set out to investigate this mouse model on C57BL/6J background and the effect the variant has on AD pathology when crossed with 5xFAD mice, generating four groups – WT, TREM2^{R47H} homozygous, 5xFAD, and 5xFAD x TREM2^{R47H} homozygous. Coronal brain slices of 4-month-old mice (n=5/sex/genotype) were immunolabeled with Thioflavin-S for dense-core plaques and ionized calcium binding adaptor molecule 1 (IBA1) for microglia. Analyzing subiculum and cortical confocal images revealed sex-related differences in dense-core Aß plaque burden and size in 5xFAD x TREM2^{R47H}, where female 5xFAD x TREM2^{R47H} mice exhibited increased plaque load compared to 5xFAD mice. In males, stark reductions in plaque load were observed. Examination of IBA1^{+} microglia revealed significant reductions in microglia volume in both TREM2^{R47H} and 5xFAD x TREM2^{R47H} mice compared to their controls. Notably, there was a significant impairment of plaque-microglia interaction in 5xFAD x TREM2^{R47H}, where a decrease in microglia and plaque colocalization was observed. Moreover, we found a significant increase in plaque-associated neuritic damage in 5xFAD x TREM2^{R47H} when immunolabeled with Lysosome-associated membrane glycoprotein 1 (LAMP1) for neuritic dystrophy. Gene expression analyses again found sex-specific effects, but collectively microglial gene expression responses to pathology were unaltered except for *Itgax (*or *Cd11c)* and *Cd74*, which failed to induce in 5xFAD x TREM2^{R47H} mice. Immunohistochemistry confirmed a reduction in both CD11C^{+} and CD74^{+} plaque associated microglia in 5xFAD x TREM2^{R47H} mice compared to 5xFAD mice. Collectively, these results show the effects of the *Trem2^{R47H}* missense mutation on plaque development and downstream pathology and highlight sex differences.

Title: Microglial lipid droplet accumulation and dysfunctional state is induced by amyloid-β exposure in neurodegeneration

Authors: P. PRAKASH[1], P. MANCHANDA[1], P. R. WIJEWARDHANE[1], C. E. RANDOLPH[1], A. D. DUNHAM[1], J. FINE[1], E. THAYER[1], C. R. FERREIRA[2], ***G. CHOPRA**[1];

Abstract: Glial cell phagocytosis is essential for the regulation of brain function during health and disease. The onset of Alzheimer’s disease (AD) has been linked to the accumulation of amyloid β (Aβ); however, the changes to glial phagocytic function affected by Aβ remain poorly understood. Previous studies have indicated that microglia in aged brains accumulate lipid droplets (LDs) and have a proinflammatory and defective phagocytic phenotype. However, the effect of Aβ on microglial lipidome and related function in neurodegeneration remains uncharacterized to date. We show that microglia from wild-type (WT) mice exposed to Aβ in culture induces upregulation of triacylglycerols (TAGs), a major component of LD, suggesting a possible role of Aβ exposure in LD formation. We used unbiased lipidomics and metabolomics to characterize 1500 lipid species categorized into 10 main classes and around 700 metabolites to identify the Aβ-associated molecular changes in microglia. Further, acutely isolated microglial cells from AD mouse models (5xFAD) show more LD accumulation compared to age-matched WT controls. These LDs comparisons of 5xFAD vs. WT were significantly higher in female mice compared to males and showed an age-dependent effect for LD accumulation. Additionally,

the 5xFAD microglia showed lower phagocytosis of Aβ, with most of the "phagocytic defect" exhibited by LD+ cells. To characterize phagocytosis, we have previously developed a human Aβ1-42 analog ($A\beta^{pH}$) that exhibits green fluorescence upon internalization into the cellular acidic phagosomes. This allowed us to image, for the first time, glial uptake of $A\beta^{pH}$in real-time in live animals. We show that the dysfunction in $A\beta^{pH}$ phagocytosis by 5xFAD microglia is a result of LD accumulation, perhaps due to chronic exposure of Aβ *in vivo*. The phagocytic dysfunction is rescued in the presence of a LD-reducing compound. We have characterized the pathway of TAG synthesis leading to LD formation and propose an Aβ-dependent LD accumulation and phagocytic dysfunction model in microglial cells. We hypothesize that increased LDs in microglia is a cellular protective mechanism to circumvent toxicity during chronic inflammation that leads to its dysfunctional state and disease progression. Characterizing the lipidome and metabolome of different glial cell subpopulations that "eat" (or do not "eat") Aβ *in vivo* will elucidate molecular mechanisms of phagocytic function and dysfunction during neurodegenerative disease and chronic inflammation.

Title: Effect of WNT pathway inhibitors on synapse loss induced by soluble Aβ oligomers

Authors: *D. NIEVES TORRES, S. SKAAR, S. H. LEE;
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The loss of excitatory synapses is a hallmark of Alzheimer's Disease (AD) resulting from the formation of amyloid beta (Aβ) plaques. Several neurodegenerative diseases have been heavily associated with disruption of WNT signaling. A WNT inhibitor Dickkopf-related protein-1 (Dkk-1) is thought to be the downstream mediator of Aβ but the detailed molecular mechanisms that trigger the Aβ-induced synapse degeneration have yet to be elucidated. Proline-rich 7 (PRR7) is a novel WNT inhibitor that upon secretion via exosomes, has been found to trigger synapse loss. To investigate the role of PRR7 in Aβ-induced synapse loss, exosomal

secretion of PRR7 upon application of soluble Aβ oligomers (ADDLs) in cultured hippocampal neurons was investigated. Interestingly, protein levels of PRR7 in exosomes were drastically increased in neurons exposed to ADDLs, suggesting that increased exosomal secretion of PRR7 is involved in Aβ-induced synapse loss. Notably, we found that Dkk-1 also increased the exosomal secretion of PRR7. Administration of a Dkk-1 inhibitor, WAY-262611 (WAY) to hippocampal neurons effectively blocked ADDLs-induced loss of excitatory synapses, quantified by immunocytochemistry analysis. These results suggest that PRR7 might be the downstream mediator of Aβ and Dkk-1 in synapse degeneration found in AD. Overall, these findings suggest that impeding these WNT pathway inhibitors can promote synapse maintenance in an AD model.

Abstract: Aims: Amyloid beta (Aβ) plaque deposition is one of the major pathological features of Alzheimer's disease (AD); however, the mechanism by which this occurs remains unclear. Microglia, the immune cells of the brain, have been shown to interact with plaques but their significance to Aβ deposition is unknown. This project aims to assess Aβ deposition in detail both in amyloid precursor protein (APP) knock-in mice, and also assess the interaction with microglia. **Methods:** Specific aggregation dynamics of individual Aβ species and plaque-associated lipids were analysed in knock-in mouse models of Alzheimer's disease (APP^{NL-G-F} and APP^{NL-F}) at a nanometer level using a novel chemical imaging paradigm termed 'iSILK', involving stable isotope labelling *in vivo* followed by MALDI imaging mass spectrometry.

Microglia morphology and localisation in relation to plaque type are additionally characterised by hyperspectral imaging. **Results:** In APP^{NL-G-F} mice, Aβ1-42 is deposited first and localises to the core of plaques, followed by further recruitment of Aβ1-42 and secondary production of Aβ1-38. In APP^{NL-F} mice, heterogeneity in the morphology and peptide composition of plaques may change microglia behaviour and density compared with in APP^{NL-G-F} mice. The role of Trem2 in the interaction of microglial with plaques will be further analysed by introduction of the Trem2R47H GWAS risk factor mutation to the APP^{NL-F} mice.**Conclusions:** iSILK can be used to distinguish between initial Aβ seeds and later deposition depending on the deposition of labelled isotopes. This furthers our mechanistic understanding of the early production and propagation dynamics of Aβ pathology.

Title: Abca7*v1599m^{Em1aduci} variant in 5xfad mice mediates differences in amyloid-beta pathology and reactive gliosis

Authors: *D. JAVONILLO[1], L. A. HOUCHIN[1], S. KAWAUCHI[2], *J. PHAN[3], C. DA CUNHA[3], K. TRAN[3], G. MILINKEVICIUTE[3], A. J. TENNER[4], F. M. LAFERLA[3], G. R. MACGREGOR[4], K. N. GREEN[3];
[2]Transgenic Mouse Facility, Univ. Lab. Animal Resources, Office of Res., [3]Inst. for Memory Impairments and Neurolog. Disorders (UCI MIND), [4]Dept. of Developmental and Cell Biol., [1]Univ. of California, Irvine, Irvine, CA

Abstract: In several large genome-wide association studies (GWAS), genetic polymorphisms of ATP-binding cassette transporter subfamily A member 7 (Abca7) have been identified as a risk factor for late-onset Alzheimer’s Disease (LOAD). ABCA7 is a member of a family of ATP-binding cassette (ABC) transporters and functions as a transmembrane protein mediating the release of cholesterols and phospholipids from cellular membranes. Previous studies have also proposed its role in mediating phagocytic clearance of amyloid beta (Aβ) oligomers within macrophages in the brain. To study the effects of ABCA7 on the development of AD relevant

pathologies we introduced an equivalent coding sequence change that has been identified as a risk variant for LOAD (V1613M) into the C57BL/6 mouse genome using CRISPR/Cas9 (V1599M). We set out to characterize the ABCA7^{V1599M} variant and investigate its impact on AD pathology when crossed with 5xFAD transgenic mice, generating four distinct groups: WT, ABCA7^{V1599M} homozygous, 5xFAD, and 5xFAD x ABCA7^{V1599M} homozygous. Histological staining using Thioflavin-S on coronal brain sections from 4-month-old mice (n=5-6 mice/sex/genotype) revealed significantly reduced burden of dense-core Aβ plaques in confocal images of both subiculum and visual cortical regions of 5xFAD x ABCA7^{V1599M} mice compared to 5xFAD mice. Biochemical analysis mirrored these findings and demonstrated stark reductions of both soluble and insoluble Aβ40 and Aβ42 levels within these same brain regions. To examine reactive gliosis to plaque burden, we immuno-stained for ionized calcium binding adaptor molecule 1 (IBA1) and glial fibrillary protein (GFAP) to visualize microglia and reactive astrocytes, respectively. Confocal analysis revealed reduced densities of both IBA1+ microglia and GFAP+ reactive astrocytes within subiculum and cortical regions of 5xFAD x ABCA7^{V1599M} mice compared to 5xFAD mice. We also found reduced plaque-associated neuritic damage in 5xFAD x ABCA7^{V1599M} mice upon immuno-staining for lysosome-associated membrane glycoprotein 1 (LAMP1) to examine neuritic dystrophy. Together, these results characterize the effects of the *Abca7^{em1Aduci}* allele and its ABCA7^{V1599M} missense mutation on 5xFAD-mediated pathology, specifically in Aβ plaque development, glial morphology, and neuritic damage. Future studies would investigate whether Aβ pathologies are delayed or exacerbated in older mice expressing the *Abca7^{em1Aduci}* mutant allele.

Title: Increased APP Gene Dose Induces Astrocyte Activation and Early Endosome Enlargement in a Down Syndrome Model

Authors: *R. ALBAY, A. H. BECKER, M. SAWA, C. OVERK, W. C. MOBLEY; Neurosciences, UCSD, La Jolla, CA

Abstract: Alzheimer's disease (AD) is the most common irreversible, progressive cause of dementia, which has become a social and economic issue. Down syndrome (DS) is caused by an extra copy of chromosome 21 (HSA21) and is believed to be linked to AD by the triplication of the amyloid precursor gene (*APP),* which is encoded on chromosome 21. Furthermore, an extra copy of *APP* is essential for the clinical presentation of AD in DS (AD-DS) and provides the basis for the *APP* gene does hypothesis. Here, we investigate the *APP* gene dose hypothesis by crossing a mouse model of HSA21 trisomy (Dp16) with an *APP* knockout model (m*APP-/-*) to generate a Dp16 mouse with one copy of the *APP* gene removed: Dp16(m*APP*++-). Glial cells and neuroinflammation are receiving increasing levels of recognition with respect to the biology of AD. Astroglia are involved in several processes both in the developing and mature brain; we asked whether *APP* gene does influences astroglia activation. To assess the possibility that astrocyte activation would characterize the young adult Dp16 brain, we examined the entorhinal cortex (EC) and medial septum (MS) of mice aged 4- and 9-months. Immunohistochemistry probing the EC show an elevated level of glial fibrillary acidic protein (GFAP) immunoreactivity (IR) in both parenchyma tissue and near the vasculature of the Dp16 mouse brain. Stereological analysis revealed a significant increase in the number of $GFAP^+$ astrocytes in Dp16 vs Dp16 (m*APP*++-) mice at both 4 and 9 months. In the MS, we observed no differences in $GFAP^+$ IR and astrocyte number between Dp16 and Dp16 (m*APP*++-) at 4 months, but a significant increase in $GFAP^+$ astrocytes at 9 months, suggesting age- and region-specific differences in *APP* pathology seen in DS. Dysregulation of early endosomes, with increased recruitment of Rab5 and enlargement, is an early feature of DS and is consistently present DS-AD and AD. To explore the role of *APP* gene does in this phenotype we asked if changes could be detected in 4- and 9-month-old mice. We again probed the EC and MS and compared 2N mice to Dp16 and Dp16 (m*APP*++-) mice. Tissue sections were stained with an antibody to Rab5 and random fields of the EC or MS were examined by fluorescent confocal microscopy and computer-aided morphometric analysis. Early endosomes with Rab5 IR were enlarged in the Dp16 with respect to 2N and Dp16 (m*APP*++-) as early as 4-months of age. In summary, studies in the Dp16 mouse demonstrated the presence of degenerative hallmarks associated with AD and AD-DS. In the case of GFAP and Rab5, the phenotype was normalized by reducing the m*APP* gene dose; providing evidence that increased m*APP* gene dose is necessary for several neurogenerative phenotypes in this model of AD-DS.

Title: Plasma from Alzheimer's Disease Patients Disrupts Astrocyte Mitochondrial Function

Authors: *T. BRANYAN[1,2], Y. EL-HAKIM[1], R. C. BARBER[3], F. SOHRABJI[1,2];
[1]Neurosci. and Exptl. Therapeut., Texas A&M Univ., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX; [3]Dept. of Pharmacol. & Neurosci., Univ. of North Texas HSC, Fort Worth, TX

Abstract: Alzheimer's disease (AD) is the most frequent cause of dementia characterized by a progressive decline in cognitive functions. Sex differences have been well documented in AD with a higher prevalence and higher rates of disease progression in women as compared to men. Cellular senescence of astrocytes and disturbances in the brain-gut axis may significantly contribute to the pathogenesis of neurodegenerative disorders. Recent evidence indicates that the gut is altered under AD disease conditions. Increased gut permeability dysregulates blood brain barrier (BBB) permeability, exposing astrocytes to circulating elements that could elicit a senescent phenotype. We obtained human plasma samples from the TARCC cohort and organized them into 24 groups based on their sex (male and female), race (Non-Hispanic white or Mexican American), diagnosis (probable AD, mild cognitive impairment or control) and Type 2 diabetes diagnosis. *In vitro* male and female human astrocyte cultures were treated with plasma from sex-matched AD and control groups. Treatment with the plasma significantly altered mitochondrial respiration in both male and female astrocytes, with AD plasma-treated cells experiencing significantly greater levels of oxygen consumption relative to control and vehicle groups. Furthermore, treatment with sodium butyrate and indole-3-carbinol, two gut metabolites commonly thought to be neuroprotective, evoked sex-specific responses in oxygen consumption rate after oxidative stress. Male astrocytes demonstrated elevated oxygen consumption in response to sodium butyrate treatment, while female astrocytes increased oxygen consumption in response to indole-3-carbinol treatment. Moreover, female astrocytes showed reduced production of ATP via glycolysis when treated with AD plasma as compared to control and vehicle treatment, resulting in a total decrease of ATP produced. Together these data indicate that exposure to the AD plasma triggers a sex-specific senescent phenotype in astrocytes that alter mitochondrial respiration, perhaps due to exposure to increased level of toxic metabolites circulating in AD plasma. In the future, studies that examine the development of astrocyte senescence will be an attractive target for the development of novel therapeutic agents to AD.

Title: Neuroinflammatory pathways shared between Alzheimer's disease and neuroHIV

Authors: *I. S. HARAHAP-CARRILLO[1,2], D. OJEDA JUÁREZ[1,3], M. KAUL[1];
[1]Div. of Biomed. Sciences, Sch. of Med., [2]Neuroscience, Col. of Natural and Agr. Sci., Univ. of California, Riverside, Riverside, CA; [3]Infectious and Inflammatory Dis. Ctr., Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: People living with HIV can develop HIV-associated neurocognitive disorders (HAND), which range from asymptomatic neurocognitive impairment to full-blown dementia. The neuropathological features of HIV infection of the brain (neuroHIV) are referred to as encephalitis (HIVE), including astrogliosis, microgliosis, and synaptic and dendritic loss. Interestingly, increased amyloid-beta (Aβ)1-42 and phosphorylated Tau has been observed in the cerebrospinal fluid of HAND patients but are considered hallmarks of Alzheimer's disease (AD), while AD brains also show an increase in microglial and astrocytic activation. Due to these similarities, we aim to identify potential mechanistic crossover between these neurodegenerative disorders. We analyzed the AD mouse model, J20, which overexpresses the mutated human amyloid precursor protein (APP) and compared it to a model of neuroHIV/HAND, HIVgp120tg mice. In the cortex (layer III) and hippocampus (CA1) of the J20 mice (12-month-old), we observed a loss in the presynaptic terminal marker synaptophysin, and an increased number of Iba1+ microglia. Sexual dimorphism was observed for the loss of synaptophysin in the hippocampus and the increased RNA expression of LCN2 in the cortex (higher in the female J20 mice). Moreover, protein expression of GFAP was increased in the cortex and hippocampus of J20 mice. Signaling pathways playing an integral role in HAND/HIVE seem to also be affected in the J20 mice, with increased activation of p38 MAPK and a trend of increased activation of ERK1/2 in the cortex. Overall, our findings in the AD and neuroHIV mouse model suggest at least a partial overlap in the activation of neuroinflammatory pathways in both disorders, and could reveal new potential targets for the treatment of neuroHIV/HAND and/or AD.

Title: Soluble and membrane-bound isoforms of fractalkine differentially regulate microglia activation and vascular damage in the diabetic retina

Authors: *D. RODRIGUEZ[1], K. A. CHURCH[1], A. N. PIETRAMALE[1], S. M. CARDONA[1], D. VANEGAS[1], K. R. NASH[2], A. E. CARDONA[1];

Abstract: Diabetic retinopathy (DR) is a microvascular complication of *diabetes mellitus* and a leading cause of blindness worldwide. Hallmarks of DR include loss of neurons, activation of resident phagocytes, compromised vasculature, and angiogenesis. Inflammation caused by microglia exacerbates the retinal integrity, resulting in glial and neuronal cell dysfunction. The microglia-neuronal crosstalk mediated by CX3CR1/FKN signaling provides a neuroprotective environment in several diseases including DR. However, CX3CR1 polymorphic variants (V249I and T280M) present in about 20-30% of the population, decrease FKN binding affinity to CX3CR1, and their role in microglia function in the retina during diabetes is unknown. Moreover, FKN exists as a soluble chemokine and as a membrane-bound (mFKN) adhesion molecule. When cleaved by a disintegrin metalloproteinase (ADAM) protein, the soluble form (sFKN) is released to exert chemoattractant properties. Previous studies show that 1) diabetic CX3CR1-KO and FKN-KO mice display worse retinal pathology, and 2) intra-vitreal administration of recombinant FKN to diabetic FKN-KO mice rescued vascular pathology. However, the mechanisms by which mFKN and sFKN regulate retinal function are still unknown. We hypothesize that during diabetes, the over-expression of sFKN using recombinant adeno-associated viruses (rAAVs) will prevent vascular and neuronal damage, compared to mFKN. To test this hypothesis, rAAVs expressing either mFKN or sFKN were delivered to FKN-KO retinas. FKN protein levels, microglial activation, fibrinogen leakage, neuronal densities, and upregulation of pro-inflammatory mediators were compared in diabetic and non-diabetic controls. We validated the expression of FKN levels in the brain and retinal protein extracts in mice that received rAAV vectors expressing mFKN or sFKN. Immunofluorescence and high-resolution confocal imaging shows that sFKN can minimize microglial activation, reduce fibrinogen deposition, and rescue neuronal loss, compared to mice administered rAAV-mFKN. In conclusion, our data suggest that rAAVs expressing mFKN or sFKN are efficient means to deliver FKN isoforms to the retina and the brain. Delivery of rAAV-sFKN, compared to rAAV-mFKN, ameliorates activation of microglia, vascular damage and rescues neuronal loss. Therefore, FKN appears to act as a neuroprotective agent in the diabetic retina and potentially serves as an alternative pathway to implement novel translational and therapeutic approaches.

Title: Microglia depletion elicits neuroprotective effects to alleviate vascular damage and neuronal cell loss in the diabetic retina

Authors: *K. A. CHURCH[1], D. RODRIGUEZ[2], I. LOPEZ-GUTIERREZ[4], D. VANEGAS[3], S. M. CARDONA[3], A. E. CARDONA[5];
[1]Univ. of Texas At San Antonio, San Antonio, TX; [2]Biol., [3]Univ. of Texas at San Antonio, San Antonio, TX; [4]Univ. Complutense de Madrid, Madrid, Spain; [5]Dept. of Biol., The Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Diabetic retinopathy (DR), an incurable eye disease caused by prolonged high glucose levels in the retina, is a common complication of diabetes mellitus and the leading cause of blindness amongst working age adults. Prolonged high glucose levels damage retinal blood vessels leading to hemorrhages, ischemia and ultimately vision loss. Microglia, the resident immune cells of the central nervous system (CNS), are believed to contribute to the development of DR as they are rapidly activated and respond to transient hyperglycemia, and reset the homeostatic threshold of the retina. As hyperglycemia persists (>4 weeks diabetes), capillary damage occurs resulting in serum proteins and DAMPs from the periphery leaking into the retina perpetuating microgliosis, low-level pro-inflammatory cytokine production and vascular damage. Early (6-8 weeks diabetes) lesions of fibrinogen-activated microglia near blood vessels and the associated vascular damage sustain and increase the release of proinflammatory mediators in the diabetic retina that correlate with neuronal loss. Therefore, we transiently depleted microglia to determine the mechanism by which resident retinal macrophages regulate neuronal and vascular damage in the retina at early stages of diabetes. We hypothesize that transient depletion of $CX3CR1^{CreER}$:$R26^{iDTR}$ microglia during the course of disease when microglia receive the early-stage environmental cues of retinal inflammation due to hyperglycemia will induce neuroprotective cues. Utilizing a genetic model to express diphtheria toxin receptor (DTR) under the tamoxifen (TAM) inducible *CX3CR1*-promoter, microglia become susceptible to the effects of diphtheria toxin (DTx). Microglia were depleted in diabetic and control mice for two weeks from six to eight weeks of diabetes. Vascular and neuronal damage were assessed at ten weeks of diabetes, two weeks after microglia depletion concluded. Our findings revealed that transient depletion of microglia induced neuroprotective cues to upregulate $TUJ1^{+}$ neurons and ameliorate

vascular damage in the diabetic retina. After depletion, repopulating microglia displayed a resting phenotype mirroring those of non-diabetic TAM controls. In conclusion these studies suggest that early transient microglia depletion during the course of disease when microglia receive early-stage activation cues, is neuroprotective by inducing the proliferation of a homeostatic microglia cell population that induce axonal regeneration of $TUJ1^{+}$ neurons and vascular repair.

Title: Activation of the p38 MAPK pathway is required for amyloid beta-induced neuroinflammatory response in human microglia

Authors: H. LIN, E. D. HAMLETT, A. ERGUL, ***G. Y. WANG**;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Alzheimer's disease (AD), the most common cause of dementia, is characterized by the accumulation of extracellular amyloid-beta peptide (Aβ) plaques and hyperphosphorylated tau-containing intracellular neurofibrillary tangles, along with the progressive loss of memory and cognitive functions. In response to Aβ accumulation, microglia are activated to facilitate the clearance of Aβ aggregates, but unfortunately this process can trigger a neuroinflammatory response that could be detrimental to neurons. Several previous studies have suggested that Aβ-induced neuroinflammation may play a significant role in the pathogenesis of a variety of neurodegenerative disorders, such as AD. Interleukin-6 (IL-6) is a well-characterized pro-inflammatory cytokine and its expression levels were significantly increased in the brains of AD patients. However, the mechanisms by which IL-6 expression levels are up-regulated in the brain tissues of AD patients have not been well elucidated previously. The major goal of this study was to investigate the role of the p38 mitogen-activated protein kinase (p38 MAPK) pathway in Aβ-induced IL-6 production in human microglia. In the present study, we show that Aβ oligomers dose-dependently stimulate IL-6 production in HMC3 human microglial cells. We also show that treatment with Aβ promotes the transcription of IL-6 and tumor necrosis factor α (TNFα) mRNA in human microglia and THP-1 human monocytes. Notably, our data indicate that Aβ selectively induces the activation of the p38 MAPK signaling pathway in human

microglial cells. Furthermore, using immunofluorescence and confocal microscopy, we found that phosphorylated (the active form) p38 MAPK and IL-6 expression levels were markedly increased in microglial cells in the brain tissues of AD patients as compared to the age-matched control subjects. Pharmacological inhibition of p38 MAPK by a set of small molecule inhibitors abrogates Aβ-induced IL-6 secretion. Collectively, these results have demonstrated a critical role for p38 MAPK activation in mediating Aβ-induced production of neuroinflammatory cytokines in human microglia, which suggest that the blockade of the p38 MAPK pathway with selective small molecule inhibitors may be exploited as a novel therapeutic approach to alleviate Aβ-induced neuroinflammation in AD.

Title: Traumatic Brain injury Induced Chronic inflammation and cognitive impairment attenuated by inhibition of stimulator of interferon genes (STING)

Authors: *J. M. PACKER, C. E. BRAY, M. WITZEL, M. OUVIÑA, N. BECKMAN, D. ADEKUNLE-ADEGBITE, J. P. GODBOUT;
The Ohio State Univ., Columbus, OH

Abstract: Neuropsychiatric complications including depression and cognitive decline develop, persist, and even worsen in the years after traumatic brain injury (TBI), negatively affecting the quality of life and lifespan. Mounting evidence indicates that chronic inflammatory processes linger after TBI, but the mechanism that drives this response is unclear. We previously reported that microglia, innate immune cells in the brain, were the primary drivers of chronic inflammation following diffuse TBI in mice. Moreover, the subacute phase of cortical inflammation 7 days post injury (dpi) was dominated by a robust type 1 interferon (IFN) response. Thus, we hypothesize that increased type I interferon signaling is critical in promoting microglial dysfunction and the subsequent transition from acute inflammation to chronic neuroinflammation after brain injury. In the current study, we targeted the IFN pathway for intervention using knock out mice for the transmembrane protein stimulator of interferon genes (STING) and interferon alpha/beta receptor (IFNAR). In these experiments, adult male wildtype (WT), $STING^{KO}$, and $IFNAR^{KO}$ C57BL/6 mice received a diffuse brain injury and indicators of

neuroinflammation and functional recovery were assessed 7 and 30 dpi. As expected, inflammatory (Cd68, Tlr4) and type 1 interferon associated genes (Tmem173, Irf3, Ifi27) were increased 7 dpi in the cortex of TBI mice compared to controls. These TBI induced increases in interferon associated genes 7 dpi were not attenuated in the global IFNAR^{KO} mice and there was no protection against TBI associated cognitive deficits in these mice. However, reduced IFN signaling profiles subacutely in the TBI-STING^{KO} mice was evident compared to TBI-WT mice and this was paralleled by reduced chronic neuroinflammation (Cd68) at 30 dpi. Chronic deficits in cortical and hippocampal dependent memory as determined by the novel object recognition and location tasks 30 dpi were attenuated in the TBI-STING^{KO} mice. Taken together, reducing type I IFN signaling after TBI through a STING-dependent intervention is effective at reducing chronic inflammation and improving functional recovery post-TBI.

Title: Role of C9orf72 in neuroinflammation and neurodegeneration

Authors: *T. A. MOTA[1], I. LORENZINI[2], S. BELL[1], T. E. MAHAN[3], R. G. SATTLER[2], D. M. HOLTZMAN[3], R. BALOH[1], D. LALL[1];
[1]Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Barrow Neurolog. Inst., Phoenix, AZ; [3]Washington Univ. In St. Louis, Saint Louis, MO

Abstract: *C9orf72* hexanucleotide expansions are the most common cause of inherited ALS and frontotemporal dementia (FTD) in European and North American populations. The GGGGCC expansion mutation in the region between exons 1a and 1b leads to both gain of function toxicity (RNA foci and RAN dipeptide repeat proteins) as well as decreased expression of the *C9orf72* transcript (loss of function). *C9orf72* repeat expansions are also found in a subset of other neurodegenerative disorders including late-onset Alzheimer's disease and Parkinson's disease. *C9orf72* is highly expressed in myeloid cells, including resident brain microglia and loss of

C9orf72 has been shown to alter immune response in these cells. To better understand connection between loss of *C9orf72* in microglia and neurodegeneration, we analyzed aged wildtype (WT) and *C9orf72* knockout (*C9orf72-/-)* animals. 12-mnth old *C9orf72-/-* mice showed increased microglial lysosomal accumulations and decreased neuronal dendritic branching than WT mice. We also transcriptionally profiled microglia from young and aged *C9orf72* knockout (*C9orf72-/-)* animals. Unbiased hierarchical clustering and integrative WGCNA analysis of the RNAseq data revealed significantly altered signatures in *C9orf72-/-* microglia, with upregulation of a gene network involving response to aggregates/neuronal injury containing Trem2 and Tyrobp, as well as a network involved in antigen presentation. To identify how altered microglial function from loss of *C9orf72* affects Aβ clearance and neuronal damage, we crossed *C9orf72-/-* animals to the 5XFAD model of Alzheimer's disease (5XFAD:C9orf72-/-) and found that *C9orf72* deficiency dramatically reduced amyloid plaque burden when compared to 5XFAD animals. 5XFAD:C9orf72-/- animals had less astrogliosis, microgliosis and fewer dystrophic neurites. While markers of overall inflammation were decreased, plaques in 5XFAD:C9orf72-/- animals were more dense, less diffuse and were associated with increased numbers of microglia. Interestingly 5XFAD:C9orf72-/- animals showed enhanced loss of dendritic branching than *C9orf72-/-* animals at similar age. Taken together, these data indicate that loss of *C9orf72* leads to intrinsic changes in microglial function that enhances plaque clearance and diminish neuronal pathology in 5XFAD animals although leading to decreased synaptic branching indicative of synaptic loss. This surprising scenario supports that loss of C9orf72 impacts microglial cells in multiple ways that synergistically influences the development of aggregate pathology and synaptic integrity in the brain.

Title: Role of microglial TLR4 in obesity-induced neural impairments

Authors: *J. LIU, C. J. PIKE;
USC Leonard Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: Obesity is associated with adverse effects on the brain and neural function, including reduced hippocampal volume, acceleration of brain aging, and increased risks for developing

Alzheimer's disease (AD) and vascular dementia. Obesity is also characterized by chronic and low-grade inflammation that affects numerous tissues. In the brain, obesity drives chronic neuroinflammation in part by increasing microglial activation and production of pro-inflammatory cytokines. Among all pro-inflammatory signaling pathways, toll-like receptor 4 (TLR4) signaling pathways may be particularly important in driving obesity-associated inflammation. TLR4 signaling is implicated as an essential regulator of systemic effects of obesity in metabolic measures and inflammation. Genetic knockout and pharmacologic inhibition of TLR4 can attenuate glucose dysregulation, insulin resistance and inflammation in peripheral tissues. TLR4 signaling in microglia has been suggested to mediate the progression of AD and several other neural disorders but its role in obesity-induced neural outcomes in is largely unknown. Therefore, we generated and analyzed mice that carry a microglial-specific deletion of TLR4 following 16 weeks of exposure to either a control or high fat diet. In male mice, absence of microglial TLR4 had no significant effects on body weight, adiposity, and metabolic measures. However, we observed significant reduction in adipose inflammation in TLR4 knockout mice fed on high fat diet. In females, lacking microglial TLR4 was associated with significant reduction in body weight and improvement of metabolic function. Furthermore, obese mice with microglial TLR4 deletion exhibited significant protection against diet-induced glial activation and impaired neurogenesis both in males and females. These findings implicate an important role for microglial inflammation in obesity-induced neural impairments. Additionally, these findings point to the potential for clinical translation of TLR4 as a therapeutic target for obesity-induced neural injury.

[3]Dept. of Neurol., Johns Hopkins Drug Discovery, Baltimore, MD

Abstract: Microglia are the resident immune cells of the central nervous system exhibiting heterogeneous and pleomorphic morphology. These microglia continually extend and retract their processes for surveillance, phagocytosis, and chemotactic migration that are dynamically modulated by niche environmental cues including neuronal hyper or hypo-activity. Microglia in the rabbit model of cerebral palsy (CP) expresses a high level of glutamate carboxypeptidase II (GCPII), which facilitates higher extracellular glutamate production and potentially contributes to neuronal hyperexcitability and excitotoxicity. We hypothesized that the dynamics of microglial processes in CP and healthy newborn kits would differ and antagonizing GCPII would influence microglial motility. Using the maternal inflammation-induced fetal-brain injury model of CP in rabbits, we explored the hippocampal microglial motility with confocal live imaging in ex-vivo brain slice preparations. We observed that cell body and phagocytic cup sizes are smaller in healthy controls compared to CP kits and microglial processes are less stable in CP kits, even when microglia are amoeboid in both healthy and CP kits. Treatment of CP kits with dendrimer conjugated 2-PMPA (d-2PMPA), a potent and selective inhibitor of GCPII, induces profound reversal of microglial process dynamics to healthy control levels within 48 hours. Our results emphasize the importance of microglial processes dynamics in determining the state of microglia in the developing brain and demonstrate how acute GCPII inhibition through d-2PMPA can effectively influence microglial motility to healthy control levels.

Title: Regulation of ionizing radiation-induced iNOS expression by a novel long non-coding RNA in microglia and a human neuroblastoma cell line

Authors: *N. W. MATHY[1], A. SHIBATA[2];
[1]Creighton Univ. Sch. of Med., Omaha, NE; [2]Biol. Dept., Creighton Univ., Omaha, NE

Abstract: Exposure of the central nervous system to ionizing radiation results in inflammation produced in part by microglial activation. Increased understanding of the regulatory factors

controlling microglial activation and direct neurotoxicity in response to ionizing radiation may aid in preventing inflammation in the CNS. Long non-coding RNAs (lncRNAs) are a class of RNA molecules that regulate gene expression via interactions with RNA-binding proteins, such as transcription factors. While many lncRNAs have been identified, the function of few has been elucidated, and thus lncRNAs represent new potential therapeutic targets to prevent inflammation in the CNS.
Our hypothesis is that the lncRNA Nostrill is induced in response to ionizing radiation and regulates the expression of iNOS, a potent neuroinflammatory mediator. Ionizing radiation was delivered using a Faxitron CellRad irradiator with varying doses of radiation to the BV2 mouse microglial cell line and human SH-SY5Y neuroblastoma cell line. Knockdown was performed using siRNA directed against the gene of interest or a scrambled control siRNA. Overexpression was performed by transfection of an expression vector containing the gene of interest, or an empty vector control.
Nostrill and iNOS both displayed a dose-response relationship, with maximal induction occurring with exposure to 10 Gy ionizing radiation. Time course analysis revealed the most significant induction of both at 6h after exposure. Interestingly, knockdown of Nostrill prior to irradiation significantly reduced the expression of iNOS to levels not significantly different than non-irradiated cells transfected with a scrambled siRNA. Conversely, overexpression of Nostrill prior to irradiation significantly enhanced the expression of iNOS. Overexpression of Nostrill without radiation exposure significantly increased iNOS expression compared to empty vector control. Translational studies in the human SH-SY5Y neuroblastoma cell line demonstrated induction of a positionally conserved lncRNA in response to ionizing radiation.
These preliminary studies demonstrated that the novel lncRNA Nostrill is induced in microglia after exposure to ionizing radiation. Further, based on the results of Nostrill knockdown or overexpression, Nostrill appears to regulate the radiation-induced expression of iNOS. Additionally, a positionally conserved lncRNA is induced in a human neuroblastoma cell line. Further studies will investigate the molecular mechanism of this regulation, and assess biological relevance based on neurotoxicity in co-culture assays.

Title: Low dose CSF1R inhibition modulates microglia and macrophage response to disease in the mouse EAE spinal cord

Authors: *D. OFENGEIM, **T. HAMMOND**, F. RAPINO, M. LAMORTE, J. SALEH, J. PROTO, J. KANE, N. HAGAN;
Sanofi, MA, MA

Abstract: At high doses CSF1R inhibitors rapidly deplete microglia in the mouse brain and have been used to study microglia function in the health and disease. However, at lower concentrations CSF1R inhibition suppresses microglia inflammatory responses in disease (Hagan et al., 2020; Jafari et al., 2021) without depleting microglia. To better understand the effect of low dose CSF1R modulation on microglia and macrophage responses and cell state in the central nervous system we performed single cell RNA sequencing (scRNAseq) on mice with experimental autoimmune encephalitis (EAE), a demyelinating autoimmune disease that triggers infiltration of T-cells and monocytes and causes microglia and astrocyte activation. We isolated immune cells and glia from the adult mouse spinal cord using transcriptional inhibitors to minimize cell isolation artifacts. Animals were treated with a low dose of a novel CSF1R inhibitor (CSF1Ri) following induction of disease. CSF1Ri treatment significantly reduced disease score compared to vehicle treated animals. scRNAseq analysis of the spinal cords uncovered a major shift in the spinal cord cellular milieu including increased numbers of activated microglia and infiltration of dendritic cells, multiple monocyte populations, and T cells. The CSF1Ri had little or no effect on the dendritic cells, astrocytes, and oligodendrocytes/OPCs and modest effects on the T cells transcriptional signature. However, the CSF1Ri significantly shifted the microglia and monocyte cell state, possibly contributing to the reduction in the inflammatory disease response and improved disease score. Microglia and monocytes cell states were also examined by flow cytometry which demonstrated a shift in microglia and monocytes cell subpopulations with CSF1Ri treatment. These results highlight the therapeutic potential of CSF1R inhibition to modulate microglia and macrophage cell state in inflammatory and neurodegenerative disease.

Title: Microglia specific p38αMAPK signaling is critical in NeuroHIV

Authors: *D. BHULLAR, R. MAUNG, M. KAUL;
Biomed. Sci., SOM,, Univ. of California, Riverside, Riverside, CA

Abstract: HIV-1 causes severe and progressive neurological impairment in humans known as HIV-associated neurocognitive disorders (HAND). The HIV-1 envelope glycoprotein gp120 is an extracellular protein that is shed from infected cells and interacts with distant uninfected brain cells like microglia, neurons and astrocytes. Transgenic mice expressing HIV-1 coat glycoprotein gp120 in astroglial cells of the brain (HIVgp120tg) display neuropathological features similar to HIV dementia patients. During inflammation, p38alpha MAPK is known to regulate the biosynthesis of pro-inflammatory cytokines in endotoxin-stimulated monocytes. Thus, p38 MAPK may be an important mediator in the development of HAND and immunodeficiency during HIV-1 infection. To determine the role of microglial p38 signaling in HIV mediated neuronal injury in vivo, we generated p38 floxed/CX3CR1-Cre HIVgp120-expressing mice that have a p38 knockout specifically in microglia and macrophages. Brain sections of these mice were stained for neuronal MAP2, synaptophysin and GFAP. Astrocytic GFAP levels remained unaffected by microglial p38 deficiency. However, we observed a significant loss of MAP2 and synaptophysin compared to non-tg controls only in HIVgp120tg animals with p38-expressing microglia but not in HIVgp120- expressing brains with microglia-specific p38 knockout, indicating p38 deficiency in microglia protected neurons from HIVgp120 toxicity. Further, we sought to analyze the changes in the microglial transcription profile in HIV glycoprotein expressing mice. We sorted by flow cytometry microglial cells from CX3CR1-Cre positive and negative gp120 tg/floxed p38alpha and non-tg/floxed p38alpha mice for gene expression analysis using RNA seq. Altogether, our study shows in vivo the critical role of microglial p38alpha MAPK in the neurotoxicity caused by the HIV-1 envelope protein, and provided a transcriptional profile of p38alpha-deficient microglia.

Title: Permethrin Exposure Primes Inflammatory Stress Response in Mouse Model of Gulf War Illness

Authors: *S. X. NAUGHTON[1], U. IQBAL[1], K. TRAGESER[1], H. WU[1], G. M. PASINETTI[1,2]; [1]Icahn Sch. of Med. at Mount Sinai, NewYork, NY; [2]James J. Peters Veterans Affairs Med. Ctr., Bronx, NY

Abstract: Gulf War Illness (GWI) is a chronic multi-symptom illness affecting roughly one third of military Veterans who served in Operation Desert Storm (1990-1991). Military service members serving in Operation Desert Storm were exposed to numerous toxic chemical agents such as pesticides, chemical weapons, and smoke from oil well fires. Additionally, service members prophylactically consumed the anti-nerve agent pyridostigmine bromide and reported high levels of stress. Soon after, a subset of Veterans began reporting a diverse array of symptoms collectively known as Gulf War Illness (GWI). In particular, Veterans suffering from GWI display a number of cognitive and psychiatric disturbances in addition to other symptoms such as chronic fatigue, gut dysbiosis, and neuropathic pain. Due to the unique combination of exposures the exact cause of GWI is not entirely known, making it difficult to develop accurate preclinical models to evaluate potential therapeutic interventions. The present study seeks to investigate the hypothesis that exposure to the pesticide permethrin primed Veterans to exhibit a heightened response to combat related stressors resulting in long term manifestations of psychiatric illness. Mice were chronically exposed to permethrin or Vehicle for 14 days followed by 7 days of unpredictable stress or gentle handling (control). Mice were then tested for anxiety like behaviors using the open field test and depressive like behaviors using the forced swim test. Our results indicate that exposure to permethrin followed by stress results in depressive, but not anxiety like behaviors. Subsequent histological analysis revealed morphological indications of microglial activation in the hippocampus of mice exposed to both permethrin and stress. We next utilized Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to block microglial priming during permethrin exposure. Transgenic mice which express G_i DREADD receptors on microglia were treated with the DREADD ligand JHU37160 during permethrin exposure, prior to stress. Microglial inhibition via DREADDs was sufficient to block microglial priming by permethrin and blocked the depressive phenotype. These findings shed light on the potential etiology of GWI, particularly with respect to psychiatric and neurological symptoms. Additionally, these results hold important implications for the Gulf War Veteran population who may be more susceptible to lifestyle factors such as stress. The preclinical model developed in this study holds important ramifications for the development of successful therapeutic strategies to treat this underserved Veteran population.

Title: Hypothermia to Recover Neuropathology and Survival after Soman-Induced Seizure

Authors: *C. MUÑOZ, T.-M. SHIH, C. ACON-CHEN, Z.-M. KEITH;
Neurosci., US Army Med. Res. Inst. of Chem. Def., APG, MD

Abstract: Organophosphorus nerve agents (NAs) irreversibly inhibit acetylcholinesterase in the cholinergic synapses and neuromuscular junction, yielding excitotoxic effects. Current medical countermeasures do not fully protect against NA-induced sustained *status epilepticus* (SSE) and brain damage. Previous animal model work verified that acute treatment with the A1 adenosine (ADO) receptor (A1AR) agonist (±)-5'-Chloro-5'-deoxy-ENBA (ENBA) suppressed SSE with improved neuropathology outcomes. However, severe hypothermia, hypotension, and sedation were experienced post-treatment. Hypothermia alone may shield the brain from injury by slowing down chemical reactions and lessening inflammation which could then recover the neurological outcome after NA-induced SSE. Therefore, we attempted to isolate the hypothermic effect from ADO and assessed the neuroprotective efficacy of direct systemic body cooling in a rat NA SSE model. Results were measured by survival, seizure termination, and neuropathology between ENBA administration and systemic body cooling. Male Sprague Dawley rats were surgically implanted with a body temperature transponder and electroencephalographic electrodes for recording brain activity. A week later, the rats were pretreated with HI-6 intraperitoneally to prevent peripheral cholinergic symptoms and thus promote survival without affecting central activity. Thirty minutes later, rats were exposed subcutaneously to soman or saline (control exposure) and then treated with ENBA intramuscularly or had their body temperature lowered directly via body cooling at 30 min after the onset of seizure. Afterwards, rat groups either were allowed to develop hypothermia as expected or received thermal support to maintain normothermic body temperatures for a period of 6 hours. The surviving rats were euthanized, perfused, and scored for neuropathology 24 hours after exposure. In terms of survival, all hypothermic soman-exposed groups regardless of ENBA or systemic cooling had significantly improved 24-hour survival compared to rats with normothermic temperatures (70.6% vs. 29.4%, p < 0.001). Seizures were equally terminated and neuropathology scores were significantly lower (p<0.01) in soman-exposed rats treated with ENBA, regardless of temperature. Thus, ENBA offered neuroprotection independently of hypothermic body temperatures. Hypothermia enhanced the overall efficacy of ENBA by improving survival outcomes but did not reduce seizure activity or neuropathology after NA-induced SSE.

Title: Honokiol acts as a neuroprotective in alcohol-induced developmental neurotoxicity in brain organoids.

Authors: *T. ARZUA, Y. YAN, C. JIANG, S. LOGAN, X. BAI;
Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Alcohol consumption by pregnant women can adversely affect the developing fetus, resulting in a spectrum of deficiencies known as Fetal Alcohol Spectrum Disorders (FASD), with a prevalence of 1.1%-5.0% in the USA. One significant consequence of FASD is alcohol-induced developmental neurotoxicity (AIDN) manifesting as cognitive impairment and behavioral problems throughout life, possibly related to neuronal cell loss, with no effective neuroprotective approach available. Honokiol, a non-pharmaceutical natural compound isolated from Magnolia tree bark, traditionally used in eastern medicine, has been recently shown to act as a protective agent in cerebrovascular injuries, epilepsy, and Alzheimer's disease. We have shown that brain organoids derived from human induced pluripotent stem cells are a promising human-relevant *in vitro* system to study the toxic effects of alcohol. With that, we hypothesized that honokiol could attenuate alcohol-induced toxicity in brain organoids. We found that alcohol concentration-dependently induced neuroapoptosis in organoids as evidenced by the increased activated caspase 3 expression and activity. Pretreatment with 50 μM honokiol for 12 hours significantly attenuated 6-hour alcohol (50 mM) exposure-induced neuroapoptosis. The 50 mM of alcohol concentration is equivalent to a blood alcohol content of 230 mg/dL, mimicking a binge-drinking episode. RT-PCR analysis showed that honokiol upregulated key neuroprotective genes, such as the immediate-early gene NPAS4. Additionally, Seahorse metabolic analysis revealed that honokiol significantly improved mitochondrial function in the alcohol-treated organoids compared with the vehicle control DMSO-treated organoids. Collectively, our findings not only corroborate the versatility of brain organoids as models for AIDN but also the novelty of honokiol as a possible neuroprotective route against alcohol-induced brain injury during development.

Title: The miRNA content of Extracellular Vesicles produced by human mesenchymal stem cells in response to a damaged nervous tissue

Authors: *A. J. DA SILVA, Jr[1,2], P. DOMIZI[4], V. BODART-SANTOS, SR[5], L. R. P. DE CARVALHO[1], R. S. LINDOSO[1], R. MENDEZ-OTERO[6,3];

Abstract: Our group has been obtaining positive results with cell therapy using mesenchymal stem cells (MSC) to treat injury models in the central nervous system. The therapeutic effect of MSC has been attributed mainly to paracrine mechanisms by releasing a wide variety of free molecules and extracellular vesicles (EVs). EVs are membrane nanoparticles that carry bioactive lipids, proteins and RNA - especially miRNAs, which can modify the physiology of the target cell. We observed that treatment with human-derived MSC (hMSC) promotes neuroprotective and regenerative effects. In this project, the objective is to characterize the EVs generated by hMSCs under different culture conditions in relation miRNA content. The hMSCs were grown under different conditions: in the presence of serum (Control); in the absence of serum for 24 hours (SD); and in the presence of damaged nervous tissue concomitant to the absence of serum (SD+Retina). We observed that most of the miRNAs present in hMSCs remain unchanged in all conditions, which are related to functions common to mesenchymal cells, cell cycle control, oxidative stress and angiogenesis. However, some miRNAs were found exclusively in the Control, SD and SD+Retina conditions, respectively. These molecular changes are reflected in the content of EVs produced by hMSCs under SD and SD+Retina conditions. Even so, EVs of both conditions contain miRNAs associated with the regulation of apoptosis and the modulation of several signaling pathways. Thus, we observed that the conditions of cultivation, especially the presence of damaged nervous tissue, alters the expression profile of miRNAs in hMSCs and their EVs, however several miRNAs associated with their therapeutic potential are not affected by the culture conditions.

Abstract: Obesity is a chronic low-grade systemic inflammatory statethat is the sixth leading cause of death worldwide. Obesity gradually activatesthe immune system inducing a constant release of pro-inflammatory cytokines inlow amounts that are produced in part by the visceral adipose system, leadingto the activation of pathways of inflammation, and contributing to thedevelopment of serious complications such as insulin resistance.Obesity-associated systemic inflammation causes increased blood-brain barrierpermeability, glial activation, and secondary neuroinflammation which is a riskfactor for developing other brain pathologies Among the brain structuresaffected with neuroinflammation associated with obesity are the cortex,hippocampus, brain stem, among others. Since neuroinflammation secondary toobesity is chronic, we wanted to see how this neuroinflammation may impact anacute event such as brain ischemia. Male C57/Bl6 mice were fed with a high-fatdiet (for 12 weeks a Bodyweight was monitored weekly, fasting glucose, andintraperitoneal glucose were determined after 12 weeks of diet and were thensummited to cortical photothrombotic to induce brain ischemia TNF α IL10, MCP1,and BDNF levels were measured by ELISA before ischemia in the cortex andstriatum. Mice with HFD gained significantly more weight than subjects fed withnormal diet from the third week of diet and glucose metabolism was also alteredsince fasting glucose and area under the curve of the glucose tolerance testwere significantly higher in HFD mice. HFD mice presented higher corticallevels of MCP1 and BDNF compared to control mice. The other cytokines did notpresent any difference when compared to the control group neither in the cortexnor the striatum. We also

found differences between the cortex and the striatumin the levels of fractalkine in the HFD group and MCP1 in the control group. Inthe other cytokines, we did not find significant differences in the brain areasanalyzed. HFD mice with ischemia presented 50% mortality compared to 100%survival of the control group. Higher cortical levels of MCP1 correlate s withperipheral findings in adipose and liver tissue of obese animals and may be aresult of the inflammatory function of microglia

Title: Lithium induced neuroprotection is mediated by mesencephalic astrocyte-derived neurotrophic factor (MANF)

Authors: *F. A. ABU-HIJLEH[1], V. PATEL[1], N. RIGG[1], B. N. FREY[1,2], R. K. MISHRA[1]; [1]Psychiatry and Behavioural Neurosci., McMaster Univ., Hamilton, ON, Canada; [2]Mood Disorders Program and Women's Hlth. Concerns Clin., St. Joseph's Healthcare, Hamilton, ON, Canada

Abstract: Background: Although introduced 70 years ago, the monovalent cation lithium remains the 'gold standard' treatment for bipolar disorder (BD); however, its therapeutic mechanism of action remains elusive. Accumulating data suggest that lithium's neuroprotective properties involve the modulation of ER-calcium binding proteins such as GRP78, coined the 'master regulator' of endoplasmic reticulum (ER) stress. Mesencephalic astrocyte-derived neurotrophic factor (MANF) is an ER-resident protein with demonstrated neuroprotective capabilities against cellular insults through its direct interaction with GRP78. The purpose of this study was to determine whether lithium neuroprotection against ER stress is associated with an increase in MANF and GRP78 through the AP-1 pathway. Additionally, ER-stress-associated proteins such as Bcl-2 and CHOP were investigated. **Methods:** Mouse striatal cells were pretreated with either PBS, lithium or lithium + AP-1 inhibitor for 6 days before being exposed to thapsigargin, an inducer of cytotoxic ER-stress for 24 hours. Cell viability gene and protein expression were quantified using MTT assays, RT-qPCR and western blots, respectively.

Results: (1) Protracted lithium treatment provides neuroprotection against thapsigargin-induced cell death. (2) Lithium neuroprotection was correlated with the elevated expression of MANF alongside pro-survival ER-stress-associated proteins, GRP78 and Bcl-2 (3) Lithium neuroprotection was attenuated upon the addition of a potent AP-1 inhibitor, alongside the diminished increase in expression of MANF and GRP78. **Conclusions:** Taken together, these data suggest that lithium's neuroprotective mechanisms involve the modulation of pro-survival ER-resident proteins such as MANF through the AP-1 transcription factor. Knockout studies using the CRISPR-Cas9 system will determine the extent of MANF's involvement in lithium neuroprotection. These findings warrant further investigation of MANF as a novel therapeutic for BD.

Title: Selenium mitigates prenatal lead-induced toxicity on cerebral cortex of Wistar rat pups

Authors: *B. E. ECHEFU, S. A. MUSA, U. E. UMANA;
Human Anat., Ahmadu Bello Univ. Zaria., Zaria, Nigeria

Abstract: Lead (Pb) is a dangerous substance to the body that particularly targets the central nervous system (CNS), especially during the early stages of development. Unfortunately, classical therapies remain inefficient in mitigating neurotoxicity associated with developmental Pb exposure on brain regions. However, co-occurring selenium, and heavy metals are known to reduce each other's effects. In this study, the counteractive impact of selenium (Se) to the toxic effects of Pb on the developing rat brain was investigated to explore early protection against developmental disruption of the cerebral cortex by Pb, using Wistar rat model. Pregnant rats were grouped into 3 group of 3 animals each. Group 1 served as control and received 2ml distilled water, group 2 received 60 mg/kg of Pb and group 3 received 60 mg/kg of Pb and 0.3 mg/kg of Se. Administration was orally from gestation day 9 till parturition. On PND 1, and 21, brain tissues were harvested for biochemical and histopathological (histochemical and histological) studies. Observations show that lead accumulated in the brain of pups in an inverse relationship with calcium. Pups in the group administered only Pb, showed evidence of serious necrosis, and neuronal degeneration when compared with the control group and the group co-administered Se and Pb. Hence, the gestational neurotoxic effect of Lead on the cerebral cortex

can be mitigated by Se. Our findings show that Selenium, an essential trace mineral of fundamental importance for animals and humans, might be beneficial in lead toxicity therapy.

Title: Breast milk-associated oxysterol reverses neonatal white matter injury through Gli2-dependent oligodendrogenesis

Authors: *A. S. CHAO[1], P. MATAK[1], K. PEGRAM[1], L. DUBOIS[2], J. W. THOMPSON[2], V. JAIN[3], N. YOUNGE[1], S. GREGORY[3], R. N. GOLDBERG[1], E. J. BENNER[1];

Abstract: White matter injury (WMI) is the most common brain injury leading to poor neurologic outcomes in premature infants. Sepsis and inflammation are significant risk factors and there are no treatment options available. Developing novel drug therapies for neonates is challenged by appropriate concerns for safety. Here, we identified oxysterols in human maternal breast milk and explored their therapeutic potential in directing neural stem cells (NSCs) into the oligodendrocyte (OL) lineage via the Sonic HedgeHog (Shh) pathway *in vitro*. Further, we investigated whether breast milk-associated oxysterols can rescue neonatal WMI *in vivo*. Oxysterols (20HC, 22(S)HC, 22(R)HC, 24HC, 25HC, 27HC) were identified in breast milk using Liquid Chromatography/Electrospray Ionization/Tandem Mass Spectrometry. NSCs were cultured from the subventricular zone (SVZ) of mice and treated with oxysterols. Cells were analyzed by immunohistochemistry, western blot, flow cytometry, and 10X single cell droplet sequencing, looking for markers of the OL lineage. Shh pathway activation was established by quantifying upregulation of target gene, Gli1, by western blot and RT-PCR. Gli-dependence was explored using pharmacological and genetic approaches. Neonatal sepsis leading to WMI was induced in mice on postnatal day 5. Mice then received either 20HC or vehicle. Stereology determined OL numbers in the periventricular white matter regions. Myelination was evaluated

by performing g-ratios to determine myelin thickness and using an unbiased Space Balls stereological probe to quantify subcortical myelinated fiber length. Motor function in mice was analyzed using the CatWalk gait analysis system. To lineage trace postnatal SVZ NSCs *in vivo*, neonatal sepsis was induced in Nestin-CreER^{T2};R26r-TdTomato pups as above, and then treated with either vehicle or 20HC. We found that Gli2 is functionally required for 20HC-induced oligodendrogenesis. Following neonatal WMI *in vivo*, 20HC treatment increased numbers of mature OLs, improved myelination and rescued motor deficits in mice. Lineage tracing experiments showed that 20HC-mediated recovery of OL deficit is mediated in part through 20HC-induced SVZ-derived oligodendrogenesis *in vivo*. Because oxysterols are found in human maternal breast milk, this approach may be further developed into a novel and safe therapeutic strategy to mitigate neonatal WMI.

Astrazeneca supplied saracatinib (Open Innovation Program)

Title: Saracatinib, a src family kinase inhibitor, mitigates gliosis and neurodegeneration in the rat (diisopropylflourophosphate) DFP model

Authors: *M. C. GAGE[1], L. WACHTER[4], K. DISHMAN[4], M. R. PUTRA[2], T. THIPPESWAMY[3];
[1]Neurosci., [3]Biomed. Sci., [2]Iowa State Univ., Ames, IA; [4]Kinesology, Iowa state university, Ames, IA

Abstract: The present study aims to determine the disease modifying potential of saracatinib, a src family kinase inhibitor, in diisopropylfluorophosphate (DFP) induced toxicity. DFP and other organophosphate nerve agents initiate *status epilepticus* (SE) via the irreversible inhibition of acetylcholinesterase. Src family kinases are upregulated following SE and are implicated in both neuroinflammatory pathways (leading to the production of proinflammatory cytokines and reactive oxygen species) and neuronal pathways associated with hyperexcitability. We therefore predicted that saracatinib treatment after SE could mitigate DFP-induced neuropathology and brain dysfunction. Male Sprague Dawley rats (7-8 weeks) were used in this study. The rats were

exposed to 4 mg/kg DFP or PBS (subcutaneous) followed immediately by 2 mg/kg atropine sulfate (intramuscular) and 25 mg/kg 2-pralidoxime (intramuscular). Midazolam (3 mg/kg, intramuscular) was administered after 20 minutes of convulsive seizures (around 30 minutes after DFP) to terminate behavioral seizures. Two hours after midazolam, saracatinib (20 mg/kg, o.p.) or vehicle was given once a day for seven days. These animals were assessed 6 weeks later for behavioral comorbidities and then terminated at 10 weeks to assess gliosis and neurodegeneration via immunohistochemistry. We found nonsignificant reduction in discrimination indexes in the novel object recognition test in DFP treated animals with minimal mitigation by saracatinib. DFP treated animals, both those administered vehicle and saracatinib, reached the goal box quicker than controls in the horizontal bar test. There were no differences between groups in the Morris Water Maze, forced swim test or rotarod apparatus. At 10 weeks, DFP significantly increased microgliosis, astrogliosis and neurodegeneration; this was significantly mitigated by saracatinib in the piriform cortex and amygdala. These findings suggest saracatinib could be a useful therapeutic intervention in the mitigation of brain pathology following organophosphate toxicity by DFP. However, the degree of mitigation of behavioral dysfunction by saracatinib require further investigation

Title: Overexpression of miR-17 promotes neuroprotection and regeneration in the central nervous system.

Authors: *F. S. L. CAMBRAIA[1], R. A. D. ALMEIDA[1], C. G. FERREIRA[1], C. R. D. O. CYRINO[1], V. MATOS[1], L. CALDI-GOMES[2], U. MITCHEL[3], V. D. T. RIBAS[1];

Abstract: Neurons of the central nervous system (CNS) of adult mammals have limited regenerative capacity, with no effective spontaneous regeneration after axonal injury. Consequently, any damage to this system, whether due to neurodegenerative diseases or traumatic injuries, leads to permanent neurological deficits. For example, in glaucoma, a multifactorial neurodegenerative disorder, optic nerve damage leads to irreversible blindness due to the progressive degeneration of the axons that make up the optic nerve and the subsequent loss of retinal ganglion cells (RGCs). Therefore, it is imperative to develop new therapeutic strategies aiming to protect neurons from death, as well as their axons from degeneration, and to promote the regeneration of injured axons. Recently, microRNAs, which are small non-coding RNA molecules involved in the control of gene expression post-transcriptionally, have emerged as interesting targets to promote neuroprotection and regeneration in the CNS. However, little is known about the role of specific microRNAs in CNS repair. In this study, we evaluated the role of miR-17 in neuroprotection and regeneration using *in vitro* and *in vivo* models of CNS injury. For that, recombinant adeno-associated virus (rAAV) vectors overexpressing miR-17 (rAAV.miR-17) or expressing only mCherry protein (rAAV.CTRL) were used to transduce primary cortical neurons *in vitro*and RGCs of adult Wistar rats *in vivo*. In the *in vitro* analysis, primary cortical neuron culture was subjected to a scratch lesion and neuritic regeneration were evaluated. The rAAV.miR-17 was able to significantly increase neurite length. For the *in vivo* analysis, RGCs were transduced with rAAV vectors, retrogradely traced by FluoroGold and subsequently an optic nerve crush was performed. Neuroprotection of RGCs was observed by overexpression of miR-17, with a significant increase in RGCs survival 28 days after the lesion. Axonal staining by the expression of mCherry revealed axonal protection in the optic nerve in the proximal and distal regions to the lesion. Immunostaining for GFAP and Iba1 in optic nerve cryosections showed no change in astrocytes and microglia, respectively. Bioinformatics analysis allowed the identification of predicted and validated mRNA targets of miR-17. Functional analysis of gene ontology of the predicted mRNA targets of miR-17 showed that several of them are involved with regeneration, degeneration and cell death. In conclusion, these findings provide new knowledge about the role of miR-17 in neuroprotection and regeneration in the CNS, and point to miR-17 as a potential therapeutic target for CNS damage, especially those affecting the optic nerve.

Title: Superior antiseizure and neuroprotective efficacy of LY293558-Caramiphen in combination when compared to midazolam against soman induced seizures in 7 days old rats

Authors: *J. APLAND[1], T. H. FIGUEIREDO[2], M. D. FURTADO[3], V. ARONIADOU-ANDERJASKA[2], V. PIDOPLICHKO[2], K. ROSSETTI[2], M. BRAGA[2];
[1]USAMRICD, Gunpowder, MD; [2]Anatomy, Physiol. & Genet., Uniformed Services Univ., Bethesda, MD; [3]Anatomy, Physiol. and Genet., USU, Bethesda, MD

Abstract: The currently approved anticonvulsant for the treatment of status epilepticus (SE) induced by nerve agents is the benzodiazepine midazolam. However, midazolam does not appear to offer neuroprotective benefits, particularly in children, probably because in the developing brain, synaptic transmission mediated via GABAA receptors, the target of benzodiazepines, is still weak or depolarizing. In the present study, we exposed 7-day-old (P7) male and female rats to 1.2xLD50 soman, and compared the antiseizure, anti-lethality, and neuroprotective efficacy of midazolam (3 mg/kg) and the combination of LY293558 (an AMPA/GluK1 receptor antagonist; 5 mg/kg) and caramiphen (an antimuscarinic with NMDA receptor-antagonistic properties; 50 mg/kg) administered 1 h post-exposure. Treatment with LY293558+CRM showed superior efficacy to stop seizures in P7 rats, the latency for re-occurrence of seizures after cessation of the initial SE was dramatically longer in the rats treated with LY293558+CRM, and the total duration of SE was significantly shorter in this group. The difference between the two treatment groups in the total duration of SE was accompanied by differences in neuropathology. Total neuronal loss and loss of interneurons in the CA1 hippocampal area and the BLA were significant in the MDZ-treated group in comparison with control non-exposed rats and with the LY293558+CRM-treated rats, at 1, 3 and 6 months post-exposure. There is an apparent deterioration over time, and at the 6-month time point, there is also some neuronal and interneuronal loss in the basolateral amygdala (BLA) of the LY293558+CRM treated group. Hippocampal volume was significantly reduced in the MDZ-treated rats but not in the LY293558+CRM-treated rats, at 3 and 6 months post-exposure. Spontaneous, background inhibitory activity was significantly reduced in the MDZ-treated group but not in the LY293558+CRM group, at 1, 3 and 6 months post-exposure, and this was accompanied by increased anxiety only in the MDZ-treated group, as determined by the Open Field and the Acoustic Startle Response tests. The appearance/incidence of spontaneous recurrent seizures was greater in the MDZ-treated group, and the difference from the LY293558+CRM group reached statistical significance at the 3-month time point. The combined administration of LY293558 and caramiphen, by blocking mainly AMPA, GluK1, and NMDA receptors, is a very effective anticonvulsant and neuroprotective therapy against soman in immature rats.

Title: Human Sensory Tissue Extraction and Research: How to Develop a Collaboration with Local Organ Procurement Organizations

Authors: *Z. BERTELS[1], A. CHAMESSIAN[1], D. BROCKMEIER[2], B. A. COPITS[1], J. S. DEL ROSARIO[1], J. LEMEN[2], J.-N. LI[1], G. MARKLIN[2], J. SACKEY[1], R. SLIVICKI[1], A. WIDMAN[1], J. YI[1], R. W. GEREAU, IV[3];

Abstract: Chronic pain conditions afflict over 100 million individuals in America and cause greatly diminished quality of life. Much is still unknown about the underlying pathophysiology of chronic pain states resulting in unsuccessful treatments and frustration from both patients and clinicians. A major hurdle slowing the progress in the development of new effective treatments is the translation from preclinical data to clinically relevant findings. Investigations of rodent sensory neurons have previously been used to explore molecular mechanisms that contribute to the development of chronic pain states, but these studies can potentially run into late-stage translational issues. The use of human tissues provides a route for direct validation of preclinical findings and further development of clinically relevant assays. Unfortunately, gaining access to human sensory tissue can be difficult and expensive. Collaboration with local organ procurement organizations offers a feasible route for access to human tissues for translational research programs. Here we describe how our group established a relationship with a local organization, Mid-America Transplant, to facilitate this work in our Pain Center. This collaboration has allowed the collection of human dorsal root ganglia, spinal cord, intervertebral discs, sympathetic ganglia and other tissues from an array of donors allowing for a diverse data set. Because of the proximity to the tissue source and optimized protocols, we obtain high quality tissues, allowing for a diverse array of physiologic, genetic and anatomical studies that have proved challenging previously. This allows for direct probing of therapeutic targets or development of new clinically relevant models. This presentation we will provide an outline to the general workflow of obtaining the human sensory tissue and its processing. With the methods outlined in this presentation we hope to discuss replication of this relationship in other labs and further facilitate clinically relevant research.

Title: Using human nervous tissues from organ donors for therapeutic discovery and translational validation - a collaboration with the Southwest Transplant Alliance and the Center for Advanced Pain Studies at the University of Texas at Dallas

Authors: *S. I. SHIERS[1], J. M. MWIRIGI[1], M. S. YOUSUF[1], D. T. FERREIRA[1], A. CERVANTES[2], J. C. REESE[2], T. J. PRICE[1];
[1]Sch. of Behavioral and Brain Sci., The Univ. of Texas at Dallas, Richardson, TX; [2]Southwest Transplant Alliance, Dallas, TX

Abstract: Rodent models have been the standard for preclinical research for decades as they offer an invaluable means to explore the functional, morphological, and molecular properties of disease. However, differences in the underlying biology between rodents and humans exist which most certainly underlies the limited success of rodent-derived therapeutic strategies into the clinic. As such, the Southwest Transplant Alliance and the Center for Advanced Pain Studies at the University of Texas at Dallas have unified forces to tackle this obstacle in therapeutic translatability and discovery. With access to nearly 300 donor collections yearly, we have generated a large tissue bank of fresh frozen human nervous tissue including dorsal root ganglia, spinal cord, vagus nerve, sciatic nerve, spinal meninges, and nodose ganglia. Additionally, with direct access to the living tissues, we can keep these tissues alive as explants for several hours and as cultures for at least 10 days. These tissues are high quality (recovered within 4 hours post-mortem) and can be used for many types of molecular assays. For instance, over the last year, we have identified human-specific analgesic targets, compared the expression of rodent-identified genes and proteins, evaluated morphological and anatomical differences between species, and assessed the functional and molecular changes of human neurons after direct application of a stimulus or therapeutic. Herein, we will discuss how our collaboration works, how we recover human nervous tissues and the basic methods and applications of these tissues for therapeutic discovery. This knowledge can be used by other laboratories and transplant organizations to achieve similar efforts around the world.

Title: Oncostatin M induces MNK-eIF4E signaling in human dorsal root ganglia

Authors: J. MWIRIGI, I. SANKARANARAYANAN, S. SHIERS, M. KUME, P. RAY, M. YOUSUF, T. J. PRICE;
Univ. of Texas at Dallas, Richardson, TX

Abstract: Neuroinflammation drives chronic pain states by modulating protein synthesis, particularly in 5' cap-dependent translation and phosphorylation of the eukaryotic initiation factor 4E (p-eIF4E). As such, oncostatin M (OSM) is part of the interleukin-6 (IL6) family of cytokines and has been implicated in neuropathic pain. However, the precise mechanism by which OSM mediates pain hypersensitivity remains to be elucidated. We have previously reported an increase in OSM transcripts in human dorsal root ganglia (hDRG) obtained from patients suffering from radicular/neuropathic pain. In a separate study using spatial transcriptomics, we show that OSM receptors (OSMR) are predominantly expressed by putative nociceptors. We first validated the effects of OSM on hDRGs by treating acutely sliced explants with 10ng/ml OSM and observed an increase in eIF4E phosphorylation, particularly in small diameter neurons and satellite glial cells. Similarly, treating dissociated human sensory neurons with OSM upregulated p-eIF4E levels in putative nociceptors. Based on this data, we aim to elucidate its role in translation signaling pathways via widescale phospho-proteomic profiling in human DRG neurons. Taken together, our work highlights the potential for new pain therapeutics by targeting inflammatory modulators such as OSM.

Title: Molecular characterization of human dorsal root ganglion (DRG) neurons by spatial RNA sequencing

Authors: *D. TAVARES FERREIRA[1], S. SHIERS[1], P. RAY[1], I. SANKARANARAYANAN[1], M. KOTAMARTI[1], A. CERVANTES[2], J. REESE[2], M. BURTON[1], G. DUSSOR[1], T. PRICE[1]; [1]Univ. of Texas At Dallas, Richardson, TX; [2]Southwest Transplant Alliance, Dallas, TX

Abstract: DRG neurons are responsible for transmitting all somatosensation (touch, proprioception, nociception and temperature) from the body to the spinal cord and brainstem. Transcriptomic studies at single-cell resolution on mouse DRG neurons have contributed to our understanding of pain and sensory mechanisms. However, a detailed molecular characterization of human DRG neurons is missing. To fill this gap in knowledge, we have conducted spatial sequencing experiments on human lumbar DRGs collected from 8 organ donors (two sections per donor). The tissues were sectioned into the capture areas of the Visium slides (containing 55 µm barcoded-spots), stained and imaged. During tissue permeabilization, mRNA from each section bound to barcoded primers and was subsequently processed for library preparation and RNA sequencing. Because each section was stained and imaged, the barcoded mRNAs and respective genes' location can be visualized within each DRG section using Loupe Browser (10x Genomics). To generate near single-neuron resolution, we selected all barcodes that overlapped a single neuron in all sections and processed them for downstream analysis. Using ~4000 barcodes that overlapped a single neuron, we identified 12 subsets of human sensory neurons: one proprioceptor, two Aß low-threshold mechanoreceptors (LTMRs), one Aß nociceptor, one Aδ-LTMR, one Aδ high-threshold mechanoreceptor (HTMR), one C-LTMR and five nociceptor subtypes. We have compared our results to both mouse and non-human primate datasets, finding many similarities, but also important differences. These comparisons highlight important implications for the translation of pain animal models and for pain target identification. We also identified sex differences in human DRG subpopulation transcriptomes, including a significant increase in CALCA expression in female pruritogen receptor-enriched nociceptors. In addition to generating near single neuron resolution, we also looked at the presence of non-neuronal cells in human DRGs. Immune cells such as T-cells and macrophages were detected throughout the DRG tissue, including near neurons. These immune cells express several ligands that can interact with neurons to potentially influence sensory mechanisms. We anticipate that our data will advance our understanding of molecular pain mechanisms in humans and facilitate the translation of basic pain neuroscience research.

Abstract: Title: Transcriptional signatures of pain-associated human DRGs: identifying relevant neuro-immune protein interaction networks from sex differential neuronal and immune gene expression profiles Authors: Pradipta R. Ray[1], Stephanie Shiers [1], Megan L. Uhelski[2], Gregory Dussor[1], Patrick M. Dougherty[2], Theodore J. Price[1] Affiliations: 1 University of Texas at Dallas, Department of Neuroscience and Center for Advanced Pain Studies; Richardson, TX, USA. 2 MD Anderson Cancer Center, Houston, TX Goals: Over 50 million Americans suffer from chronic pain, with opioids being the primary drug used to treat pain. In order to develop non-opioid drugs for treating chronic pain, molecular mechanisms of chronic pain need to be understood and putative drug targets identified. Our goal is to quantify whole transcriptome RNA abundances using RNA-seq in pain-associated human DRGs from vertebrectomy patients, and to comprehensively identify molecular changes in these samples by contrasting them with non-pain associated DRGs. Methods: RNA was extracted from the excised DRGs, and cDNA library prepared using stranded, single-end library preparation kit from Illumina, mapped to the reference transcriptome using STAR, and relative abundances quantified using Stringtie. Comparing gene expression distributions across pain-associated and non-pain-associated DRGs in a sex-specific manner identify pain-associated genes for males and females. Gene co-expression modules for these differentially expressed genes are identified. Ligand - receptor signaling based on the set of differentially expressed genes reveal a clear picture of sex differential neuro-immune signaling. Results: We have currently sequenced over 80 human

DRGs, with over 50 having mRNA libraries enriched in neuronal mRNA. Our differential expression analysis revealed a sex differential set of differentially expressed genes in males (including IL1B, TNF, CXCL14, OSM) and females (including CCL1, CCL21, IL2RA, PENK and TRPA1). A small subset of pain-associated genes are common to both sexes (GLRA3, BCL3). Co-expression modules reveal enrichment in JUN-FOS signaling in males, and centromere protein coding genes in females. Neuro-immune signalling pathways reveal multiple cytokine signaling pathways in males (OSM, LIF, SOCS1) and females (CCL21, IL2RA). We have validated a some of these findings using RNAscope studies. Conclusions : Sex differential molecular pathology for chronic pain in males and females suggest the need to sex specific pain therapies. Identification of distinct T cell, B cell and macrophage signature reveals the need for immune cell profiling in chronic pain associated tissues.

Title: Fmrp is present in the peripheral and spinal arbors of a subset of primary nociceptors in humans.

Authors: *M. E. MITCHELL, D. F. TAVARES, S. I. SHIERS, A. AHMAD, T. J. PRICE; Neurosci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Current chronic pain therapies remain largely ineffective forcing millions of individuals across the globe to overcome their often, persistent and debilitating symptoms without adequate relief. Moreover, advancement in effective therapies is rare. A major obstacle

is that treatments targeting nociceptive mechanisms identified in rodent models rarely perform in clinical settings. This underscores the variation in chronic pain mechanisms between rodents and humans. Therefore, we need to interrogate the basic biology of human nociceptive function and regulation. A wealth of work in rodent models has shown that long-term, maladaptive plasticity in primary nociceptors drives chronic pain states. Activity-dependent changes in axonal translation regulation critically contribute to this. This is best studied in the peripheral branches of primary nociceptors, and emerging evidence indicates local translation also plays a role in their spinal terminals. In humans, it is unclear how local translation regulation in these presynaptic compartments contributes to primary nociceptor plasticity. We approached this question immunostaining and imaging human spinal cord and nerves for Fragile X Mental Retardation Protein or FMRP. It is an RNA-binding protein and critical regulator of local translation in neurons. Mutations in the gene encoding FMRP cause Fragile X Syndrome (FXS), the most common heritable form of autism spectrum disorders (ASD). As in many forms of ASD, FXS is associated with sensory processing deficits, including abnormalities in nociceptive sensitization, that arise from aberrant FMRP-dependent synaptic plasticity. In brain, it is well-established that FMRP couples synaptic signals to changes in local translation. In FXS, this translation is uncoupled from receptor and/or kinase activation impairing synaptic sensitivity and plasticity. Fragile X mice exhibit strikingly decreased nociceptive sensitization, blocked inflammation-induced hypersensitivity, and delayed onset of allodynia in neuropathic pain. This is associated with mTOR signaling that is uncoupled from stimulation in primary nociceptors. In WT mice, FMRP is present in the peripheral and spinal branches of a subset of these afferents where it is in RNPs. Here, we show that FMRP is also present across these branches of a subset of primary nociceptors in human nerve and spinal cord. We found it is notably abundant in distinct primary nociceptive compartments in Lissauer's tracts and in Lamina I/II glomeruli. Overall, these findings are consistent with rodent data indicating that intact sensitization and normal onset of chronic pain require FMRP-regulated axonal translation.

Abstract: Diabetes is a metabolic disorder characterized by abnormally high glucose levels due to a lack of insulin production or an insensitivity to insulin. Over 10% of the US population is diagnosed with diabetes and another 35% suffer from prediabetes. As much as half of the diabetic population will develop peripheral neuropathy during their disease course. Previous studies in animals and humans have linked methylglyoxal (MGO), a reactive product of glycolysis, to diabetic neuropathic pain (DNP). However, exactly how MGO causes neuropathic pain in diabetes remains enigmatic. We have recently demonstrated in rodent dorsal root ganglia (DRG) that MGO engages the integrated stress response (ISR) by inhibiting translation elongation through phosphorylating eukaryotic initiation factor 2α (p-eIF2α) via a host of kinases that respond to cellular stress. This results in a repression of global translation while increasing the translation of stress-responsive genes. The absence of eIF2α from the translation machinery is compensated by another initiation factor, eIF2A. Using human DRG explants and nerves obtained from organ donors, we first demonstrate that 24-hour treatment with MGO at 1uM, a concentration typically found in the serum of individuals with DNP, is sufficient to induce the integrated stress response as well as upregulate the expression of eIF2A. In vitro, dissociated human sensory neurons show elevated levels of p-eIF2α and eIF2A, particularly in putative nociceptors. We then used a newly characterized global knockout eIF2A mouse to assess the contribution of eIF2A to MGO-induced pain hypersensitivity. Intraplantar injections of MGO (2, 7.2, and 20 ng) produced mechanical pain hypersensitivity in wild-type animals but not in eIF2A-null mice. Similarly, intraperitoneal administrations of MGO (5 mg/kg) produced tactile allodynia in wild-type mice but failed to do so in eIF2A-null animals. To further confirm the role of eIF2A in ISR-mediated pain, a single hindpaw injection of tunicamycin (10 ug), a potent ISR inducer, established chronic mechanical hypersensitivity in wild-type animals while the eIF2A knock-out animals did not show a change in mechanical sensitivity. Further biochemical analysis confirmed an increase in p-eIF2α and eIF2A in the sciatic nerve and DRG of MGO-treated animals. Our findings show that MGO induces the ISR in human sensory neurons, DRG explants, and nerves at a concentration associated with neuropathic pain in diabetic patients. Our work indicates that eIF2A likely regulates the translation of proteins associated with mechanical pain hypersensitivity following MGO and that these proteins may represent new targets for DNP.

Title: Igg from fibromyalgia patients causes hyper-excitability of peripheral sensory neuronsin mice

Authors: *M. R. ISRAEL[1], N. VASTANI[1], S. SENSI[2], C. GENTRY[1], A. GOEBEL[3], S. BEVAN[1], D. A. ANDERSSON[1];
[1]King's Col. London, London, United Kingdom; [2]Univ. of Liverpool, Liverpool, United Kingdom; [3]Walton Ctr. NHS Fndn. Trust, Liverpool, United Kingdom

Abstract: Background: Fibromyalgia is a syndrome characterised by widespread pain, fatigue and mental fog in which 40 - 60% percent of patients also experience parathesiae and pain exacerbated by changes in temperature. We have recently shown that some of the symptoms, including altered responses to nociceptive pressure, cold and non-stimulus evoked symptoms such as fatigue can be faithfully recapitulated in mice (Goebel et al, 2021). Mice administered with patient derived IgG have decreased thigh pressure and cold evoked thresholds compared to healthy control treated mice. The mechanism that underlies these pain behaviours is unknown however patient derived IgG is accumulated in dorsal root ganglion (DRG) tissue in these passive transfer experiments. Furthermore, both patients and mice treated with patient IgG showed a decrease in intra-epidermal nerve fiber density compared to healthy controls. We hypothesised that some of the patients symptoms are caused by changes in excitability and responsiveness to stimuli (mechanical, cold) of peripheral sensory neurons. **Methods:** IgG was isolated from FM patients (n = 4) and healthy control serum (n = 4). Female C57Bl/6 mice were treated with 8 mg (0.4 ml, i.p) patient -derived IgG or healthy control IgG and assessed for pressure and cold sensitivity. We then used whole cell patch clamp and *ex vivo* nerve recordings from cultured dorsal root ganglion cells and skin - saphenous preparations. **Results:** DRGs isolated and cultured from mice administered with IgG were broadly hyper-excitable compared with HC treated DRG. Specifically, FM DRG had a decreased rheobase, increased input resistance and fired more action potentials per ramp stimulus. *Ex vivo* sensory nerve fibers from FM treated animals were also broadly more excitable than HC treated. Canonical nociceptors, Aδ; and C-mechano fibers have decreased mechanical thresholds but do not fire significantly more action potentials per stimulus. There is a significant increase in the proportion of C fibers that respond to cold stimulus. Low threshold mechano receptors (Aß-SA, Aß-RA) have significantly increased responses to mechanical stimulation. A subset of Aß fibers developed *de*

novo cold sensitivity in FM treated animals. **Conclusions:** In this study, we define the precise changes in peripheral nerve excitability that are caused by auto-reactive IgG in FM patients. Mice administered with patient derived IgG have hyperexcitable sensory neurons. Most significantly, we have identified a subset of Aß fibers that have developed cold sensitivity after IgG treatment. Comprehensive changes in excitability may explain the diverse symptomology of patients.

Title: Basal forebrain GABAergic projections to the olfactory bulb are rapidly recruited by odor encounters in a stimulus specific manner

Authors: *P. S. VILLAR[1], R. C. ARANEDA[1], D. ALBEANU[2];
[1]Univ. of Maryland, College Park, MD; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The output of the olfactory bulb is tightly regulated by top-down signals. Among these, a heterogeneous collection of neurons in the basal forebrain broadly integrates cortical and subcortical afference, and broadcasts neuromodulatory and GABAergic input throughout all bulb layers. To date, however the dynamics and functional roles of these projections in controlling olfactory representations remain unknown. Here, we used multiphoton calcium imaging in awake mice to investigate the recruitment of these descending GABAergic projections in olfactory processing. GABAergic boutons were spontaneously active across bulb layers, exhibiting brief activity bouts in naïve mice. Boutons of the same axonal branch showed significantly higher correlation than those belonging to different axons, confirming their homogeneous activation. Odor presentation resulted in sparse responses across different bulb layers, in an odorant and concentration specific manner. Across multiple odorants, boutons responded by either enhancement or suppression of baseline activity, while mixed-type responses were rarely observed. The dynamics of these calcium signals were similar to the odor responses

exhibited by bulbar glutamatergic projections originating in the piriform cortex, characterized by fast onset and diverse decay times. Since both glutamatergic and GABAergic feedback projections share the same targets in the bulb, our results suggest that the bulb output is under the influence of descending signals able to rapidly change their polarity. In ongoing experiments, we are assessing the contribution of the olfactory cortex in carrying predictive signals and shaping the odor representations of these GABAergic inputs in task-engaged animals, in familiar odor scenes and to novel, unexpected stimuli. Our results indicate that the basal forebrain GABAergic projections to the bulb are rapidly recruited by odor encounters and develop diverse and stimulus specific responses.

Title: The effect of neuromodulation of the olfactory bulb on cortical odor processing.

Authors: *K. MAMA[1], O. D. ESCANILLA[4], M. EINHORN[2], M. LITVACK[1], A. MEZHERITSKIY[1], C. LINSTER[3];
[2]Psychology, [3]CPL & Neurobio. and Behavior, [1]Cornell Univ., Ithaca, NY; [4]Binghamton Univ., Binghamton, NY

Abstract: Sensory and cortical neural networks are strongly interconnected and reciprocally affect each other when processing information. In the olfactory system, modulation of bulbar neural dynamics by various neuromodulators affects learning and memory as measured behaviorally. Because odor memories are likely to be formed and stored in networks postsynaptic to bulbar networks, we ask how bulbar neural dynamics affect cortical odor representation. We show how cortical odor representations can be predictive of behavioral measures pertaining to memory stability, duration, and specificity, as predicted by our computational modeling studies. Behaviorally and computationally, dynamics in bulbar networks have been shown to strongly modulate cortical readout and plasticity.
In our study, rats are passively exposed to a set of five odorants, each presented five times in a randomized order over a thirty-minute period, both before and after neuromodulation of the olfactory bulb. In each rat, we record field potentials and unit responses to odors in the olfactory bulb and cortex simultaneously using surgically implanted recording electrodes. To modulate

bulbar dynamics, we locally manipulate cholinergic activity by infusing the olfactory bulb either with saline, cholinergic antagonists, or cholinergic agonists. To eliminate motivational confounds (for this first study) and to have access to respiration signals, rats were tested in a custom-designed cage equipped with pressure sensors and olfactometer inputs. This enables the recording of respiratory activity and allows for precise odor delivery without the need for prior behavioral conditioning. With this setup, we observed changes in cortical odor responses and dynamics driven by changes in bulbar dynamics. We are analyzing to what extent these are accompanied by plasticity-driven effects in response to repeated odor stimulation. So far, predictions from behavioral studies and computational modeling are confirmed. The next step will be to use food motivated odor learning paired with recordings and manipulations of bulbar dynamics.

Title: In vivo calcium imaging of accessory olfactory bulb mitral cells during social interactions

Authors: S. T. BYERS, *K. J. MONK, I. G. DAVISON;
Dept. of Biol., Boston Univ., Boston, MA

Abstract: The vomeronasal system plays a pivotal role in guiding social behavior through the sensing of behaviorally-relevant chemosignals (e.g., pheromones). While responses to social cues have been characterized in the accessory olfactory bulb (AOB), much less is known how such chemosignals are represented during unrestrained interactions that elicit natural social behaviors. Here, using miniscope Ca2+ imaging of AOB activity in freely moving mice, we assess how the AOB encodes sensory information during social investigations of male and female conspecifics from various background strains. First, in constrained interactions, experimental animals are allowed to investigate restricted body regions of various partners, allowing us to image sensory-evoked responses to facial or anogenital regions associated with distinct chemosignals with high spatiotemporal precision. Second, we allow mice to freely investigate and interact with a range of probe animals while recording evoked activity. In both

cases, while a subset of glomeruli show strongly selective activation for male and female probe animals, most show mixed responsiveness. We also find selective activation to chemosignals located on different body regions, reflecting the distinct cues secreted at these locations. We analyzed the microstructure of social interactions and found that mice tend to structure their investigations as sweeps from nose to tail over one to two seconds, suggesting there may be preferred sequences of social investigations that could serve to bias incoming sensory information. However, the rapidity of investigation sequences contrasts with the prolonged timescale of AOB neural activation, suggesting that the AOB and vomeronasal system integrate information across extended timescales rather than directly mapping individual sensory events onto discrete behavioral responses. Together, these findings extend our understanding of how the AOB represents behaviorally-relevant chemosignals in support of social behavior.

Title: Combining natural and synthetic stimulation to unravel the rules governing sensory processing

Authors: *J. V. GILL[1], D. ASUA[2], S. SHOHAM[2], D. RINBERG[1];
[1]Neurosci. Inst., [2]Tech4Health Inst., New York Univ. Langone Hlth., New York, NY

Abstract: Animals rely on their senses for survival. The speed and precision of sensory guided behavior is enabled by multiple stages of computation from the peripheral to the central nervous system. However, what computations are performed, and how the functional connectivity of sensory circuits support perception is still largely unknown. The mouse olfactory bulb provides an ideal model for investigating the connection between the structure of connectivity and functional output, given the ease of access to both the input (glomeruli) and output (mitral cell) layers for recording and manipulation. To this end we developed a system for simultaneous large-scale 2-photon calcium imaging and holographic stimulation in the olfactory bulb of awake mice, permitting interrogation of circuit function with single neuron and action potential resolution. Using this technique, we recently demonstrated that manipulating activity in small groups of mitral cells, the projection neurons of the mouse olfactory bulb, can have a large impact on perception. Yet, it is unknown what computation is performed by the bulbar network,

and how odor representations are reshaped by the interactions between excitatory projection neurons and inhibitory interneurons.
To address this knowledge gap, we first explored the structure of encoding at the level of mitral cells in awake mice, presenting a large battery of odors while recording the responses of populations of mitral and granule (inhibitory) cells using 2-photon calcium imaging. From these responses we found a low-dimensional projection which well-preserved the distances in odor tuning between neurons. We then probed the structure of functional connectivity between mitral cells by individually activating neurons using holographic photostimulation while measuring the effect on the local population. While mitral cells are predominantly interconnected by inhibitory interneurons, without anatomical evidence for direct excitatory connections, we surprisingly observed a mixture of excitatory and inhibitory influence exerted between mitral cells. In ongoing experiments and analyses we attempt to relate the sign and strength of coupling between mitral cells to distances in odor tuning to determine how local connectivity reshapes odor representations.

Title: Neurogenesis of Calretinin-expressing neurons in the mouse olfactory bulb

Authors: *T. R. BRECHBILL[1], T. KUNKHYEN[2], C. E. CHEETHAM[3];
[2]Neurobio., [3]Dept. of Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Throughout adulthood, neuronal progenitors are born in the mouse subventricular zone (SVZ) and migrate to the olfactory bulb (OB) via the rostral migratory stream. There, the immature neurons migrate radially and differentiate into several molecularly and functionally distinct neuronal types. One of these is the calretinin (CR)-expressing neurons, a subtype of GABAergic interneurons. CR+ neurons have very high densities within the glomerular layer (GL) and the granule cell layer (GCL) and much is unknown about their role in olfactory function. The goal of this study was to determine whether OB CR+ neurons are dependent on sensory input from OSNs for their survival, and whether additional CR+ neurons are generated when sensory input is restored.
To test this, we specifically ablated olfactory sensory neurons in the OE, which provide sensory input to the OB and themselves regenerate, using methimazole (MMZ). 75 mg/kg of either MMZ

or sterile saline was injected intra-peritoneally in 8-week-old C57BL/6J mice. Mice were transcardially perfused at 7, 14 or 35 days post-injection to assess the effect of loss followed by regeneration of sensory input. OBs from 3-5 mice per time point were dissected and cut into 40-micron coronal sections. We used sections 25% (anterior), 50% (central) and 75% (posterior) along the anterior-posterior axis. Immunohistochemical staining for calretinin was performed and sections were imaged using a large area scanning widefield fluorescence microscope (Nikon-90i) using a 10x objective. We determined the density of CR+ neurons in the GL, EPL and GCL, using DAPI fluorescence to define each layer.
Interestingly, 7 days post-injection, CR+ neuron density was higher in MMZ-treated than in saline-treated mice in both the GL and EPL ($P < 0.001$ for effect of MMZ treatment, 2-way ANOVA). However, CR+ neuron density was similar in the GL and EPL of MMZ- vs. saline-treated mice at 14- and 35-days post-injection. In contrast, there was no significant difference in CR+ neuron density in the GCL between MMZ- and saline-injected mice. Between 7 and 14 days post-MMZ, CR+ neuron density decreased significantly in the GL ($P = 0.027$) and showed a strong tendency to decrease in the EPL ($P = 0.069$). We are currently determining the contribution of changes in CR expression, integration of newborn CR+ neurons and cell death on changes in CR+ neuron density in the GL and EPL.
Overall, our data suggest that GL CR+ neurons are not as reliant on OSN input for their survival as other GL GABAergic interneuron subtypes, such as dopaminergic neurons. Our data also highlight differences in the activity dependence of CR+ neuron density in the GL/EPL vs. the GCL.

Title: Nonlinear representations of odor mixtures in feedforward and feedback pathways of the olfactory system

Authors: *J. D. ZAK, V. N. MURTHY;
Mol. and Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: Sensory systems are organized hierarchically. Early stages efficiently format transduced signals and successive processing steps perform more complex computations to extract relevant sensory representations. This feedforward hierarchy is broken early in the olfactory system, where dense feedback projections from cortical regions arrive at the olfactory bulb. In fact, the descending inputs from the cortex to the olfactory bulb outnumber the afferent inputs it receives from the sensory periphery. Therefore, revealing how these projections, both feedforward and feedback, contribute to the coding of complex stimuli is necessary for understanding the sensory processing that takes place in both the olfactory bulb and cortex. We expressed calcium indicators in olfactory sensory neurons, or the piriform cortex, and used multiphoton imaging to measure the stimulus-response properties of feedforward and feedback projections to the olfactory bulb in awake and freely breathing mice. We used two odor delivery paradigms that revealed surprising aspects of how odors and their mixtures are represented in cortical projections. First, monomolecular odors spanning a concentration range of more than three odors of magnitude evoked responses in feedback axons that, as a population, and like feedforward inputs, increased with concentration. However, at the level of individual boutons, we observed odor responses that had complex, non-monotonic concentration dependence that often reflected a preferred range. We next imaged bouton responses to odor mixtures that contained between 2 and 14 components. Feedback bouton responses were highly sublinear and even more so than feedforward inputs to the olfactory bulb. The activity in feedback projections typically mirrored the response of a single mixture component. Finally, we compared how similar mixtures, based on their component identities and activity patterns, are represented in feedforward and feedback projections. These results suggest that the piriform cortex may be providing highly demixed sensory information to the olfactory bulb, dominated by individual odor components. Future studies will focus on how the nonlinear activity patterns in cortical projections are inherited by olfactory bulb projection neurons.

Title: A non-canonical feedforward pathway for computing odor identity

Authors: *H. CHAE[1], A. BANERJEE[1,2], M. DUSSAUZE[1,2], D. F. ALBEANU[1,2];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Cold Spring Harbor Lab. Sch. for Biol. Sci., Cold Spring Harbor, NY

Abstract: Elucidating the neural circuits that enable robust odor identification remains a fundamental challenge in olfaction. The prevailing view is that odor identity is computed within the piriform cortex (PC), drawing from mitral cell input from the olfactory bulb (OB). Here, we assessed the validity of this model by measuring the interplay between feedforward and feedback signals across different olfactory areas in representing odor identity by leveraging cell type specific analysis. In awake mice, we monitored the odor responses of the two classes of OB outputs, the mitral and tufted cells via multiphoton microscopy, as well as from their major cortical targets, the piriform cortex and the anterior olfactory nucleus (AON) respectively using tetrode micro-drives. We find that tufted cells, which strongly innervate the AON, substantially outperform mitral cells in decoding both odor identity and intensity, as well as in intensity invariant decoding, acting in a largely feedforward fashion. Cortical-bulbar feedback from the piriform cortex regulates the activity of mitral cells while the AON preferentially regulates the activity of tufted cells, matching biases in feedforward connectivity. Moreover, piriform cortex feedback specifically restructures the mitral cell responses leaving tufted cell responses largely unaltered, while feedback from the AON preferentially controls the gain of tufted cell odor representations. Finally, preliminary electrophysiology recordings indicate that the AON neural ensembles outperform piriform cortex ensembles in decoding both odor identity and concentration information, thus reflecting differences between their tufted and mitral cell inputs. These results indicate that, unexpectedly, the non-canonical tufted cell-to-anterior olfactory nucleus pathway plays a major role in mediating odor recognition and discrimination and re-define our understanding of how and where odor identity and intensity are computed across the brain

Title: Transformation of Whisker Touch Representations from Layer 4 to Layer 2 in Primary Vibrissal Somatosensory Cortex

Authors: B. VOELCKER, R. PANCHOLI, L. RYAN, S. P. PERON;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Sensory input arrives from thalamus in cortical layer (L) 4. From L4, information flows predominantly to superficial layers, so that L4 to L2 constitutes one of the earliest cortical feedforward networks. Despite extensive study, the transformation performed by this network remains poorly understood. We use volumetric two-photon calcium imaging in L2-4 of primary vibrissal somatosensory cortex (vS1) to densely sample activity as transgenic mice expressing GCaMP6s in excitatory neurons perform an object localization task with two whiskers. We find that the touch response sparsens superficially and becomes more reliable. Touch-evoked pairwise correlations among the whole touch cell population increase superficially. In addition, L3 and L2 contain ensembles of ~20 extremely highly correlated neurons, that reliably respond to specific types of touch. Our results show that from L4 to L2, cortex transitions from a dense probabilistic code to a sparse and robust ensemble-based code.

Title: The role of individual barrels in object localization behaviors

Authors: *L. RYAN[1], M. LAUGHTON[1], A. SUN-YAN[1], R. PANCHOLI[1], B. VOELCKER[1], S. P. PERON[2];

Abstract: In the rodent, the vibrissae constitute a crucial sensory organ, with around twenty percent of the somatosensory cortex dedicated to processing information from the whiskers. This cortical area projects to higher order sensory and motor areas and is likely a crucial node for sensorimotor integration during behavior. However, the behavioral role of vibrissal primary somatosensory cortex (vS1, or 'barrel cortex') is unclear. Large-scale lesions, which targeted vS1 but typically included additional brain areas, such as secondary vibrissal somatosensory cortex, suggest that vS1 is necessary for rodent performance on whisker-based object localization tasks where mice must discriminate between contacts at two or more positions. In object detection tasks, cortical lesions produce a transient behavioral decrement, but mice recover within a day or two. The large extent of these lesions, as well as the fact that they require

surgical intervention which necessitates extensive recovery, makes these results difficult to interpret. Past optogenetic silencing and pharmacological inactivation experiments also lack barrel-scale resolution. Thus, the role of vS1, and of individual barrels, in localization behaviors remains unclear. In gap crossing tasks, barrel-scale lesions result in performance decrement. We lesion individual barrels in mice performing an object localization task with a single spared whisker. Mice expressing GCaMP6s and implanted with a cranial window perform an object localization task with a single spared whisker in which they touch multiple anterior and posterior object positions, reporting pole position by licking one of two lickports. We target and lesion the individual vS1 barrel of the spared whisker (typically, C2) using prolonged exposure to a high-powered femtosecond laser source. Lesions are confined to vS1, and lesion extent ranged from 0.07 +/- 0.02 mm^3 (mean +/- S.D.; n = 4, volume of a single barrel: 0.07 mm^3). Barrel lesions result in an irreversible decline in behavior in mice trained on an object localization task. Mice are retrained on a detection task following the lesion. A separate cohort of mice trained on a go/no go vibrissal detection task showed no behavioral decrement following vS1 lesions. Thus, individual vS1 barrels are critical for animals to perform discrimination, but not detection, tasks with the whisker whose stimulation drives the lesioned barrel. We demonstrate a reproducible and non-invasive lesioning technique that allows for high-throughput experiments testing areal necessity and the contribution of individual cortical areas to the distribution of behaviorally relevant information throughout cortex.

Title: Cortical dynamics during optical microstimulation task training

Authors: *R. PANCHOLI[1], L. RYAN[1], B. VOELCKER[1], S. P. PERON[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: Theoretical studies of cortical plasticity have predicted that repeated activation of a group of neurons should drive a host of changes in primary sensory cortex. However, technical limitations with stimulation and recording techniques, as well as noise and plasticity introduced at processing stages prior to cortex, have made it difficult to interpret cortical network changes resulting from sensory stimulation. Here, we train transgenic mice expressing GCaMP6s in cortical pyramidal neurons to perform an optogenetic pulse count discrimination task. Mice must

use activity evoked in layer 2/3 of primary vibrissal somatosensory cortex (vS1) to report whether the number of optogenetic LED pulses presented to cortex was high or low. As mice learn to perform this task, we use two-photon calcium imaging to track vS1 neural dynamics across learning. We find distinct populations of neurons whose activity declines, remains stable, or increases over the course of training. These changes are consistent with theoretical models of repeated cortical stimulation showing increased feedback inhibition for highly responsive neurons. A decoding analysis further allows us to track choice-related activity dynamics across learning and reveals neurons whose activity is highly correlated with animal choice. Future experiments will explore the behavioral impact of neurons with varying levels of stimulus-evoked and choice-related activity.

Title: Laminar specificity of learned sensory, sensory-motor, and motor signals in frontal cortex during a whisker detection task

Authors: *B. ZAREIAN[1], A. LAM[2], E. ZAGHA[1];
[1]Dept. of Psychology, Univ. of California Riverside, Riverside, CA; [2]Biomed. Sci., Univ. of California, Riverside, Riverside, CA

Abstract: Laminar specificity of learned sensory, sensory-motor, and motor signals in frontal cortex during a whisker detection taskWhisker motor cortex (wMC) has been shown to be important in lateralized attenuation of sensory information and sensory-motor transformation in a selective whisker detection task in mice (Aruljothi et al. 2020, Zareian et al. 2021). Laminar profile of attenuation and how the sensory signal leads to generation of a motor signal remains elusive. To explore the answer, we used laminar electrophysiological recording during behavior to characterize laminar propagation of sensory signals within the frontal cortex and interhemispheric propagation between bilateral frontal cortices. Importantly, we restricted our analyses to 100 ms post-stimulus where there is less interference from movement. We show that the sensory signal is similar within supragranular layers between the target and distractor wMC, yet different in infragranular layers (Target wMC>Distractor wMC). Also, within the target hemisphere, we found proportionally more motor than sensory signals in layer 6. Furthermore,

we found that choice signals appear earlier in infragranular layers. Regarding interhemispheric communication, more target signal reaches the distractor wMC overall than distractor signal reaching target wMC. However, proportionally there is more percent attenuation of sensory signal from target wMC to distractor wMC than the opposite direction. These findings suggest that within wMC, sensory signals in supragranular layers are largely context-independent, with task-dependent sensory and choice signals prominent in layer 5 and large motor signals in layer 6. Ongoing studies are comparing cortical propagation to subcortical pathways.

Title: Population-level fiber photometry recording of A11 activity in different behavioral contexts

Authors: *E. M. S. THURSTON[1,7,2], L. A. MOLINA[2], V. A. LE[3], N. CHENG[4,5], K. MURARI[3,7], P. J. WHELAN[6,7,5];
[1]Dept. of Neurosci., [2]Cumming Sch. of Med., [3]Dept. of Electrical and Software Engin., [4]Dept. Comparative Biol. and Exptl. Med., [5]Fac. of Vet. Med., [6]Univ. of Calgary, Calgary, AB, Canada; [7]Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: The dopaminergic A11 nucleus is found in many vertebrate species. Previous work from our lab has shown that photostimulation of the dopaminergic A11 population in mice increased locomotor behaviors. In contrast, avian research has shown an increase in *fos* expression following courtship singing or copulation behaviors. We investigated activity levels of the A11 region during sociosexual, locomotor, or arousal-based behaviors. C57BL6/J male mice 8-10 weeks old were injected with GCaMP6s (pAAV.CAG.GCamP6s.WPRE.SV40) into the A11 region and implanted with an optrode to record fluorescence as a proxy for neuronal activation. Following a 4-week incubation period, mice were handled and habituated to the testing conditions, and then tested in a variety of behavioral paradigms while synchronized photometry recording was conducted: open field, elevated plus maze, and presented with novel stimuli in a custom testing arena including a male or female C57 mouse or a novel object. Mouse

testing order was randomized to minimize order effect. Behavioral data were extracted from videos of these tests (TopScan or a custom tracking software), and behaviors were correlated to A11 calcium transients using a custom MATLAB script. Our results suggest that the A11 region is associated with lower-anxiety behaviors such as grooming, or exploration in an elevated plus maze test. In addition, A11 calcium transients were increased following the presentation of a novel object, but calcium transients were increased or decreased depending on social context. This research is the first to investigate population-level activity of this region correlated with a variety of behaviors. Our study highlights the context-specific activity patterns of the A11 across a standard behavioral battery of tests.

Title: Exploring the inheritance of Threat Sensitivity

Authors: *A. KIM[1], B. J. MARLIN[2];
[1]Columbia Univ., New York, NY; [2]Neurobio., Columbia Univ. Zuckerman Inst., New York, NY

Abstract: Alexis KimSFN AbstractJuly 15th, 2021Abstract Transgenerational epigenetic inheritance (TEI) is the ability of an organism to transmitbiological markers from one generation (F0 generation) to the subsequent generation (F1generation) without perturbing the intrinsic genome. The inheritance of these markers may alterthe phenotype of succeeding generations and offers a channel for the transmission ofenvironmental information. TEI has been exhibited in the inheritance of paternal stress wherebymale mice conditioned to a specific odor with a painful shock, demonstrated heightenedsensitivity and aversive behavior toward the odor. Consequently, we have found that theoffspring of the olfactory fear conditioned (OFC) male mice, exhibited increased olfactorysensory neurons (OSN) attuned to the odor that their fathers have feared, in comparison to thecontrol. To further explore the gravity of this inheritance, we examine the arousal of the F1generation upon presentation of various odors, including the odor that their forefathers havelearned to fear. Arousal marks a change in internal state preluding perception and is keenlymediated by noradrenaline, released by the Locus Coeruleus (LC). Arousal has been linked tostress, transmitted by inputs from the central nucleus of the amygdala (CeA)

projecting to theLC. We intend to measure the state of arousal using pupillometry on OFC males and their F1offspring. Pupil dilation is directly mediated by noradrenergic projections by the sympatheticnervous system. By verifying arousal in the presence of the odor, the stress response may berecruited supporting the inheritance of stress.**Methodology**To establish the F0 population, we plan on conditioning 2 male (C57BL/6J) mice, test subjectand a control, to an odor with a total of 5 odors for the study (n = 10). Four of the five odors arespecific to one receptor in the main olfactory epithelium, while the other odor is well known tobe innately aversive. The F0 generation will then breed with naive wildtype females to generatethe F1 generation. Both F0 and F1 generations will then undergo a behavior paradigm wherethey are presented various odors, including the conditioning odor, at random and their pupilsize will be measured throughout the experiment.**Significance**This study aims to understand the ways in which a novel aversive behavior in one generationmay become innate in the next generation.

Title: Brain-wide imaging of network dynamics after chemogenetic activation of the locus coeruleus by MEMRI: Implications of tonic noradrenergic activity on brain-behavior.

Authors: *T. W. USELMAN[1], R. E. JACOBS[2], E. L. BEARER[1,3];
[1]Dept. of Pathology, Univ. of New Mexico - Hlth. Sci. Ctr., Albuquerque, NM; [2]Zilkha Neurogenetic Inst., USC Keck Sch. of Med., Los Angeles, CA; [3]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Monoaminergic systems including the noradrenergic system (NS) regulate brain-wide physiology in responses to stress, reward, and many other experiences. Dysregulation of normal NS activity is associated with altered states i.e. anxiety/depression, or cocaine use. Activity of noradrenergic neurons in the locus coeruleus (LC) releases norepinephrine in distal brain regions ultimately modulating post-synaptic pyramidal and interneuron firing in salience information processing. Our hypothesis is that tonic activation of LC will increase activity in stress- and reward-mediating regions, e.g. BNST, Hyp, Amg, VTA, and NAc. Here, we investigate chemogenetic activation (hM3Dq) of LC by performing behavioral recordings in parallel with brain-wide manganese-enhanced MRI (MEMRI). Intraperitoneal injections of paramagnetic

Mn(II) (0.3 mmol/kg) highlights brain activity in awake behaving mice by T1-weighted MRI. Adult mice were subjected to either longitudinal MEMRI (n = 12) or open field behavior (n = 8) to assess the effects of CNO±hM3Dq expression. Naïve C57BL6J mice were first video recorded and behavioral parameters tracked, before and after intraperitoneal administration of CNO (3 mg/kg), using Noldus Ethovision XT15. All mice underwent stereotactic injection of CAV2-PRS-hM3D(Gq)-mCherry targeting the LC (AP = -5.4, ML = ±0.80, DV = -3.80). Behavior was again recorded before and after CNO 4-8 weeks post-injection. Another hM3D expressing group was imaged for Mn(II) accumulation before and after CNO (3 mg/kg). A third control group was imaged using the same MEMRI procedures to examine the effect of CNO without hM3D expression. The effect of CNO was monitored by the pupillary light response. Expression of the transgenes was confirmed by microscopy of brain sections through LC. Preliminary data show that CNO alone influenced the pupillary light response, which increased with hM3Dq expression. Expression was localized to bilateral LC. Mn(II) accumulation increased signal intensity in the hippocampus. CNO alone reduced exploratory behavior. MEMRI images are being analyzed for neural activity patterns by statistical parametric mapping (SPM), segmentation of 90 brain regions, cross-correlation analysis, and Louvain community detection. Principal component analysis of behavioral parameters will be compared statistically to patterns of regional brain activity to correlate the two modalities. We conclude that this imaging/behavior strategy will directly test our hypothesis and provide insight into the effect of NS on brain-wide neural activity including critical regions of the salience network. Title: A novel intersectional tool to study locus coeruleus subpopulations

Authors: *A. C. HUGHES, G. POLLARD, L. A. SCHWARZ;
St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Advances in genetic profiling have furthered our understanding of the neuronal subpopulations present in the brain. As these classifications grow in specificity, so too does our need to target these unique populations selectively. Current intersectional strategies target these subpopulations by utilizing viral constructs to deliver a payload that is expressed after

subsequent recombination events mediated by different recombinases (i.e., Cre and Flp). However, these targeting approaches often require multiple viral constructs, bulky silencing regions, or complex cloning strategies, thus limiting their use and adaptability. I have developed a novel, single-construct intersectional targeting strategy that is easily customizable and allows for the delivery of large payloads. I will use this ConVERGD (Conditional Viral Expression by Ribozyme Guided Degradation) strategy to target specific neurons within the locus coeruleus (LC). As the primary source of norepinephrine (NE) for the adult brain, the LC is a major regulator of diverse arousal states. Less known is how the genetic diversity of the LC neurons contributes to this regulation. Using ConVERGD constructs, I am able to target a novel subpopulation of LC neurons producing both NE and the stress-related endogenous opioid dynorphin (Dyn). These studies showcase ConVERGD as a versatile tool capable of targeting genetic subpopulations of neurons. Through this work, we hope to reveal Dyn+/NE+ LC neurons as a clinically relevant neuronal population that contributes to the aversive attributes of stress.

Title: Sex-specific effects of stressor exposure on coping behavior and locus coeruleus activity in the defensive shock probe burying task

Authors: *J. TKACZYNSKI, B. DUFFY, D. F. MANVICH, D. J. CHANDLER;
Dept. of Cell Biol. & Neurosci., Rowan Univ. Sch. of Osteo. Med., Stratford, NJ

Abstract: Stress is a physiological state that occurs in response to threatening stimuli that is characterized by specific endocrine and behavioral changes that aid in survival. One structure in the brain that is stress-responsive and contributes directly to anxiety-like behavior and affect is the noradrenergic nucleus locus coeruleus. Previous observations from our laboratory have shown that an acute stressor, a single episode of combined physical restraint and predator odor exposure, leads to long-lasting changes in LC physiology and anxiety-like behavior in the open field test in adolescent rats. Interestingly, however, male and female rats show opposing changes in both measures. We propose that these differences in stress-induced anxiety-like behavior represent a sex-based difference in coping strategies. In order to investigate this, we plan to use the defensive shock probe burying task along with secondary physiological measurements of serum corticosterone concentration and locus coeruleus c-Fos expression. Preliminary data

suggest that males with a history of prior stressor exposure exhibit more active burying behavior, while females exhibit more passive avoidance behavior. Despite the sex-specific responses to stressor exposure in burying behavior, there are no apparent differences in serum corticosterone concentrations according to sex or treatment. We also hypothesize that males with a history of stressor exposure will show reduced c-Fos expression following the shock probe task, relative to control males, while females will show the opposite trend. These findings will help to clarify the role between sex, stress, and coping behavior.

Title: Stress related network activity in the intact adrenal medulla

Authors: *J. R. LOPEZ RUIZ[1], S. A. ERNST[2], R. W. HOLZ[3], E. L. STUENKEL[1,4];
[1]Mol. and Integrative Physiol., [2]Cell and Developmental Biol., [3]Pharmacol., Univ. of Michigan, Ann Arbor, MI; [4]Col. of Hlth. and Life Sci., Hamad Bin Khalifa Univ., Doha, Qatar

Abstract: The adrenal medulla plays a critical role in mammalian homeostasis and the stress response. It is populated by clustered chromaffin cells that secrete epinephrine or norepinephrine along with peptides into the bloodstream affecting distant target organs. Despite been heavily studied, the central control of adrenal medulla and in-situ spatiotemporal responsiveness remains poorly understood. For this work, we continuously monitored the electrical activity of individual adrenomedullary chromaffin cells in the living anesthetized rat using multielectrode arrays. We measured the chromaffin cell activity under basal and physiological stress conditions and characterized the functional micro-architecture of the adrenal medulla. Under basal conditions, chromaffin cells fired action potentials with frequencies between ~0.2 and 4 Hz. In the anesthetized animal, chromaffin cells were exclusively driven by sympathetic inputs coming through the splanchnic nerve. Furthermore, chromaffin cells were organized into independent local and distant networks in which cells fired in a specific order, with latencies from hundreds of microseconds to a few milliseconds. Electrical stimulation of the splanchnic nerve evoked the

exact spatiotemporal firing patterns that occurred spontaneously. Hypoglycemic stress, induced by insulin administration resulted in increased activity of a subset of the chromaffin cells. In contrast, respiratory arrest induced by lethal anesthesia resulted in an increase in the activity of the entire adrenal medulla before cessation of all activity. These results suggest a stressor-specific activation of adrenomedullary chromaffin cell networks and revealed a surprisingly complex electrical organization and circuitry that likely reflects the dynamic nature of the adrenal medulla's neuroendocrine output during basal conditions and during different types of physiological stress.

Title: Defining neuronal subtypes and their connectivity in the nucleus incertus

Authors: *E. SPIKOL[1], J. CHENG[2], M. MACURAK[3], A. SUBEDI[3], M. E. HALPERN[2]; [1]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Mol. and Systems Biol., Dartmouth Geisel Sch. of Med., Hanover, NH; [3]Embryology, Carnegie Inst., Baltimore, MD

Abstract: The nucleus incertus (NI), an understudied brain region at the midline of the floor of the 4th ventricle, has been implicated in the response to aversive stimuli, and is the main site for producing the neurohormone Relaxin-3 (Rln3). Not all neurons in the NI produce Relaxin-3, but little is known about the differences between *rln3*-positive and *rln3*-negative populations. Larval zebrafish serve as a powerful vertebrate model to investigate these conserved neural pathways, and their transparency and genetic tractability are advantageous for monitoring and manipulating specific neuronal subpopulations. We found that a group of neurons that express *goosecoid 2* (*gsc2*) is located just anterior to *rln3* neurons in the zebrafish hindbrain. We used CRISPR/Cas9 targeted integration to generate transgenic lines for selective labeling and manipulation of *gsc2* and *rln3* expressing neurons to understand their identity, connectivity, and function. Anatomical, hodological and neurochemical characteristics of the *gsc2* and *rln3* neurons are consistent with NI identity. However, these adjacent neuronal subsets differ in their spontaneous activity and their responses to aversive stimuli as measured by genetically encoded calcium indicators. Additionally, *gsc2* and *rln3* neurons differ in their efferent and afferent connectivity: their axons

terminate within different regions along the dorsoventral extent of the midbrain interpeduncular nucleus (IPN). The NI is also thought to receive projections from the IPN in a reciprocal manner and is a proposed target of the dorsal habenula (dHb)-IPN neural pathway. Our data indicate that optogenetic activation of the dHb-IPN axis increases activity in *gsc2* neurons, but not in *rln3* neurons. Perturbation of these two distinct neuronal subgroups, by ablation or disrupting their activity, will provide additional information on their specialized functions and the role of the NI in the stress response.

Title: 2-arachidonoylglycerol signaling in the lateral habenula: impacts on stress coping behavior and downstream immediate early gene expression

Authors: *H. R. WRIGHT[1], D. E. GINDER[2], J. L. RICHIE[1], Z. D. G. FISHER[1], A. M. BROWN[1], R. URRUTIA-CARMAGO[1], R. A. FUCHS[1], R. J. MCLAUGHLIN[1,2]; [1]Integrative Physiol. and Neurosci., [2]Psychology, Washington State Univ., Pullman, WA

Abstract: Individual differences in stress coping strategies impact the development of stress-related disorders and are orchestrated in part by activity of dopamine (DA) neurons in the ventral tegmental area (VTA) and serotonin (5-HT) neurons in the dorsal raphe nucleus (DRN). The lateral habenula (LHb) regulates both DA and 5-HT activity via inhibitory neurons within the rostromedial tegmental nucleus (RMTg) that project to the VTA and DRN. Our previous data indicate that the endocannabinoid (eCB) 2-arachidonoylglycerol (2-AG) is recruited in the LHb during stress, and intra-LHb cannabinoid type-1 receptor agonist or inverse agonist administration increases avoidant and approach behavior respectively, suggesting that manipulating the concentration of 2-AG by interfering with its synthesis or metabolism may affect LHb-mediated regulation of behavioral responses. However, the role of LHb 2-AG in the expression of stress coping strategies and the downstream mechanisms underlying these effects remain unknown. Thus, we set out to determine if altering LHb 2-AG concentration during acute or chronic social defeat stress (SDS) affects coping behavior and downstream expression of the immediate early gene zif/268. Male Sprague Dawley rats (n=12/group) were implanted with bilateral cannula aimed at the LHb. Rats were randomly assigned to receive a microinfusion of

the 2-AG hydrolysis inhibitor MJN110 (0, 0.5, or 1 μg/side) prior to acute SDS exposure. In the chronic SDS experiment, rats underwent 7 daily SDS sessions and were randomly assigned to receive a microinfusion of the 2-AG synthesis inhibitor DO34 (0, 0.07, or 0.7 μg/side) prior to the last session. Sessions were video recorded for blinded analysis with deep learning pose-estimation and predictive classifier software to identify behaviors. Rats from the chronic SDS experiment were then euthanized 2 hr after the SDS session and brain tissue encompassing the VTA, RMTg, and DRN was sliced, fixed, and stained for analysis of zif/268 expression using immunofluorescence. Contrary to our predictions, preliminary results indicate that rats receiving 0.5 μg MJN110 avoided the resident rat significantly less than vehicle-treated rats. We expect that decreasing LHb 2-AG will promote active approach behavior under conditions of chronic SDS, which will correlate with increased VTA DA, increased DRN 5HT, and decreased RMTg zif/268 immunofluorescence compared to vehicle. Completion of these studies will contribute to a growing body of evidence suggesting a fundamental role for eCBs in regulating LHb activity and further our understanding of brain circuits/mechanisms that give rise to divergent stress coping strategies.

Title: Impact of ghrelin signaling on glucagon-like peptide 1 (GLP-1) and prolactin-releasing peptide (PrRP) neural activation and anxiety behavior following cognitive stress in fasted rats

Authors: K. A. COAKLEY, *J. W. MANISCALCO;
Regis Univ., Denver, CO

Abstract: Anxiety-based eating disorders are prevalent, insidious, and particularly devastating. While the anxiolytic properties of fasting may result from a sense of control from regulating food intake, there may also be more basic neurobiological mechanisms by which caloric restriction reduces stress and anxiety. Previous work demonstrates that fasting in rodents leads to reductions in anxiety-like behavior in conjunction with reduced activation of stress-responsive neural circuits, including hindbrain glucagon-like peptide 1 (GLP-1) and prolactin-releasing peptide

(PrRP) neurons. Activation of these neurons contributes to neural, behavioral, and physiological stress responses, and the ability of fasting to reduce activation of these neurons may contribute to behavioral alterations observed in eating disorders. However, it is currently unclear how periods of fasting reduce behavioral anxiety and stress-induced neural activation in the hindbrain. Ghrelin - an orexigenic gut hormone - is released from the gastrointestinal tract during fasting and its signaling can reduce activation of brainstem neurons. Our recent findings indicate that elevated ghrelin levels during fasting are partially responsible for suppressing brainstem neural activation and behavioral responses to systemic cholecystokinin-8, a visceral (bodily) stressor. Considering this, we investigated whether increased ghrelin signaling is also responsible for reducing neural and behavioral responses to cognitive (anticipatory) stressors during fasting. Following an acute overnight fast, rats were administered intraperitoneal injections of either saline vehicle or ghrelin receptor antagonist (GRA). Thirty minutes following injection, rats were placed individually on an illuminated elevated platform for 5 minutes and then sacrificed by transcardial perfusion. Immunohistochemical colocalization of cFos and GLP-1 or PrRP neurons was used to assess neural activation following stress exposure. A separate cohort of overnight fasted rats also received either saline or GRA prior to placement on an elevated plus maze (EPMZ) to assess anxiety-like behavior. Interestingly, we found no differences in cognitive stress-induced activation of GLP-1 or PrRP neurons between the saline and GRA rats. Similarly, we observed no differences in anxiety-like behavior (time spent/entries into the open and closed arms of the EPMZ) between saline and GRA treated rats. Our findings suggest that elevated ghrelin levels are not responsible for reducing anxiety-like behavior and cognitive stress-induced hindbrain neural activation during acute fasting.

Title: Hindbrain glucagon-like peptide (GLP1) neurons give rise to highly collateralized axonal projections

Authors: *L. RINAMAN[1], H. ZHENG[2];
[2]Psychology, [1]Florida State Univ., Tallahassee, FL

Abstract: GLP1 neurons in the caudal nucleus of the solitary tract (cNTS) and intermediate reticular zone (IRt) project widely to CNS regions that regulate autonomic outflow, endocrine

function, food intake, and other motivated behaviors. While the distribution of axons arising from GLP1 neurons is well established in rodents, it is unclear whether GLP1 neurons in the cNTS and IRt target similar brain regions, and whether axons of individual GLP1 neurons collateralize to reach multiple targets. The present study addressed these questions using our newly established Sprague Dawley Cre-driver rat model (i.e., Gcg-Cre). In each rat, two Cre-dependent, retrogradely transported AAVs expressing distinct fluorophors (i.e., AAVrg-EF1a-DIO-hChR2:*mCherry*, or AAVrg-EF1a-DIO-hChR2::*EYFP*) were microinjected stereotaxically into the hypothalamus (PVN) and ipsilateral bed nucleus of stria terminalis (avlBST) to differentially label cell bodies and axon collaterals of GLP1 neurons innervating one or both sites. Rats were perfused 3-4 wk later, and sections processed to enhance red and green fluorophore detection. Axonal inputs to the PVN and avlBST arose from both cNTS and IRt neurons, and large subsets of neurons in both hindbrain locations were double-labeled. In addition, both single- and double-labeled axon collaterals arising from PVN- and avlBST-projecting GLP1 neurons were observed in every medullary, midbrain, diencephalic and telencephalic region known to receive GLP1 axonal input. We conclude that individual GLP1 neurons within the cNTS and IRt project in a reticular-like manner to target widespread CNS regions. This property likely subserves a broad modulatory role of hindbrain GLP1 neurons on widely dispersed neural circuit nodes, and should be kept in mind when using optogenetics or other approaches designed to investigate the role of GLP1 signaling to specific CNS regions.

Title: The role of endogenous dynorphin-kappa opioid receptor (DYN-KOR) system in stress-mediated affective disorder and alcohol self-administration in male and female mice

Authors: *S. AHMEDYAR[1], K. LUTFY[2];
[2]Pharmaceut. Sci., [1]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: We investigated the role of endogenous dynorphin-kappa opioid receptor (DYN-KOR) system in the development of stress-mediated affective disorders following a novel repeated variable stress (RVS) exposure model in male and female mice. Subsequently, we assessed the impact of the 10-day RVS model on alcohol self-administration using a free-access one-bottle choice (OBC, 6% EtOH) paradigm in the home cage for 7 weeks. Following a 1-week

withdrawal period, mice were given free-access in a two-bottle choice (TBC) paradigm (6% EtOH vs H_2O then 12% EtOH vs H_2O) for 2 weeks. Next, we assessed for anhedonia with TBC (0.5% sucrose vs water) 48h after a final withdrawal. Naive male (n= 11, 1.6-8.2 months) and female (n=11, 1.6-13.6 months) preprodynorphin (ppDYN) null mice and their male (n=10, 1.6-8.2 months) and female (n=14, 1.6-13.6 months) littermates/controls were used. We also evaluated the effect of weekly administration of KOR antagonist nor-BNI (10 mg/kg) in female C57BL6/J mice (n=9 per treatment/age group, 1.5-12.3 months). Each experiment was repeated 2-3 times and the experimenter was blind to genotype/treatment. Data were mean ± S.E.M. and analyzed by 2-or 3-way ANOVA followed by Fisher's LSD *post-hoc* test with significance set at $p<0.05$. Our results showed no age-related difference in anxiety-like behavior between mice of the two genotypes in both sexes. Old male and female mice lacking ppDYN (KO) exhibited higher immobility than their old wild-type (WT) controls. Immobility time was greater in young WT mice compared to old WT counterparts in both sexes. However, age-related differences were not observed in saline-or nor-BNI-treated C57BL6/J mice nor KO mice. In the OBC, young female ppDYN WT and KO consumed more 6% EtOH than their old controls. There was no difference in EtOH or sucrose consumption/preference between mice of the two age groups. Yet, when young and old female mice of each genotype were combined, female ppDYN KO mice appeared to consume more 6% EtOH compared to WT controls in the OBC but showed less preference for EtOH than WT controls in the TBC. Also, female ppDYN WT mice showed greater sucrose preference than KO mice. In contrast, nor-BNI-treated C57BL6/J mice showed no differences in both EtOH and sucrose intake/preference compared to their saline-treated controls. Together, these results suggest that the DYN-KOR system may be involved in stress-related depressive-like behaviors and subsequent alcohol consumption in female mice. However, these changes could be developing in early age as we did not observe similar changes in nor-BNI-treated mice during adulthood. Studies are underway in male mice of the two genotypes for alcohol consumption.

Title: Sex-dependent effects of adolescent alcohol and THC co-use on working memory and behavioral flexibility in rats.

Authors: *L. CARRICA, F. WALTER, III, C. CHOI, L. SHI, B. NOONAN, D. TKAC, N.-C. LIANG, J. M. GULLEY;
Univ. of Illinois, Urbana-Campaign, Champaign, IL

Abstract: Previous work in both animal models and humans has demonstrated that exposure to either alcohol or THC, the primary psychoactive component of cannabis, can lead to adverse consequences including deficits in learning, behavioral flexibility, and attention. Additionally, co-use of these substances is relatively common among adolescents and is associated with worse outcomes than the use of either drug alone. In this study, male and female rats were assigned to one of four groups: vehicle/vehicle, 10% ethanol/vehicle, vehicle/THC (3.0-10.0 mg/kg/day), or ethanol/THC. Rats were allowed to self-administer either drug(s) or vehicle from P28-P47. They were subsequently food restricted and underwent training and testing on a lever press, delayed-matching-to-position (DMTP) task from P60-P111. Our hypothesis was that rats who voluntarily consumed both THC and alcohol during adolescence would exhibit reduced accuracy on a working memory task compared to both controls and rats who consumed either drug alone. Our preliminary results suggest that there was an effect of sex as well as a sex-by-treatment interaction on performance on the DMTP task at long response delays, as well as on behavioral flexibility as assessed by a rule shift to a delayed-nonmatching-to-position (DNMTP) task. Females from all exposure groups (except the THC-only rats) outperformed their male counterparts in DMTP testing at long delays, as well as on the DNMTP task. This preliminary analysis suggests that the detrimental effects of THC and alcohol alone, as well as their co-administration, are dependent on sex.

Title: The effects of alcohol and THC co-use during adolescence on synaptic plasticity in the medial prefrontal cortex of Long Evans rats

Authors: *L. SHI[1], S. KANG[2], C. CHOI[3], B. L. NOONAN[3], L. K. CARRICA[3], N.-C. LIANG[4], J. M. GULLEY[5];
[1]Psychology Dept., Univ. of Illinois, Urbana-Campaign, Champaign, IL; [2]Dept. of Pharmacol., Northwestern Univ., Chicago, IL; [3]Psychology Dept., Univ. of Illinois, Urbana-Champaign,

Champaign, IL; [4]Psychology Dept., Univ. of Illinois-Urbana Champaign, Champaign, IL; [5]Psychology Dept., Univ. of Illinois At Urbana-Champaign, Champaign, IL

Abstract: Adolescent exposure to alcohol or delta-9-tetrahydrocannabinol (THC), which is the main psychoactive component in cannabis, has been associated with structural and functional changes in the brain of adult humans and laboratory animals. Considerably less is known about the neurobiological effects of combined exposure to these drugs, which is potentially problematic given that adolescents who use these drugs often consume them together. Here, we addressed this by using male and female Long Evans rats to investigate if adolescent exposure to alcohol-only, THC-only, or combined alcohol-THC would influence synaptic plasticity in the medial prefrontal cortex (mPFC) during adulthood. From postnatal day (P) 30 to P45, rats (n=6/sex/group) voluntarily consumed 0.1% saccharin (SACC) or 10% ethanol in SACC and were injected (s.c.) with vehicle or escalating doses of THC (3.0-20.0 mg/kg). They were sacrificed during young adulthood [P70 to P88] for *in vitro* brain slice recordings (n=4 slices/group) of field EPSPs in layer 5/6 of the prelimbic cortex (PL). Preliminary results suggest high-frequency stimulation (HFS) delivered in layer 2/3 of the PL induced long-term depression (LTD) in controls, but the magnitude of LTD decreased in rats exposed to THC-only or alcohol-only. In alcohol-THC rats, HFS induced a long-term potentiation (LTP)-like response. These preliminary findings suggest that combined use of these two drugs during adolescence may induce enduring changes in mPFC circuitry that are unique to those induced by using either drug alone. We hypothesize that these circuit-level modifications are due to drug-induced alterations in the development of inhibitory signaling in the mPFC.

Abstract: Bacterial colonization of the infant's gut begins at birth when birth exposes the newborn to a set of bacteria coming from the mother's gut. On the other hand, alterations in gut microbial richness and diversity are associated with several neuropsychiatric disorders, including drug addiction. Preliminary results show that oral administration of a broad-spectrum non-absorbable antibiotic cocktail to a pregnant Sprague-Dawley dam from E18 until P7, lowers gut microbial diversity and richness, while at the same time affecting dopamine receptor expression at the NAcc and VTA in male offspring at P35. Thus, the main aim of this study is to evaluate if early-life exposure to antibiotics (ELEA) impacts drug-seeking behavior, locomotor activity, dopamine receptors levels, and *in vivo* striatal dopamine release in male and female adult offspring of dams treated with antibiotics in the peripartum. Control animals came from dams given only vehicle. ELEA increased preference for methylphenidate (MPH) in the adult male offspring, compared to its control. Interestingly, ELEA females showed a lower preference for MPH than control females. Also, DOPAC levels are lower in both males and females ELEA rats in comparison to controls. Protein analysis revealed changes in the expression of dopamine receptors 1 and 2, and tyrosine hydroxylase throughout the mesocorticolimbic circuit of ELEA rats, in comparison to their respective controls. Finally, female ELEA rats release more striatal dopamine than control females in response to MPH. Altogether, these results suggest that early-life alterations in the development of the microbiota-gut-brain axis affect the mesocorticolimbic structure, and hence, the response to drugs, in adulthood.

[3]Inst. of Genome Sciences, Univ. of Maryland, Baltimore, MD

Abstract: Since the early 2000s, there has been an increase in opioid consumption within the US, including among pregnant women. Use of the synthetic opioid fentanyl has increased ~300% within the last decade. However, little is known about the molecular mechanisms underlying fentanyl use particularly during brain development. Using a rodent model of perinatal fentanyl exposure, we previously demonstrated a lasting emotional and sensory deficit at adolescent and adult ages, consistent with human findings.
In the present study, our aim is to understand the neurobiological mechanisms occurring with developmental fentanyl exposure. We use a Multi-omic sequencing approach to investigate the transcriptional programs dysregulated in fentanyl use in a brain tissue specific manner. Fentanyl was administered in drinking water of pregnant dams from embryonic day 0 through gestational periods until weaning at P21. Tissue punches were collected from 5 brain areas from juvenile aged mice (~P35) and processed for RNA-sequencing. Brain regions analyzed include emotional/reward brain regions: nucleus accumbens (NAc), ventral tegmental area (VTA), prelimbic (PrL) region of the prefrontal cortex and sensory brain regions: primary somatosensory cortex (S1) and ventrobasal (VB) thalamus. These experiments were performed in both sexes as we had observed sex differences in some of the lasting behaviors. We identified differentially expressed gene sets, and performed enrichment analysis, weighted gene coexpression network analysis (WGCNA), and upstream transcription factor analysis. We observed sex driven differences in differentially expressed gene sets within all brain regions analyzed. We identified upstream transcriptional programs and hub genes that could mediate the lasting behavioral changes in fentanyl use. Collectively, our studies are identifying unique gene expression adaptations across multiple brain regions relevant for lasting behaviors observed in perinatal fentanyl exposed mice.

Title: Methadone elicits a robust transcriptional response during fetal brain development modeled in cortical organoids

Authors: *I. DWIVEDI, D. ZHOU, G. G. HADDAD;
Pediatrics, UC San Diego, La Jolla, CA

Abstract: The recent national opioid epidemic has included a rise in the number of pregnant women seeking treatment for opioid use disorder, which involves the use of methadone, a synthetic opioid analgesic that attenuates withdrawal symptoms. Despite its benefits for mothers, however, fetal exposure to methadone has been shown to induce long-term neuro-cognitive sequelae. Most neurological studies on the effects of methadone exposure have been conducted in murine models or postnatally in humans. Consequently, very little is known about how the drug impacts cellular and molecular human fetal brain development *in utero*. Induced pluripotent stem cell (iPSC)-derived human cortical organoids (hCOs) provide a unique opportunity to assess these aspects of neurodevelopment *in vitro.* Here, we took advantage of hCO technology to probe the molecular underpinnings of methadone's cellular effects on cortical neurogenesis. We conducted bulk mRNA sequencing of 2-month-old hCOs derived from two cell lines that were chronically treated with a clinically relevant dosage of 1 μM methadone. Differential expression analysis (DESeq2) revealed a robust transcriptional response to methadone in hCOs derived from both cell lines, with over 2000 significantly differentially expressed genes common to both ($|FC| \geq 1.5$, p-adj < 0.05). Through pathway enrichment, gene ontology (GO), and network analyses, we observed that chronic treatment with methadone downregulates a hierarchy of 146 extracellular matrix (ECM)-related structural and regulatory genes in hCOs. This includes a key group of genes encoding matricellular proteins (MCPs) and their upstream regulator TGFβ1, which are highly active during development as mediators of ECM structure and degradation. During development, this ECM-regulatory pathway is known to influence cellular proliferation, survival, and migration, as well as neurite outgrowth and synaptogenesis, all of which are associated with the top significantly enriched pathways and GO biological processes in our analyses. Consequently, suppression of this ECM axis may give rise to the cellular phenotypes and ultimate neurobehavioral sequelae associated with fetal methadone exposure. We believe that the results from our study will contribute not only to better informed treatments for pregnant women with opioid use disorders but also to early pharmacological interventions for infants exposed to methadone.

Title: Naltrexone effects on conditioned approach and orbitofrontal cortex firing activity in adult female rats exposed to binge alcohol in adolescence

Authors: *J. A. POCHAPSKI[1], A. GÓMEZ-A[2], C. A. BOETTIGER[3], C. DA CUNHA[1], D. L. ROBINSON[2];
[1]Biochem., Univ. Federal do Parana, Curitiba, Brazil; [2]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Psychology & Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: Adolescence is a critical period of brain development, when exposure to addictive drugs can induce long-term impairments to frontolimbic structures, including the orbitofrontal cortex (OFC). In this study, we examined the effects of naltrexone (NTX), an opioid receptor antagonist used for the treatment of alcohol use disorder, on OFC neuronal activity of adult female rats with a history of adolescent intermittent ethanol (AIE) exposure during Pavlovian conditioned approach (PCA). We hypothesized that AIE exposure would promote an enhancement in the OFC response to the conditioned stimulus (CS), and that NTX administration would attenuate this effect. Sprague-Dawley female rats received AIE (5 g/kg intragastric ethanol, 2-day-on/2-days-off) or water (CON) through adolescence (P25-54). In adulthood (~P70) rats began PCA training, where a 30-second CS, presented as a cue light and lever extension, predicted delivery of a 20% sucrose reward. After training, electrode arrays were implanted in the OFC, and electrophysiological recordings were performed during PCA sessions. OFC neuronal activity was evaluated during a PCA baseline session followed by three (counterbalanced) PCA sessions where saline, 1 mg/kg NTX, or 3 mg/kg NTX was administrated (i.p.) 15 minutes prior to the session. Preliminary results demonstrate that NTX administration decreased the number of lever presses and slowed the latency to press in both AIE and CON rats. Conversely, AIE-exposed rats made fewer conditioned receptacle entries than CON-exposed rats, but no robust NTX effect was observed. As we hypothesized, AIE exposure resulted in an enhanced OFC activity in response to CS onset and CS offset events during the PCA baseline session. While NTX effects on the firing rate in response to CS onset and CS offset was minimal, 3 mg/kg NTX robustly decreased the average firing rate of OFC neurons across the whole PCA session only in the AIE-exposed group. These preliminary data demonstrate long-lasting AIE-exposure effects on the OFC processing of conditioned cues and suggests exposure-specific effects of NTX on OFC activity. Future analyses will further determine whether NTX affected behavior and OFC neuronal firing rates in rats with high levels of sign tracking (conditioned approach to the CS) compared to rats engaged in high levels of goal tracking (conditioned approach to the reward receptacle).

Title: Benzos and Booze: Effects of Adolescent Exposure to Benzodiazepine on Adult Alcohol Consumption

Authors: *Z. PLATOW, M. S. MCMURRAY;
Psychology, Miami Univ., Oxford, OH

Abstract: Benzodiazepines are strong anxiolytic drugs that act at GABA receptors, resulting in overall inhibition of the CNS. Benzodiazepines are one of few drugs that can be both prescribed by a doctor, but also recreationally abused. One in five high schoolers report using benzodiazepines either medically or recreationally. However, the longitudinal effects of benzodiazepine use during adolescence have not been well-investigated. The purpose of this experiment was to determine the effects of benzodiazepine exposure during adolescence on immediate stress levels and later adult alcohol self-administration in rats. Beginning at Postnatal Day (PND) 35, 48 male and female long-evans rats were injected with either 3.2 mg/kg lorazepam (experimental group, N=24) or vehicle (control group, N=24) every other day until PND50. Open Field Test (OFT) and Elevated Zero Maze (EZM) compared stress levels on PNDs 40, 50, and 52 (injection off-days) and PND90. Ethanol self-administration began at PND90 and continued until PND110. At PND110, the animals were given an injection of alcohol 45 minutes before perfusion. Brain tissue was stained with c-fos to evaluate neural activity in the ventral tegmental area and nucleus accumbens. On non-treatment days, benzodiazepine treated rats were shown to have higher adolescent stress levels by both the OFT and EZM results. This difference was greatest at PND52, two days after the final benzodiazepine injection. Preliminary data analysis suggests that these differences in stress persist into adulthood, as shown by the results of the OFT and EZM tests performed on PND90. Additionally, early results regarding ethanol self administration levels indicate that the benzodiazepine-treated rats self administered more ethanol during a 4 hour period than the control rats. Preliminary tissue analysis indicates that the benzodiazepine-treated rats had higher neural activity levels in response to alcohol, which suggests that cross-tolerance was developed due to adolescent benzodiazepine exposure. Based on the results of this study, it appears that adolescent exposure to or abuse of benzodiazepines

causes persisting and long-lasting changes to the brain, ultimately resulting in higher adulthood stress levels and a distorted behavioral response to alcohol.

Title: Alcohol-induced endoplasmic reticulum stress in neuronal cells of the rat hippocampus.

Authors: *K. HERNÁNDEZ-FONSECA, T. SÁNCHEZ-MEDINA;
Neurochemistry, Inst. Nacional De Psiquiatría "Ramón de La Fuente", Mexico city, Mexico

Abstract: Introduction: The Central Nervous System is particularly vulnerable to ethanol-induced damage. They have been observed pathological alterations in brain structure and neuronal function in patients and animal models treated prenatally with alcohol. The cause of ethanol-induced neurodegeneration is unclear; however, it has proposed the participation of endoplasmic reticulum stress in alcohol-induced neuronal damage, such *in vitro* as *in vivo* (Ji, 2012). The endoplasmic reticulum (ER) is essential for synthesizing and modifying proteins, storing and releasing calcium, and promoting lipid biosynthesis and drug detoxification. Dysregulations of the homeostatic state of the ER produce an accumulation of misfolded proteins; under these conditions, the unfolded protein response (UPR) is activated. The UPR has a purpose of restoring homeostasis of the ER, of reducing ER protein load entails the upregulation of the folding machinery along with an expansion of the ER lumen and enhanced degradation of terminally misfolded proteins through ER-associated degradation (ERAD). In addition, UPR activation also causes a temporary shutdown of general translation accompanied by the degradation of a select group of mRNAs encoding secretory proteins and proteins delayed at the translocon, a process known as pre-emptive quality control. Three different ER stress sensors sense the accumulation of unfolded proteins in the ER lumen: two protein kinases, IRE1 (inositol requiring enzyme/endonuclease 1) and PERK (double-stranded RNA-activated protein kinase (PKR)—like ER kinase) and the transcription factor ATF6 (activating transcription factor 6). **Objectives:** To assess whether acute alcohol exposure induces RE stress in the rat brain**.** **Materials and Methods:** Male rats Wistar (200-250 g) were administered intraperitoneally with water (control) or ethanol (3 g/kg, 25%). Furthermore, they were sacrificed 0.5, 1, 2, 4, 8, 12 y 24 hours after treatment. The brains were extracted, dissected, and homogenized, and the expression of ER stress proteins was examined by Western blotting. Results: A significant

increase was observed in the expression of ER stress proteins and activation of the UPR pathway. **Discussion**: Our results show that exposure to ethanol induces a significant increase. The possible cause that triggers this ER stress during alcohol consumption could be the primary metabolite of alcohol degradation, acetaldehyde, which can form protein adducts, induces oxidative stress, and dysregulates calcium homeostasis. **Conclusion:** Acute exposure to ethanol induces ER stress in hippocampal neuronal cells by activating the UPR pathway.

Title: Transcriptional analysis of the nucleus of the solitary tract after alcohol dependence and stress

Authors: *E. GRANTHAM[1], G. R. TIWARI[2], O. PONOMAREVA[1], M. F. LOPEZ[3], H. C. BECKER[4], R. D. MAYFIELD[5];
[2]Waggoner Ctr. for Alcohol and Addiction Res., [1]Univ. of Texas at Austin, Austin, TX; [3]Psychiatry, Med. Univ. of South Carolina, Charleston, SC; [4]Charleston Alcohol Resch Ctr., Med. Univ. South Carolina, Charleston, SC; [5]Univ. Texas-Austin, Austin, TX

Abstract: Stress exposure contributes to the development of drug and alcohol addiction. Animal models show that stress exacerbates alcohol consumption in alcohol-dependent animals. The nucleus of the solitary tract (NTS) is a critical brainstem region for integrating and relaying peripheral signals to regulate stress responses. To examine the molecular adaptions within this brain region that may contribute to stress-induced alcohol drinking, we exposed animals to chronic intermittent bouts of ethanol vapor (CIE), forced swim stress (FSS), or both (CIE + FSS) and then transcriptionally profiled the NTS at three different timepoint after the last vapor exposure (0-h, 72-h, and 186-h). Using the three timepoints, we were able to identify transient, persistent, and compensatory gene expression patterns related to each of the behavioral treatments. We identified type I interferon signaling as a critical pathway in the development of alcohol dependence. Using likelihood ratio tests, we identified genes that were differentially expressed across time and between groups. Clustering analysis of these genes identified a subset

of genes that fail to normalize in the CIE + FSS group, but not the others. These genes were enriched for cell-to-cell signaling and cellular function pointing to long-term synaptic and structural changes in this brain region because of CIE + FSS. Overall, these results summarize the transcriptomic changes across time in the NTS that may be critical to the development of stress-induced elevations in alcohol consumption and alcohol dependence.

Title: Escalation of ethanol intake after innate immune activation by TLR3 agonist, Poly(I:C), in male mice is associated with cell type-specific changes in gene expression

Authors: *B. KISBY[1], O. PONOMAREVA[1], A. BATTENHOUSE[2], Y. BLEDNOV[3], R. D. MAYFIELD[3], M. M. MCMANUS[1], S. SHANMUGAM[1], R. O. MESSING[3], R. A. HARRIS[3], I. PONOMAREV[1];
[1]Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [2]Ctr. for Biomed. Res., [3]Waggoner Ctr. for Alcohol and Addiction Res., Univ. of Texas at Austin, Austin, TX

Abstract: Excessive alcohol (ethanol) consumption is one of the criteria for alcohol use disorder (AUD). AUD is associated with innate immune activation and previous work showed that repeated injections of the TLR3 agonist, Poly(I:C) (PIC) results in immune activation and in escalation of alcohol consumption in C57BL/6J (B6) male mice. We hypothesized that immune activation by PIC causes cell type-specific changes in gene expression in brain reward regions, some of which may drive excessive drinking. We used Every-Other-Day (EOD) ethanol drinking procedure and repeated PIC injections to study the effects of ethanol and immune activation on brain gene expression. B6 male mice were given a total of 9 injections of either saline or 10 mg/kg of PIC every 4 days and were given access to EOD ethanol or water, resulting in 4 groups: saline/water (SW), saline/ethanol (SE), PIC/water (PW), and PIC/ethanol (PE). Brains were harvested 24 hours after the final ethanol session, 6 brain regions (mPFC, Nucleus Accumbens, BNST, Amygdala, Ventral Hippocampus, VTA) were dissected, gene expression was measured using RNA sequencing (RNA-Seq) and compared among the groups. In addition, cell-type specific expression in the mPFC was measured in separate groups of animals using single nucleus RNA-Seq (snRNA-Seq). Repeated PIC injections resulted in escalation of ethanol

consumption in the PE group compared with SE animals. Differential expression analysis of RNA-Seq data identified individual genes (DEGs) and functional groups associated with the effects of innate immune activation, ethanol exposure or both. Compared to the effects of ethanol, immune activation resulted in more drastic changes in gene expression. Specifically, we identified several differentially regulated inflammatory pathways in the PE group versus the SE group across all brain regions. Many genes differentially expressed between the groups were markers of specific cell types (e.g., *Slc17a8* for neurons; *Gfap* for astrocytes; *C1qb* for microglia; *Kdr* for endothelial cells). The snRNA-Seq analysis identified major cell types in mPFC based on cell-specific transcriptional profiles, which included several classes of glutamatergic and GABA-ergic neurons, microglia, oligodendrocytes, endothelial cells, and astrocytes, with many cell-specific genes being regulated by immune activation, ethanol drinking, or both. These cell-specific DEGs and molecular pathways are mechanistic candidates for immune-modulated escalation of ethanol consumption. Supported by R01 AA027096.

Title: Ethanol prevents constitutive decrement of tau phosphorylation immunofluorescence in the cultured neonatal rat hippocampus: Implications for Fetal Alcohol Spectrum Disorders

Authors: *C. BAILEY, J. E. JAGIELO-MILLER, P. KELLER, A. WILCOX, M. A. PRENDERGAST;
Univ. of Kentucky, Lexington, KY

Abstract: Fetal Alcohol Spectrum Disorders (FASDs) are comprised of developmental, behavioral, and cognitive abnormalities caused by prenatal alcohol (EtOH) exposure, affecting an estimated 2%-5% of children and costing $4 billion annually in the United States. While some behavioral therapies are beneficial, the neurochemical mechanisms that underpin FASDs need further elucidation for development of efficacious therapeutics. The role of the tau protein in the hippocampus is especially likely to be involved. Tau catalyzes microtubule polymerization and

maintains structural support for neurons. However, this function is disrupted by hyperphosphorylation (referred to as p-tau). Most of what we know with regard to the cognitive and behavioral ramifications of p-tau comes from neurodegenerative tauopathies, such as Alzheimer's disease. Many of the cognitive deficits observed in neurodegenerative tauopathies overlap to some degree with what is observed in juvenile developmental disabilities, such as FASDs (e.g., selective memory, executive dysfunction, learning difficulties). Thus, the tau protein may be one important mechanism of dysfunction in FASDs, but there is not yet an empirical basis for a tauopathic characterization of FASDs. The purpose of this study is to provide such a basis. We sacrificed 26 Sprague-Dawley rats at postnatal day 10 (3rd trimester human equivalent); organotypic hippocampal slices (N = 242; 111 females) were cultured for 6 days *in vitro* (6DIV; baseline – received no EtOH) prior to any manipulation. We exposed a random 50% of hippocampal slices to 5 days of EtOH (50mM; human equivalent 0.23 BAC) between 6DIV and 11DIV. We placed slices back into regularly replenished media for the remainder of the study. We divided the slices into four groups based on when we visualized and quantified p-tau at the pathological Threonine231 (Thr231) residue. These groups were visualized at 6DIV, 12DIV, 18DIV, and 24DIV. Separate p-tau measures were taken for the subregional hippocampal cornu ammonis 1 (CA1), CA3, genu, and dentate gyrus (DG). No sex differences were detected. EtOH treatment interacted with DIV in the CA1, genu, and DG. In the control group, longer DIV was associated with decreased p-tau fluorescence in the CA1, CA3, genu, and DG. However, in the EtOH-exposed group, the p-tau fluorescence was sustained across DIV in the CA1, genu, and DG. This is the first study to show that EtOH exposure widely prevents tau Thr231 dephosphorylation in the perinatal hippocampus. These findings could lead to innovative pharmacotherapeutic targets for the treatment of cognitive deficits seen in FASDs.

Title: The influence of R7 RGS proteins on inhibitory signaling in VTA dopamine neurons and alcohol consumption

Authors: M. C. DEBAKER[1], T. R. ROSE[2], E. H. MITTEN[1], R. GAO[3], E. MARRON[3], A. M. LEE[3], K. D. WICKMAN[3];
[1]Grad. Program in Neurosci., [2]Grad. Program in Pharmacol., [3]Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Alcohol use disorder (AUD) is a prevalent medical problem, and the long-term success of current treatments is low, emphasizing the need for new therapeutic approaches. Dopamine (DA) neurons in the ventral tegmental area (VTA) play a critical role in reward and motivation. All drugs of abuse, including alcohol, enhance VTA DA neurotransmission. Increased DA levels can trigger inhibitory G protein-dependent feedback pathways in VTA DA neurons, controlled by $GABA_B$ ($GABA_BR$) and D_2 dopamine (D_2R) receptors, that temper VTA DA neuron output. Alcohol-induced adaptations to these inhibitory feedback pathways may promote development of AUD. Regulator of G protein Signaling (RGS) proteins modulate the strength and sensitivity of G protein-dependent signaling by accelerating G protein deactivation. Members of the R7 subfamily of RGS proteins, which includes RGS6, RGS7, RGS9, and RGS11, have been implicated in drug-related behaviors. Moreover, mice constitutively lacking RGS6 displayed decreased alcohol consumption and reward. The relevant neuron populations underlying this phenotype remain unknown. Using fluorescent *in situ* hybridization, we show that RGS6 and RGS7 are expressed in VTA DA neurons. We used slice electrophysiology to assess the effects of constitutive RGS6 or RGS7 ablation (RGS6KO, RGS7KO) on the strength and sensitivity of $GABA_BR$- and D_2R-dependent signaling. We observed larger somatodendritic currents evoked by the D_2R agonist quinpirole in VTA DA neurons from RGS6KO and RGS7KO mice as compared to wild-type controls ($p=0.005$, n=6-7/sex), but no genotype difference in baclofen-induced currents ($p=0.795$, n=6-7/sex). In a drinking-in-the-dark (DID) paradigm, RGS6KO mice consumed less alcohol compared to wild-type mice ($p=0.0005$, n=11-12/sex), whereas RGS7KO mice consumed similar levels of alcohol compared to wild-type mice ($p=0.682$, n=2-5/sex). To determine whether RGS6 in VTA DA neurons modulates alcohol consumption, we utilized a viral CRISPR/Cas9-mediated ablation approach in VTA DA neurons of adult mice. Guide RNAs (gRNAs) targeting RGS6 or LacZ control were injected into the VTA of DATCre(+):Cas9GFP mice. The impact of viral treatment on D_2R-dependent signaling was assessed electrophysiologically, by measuring quinpirole-induced currents, and behaviorally, using a DID paradigm. Preliminary results indicate that RGS6 gRNA-treated mice consume less alcohol compared to controls ($p=0.0172$, n=8-13/sex), mirroring the phenotype observed in RGS6KO mice. Collectively, our data suggest that RGS6 modulates voluntary alcohol consumption in part via its negative regulation of D_2R-dependent signaling in VTA DA neurons.

Title: Dreadd and pharmacological inhibition of cerebellar granule cells alter excess alcohol consumption behavior in c57bl/6j mice

Authors: *C. ERIKSON, T. THUET, K. DOUGLAS, D. ROSSI;
Washington State Univ., Pullman, WA

Abstract: Genetic differences in cerebellar sensitivity to alcohol (EtOH) influence EtOH consumption phenotype in animal models, and contribute to risk for developing an alcohol use disorder (AUD) in humans. Recent work from our lab determined that similar to other rodent genotypes, EtOH modulation of cerebellar granule cell (GC) tonic $GABA_AR$ currents is of opposite polarity between C57BL/6 sub-strains, which reflects their respective divergent EtOH consumption phenotypes (ie; B6J: suppression/high EtOH consumption & B6N: enhancement/low EtOH consumption). To assess whether this relationship was causal, we tested whether inhibition of cerebellar GCs in high EtOH consuming B6J mice (using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) and pharmacological techniques) reduces excess EtOH consumption behavior. DREADD "GCGiD" mice were created by crossing B6J Gabra6-Cre mice, which express CRE recombinase under the $GABA_AR$ α6 subunit promoter, with R26-LSL-Gi-DREADD mice from the Jackson Laboratory, thereby ensuring selective hM4Di mutant G protein-coupled receptor expression exclusively in cerebellar GCs. Prior to behavioral experiments, we confirmed, using electrophysiology, that bath applied clozapine-N-oxide (CNO) inhibited cerebellar GCs, and consequently reduced mossy fiber afferent-evoked Purkinje cell output. Interestingly, our data indicate that inhibition of cerebellar GCs by CNO may not be via potassium channel activation but rather enhancement of extrasynaptic $GABA_A$ receptor-mediated tonic current. Contrary to our prediction, GCGiD mice that had been trained in a two-bottle choice, drinking in the dark paradigm (2BC-DID) exhibited a significant increase in the g/kg of a 10% EtOH/10% sucrose mix when CNO was administered i.p. 30-minutes before a 2BC-DID trial. As this was unexpected, we followed up with a pharmacological approach. In voltage-clamped GCs from B6J mice, bath applied Ro15-4513 originally thought to be an α4, α6 $GABA_AR$ inverse agonist, enhanced the GC tonic $GABA_AR$ current and prevented subsequent suppression by EtOH. Accordingly, and in support of our hypothesis, i.p. administered Ro15-4513 (10mg/kg) 5-minutes prior to a 2BC-DID trial significantly reduced the total g/kgs 10% EtOH consumed, licks on the 10% EtOH bottle, and mean BEC achieved. These results highlight the genetically determined divergent response of

GC GABAergic inhibition to EtOH as a possible identifiable risk factor for developing an AUD, and provide an obvious target for pharmaceutical intervention.

Title: Neuroimmune-mediated alcohol effects on ventral tegmental area microglia and infiltrating leukocytes

Authors: *C. A. SMALL, T. J. CLARKE, J. N. BRUNDAGE, J. D. OBRAY, C. M. MORENO, S. WEBER, J. T. YORGASON, S. C. STEFFENSEN;
Brigham Young Univ., Provo, UT

Abstract: Microglia are the primary immune cells in the central nervous system (CNS) and are referred to as its “resident” macrophages. However, their role has recently been shown to extend far beyond immunity. The effects of ethanol on the brain are closely linked to neuroimmune responses, mediated by microglia that are present in the healthy brain from the time of development. Normally, the blood-brain barrier (BBB) prevents the infiltration of cells and foreign pathogens from crossing from the periphery into the CNS. However, peripheral monocytes are known to infiltrate the CNS in response to seizures, traumatic brain injury, infection, and multiple sclerosis. The aim of this study was to determine the effect of acute ethanol (EtOH) on microglia activation and monocyte infiltration into the CNS. We hypothesized that acute EtOH would lead to an increase in neuroinflammation by activating “resident” microglia to an inflammatory polarization (M1) and induce the infiltration of macrophages across the BBB. Using the Macrophage FAS-Induced Apoptosis (MaFIA) mouse model (GFP+ on Csf1r promoter), fluorescent microscopy, and flow cytometry we assessed the presence and phenotype of microglia and infiltrating macrophages following 1, 2, and 4 g/kg ethanol at 0.5, 1, and 2 hours post-injection. By measuring volume/surface area of microglia in the ventral tegmental area (VTA) and nucleus accumbens (NAc) following EtOH, we found that EtOH enhanced the number of macrophages in the blood, caused microglia activation in the VTA and NAc, and that microglia shifted toward an M1 polarization. However, some of our findings were counter to our hypothesis. We found that EtOH decreases the number of infiltrating monocytes in the VTA and NAc. It is possible that other cells like T and B cells are

recruited across the BBB. In addition, depleting macrophages in the blood approximately 50% with liposomal clodronate reduce the inhibitory effects of EtOH on VTA GABA neuron firing rate vs clodronate control liposomes at 24 hours post injection. These findings suggest a neuroimmune connection for acute EtOH use and challenge the dogma that EtOH has exclusively central effects on dopaminergic neuronal activity and release. Studies are ongoing to determine the effects of macrophage depletion on EtOH enhancement of DA release and behavioral effects. Keywords: alcohol, microglia, macrophage, inflammation, cytokines, neuroimmune

Title: Proteomic analysis of central amygdala systems regulated by mifepristone in the context of alcohol dependence

Authors: *L. MONTEAGUDO-ROMERO, K. N. EDWARDS, J. J. GUIDRY, S. EDWARDS;
LSU Hlth. Sci. Ctr., New Orleans, LA

Abstract: Alcohol use disorder (AUD) is a chronic psychiatric disorder characterized by escalated alcohol use and the emergence of negative emotional states during withdrawal. Studies have shown a dysregulation of glucocorticoid signaling in AUD, both at the level of the HPA axis and within specific brain areas such as the central amygdala (CeA). Excessive activation of brain GRs is hypothesized to promote cognitive dysfunction, negative emotional states, and escalated drinking, all common features of AUD. Previous work in our lab has demonstrated an increase in GR phosphorylation in the CeA during alcohol withdrawal in dependent animals. Importantly, the GR antagonist mifepristone reduces escalated alcohol drinking in both rodents and humans. Investigation of functional neuroadaptations in CeA protein networks in the context of alcohol dependence and mifepristone therapy is crucial to our understanding of these conditions. The main aims of this study were to first determine differential CeA protein expression profiles in alcohol dependence and then to examine which of these are “normalized” by mifepristone treatment. Male Wistar rats underwent 10 weeks of exposure to either chronic intermittent ethanol vapor (CIEV) or air (control condition). In week 7, half of the animals

received subcutaneous placebo pellets and the other half received mifepristone pellets (21-day slow release). Three weeks after, rats were sacrificed during acute (6hr) withdrawal from CIEV (and identical time in controls) and the CeA was taken for proteomics analysis. Ingenuity pathway analysis revealed that out of 3050 proteins detected in the CeA, 253 were altered by alcohol (but not mifepristone), whereas an additional 142 were altered by alcohol and "normalized" by mifepristone. Several of these in the latter category represent "druggable" targets and novel treatment avenues for AUD that will be further investigated in future behavioral studies.

Title: Loss of cholinergic phenotype in basal forebrain neurons following adolescent intermittent ethanol exposure is mediated by the p75 neurotrophin receptor

Authors: *B. T. KIPP[1], L. M. SAVAGE, Ph.D.[2];
[1]Binghamton Univ., Binghamton, NY; [2]Psychology-Behavioral Neurosci., Binghamton Univ. Dept. of Psychology, Binghamton, NY

Abstract: Basal forebrain cholinergic neurons enter a period of protracted quiescence following adolescent intermittent ethanol exposure with significant reductions in the expression of choline acetyltransferase (ChAT) and vesicular acetylcholine transporter (vAChT), however the mechanism through which this occurs is unknown. To date, activity at the p75 neurotrophin receptor (p75NTR) appears to drive the suppression of the neuronal basal forebrain cholinergic phenotype in multiple disease states, but p75NTR has not been examined in relation to cholinergic cell pathology in ethanol models. We administered a novel p75NTR modulator, LM11A-31, during ethanol exposure to determine if cholinergic neurons could be protected from developmental ethanol toxicity. Male and female Sprague Dawley rats underwent a adolescent intermittent ethanol exposure (AIE) which mimics the binge withdrawal ethanol consummatory pattern of alcohol drinking typically observed in adolescents. Rats received oral gavages of 5g/kg of 20% ethanol from post-natal day 25-45 with and without LM11A-31, or volume matched

water. Western blot data suggests that modulating the p75NTR during ethanol exposure protects ChAT expression in the nucleus basalis magnocellularis, and vAChT expression in the prefrontal cortex. Additionally, it appears that LM11A-31 administration during ethanol exposure prevents the loss of hippocampal neurogenesis as measured through doublecortin. Based on this preliminary data, we will measure changes in neurotrophin and proneurotrophin expression at cholinergic basal forebrain projection sites following AIE during the final ethanol intoxication, acute withdrawal, and protracted withdrawal to identify potential p75-ligand interactions that are responsible for driving the suppression of neuronal cholinergic phenotype in development models of ethanol exposure.

Title: Exercise opens a 'molecular memory window' to facilitate changes in gene expression, synaptic plasticity and memory

Authors: *A. A. KEISER[1], T. DONG[1], E. A. KRAMÁR[1], C. BUTLER[2], D. P. MATHEOS[1], L. TONG[2], N. C. BERCHTOLD[2], S. CHEN[3], M. SAMAD[3], C. MAGNAN[3], J. BEARDWOOD[1], S. SHANUR[1], A. RODRIGUEZ[1], P. BALDI[3], C. W. COTMAN[2], M. A. WOOD[1];

Abstract: We have previously demonstrated that exercise enables hippocampal-dependent learning in conditions that are normally subthreshold for encoding and memory formation and depends on hippocampal induction of brain-derived neurotrophic factor (BDNF) as a key mechanism. In male mice with prior exercise experience, only a brief exercise period is required to reactivate the increase of BDNF in the hippocampus, suggesting that there exists a 'molecular memory' for the prior exercise experience that facilitates subsequent learning. Here, we find that

brief 2-day re-introduction to exercise following a sedentary delay was sufficient to re-gain cognitive benefits in object location memory and enhance hippocampal LTP (similar to effects of initial exercise) relative to controls. We hypothesize that an epigenetic molecular memory of exercise as a previous experience primes specific genes for subsequent activation upon new learning, resulting in facilitated memory formation. RNA-Sequencing data from dorsal hippocampus tissue taken from male mice during the memory consolidation window, post-exercise, demonstrates that different exercise parameters led to distinct transcriptional profiles. Data point to a novel plasticity protein, ACVR1C as being up-regulated in conditions in which exercise facilitates learning and maintained throughout the 'molecular memory window' for exercise. Using intra-hippocampal delivery of AAV1-ACVR1C point mutant constructs, we find that ACVR1C bi-directionally modulates hippocampus-dependent learning and memory as observed by either disrupted or facilitated performance in object location memory and context fear conditioning. Using slices from the same mice, we also find bi-directional modulation of hippocampal LTP. Together, these data point to ACVR1C as critical in learning and memory and as a potential key contributor in the maintenance of the 'molecular memory window' for exercise.

Title: GluN2B-containing NMDA receptors in the dorsal hippocampus are involved in memory labilization and reconsolidation effects of delta-9 tetrahydrocannabinol

Authors: *A. M. RAYMUNDI, J. M. B. SOHN, B. W. SALEMME, C. A. J. STERN;
Univ. Federal do Paraná, Curitiba, Brazil

Abstract: Labilization is a boundary condition to memory retrieval-induced reconsolidation. Evidence suggests that GluN2B and GluN2A-containing NMDA and cannabinoid type-1 (CB1) receptors located in the dorsal hippocampus (DH) may contribute to these processes. Delta-9-tetrahydrocannabinol (THC) is a partial agonist of CB1 receptors, however, its effects on

labilization are unexplored. The present study aimed to investigate whether and how THC affects fear memory labilization and reconsolidation. Male Wistar rats with bilateral cannulas implanted to the DH were conditioned to Context A. 20 min before a brief memory retrieval, rats were treated with THC i.p. (0.002 or 0.3 mg/kg) or vehicle (VEH) and, immediately after, received VEH or anisomycin (ANI, protein synthesis inhibitor) into the DH. In experiment 2, 20 min before retrieval, rats received VEH or THC 0.3 i.p. and VEH, PEAQX (GluN2A-NMDA receptor antagonist), or ifenprodil (IFE; GluN2B-NMDA receptor antagonist) into the DH. Immediately after retrieval, rats received VEH or ANI. In the third experiment, 20 min before retrieval, rats received VEH or THC 0.002 i.p. and VEH, PEAQX, or IFE into the DH. 1 and 7 days later the animals were exposed to Test A_1 and Test A_2 to evaluate the drug effects. Repeated-measures ANOVA followed by Newman-Keuls post hoc test was used. Results were expressed as mean ± SEM of the percentual freezing time. All procedures were approved by the local ethics committee #1247. The infusion of ANI into the DH (Test A_1: 32.4 ± 5.6; Test A_2: 23.7 ± 5.1) or the treatment with THC 0.002 (Test A_1: 42.6 ± 6.0; Test A_2: 23.7 ± 5.2) before memory retrieval significantly reduced the freezing behavior during Test A_1 and Test A_2 when compared to controls (Test A_1: 74.1 ± 4.7; Test A_2: 52.4 ± 8.1), suggesting an impairment in memory reconsolidation. The pretreatment with THC 0.3 abolished the ANI-induced effect (Test A_1: 68.5 ± 6.1) when compared to control (Test A_1: 74.1 ± 4.7), suggesting an impairment in memory labilization. This effect was restored by the blockade of GluN2B in the DH (Test A_1: 15.6 ± 4.3), but not GluN2A (Test A_1: 60.8 ± 5.4), when compared to control (Test A_1: 69.5 ± 4.8). The blockade of GluN2B, but not GluN2A, impaired the THC 0.002 (Test A_1: 74.3 ± 5.4) effect in memory reconsolidation when compared to control (Test A_1: 68.7 ± 5.0). Our findings indicate a bidirectional effect of THC, whereas an ultra-low dose impaired memory reconsolidation, a higher dose hindered its labilization. These effects depended on hippocampal GluN2B-NMDA receptors, suggesting that activation of CB1 receptors may modulate the contribution of hippocampal GluN2B subunits to memory labilization and reconsolidation.

Title: Destabilization of strongly encoded spatial memories in mice requires muscarinic cholinergic receptor activation

Authors: *A. E. HUFF[1], W. S. MESSER, JR[2], B. D. WINTERS[1];
[1]Dept. of Psychology and Collaborative Neurosci. Program, Univ. of Guelph, Guelph, ON, Canada; [2]Pharmacol. and Exptl. Therapeut., Univ. of Toledo, Toledo, OH

Abstract: Previously consolidated memories can become destabilized following exposure to reminder cues associated with the original learning experience. This renders the memory labile and vulnerable to modification. This updating can include strengthening, weakening, or integrating new information into the existing memory. A destabilized memory must then be reconsolidated to persist in long-term memory. Stronger or older memories can be destabilization-resistant, but exposure to salient novelty during memory reactivation can render them labile. Using rats, we have previously shown that object and spatial memory destabilization requires acetylcholine acting at muscarinic cholinergic receptors (mAChRs) within perirhinal cortex and the dorsal hippocampus, respectively. Here, we utilized the hippocampus-dependent object location task to demonstrate that 1) NMDA receptor antagonism with MK-801 (0.1 mg/kg, ip) prevents spatial memory reconsolidation in male C57BL/6 mice; 2) strongly encoded object location memories resist destabilization, but exposure to novelty during reactivation renders them labile and vulnerable to weakening; 3) non-specific mAChR antagonism with scopolamine (0.3 mg/kg, ip) prevents both standard and novelty-induced destabilization of object location memories; and 4) activation of M_1 mAChRs during memory reactivation mimics the effect of novelty, facilitating destabilization of an otherwise-resistant object location memory in the absence of salient novelty during reactivation. This research provides converging evidence to support the idea that acetylcholine acting at mAChRs is critical for destabilization of different types of otherwise-resistant memories, which could be a general mechanism for this process. In addition, this research broadens our understanding of long-term memory storage dynamics and suggests implications for the understanding and treatment of disorders characterized by inflexible memories, such as Alzheimer's Disease and PTSD.

Title: Age-related object memory modification impairments can be ameliorated by systemic M1 muscarinic acetylcholine receptor activation

Authors: *K. H. JARDINE, S. D. MCGRAW, H. EDWARDS, B. D. WINTERS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Memory reactivation opens the door for memory trace updating. Upon reactivation, synaptic connections within the memory trace can destabilize and remodel for a brief period before being re-consolidated. In some cases, however, memories show resistance to modification. For example, memory updating deficits are commonly reported among older individuals, especially for navigational information. There is currently no treatment for these memory updating deficits, potentially due to a limited understanding of neural factors facilitating reactivation-based declarative memory updating. Our lab suspects that the cholinergic system has the unique potential to promote the updating of inflexible memories. In support of this, we previously found that muscarinic acetylcholine (ACh) receptor (mAChR) signalling at the M1 subtype within perirhinal cortex (PRh) is critical for object memory destabilization and reactivation-based object memory updating. Also, ACh apparently supports the prediction error signal for non-affective information, and an element of prediction error during memory reactivation seems to reliably induce destabilization. Correspondingly, in aging and memory research, there is a well-established decline in cholinergic transmission and reduced cortical mAChR levels in the aging brain, which could explain age-related memory inflexibility. Considering these findings, we hypothesize that age-related cholinergic system dysfunction underlies memory updating deficits experienced by elderly individuals; thus, promoting mAChR signalling during memory reactivation could restore these deficits. First, to explore this hypothesis, we needed to characterize declarative memory updating performance in mice at different ages. We used the post-reactivation object memory modification (PROMM) task for mice—where a reactivated object memory is updated with new contextual information—to measure object memory updating in 3-, 6-, and 12-month-old mice. We found that 3-month-old mice showed intact PROMM task performance, 6-month-old mice showed a mild impairment, while 12-month-old mice seemed severely impaired. Next, we assessed whether activating M1-mAChRs during reactivation could restore object memory updating in the 12-month-old group. To test this, we administered the M1-selective agonist CDD-0102A prior to object memory reactivation in the PROMM task in 12-month-old mice. Remarkably, pre-reactivation systemic M1-mAChR activation enhanced PROMM task performance of 12-month-old mice. Here we showed a promising strategy for promoting the maintenance of memory accuracy as we age.

Title: The activity of phosphodiesterases 4, 4B and 4D in the dorsal hippocampus contributes to sustaining the fear memory after retrieval

Authors: *J. M. B. SOHN[1], N. C. CARDOSO[1], J. PRICKAERTS[2], C. A. J. STERN[1];
[1]Dept. of Pharmacol., Univ. Federal do Paraná, Curitiba, Brazil; [2]Dept. of Psychiatry and Neuropsychology, Maastricht Univ., Maastricht, Netherlands

Abstract: Upon retrieval, a consolidated memory can become destabilized and subsequently restabilized by the reconsolidation process. Modulation of 3´, 5´cAMP signaling by inhibiting phosphodiesterase 4 (PDE4) regulates protein kinase A (PKA) activity and has emerged as a potential target for improving memory consolidation and extinction persistence. However, the role of PDE4 in memory reconsolidation remains unexplored. The aim of the present study was to investigate the role of PDE4 and its subtypes PDE4B and 4D in fear memory reconsolidation. Adult male Wistar rats with bilateral cannulas implanted to the dorsal hippocampus (DH) underwent contextual fear conditioning to Context A. After a brief memory retrieval, roflumilast (unselective PDE4 inhibitor; ROF 9 ng/0.5 µl/side), A33 (PDE4B inhibitor; 1 µM/0.5 µl/side), Gebr-32A (PDE4D inhibitor; 1 µM/0.5 µl/side) or vehicle (VEH) were injected into the DH. One and 10 days later the animals were exposed to Test A_1 (TA_1) and Test A_2 (TA_2), respectively, to evaluate the drug effects. In experiment 2, animals were treated with ROF, A33, Gebr-32A, or VEH 5 min after a brief memory retrieval. TA_1 was omitted and the animals were exposed only to TA_2 10 days later. In experiment 3, animals were treated with ROF or VEH 5 min after a brief memory retrieval. 5 min after TA_1, animals received VEH or anisomycin (ANI; protein synthesis inhibitor; 20 µg/side) and were exposed to TA_2. All experiments were approved by the local ethics committee. The results are expressed as mean ± S.E.M. Animals treated with ROF (20.9 ± 6.1), Gebr-32A (13.4 ± 4.7) or A33 (17.4 ± 1.7) presented significantly less freezing behavior than controls (53.0 ± 6.0) during TA_2, but not during TA_1. When TA_1 was omitted, animals treated with ROF (41.1 ± 10.1), Gebr-32A (40.5 ± 11.3) or A33 (42.3 ± 8.8) behaved similarly to controls (35.3 ± 12.8) during TA_2, suggesting that TA_1 exposure is necessary for PDEs inhibition effect. Animals treated with ROF after retrieval and ANI immediately after TA_1 did not show significantly different levels of freezing during TA_2 (ROF-ANI: 29.0 ± 5.2) when compared to controls (53.3 ± 6.7), suggesting that protein synthesis during TA_1 is partially involved in PDEs inhibition effect. No difference among VEH-ANI-treated group (31.5 ± 5.8) when compared to controls (53.3 ± 6.7) was observed. The results suggest that upon retrieval, the hippocampal activity of PDE4, mainly subtypes 4B and 4D, is not required for fear memory reconsolidation, but is involved in sustaining fear memory in a long-term manner. The present results suggest that behavioral tagging mechanisms might underlie the effects of PDE4, 4B, and 4D inhibition.

Title: Phosphorylation state of histone deacetylase 3 (HDAC3) modulates long-term memory formation and synaptic plasticity

Authors: *A. C. RODRIGUEZ[1], A. A. KEISER[1], E. A. KRAMÁR[1], T. DONG[1], J. L. KWAPIS[2], D. P. MATHEOS[1], M. A. WOOD[1];
[1]Neurobio. & Behavior, Univ. of California, Irvine, Irvine, CA; [2]Dept. of Biology, Ctr. for Mol. Investigation of Neurolog. Disord, Penn State Univ., University Park, PA

Abstract: Histone deacetylase 3 (HDAC3) negatively regulates long-term memory in the hippocampus by inhibiting transcription of genes important for learning and memory. While several studies have shown that inhibiting or deleting HDAC3 in hippocampal neurons facilitates memory formation, the mechanisms regulating HDAC3 activity are less understood. However, previous studies from our lab suggest that the phosphorylation state of HDAC3 modulates its enzymatic activity and consequently, may be important in regulating long-term memory. We previously found in a collaborative study that the expression of point mutant constructs mimicking phosphorylation of HDAC3 in cultured dorsal root ganglion cells negatively regulates spinal cord recovery after injury. Unpublished data from our lab also revealed that HDAC3 phosphorylation levels were elevated in hippocampal neurons of aging (18-month-old) mice which correlated with impaired performance on an object location memory task in comparison to young mice. Taken together, these findings lead us to hypothesize that phosphorylation of HDAC3 likely negatively regulates hippocampal-dependent memories. To test this, we developed an HDAC3 phosphomimetic mutant virus to study the function of phosphorylated HDAC3 on hippocampal-dependent memory formation. Mice received infusions of either the HDAC3 phosphomimetic virus or an empty vector virus into the dorsal hippocampus. Then, we tested mice on an object location memory (OLM) task before measuring synaptic plasticity with slice electrophysiology in CA1. Mice expressing the HDAC3 phosphomimetic mutant in the dorsal hippocampus had impaired OLM performance and synaptic plasticity in CA1 in comparison to mice that received the empty vector virus. Overall, our findings indicate that phosphorylated HDAC3 disrupts hippocampal-dependent memory formation and synaptic plasticity. It’s possible that increased levels of phosphorylated HDAC3 in the hippocampus could contribute to memory impairments associated with aging.

Title: Histone post-translational modifications underlying the persistent effects of early-life exercise on hippocampal memory

Authors: *A. M. RAUS[1], S. YANG[4], T. FULLER[2], N. E. NELSON[3], S. D. A. VALIENTES[2], E. BASSEY[5], A. S. IVY[2];
[1]Physiol. and Biophysics, [2]Pediatrics, Univ. of California, Irvine Sch. of Med., Irvine, CA; [3]Physiol. and Biophysics, Univ. of California, Irvine Sch. of Med., Irivne, CA; [4]Sch. of Biol. Sci., Univ. of California, Irvine, Irvine, CA; [5]Col. of Natural Sci., Univ. of Texas at Austin, Austin, TX

Abstract: Introduction: Early-life experiences such as exercise can influence memory function throughout life. Understanding the molecular mechanisms by which early-life exercise (ELE) influences memory can lead to novel interventions for ameliorating disorders of memory function. Our lab recently demonstrated that exercised juvenile rodents exhibited improved hippocampal long-term memory and basal synaptic physiology that lasted into adolescence (Ivy et al., *Sci Rep* 2020). Epigenetic mechanisms, such as histone modifications, are strong candidates underlying this phenomenon: they can bridge environmental experiences with gene expression, can be persistent or transient, and can have lasting influences on neuronal function. We hypothesize that exercise in early life facilitates enabled memory formation in adolescence by promoting stable epigenetic modifications at neuroplasticity-associated genes. Methods: We crossed a mouse line expressing *loxP*-flanked Gt(ROSA)26Sor$^{tm1(CAG\text{-}birA,\text{-}mCherry/Rangap1,\text{-}EGFP/Rpl10a)Evdr}$ (known as NuTRAP) with mice expressing Emx1$^{IRES\ cre}$ for evaluating transcriptional profiles and histone modifications (H4K8ac, H3K27me3) from isolated hippocampal neurons expressing the NuTRAP cassette. “Emx-NuTRAP” mice were either sedentary or underwent three weeks of voluntary running (postnatal days (p)21-41). Hippocampal tissue was collected on p42. Samples were processed using the INTACT (isolation of nuclei tagged in specific cell types) and TRAP (translating ribosome affinity purification) techniques from the same single cell suspension, followed by CUT&RUN-seq and RNA-seq . RT-qPCR and RNA-seq was also performed on wild-type mice that underwent ELE (for either 1 or 3 weeks) followed by object location memory training (Ivy et al., *Sci Rep* 2020). RT-qPCR and ChIP-qPCR for H4K8ac was performed from hippocampi of wild type mice after ELE alone. Results: After 3 weeks of ELE (p21-41), Emx-NuTRAP mice showed increased memory-

associated gene expression, including BDNF. CUT&RUN-seq data to assess H4K8ac and H3K27me3 occupancy is currently being analyzed. 1-week of ELE (p21-27) was sufficient to increase H4K8ac occupancy at the NR4A1 promoter when evaluated at p42, but insufficient to produce persistent altered NR4A1 gene expression. Preliminary RNA-seq on dorsal hippocampus from wild-type mice after a sub-threshold learning event indicates increased expression of memory-associated genes. Conclusions: Early-life exercise alters histone post-translational modification occupancy, potentially providing a mechanism for priming memory-associated gene expression after a sub-threshold learning event.

Title: Spatial-temporal regulation of a novel lncRNA

Authors: I. ESPADAS, E. GRINMAN, J. WINGFIELD, B. RAVEENDRA, ***S. PUTHANVEETTIL**;
The Scripps Res. Inst., Jupiter, FL

Abstract: Specific changes in the gene transcription are a pre-requisite for long-term memory (LTM) storage. However, it remains largely unknown whether transcriptional changes in long noncoding RNAs (lncRNAs) are associated with learning and whether these changes mediate the consolidation of long-term memories (LTM). Here we report the identification of lncRNA D17Rik from the unbiased analysis of gene expression changes in dorsal CA1 neurons of mouse hippocampus following contextual fear conditioning (CFC). D17Rik expression is upregulated specifically in CA1 neurons within an hour of CFC training. We find that the knock-down (KD) of D17Rik in CA1 does not affect acquisition, recall or extinction of CFC memory, but impairs consolidation of CFC memory. Importantly D17Rik KD in CA3 neuron does not affect consolidation suggesting a specific role for D17Rik in CA1 neurons. Our study illuminates the significance of spatial-temporal regulation and function of D17rik lncRNA in LTM.

Title: Role of DNA recombination in long term memory formation in honey bee

Authors: *F. NOEL[1], L. SANCHEZ[1], A. MEHMET[1], M. GIURFA[2], T. GIRAY[1];
[1]Dept. of Biol., Univ. of Puerto Rico, Rio Piedras campus, San Juan, PR; [2]CNRS, Univ. Paul Sabatier Toulouse III, Toulouse, France

Abstract: Over days, bee colonies trade changing floral resources through plastic behaviour of foragers. Foragers may,meticulously, decide to visit a particular flower because they know the visit is worth. This mechanism of selection based on learning, may help us understand the process of Long term memory (LTM) formation and consolidation. Arabinoside cytosin (ARA-C), as an antimetabolite drugs, is known to inhibit DNA synthesis. The process of memory formation depends on the transcription and translation of DNA, but the role of DNA recombination in memory stabilization is unknown. Here, we asked if inhibition of DNA recombination affect LTM formation. In this study we used ARA-C to block the DNA recombination process in honey bee. Previous studies have shown that ARA-C causes a progressive decreaseof cognitive activity in patients treated for breast cancer. Considering this drug's side effect, we hypothesized that ARA-C would block the LTM formation without affecting affecting the learning process. We analyzed the STM formation 20 minutes after completing the conditioning and the LTM 24 hours after, obtaining no significant differences in the proportion of individuals exhibiting STM. However, we found a significant difference in the LTM and no LTM expression between both groups. We discuss these results of the role of the DNA recombination in the LTM consolidation.

Title: A selective role for the mPFC during choice & deliberation, but not spatial memory retention over short delays.

Authors: *K. S. KIDDER[1], J. T. MILES[1], P. M. BAKER[3], V. I. HONES[1], D. H. GIRE[2], S. J. MIZUMORI[1];
[2]Psychology, [1]Univ. of Washington, Seattle, WA; [3]Psychology, Seattle Pacific Univ., Seattle, WA

Abstract: Past research reveals that the medial prefrontal cortex (mPFC) and hippocampus (HPC) are both structures vital to spatial-working memory and decision-making. Recent evidence suggests that interactions between these two structures are dynamic and task dependent. However, there exists uncertainty surrounding the specific conditions that recruit the mPFC during these tasks, specifically regarding its role in retaining spatial information in memory during delay periods. To address this issue, we tested rats on a spatial-delayed alternation (SDA) task in which we utilized a closed-loop optogenetic system to transiently disrupt mPFC activity during different task epochs (delay, choice, return). By analyzing the effects of mPFC disruption on choice accuracy and a deliberative behavior known as vicarious-trial-and-error (VTE), our study revealed several interesting findings regarding the role of the mPFC in spatial-working memory tasks. The main findings include: (1) choice accuracy in the SDA task was impaired when the mPFC was disrupted during the choice epoch and was not impaired when disruption was applied to delay or return epochs. (2) mPFC disruption resulted in a non-epoch specific reduction in VTE occurrence, however there was a strong trend towards less VTEs occurring after choice epoch disruption. (3) The decrease in choice accuracy following mPFC disruption was significantly correlated with a decreased occurrence of VTE behaviors. Taken together, findings from this study suggest that, during spatial decision-making, contributions made by the mPFC are specific to points of deliberation and choice (not delay), and that VTEs are a deliberative behavior which relies on intact mPFC function.

Title: Vicarious trial and error classification using trajectories and hippocampal oscillations

Authors: *J. T. MILES, K. S. KIDDER, Z. WANG, Y. ZHU, D. H. GIRE, S. J. Y. MIZUMORI;
Univ. of Washington, Seattle, WA

Abstract: Vicarious trial and error behaviors (VTEs) indicate periods of indecision during decision-making, and have been proposed as a behavioral marker of deliberation. In order to understand the neural underpinnings of these decision-making variants, researchers need the ability to readily and confidently distinguish VTEs from non-VTEs. Here we utilize a small set of trajectory-based features and standard machine learning classifiers to identify VTEs from non-VTEs for rats performing a spatial delayed alternation task (SDA) on an elevated plus maze. We also show that previously reported features of the hippocampal field potential oscillation can be used in the same types of classifiers to separate VTEs from non-VTEs with above chance performance. However, we caution that the modest classifier success using hippocampal population dynamics does not identify many trials where VTEs occur, and show that combining oscillation-based features with trajectory-based features does not improve classifier performance compared to trajectory-based features alone. Overall, we propose a standard set of features useful for trajectory-based VTE classification in binary decision tasks, and support previous suggestions that VTEs engage a network including, but likely extending beyond, the hippocampus.

Title: Coordinated respiratory and brain rhythms during spatial navigation and learning

Authors: *A. SHERIFF, L. M. KAY;
Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: Several recent studies have demonstrated a role for the respiratory rhythm in widespread oscillatory coherence throughout the limbic system and neocortex, similar to other global rhythms. The nasal respiratory rhythm, which produces robust olfactory bulb (OB) oscillations, has especially been related to episodic memory, locomotion, and exploration. The piriform cortex (PC) is implicated in propagating the OB driven respiratory rhythm, however this region has not been studied along with both hippocampal theta and nasal respiratory rhythm during exploratory behaviors. Here, we characterize dynamic respiratory and theta network configurations associated with the perceptual environment during spatial navigation and learning. In the first set of experiments, local field potentials (LFPs) were recorded in olfactory areas including the OB and PC, along with CA1 and dentate gyrus of the hippocampus, and the primary visual cortex, simultaneously with nasal respiratory recordings during spatial navigation in rats. We compared interactions among these areas while rats foraged with either visual or olfactory spatial cues. In both modalities we found high systemwide coherence in two frequency bands matching slow and fast respiratory rates. Granger causality shows dynamic interactions between primary sensory areas depending on the sensory modality of the foraging environment. Phase amplitude coupling analysis shows respiratory and theta coupling at beta and gamma frequencies between olfactory, hippocampal and visual areas. In the second set of experiments, half of the rats from the first experiment were used along with another set of rats in which we also recorded from primary somatosensory, secondary motor, medial parietal association, and medial entorhinal cortices. All rats were trained on a spatial learning task in which they had to navigate to a learned location using either visual or olfactory cues. We compared measures of neural interaction dependent on modality of spatial cues and naïve versus learned states. High levels of coherence were seen between limbic system and sensory cortices at a single frequency around hippocampal theta (~7-8 Hz). Beta (15-35 Hz) and high gamma (60-100 Hz) interactions seen with Granger causality emerged among somatosensory, motor, olfactory, and hippocampal areas during spatial learning which also couple to respiratory and theta rhythms. Our results support the hypothesis that respiration works dynamically with hippocampal theta as part of a master clock for global brain connectivity and help to characterize the role of these coordinated rhythms in cognitive behaviors.

Title: Prefrontal-hippocampal interactions are modulated by optogentically paced theta oscillations during the encoding and maintenance phases of spatial working memory

Authors: *S. SRIKANTH[1], Y. HU[1], J. K. LEUTGEB[1], S. LEUTGEB[1,2];
[1]Neurobio. Section, Div. of Biol. Sci., UCSD, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, Univ. of California, La Jolla, CA

Abstract: Brain oscillations provide a synchronizing signal for the coordination of spike timing across brain regions, thereby supporting cognitive functions such as working memory. Theta oscillations (7-9 Hz) in the hippocampus, which are generated by pacemaker cells in the medial septal area (MSA), have been found to be important for learning and memory. In addition, interactions between the hippocampus and the prefrontal cortex have been established to be critical for spatial working memory. In this study, we manipulated the precise timing of theta oscillations through optical stimulation of the MSA and investigated the effects of these manipulations on local field potentials and single unit firing patterns in the medial prefrontal cortex. We recorded local field potentials from the hippocampus and medial prefrontal cortex as well as single units from the medial prefrontal cortex while mice performed a delayed spatial alternation task. In mice (n = 6) with channelrhodopsin (ChR2) expression in parvalbumin-positive MSA cells, we show that local field potentials in the hippocampus as well as the medial prefrontal cortex are strongly entrained to optical stimulation of the MSA at accelerated (12 Hz), decelerated (4 Hz) and endogenous (8 Hz) theta frequencies. However, only a subset of local neuronal populations within the medial prefrontal cortex are entrained to the artificially stimulated oscillations (4 Hz: 44% of n=209 cells, 8 Hz: 48% of n=204 cells, 12 Hz: 37% of n=181 cells). Moreover, this entrainment, as measured by the phase locking value, is stronger upon stimulation at 8 Hz compared to 4 Hz or 12 Hz (4 Hz: $p=0.14$, $Z=-1.47$; 8 Hz: $p<.001$, $Z=-3.91$; 12 Hz, $p=0.14$, $Z=-1.45$ Wilcoxon Rank Sum Test). We also found that during spatial working memory the entrainment of mPFC neurons was stronger during the encoding and maintenance phases of a delayed alternation task in comparison to other phases of behavior in response to the 8 Hz and 12 Hz stimulation (Encoding - 4 Hz: $p<.05$, $Z=2.52$, 8 Hz: $p<.001$, $Z=-4.45$, 12 Hz: $p<.05$,$Z=-2.78$; Maintenance - 4 Hz: $p=0.07$, $Z=1.80$, 8 Hz: $p<.001$, $Z=-4.00$, 12 Hz: $p<.05$, $Z=-2.61$; Choice - 4 Hz: $p=0.16$, $Z=1.37$, 8 Hz: $p=0.26$, $Z=-1.12$, 12 Hz: $p=0.33$, $Z=-0.97$, Wilcoxon Rank Sum Test). Spatial firing properties of medial prefrontal cortex neurons remained unaltered in response to stimulation at any of the three frequencies. None of the effects on neural oscillations were observed in control mice with GFP expression in MSA (n = 7) These results suggest that neuronal computations are coordinated by theta oscillations in the medial prefrontal cortex and the hippocampus predominantly during task phases when information is encoded and maintained.

Title: Representational stability in the cortical head-direction circuit

Authors: *S. SKROMNE CARRASCO, G. VIEJO, A. PEYRACHE;
Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstract: Primary sensory cortical areas are characterized by low-level representations of sensory inputs, but whether these representations are stable over a long period of time or whether they are continuously renewed is still unclear. The head-direction (HD) signal is essential for the spatial navigation system. In the cortex, it is processed by the postsubiculum (PoSub). HD cells each fire for a specific direction of the head of the animal in the horizontal plane and constitute a vast majority of PoSub principal neurons. To address the question of representational stability, we used one-photon calcium imaging with portable microscopes ("miniscopes") to longitudinally monitor ensembles of HD cells in the PoSub over periods of weeks in freely moving animals visiting several different environments. In the PoSub, the representation of the HD signal was stable at two levels. First, the pairwise offset between HD neurons was preserved for several weeks, indicating that the subcortical representation of the HD signal is certainly itself stable and that thalamocortical integration is rigid. Second, the orientation of the HD signal at the population level was maintained in a given environment over the same period of time, suggesting that the HD system preserves long-term memories of spatial orientation in different environments. Together, these findings shed light on how spatial information is represented over time in the brain's navigation system.

Title: Organisation of population activity in the head-direction generator

Authors: *G. VIEJO, S. SKROMNE CARRASCO, A. PEYRACHE;
Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada

Abstract: Thalamic head-direction (HD) neurons of the anterodorsal nucleus (ADN) increase their firing rates as a function of the head direction of the animal in the horizontal plane. ADN neurons maintain a coherent signal during all phases of sleep (Peyrache et al, 2015), in agreement with the hypothesis that the system is governed by attractor dynamics. The lateral mammillary nucleus (LMN) is the main input of AD and is believed to be a key structure for HD signal generation. Yet, the internal dynamics of this structure remain unknown. To investigate the organisation and transformation of the population activity in the head-direction generator, we recorded neuronal population simultaneously in LMN and ADN in freely moving mice using silicon probes. Like in ADN, HD neurons in LMN show coherent activity during wakefulness and Rapid Eye Movement (REM) sleep. However, pairwise coordination in LMN was not preserved during non-REM sleep (NREM) in LMN. Specifically, HD neurons in LMN sometimes fire together during NREM sleep even if they fire for opposite directions during wakefulness, as opposed to their downstream reader ADN where coordination is always maintained. These findings show that the HD thalamocortical network exhibits attractor dynamics during NREM sleep, independent of its inputs. Overall, these observations suggest that the thalamus is not a passive relay of incoming signals to the cortex, but plays an active role in sensory processing.

Title: Dorsoventral gradient of UP-state onset in mouse post-subiculum

Authors: *D. MEHROTRA[1,2], A. J. DUSZKIEWICZ[2,3], D. LEVENSTEIN[2,4], G. VIEJO[2], A. PEYRACHE[2];
[1]Integrated Program in Neurosci., [2]Montreal Neurolog. Inst. and Hosp., McGill Univ., Montreal, QC, Canada; [3]Ctr. for Discovery Brain Sciences, Univ. of Edinburgh, Edinburgh, United Kingdom; [4]MILA, Montreal, QC, Canada

Abstract: Functional gradients along an anatomical axis are a common feature of the spatial navigation system. For example, the medial entorhinal cortex (MEC), containing grid and head-direction (HD) cells, is organized along its dorsoventral (DV) axis. From dorsal to ventral MEC, grid cells show discrete increase in grid spacing and HD cells show gradual decrease in their tuning specificity. These observations beg the question of whether such functional gradients are intrinsic to the MEC or are inherited, at least in part, from their inputs from the post-subiculum (PoSub), which is the main cortical recipient of the thalamic HD signal.
PoSub is a major input to MEC, conveying HD information critical for the generation of the grid code. We focused our investigation on the population activity dynamics during non-Rapid Eye Movement (NREM) sleep, where intrinsic properties of a system can be studied in the absence of sensory inputs.
We used 64-channel linear electrode arrays to conduct simultaneous population recordings along the whole DV axis of the PoSub in adult male mice. NREM sleep is characterized by aperiodic fluctuation of neuronal population activity between activated “UP” states and “DOWN” states during which most cells are hyperpolarized. Preliminary analysis identified reliable sequential activation of PoSub cells at the beginning of UP states as a function of recording depth, where UP states in the dorsal part of PoSub (adjacent to retrosplenial cortex) began earlier than the UP states in the ventral part (adjacent to ventral presubiculum). The spatial distribution of UP state onset could not be solely explained by increased excitability of early firing cells.
UP-DOWN state transitions were near-synchronous along the DV axis, therefore suggesting that the main difference along the axis was the duration of the DOWN states. This could possibly result from a gradient of excitatory recurrence in the network, stronger recurrence leading to shorter DOWN states. In the HD system, excitatory recurrence is expected to play a major role in attractor dynamics and shaping of individual cell tuning. A computational model in which the probability of recurrent excitation was graded along the DV axis recapitulated our main observations.
Overall, these findings demonstrate a gradient of neural dynamics along the DV axis of the PoSub, possibly reflecting a gradient of excitatory collaterals. Further experiments will look at the anatomical and functional relationship between the PoSub and the MEC to provide further insight into the organization of the limbic system and its role in spatial navigation and memory.

Title: Functional characterisation of inhibitory head-direction tuning in the cortical head-direction system

Authors: *A. J. DUSZKIEWICZ[1], S. SKROMNE CARRASCO[1], E. OWCZAREK[1], E. BROWN[1], E. R. WOOD[3], A. PEYRACHE[2];
[2]Montreal Neurolog. Inst., [1]McGill Univ., Montreal, QC, Canada; [3]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Local inhibition is critical for the maintenance of high-fidelity single-cell tuning across many cortical areas. Furthermore, excitatory-inhibitory recurrent connectivity is thought to support attractor dynamics in many of the brain's spatial navigation systems. However, while the firing patterns of inhibitory interneurons in these areas are known to be spatially non-uniform, not much is known about the principles governing their spatial tuning as well as its contribution to the local attractor dynamics. In order to investigate it, we surveyed the spatial tuning properties of putative fast-spiking interneurons (FS cells) in the cortical head-direction (HD) system - the most fundamental of the brain's allocentric spatial representation systems. To that end, we used 64-channel linear electrode arrays to conduct population recordings parallel to the cortical layers in postsubiculum (PoSub) of freely moving mice (n = 19), and recorded assemblies of up to 174 PoSub cells. We first established that the firing rate of PoSub-FS cells (n = 256) varies by an average of 50% as a function of animal's HD and that this HD tuning is stable both within and across exploration sessions and follows rotation of a distal landmark to the same degree as PoSub-HD cells. What is more, FS cell tuning curves could be recreated from PoSub population activity during wake as well as during sleep, indicating that it is largely tied to the internal dynamics and connectivity within PoSub. We then identified putative synaptically-connected HD-FS cell pairs in the dataset and determined that FS cells receive most of their inputs from HD cells within a 100 μm radius and that FS cell HD tuning reflects the tuning of their presynaptic partners. In order to determine if HD tuning of PoSub-FS cells exhibits any particular patterns, we treated FS cell HD tuning curves as continuous periodic signals and used Fourier analysis to decompose them into component frequencies. We found that only the first three frequency components are over-represented in FS tuning curves in comparison with the

shuffled distribution, illustrating that FS cell tuning curves tend to have one, two or three symmetrically-distributed peaks. Overall, to our knowledge these results constitute the first systematic characterisation of HD tuning in FS cells. We further hypothesise that such patterned tuning of PoSub FS cells serves to enhance the fidelity of the cortical HD signal.

Title: Investigation of circuits underlying integration of heading inputs in retrosplenial cortex

Authors: *K. K. SIT[1], M. J. GOARD[2];
[1]Univ. of California: Santa Barbara, Santa Barbara, CA; [2]Molecular, Cell. and Developmental Biol. / Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Navigation is fundamentally dependent on an accurate internal representation of position and heading. Although position and heading can be maintained in the absence of sensory input, they are continuously updated by sensory information to ensure accuracy. However, it is not well understood how incoming sensory information is incorporated into an internal representation of navigational variables. The mammalian navigation system, particularly the head direction (HD) network, is an ideal framework for investigating this question. The HD network is responsible for generating a heading signal that informs an animal of its orientation relative to its environment. Although a number of sensory inputs contribute to the signal, visual cues are particularly important for anchoring the heading signal to the environment. Here, we use two-photon microscopy to image neurons in the retrosplenial cortex (RSC) of head fixed mice while a physical floating air platform rotates around them to investigate the contribution of visual cues on heading. First, we find robust heading responses in the RSC, even under head fixation, suggesting that non-vestibular sensory information is sufficient to maintain internal heading. Secondly, we sought to understand the contributions of visual cues to the HD network, so we altered the floating air platform to have symmetrical cues, as well as to record in both light and dark periods. We found multiple different response profiles in the RSC, with some cells showing strong coupling to visual cues while others responded to heading independently of cues,

suggesting heterogeneity of cell tuning in the RSC. Finally, we show that one class of these cells integrates visual cues and heading signals to produce a high-fidelity representation of heading in a variety of conditions, suggesting that these cells are a strong candidate for integrating sensory information into the HD network. These results suggest that the heading representation is not entirely dependent on vestibular information over short time periods, and that visual cues contribute to producing a robust and accurate signal in the HD network.

Abstract: From visual perception to language, sensory stimuli are interpreted differently depending on prior hypotheses. Recurrent dynamics in neural networks have been identified as a mechanism for changing the interpretation of stimuli, but whether the same neural dynamics can form, maintain, and employ hypotheses to interpret ambiguous stimuli is unknown. Here, we show that mouse Retrosplenial cortex (RSC) can integrate information over time to form hypotheses and perform spatial reasoning through recurrent dynamics. We developed a task in which mice navigate using locally ambiguous landmarks that can only be identified through their spatial relationship to each other, requiring sequential refinement of hypotheses. Neurons in RSC and in artificial neural networks (ANNs) trained on the task encoded mixtures of spatial hypotheses, current location, and sensory data, and were constrained by stable attractor

dynamics. The ANN resolved ambiguous landmarks by encoding spatial hypotheses as locations in neural activity space from where identical sensory inputs led to their correct interpretations via stable attractor dynamics; this computation was mirrored in RSC. Our results indicate that interactions between hypotheses and sensory data in recurrent circuits can provide a substrate for complex sequential cognitive processes.

Title: Somato-dendritic computations provide a mechanism for landmark-mediated self-localization

Authors: *L. FISCHER, L. XU, K. MURRAY, M. T. HARNETT;
MIT, Cambridge, MA

Abstract: Spatial navigation requires rapid integration of novel sensory information with internal state representations of location. While sensory processing is optimized to rapidly detect behaviorally relevant stimuli, internal state representations must provide stable readouts even if environmental information is scarce. These requirements apply diverging demands on the neural dynamics governing information processing but the mechanisms underlying their interactions remain unknown. Here we tested how sensory inputs are reconciled with self-localization estimates by recording from neurons in retrosplenial cortex (RSC) while mice learned to use visual landmarks to locate rewards in virtual reality. We found a pronounced shift in RSC neurons from representing mostly self-referenced (egocentric) variables to expressing mostly environment-referenced (allocentric) codes that were dependent on behavioral context. A computational model utilizing somato-dendritic interactions in multi-compartment neurons enabled accurate, context-dependent correction of self-localization estimates which were represented by an attractor network. When behavioral context was switched in such a way as to render landmarks irrelevant, activity of both real and model neurons significantly decreased. Single-compartment neurons were unable to switch between behavioral contexts. Our results

propose a new mechanism for context-dependent integration of sensory information with internal state representations in retrosplenial cortex.

Abstract: The significant post-processing of two-photon imaging data is usually done either after the experiments, or in a rudimentary way during data acquisition. We have developed Neuronal Analysis in Real Time (NeuroART), software that taps into microscope data streams to provide real-time readout of neuronal activity and downstream analysis during image acquisition. NeuroART has been tested on the most widely used two-photon microscopes and operates in parallel with a range of popular microscope software and image formats. The software package allows for the integration of existing image analysis approaches as we demonstrate by integrating the automatic neuronal cell identification routines from CaImAn (Giovannucci et al, ELife 8, e38173 (2019)).
Utilizing NeuroART, experimenters gain knowledge of the data quality in real time and can identify neurons of interest based on quantitative analysis of the ΔF/F traces of each neuron. As a first demonstration of downstream analysis capability, NeuroART employs a pairwise correlation-based analysis to construct functional networks and identify the most population-correlated neurons in the field of view. The downstream analysis within the real-time loop can run in real time on a standard laptop.
We also demonstrate integration of stimulus information on the example of auditory stimuli, which enables real-time quantification of sound encoding in neurons. During the experiment, tones of different frequencies and sound pressure levels are presented repeatedly over many individual trials and the NeuroART application computes the receptive field and tuning of each

neuron within a field of view of the auditory cortex in real time. With these capabilities, NeuroART can enable model-guided experiments for a wide range of microscope platforms.

Title: Marmoset Brain Mapping V4: Cortical Parcellation Based on Awake Resting-State fMRI Data

Authors: *X. TIAN[1], Y. CHEN[3], C. TONG[4], P. MAJKA[5], Y. SANZ-PERL[6], D. SZCZUPAK[7], G. DECO[8], M. ROSA[9], Z. LIANG[10], A. C. SILVA[2], C. LIU[11];

Abstract: The common marmosets (*Callithrix jacchus*), a New World non-human primate, have increased interest in biomedical and neuroscience research and have many advantages for neuroimaging techniques. As a critical open scientific resource for marmoset research, our Marmoset Brain Mapping project (*marmosetbrainmapping.org*) provides a comprehensive set of atlases and analysis tools to facilitate neuroimaging and connectome studies of the marmoset brain. So far, we have released three versions: 1) the cortical parcellation templates based on *ex-vivo* multi-modal MRI (*Liu et al., 2018*); 2) white matter fiber pathways based on ultra-high resolution *ex-vivo* diffusion MRI (*Liu et al., 2020*); and 3) the *in-vivo* population templates and surface analysis tools (*Liu et al., 2021*). Although these versions provide helpful tools to map the neuroanatomy and structural connectome of marmoset brains, a detailed description of their functional neuroanatomy is still lacking. Here, we present the fourth version (v4) of our Marmoset Brain Mapping Project, which provides a functional parcellation of the marmoset

cortex. In addition, in this version, we attempt to solve limitations faced by non-human primate (NHP) data repositories in accelerating the availability of shared, open resources and standards to support neuroimaging studies. The new v4 comprises the following merits: 1) The largest multi-center (with standardized protocols) “awake” resting-state test-retest fMRI dataset, which currently consists of 42 adult marmosets, 62 sessions, and 721 runs (17 min *per* run).2) A novel pipeline for obtaining the cortical functional parcellation, providing a dense connectome, resting-state brain networks, and fine-grained cortical parcellations of marmosets at both the population-level and individual level.3) Test-retest analysis and task-based verification to systematically evaluate the variability of both functional connectivity and cortical parcellations across sites, animals, and sessions.4) Computational modeling tools to examine the relationship between the functional and structural connectivity maps obtained with rs-fMRI, diffusion MRI and neuronal tracing databases. In all, the new Marmoset Brain Mapping v4 and its associated awake rs-MRI data will be an essential open resource for mapping the functional parcellation of the marmoset brain, and to enable large-scale comparative studies of NHP brain architectures.

Title: Community sourced AAV Data Hub.

Authors: *J. S. NASSE, A. ABITUA, M. FAN;
Addgene, Watertown, MA

Abstract: The use of AAV vectors in neuroscience research has continued to increase year after year as new tools to view, control, and manipulate the brain are discovered and improved upon. In addition to new functional tools being developed, modifications in AAV capsid proteins and novel promoters have also dramatically increased in recent years. While the expansion of viral vector tools is immensely beneficial to neuroscience research, there are many technical issues that need to be well understood and considered when designing and performing experiments with AAV vectors. Information on the many caveats and nuances in the use of these viral vector tools is often difficult to obtain as negative results and details of troubleshooting efforts are often not published or widely disseminated. In an effort to address this problem, Addgene began beta-testing a community sourced AAV Data Hub (DH) in late 2019. The goal of Addgene’s AAV data hub is to provide a community driven resource for scientists to share experimental details

and caveats about using AAV tools to expand the scientific knowledge base, and to reduce the time and effort spent testing the multitude of variations available for vectors, promoters, and serotypes that a given experiment may require. Despite our initial success in obtaining over 130 data submissions, recent efforts to expand the number of data submissions have been challenging. In an effort to improve and expand the DH we sent a survey to over 5000 researchers that had received AAV vectors from Addgene to determine what the data needs of the community are, assess what motivates scientists to share data, and reveal what inhibits them from sharing data. We received over 180 responses to the survey. An overwhelming number of respondents (~76%) indicated that more data regarding experimental outcomes including negative or unexpected results are desired. The main reason people indicated for not submitting data was a lack of knowledge about the DH (~51%). However, there were also concerns regarding submitting unpublished data (~23%) and concerns over data quality for submission (~28%). Our results highlight a fundamental problem and paradox in the scientific community where there is great need and desire for data that is not commonly published (i.e. negative and troubleshooting data) and a hesitancy to release this type of data. By increasing community awareness and improving incentives for sharing, we seek to build-up this resource to fulfill the needs of the Neuroscience community.

Title: Large scale morphology-based similarity search across digital reconstructions of neural arbors

Authors: *B. LJUNGQUIST, M. A. AKRAM, G. A. ASCOLI;
Ctr. for Neural Informatics, Structures & Plasticity, Dept. of Bioengineering, Col. of Engin. and Computing, George Mason Univ., Fairfax, VA

Abstract: Function of the nervous system depends on neuronal and glial morphology. Continuous advances in imaging, microscopy, and tracing software have provided an increasingly abundant availability of 3D reconstructions of arborizing dendrites, axons, and processes, allowing their detailed study. However, there is a lack of efficient, large-scale

methods to compare and rank their similarity. Using the NeuroMorpho.Org database, we present a similarity search software enabling fast morphological comparison of hundreds of thousands of cellular reconstructions from various species, brain regions, cell types, and preparation protocols. We have compared the performance of different measures of morphology available for these datasets: 1) summary morphometrics calculated by L-Measure, 2) persistence vectors, a vectorized descriptor of branching structure, 3) the combination of the two. For each of these, we also investigated the impact of applying dimensionality reduction using principal component analysis (PCA). We assessed qualitative performance by gauging the ability to rank neurons in order of visual similarity. Moreover, we evaluated information content by examining explained variance and, as a benchmark, the ability to identify occasional duplicate reconstructions of the same specimen. We also investigated the execution time of searches as well as the effect of varying the database size. Our results indicate that the combined method with applied PCA provides an information-rich basis that enables efficient and precise comparison of neural morphology. The performance was also found to be independent of database size and to scale linearly with larger query sizes (number of neurons for which similarity is searched). We have made the similarity search method available as an online software tool both through a user-friendly graphical interface and as an API for machine users.

Title: Inter-method variability in the association between gray matter volume and glutamate levels in the cingulate cortex

Authors: *J. LEE[1], J. ARCHIBALD[2], E. L. MACMILLAN[3], J. L. K. KRAMER[1];
[1]Dept. of Anesthesiology, Pharmacol. and Therapeut., [2]Dept. of Exptl. Med., [3]Dept. of Radiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Glutamate, the primary excitatory neurotransmitter in the central nervous system, is of high interest to neuroscientists due to its integral involvement in the transmission and generation of signals. Proton magnetic resonance spectroscopy (^{1}H-MRS), is a non-invasive technique that allows for the measurement of neurochemicals, including glutamate. Previous literature shows glutamate exists in higher concentrations in gray matter (GM) compared to white matter (WM). For this reason, tissue fraction corrections are routine components of MRS analysis pipelines.

Although the positive association between brain GM volume and glutamate concentration is well established, the variability of this relationship resulting from the use of different tissue fraction estimating methods has not been thoroughly investigated. This study examines the relationship between different brain tissue estimating tools and uncorrected levels of glutamate in the cingulate cortex. These tools include neuroimaging softwares FMRIB Software Library (FSL), Advanced Normalization Tools (ANTs), and Statistical Parametric Mapping (SPM). Data were collected from healthy participants (n=5, 2F, age mean=29±6.9, age range=20-39) on a 3T Philips Ingenia Elition with a 32 channel SENSE head coil. Individual FIDs were pre-processed (eddy current correction, frequency alignment, visual inspection) in MATLAB (R2016b). The data was fitted using LCModel (v6.3-1H). To examine the relationship between glutamate levels and tissue fractions, uncorrected glutamate values were used (i.e., institutional units). The 3D T1 data were skull-stripped and segmented into GM, WM, and cerebrospinal fluid (CSF) using each of the neuroimaging softwares. A linear regression analysis on GM volume and glutamate levels in the anterior cingulate cortex (ACC) based on preliminary results revealed the coefficient of determination (R^2) to be 0.06, 0.11, and 0.34 for FSL, ANTs, and SPM respectively. These findings will be further examined in a larger sample size and in three more voxels across the cingulate cortex. Additionally, a deep learning algorithm using a convolutional neural network will be applied, and its performance will be compared alongside the other brain tissue estimating methods (FSL, ANTs, and SPM). The discrepancy in the R^2 values resulting from the use of different neuroimaging softwares exemplifies inter-method variability in the association between GM volume and glutamate levels in the cingulate cortex. This study highlights the importance of cross-validating findings from anatomical images with different neuroimaging tools to ensure accurate and reliable results in future studies.

Title: Data interface and apps for systems neurophysiology and imaging

Authors: *S. VAN HOOSER, D. GARCÍA MURILLO, O. ROGOVIN, Y. ZHAO, S. CHEN, Z. WANG, Z. KEELEY, D. SHIN, V. M. SUÁREZ CASANOVA, Y. ZHU, L. MARTIN, O. PAPAEMMANOUIL;
Brandeis Univ., Waltham, MA

Abstract: New technological advances and a vital industry supporting neuroscience research has resulted in an explosion of techniques and file formats. While these new methods enable innovative and creative experiments, the myriad of data formats and analysis approaches used in different labs makes rapid adoption of these new techniques and sharing with interested third parties, such as theorists, difficult. Standard file formats and standard interfaces are needed to facilitate sharing, reproducibility and rigor in analysis, and distribution of data.
We present a data interface standard for neurophysiological and imaging data. The standard is not a file format but rather is a systematic means of specifying and accessing data used in the neurosciences, including voltage waveforms, imaging data, spike times of neurons, and intensity values in regions-of-interest within imaging data. The data interface standard can be implemented in any programming language. On the one hand, the interface includes tools for reading files from several Multifunction Data Acquisition Devices, 2-photon microscopes, and stimulus devices, and tools for handling the fact that different investigators often organize their data differently on disk. On the other hand, the interface contains a powerful extendible database so that the results of analyses and extracted quantities can be stored and queried. These features allow for an eco-system of best-of-breed "apps" to be developed or converted from existing open source tools, that store standardized results in the database.

Title: Neurodecoder: an open-source package for reproducible neural population decoding

Authors: *E. MEYERS[1], X. FANG[2];
[1]Yale Univ., New Haven, CT; [2]Univ. of California Merced, Merced, CA

Abstract: Neural population decoding is a powerful data analysis method for understanding how the brain processes information (Meyers and Kreiman, 2011). However, running a decoding analysis is significantly more complex than running traditional neural analyses. To make it easier to run decoding analyses, we have previously developed the Neural Decoding Toolbox (www.readout.info) in MATLAB (Meyers, 2013). While the Neural Decoding Toolbox has been

successfully used by a number of research groups (e.g., Schmitt et al. Nature, 2017, Kamiński et al, Neuron 2020, Dotson and Yartsev, Science, 2021), there are additional ways to make running decoding analyses even simpler. In this work we introduce the NeuroDecodeR package, which runs population decoding analyses using the R programming language. Like the Neural Decoding Toolbox, the NeuroDecodeR package is designed in a modular fashion allowing research to try different classifiers and preprocessing algorithms, and to run temporal cross-classification and generalization analyses. The NeuroDecodeR package also makes it easy to develop new methods for quantifying decoding results, to log/save results, and to run code in parallel. Advantages of using the R programming language is that it is free, and there is a rich ecosystem in R for creating reproducible data analysis documents. We have also been developing a web application (a Shiny app) that allows researchers to run reproducible decoding analyses by selection options through a graphical user interface. This platform generates pdfs that contain code and plots of the results (by knitting an automatically generated R Markdown file a pdf), which will further simplify and speed up the time it takes to analyze data.

Title: Protecting the integrity and provenance of research data with Open Science Chain

Authors: *S. SIVAGNANAM, V. NANDIGAM, M. SHANTHARAM, K. LIN, S. SAKAI; UCSD, La Jolla, CA

Abstract: In neuroscience large amounts of experimental and imaging data are produced in a wide variety of formats and are utilized to develop data-driven computational models for elucidating neuronal and network functions. Investigators whose research involves sophisticated processing of large amounts of these multimodal data require techniques to ensure its integrity, especially when trying to build upon prior research work done by other scientists. When the scientific dataset evolves or is reused in workflows creating derived datasets, the integrity of the dataset, its metadata, and the provenance needs to be securely preserved while providing assurances that they are not accidentally or maliciously altered during the process.
Open Science Chain (OSC) provides a cyberinfrastructure platform where the integrity information about scientific dataset is stored and managed in a consortium blockchain. Other researchers can independently verify authenticity of scientific data using the information stored

in the blockchain and provide feedback when the data cannot be validated. OSC allows researchers to store the cryptographic hash of the data as a manifest in the blockchain along with the metadata. The metadata entities includes the dataset location (e.g., DOI, URL), description, keywords, and contributor information. When updates are made to a dataset or data collection in OSC, all metadata changes, including the SHA256 checksum for every file in that data collection, are tracked in the blockchain, enabling users to view a detailed, immutable history of that dataset over time. Researchers can also link external repositories (e.g., GitHub) and other datasets contributed to OSC to create a detailed workflow of their scientific experiment, linking multiple sources of data and computational code used in their published results.
To lower the complexity barrier for use of this technology and to promote adoption, a web-based portal is developed with seamless user interfaces for interacting with the underlying blockchain. A python-based command line utility is also available that can be used from within a researcher's environment or integrated into research workflows. Neuroscience researchers, especially those involved in collaborative research will benefit from using the OSC to track the dataset that maybe generated and maintained at various locations. Members of research labs will benefit from tracking the provenance of data produced and referenced during different stages of research by various members. OSC aims to enhance data sharing and reproducibility in the neuroscience community by increasing the confidence of the scientific results.

Title: Actionable event annotation in neuroimaging: HED-3G principles and practice

Authors: *K. ROBBINS;
Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Introduction: HED-3G is an evolution of the Hierarchical Event Descriptor system to move experiment annotation beyond cryptic keywords and scattered documentation to a standardized annotation of experimental structure that can be directly used by analysis tools to perform sophisticated analyses based on events and other metadata. Rationale: Event markers associate a time-delimited phase of or change in an identifiable process with a defined time point

or period. While event-markers play a central role in organizing neuroimaging and other experimental data, current annotation practice mostly relies on local laboratory strategies for labelling events and other information such as task and experimental design. As a result, data analysts must often resort to assembling information scattered across publications, stored metadata, and internal laboratory documents and must then write custom computer code to perform analyses. Methods: HED-3G provides a vocabulary, software infrastructure, and tools for detailed event annotation. HED-3G standardizes strategies for deciding which events to report, how to annotate them, and how to incorporate the information into analyses and information extraction tools. Researchers using HED-3G first declare the relevant concepts needed to describe their experiment including presented experimental stimuli, participant responses, tasks, and experimental conditions, and describe the temporal structure of their experiment. Researchers then express this information using a standardized, structured vocabulary. The HED-3G infrastructure provides a mapping from defined concepts to event annotations that enables powerful cross-study analysis. Validation tools available online and as Python and JavaScript modules ensure consistency and compliance with the HED-3G specification. The standardized vocabulary and structure allow researchers to use a set of standard tools, eliminating the need for creating customized code. HED-3G is integrated into the BIDS (Brain Imaging Data Structure) system for organizing and sharing datasets. Results: We have developed several case studies that demonstrate the effectiveness of HED-3G in annotating a variety of features and experimental concepts in machine-actionable form. Other aspects of the HED-3G ecosystem are addressed in related posters (Truong: tools), (Makeig: extensions), (Delorme: EEGLAB integration) (Pal Attia: clinical use), (Denissen: fMRI). Conclusions: HED-3G can dramatically improve the utility of neuroimaging and behavioral data. Our challenge is now to encourage researchers to incorporate HED annotation into their new, existing, and shared data.

Title: Yap/ Taz dysregulation contributes to brain pathology in tuberous sclerosis complex

Authors: *B. K. TERRY[1,2], R. PARK[1,2], P. B. CRINO[3], S. KIM[1,2];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Dept. of Neural Sci., Temple Univ., Philadelphia, PA;
[3]Neurol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: The genetic disorder Tuberous Sclerosis Complex (TSC) is characterized by the development of benign tumors throughout the body. TSC is caused by mutations in the hamartin (*TSC1*) and/or tuberin (*TSC2*) genes, resulting in hyperactivation of the mammalian target of rapamycin complex 1 (mTORC1) due to reduced Rheb1 inactivation. Brain involvement is seen in the majority of those with TSC and multiple neuropathological features have been previously described. These include the presence of cortical tubers, subependymal nodules, enlarged cells, and disrupted cortical lamination, all of which can contribute to the development of epilepsy and developmental delays. However, while we know that these features are tied to hyperactive mTORC1 signaling, the primary molecular and cellular mechanisms behind the disruptions in brain pathogenesis are not well understood. One pathway that has been recently tied to mTORC1 signaling is the Hippo-Yap/Taz signaling pathway, an evolutionarily conserved pathway that is critical for processes such as organ size control. The purpose of this study was 1) to determine whether Yap/Taz levels are dysregulated in TSC patients and in a TSC animal model and 2) to determine if targeting Yap/Taz could improve TSC-related developmental defects in the cortex of our TSC mouse model. First, to evaluate how mTORC1 hyperactivation impacts Yap/Taz signaling pathway members, we used Western Blotting and immunohistochemistry to measure the levels of these proteins in a human cortical tuber sample, versus control human cortical samples, and in the cortices of *Tsc2* conditional knockout (cKO) animals, versus that of WT controls. Interestingly, we found that total Yap/Taz levels are elevated in both the human cortical tuber sample and in embryonic day 16 *Tsc2* cKO cortexes when compared to control samples. Next, to determine whether reduction of Yap/Taz could rescue the pathological features seen in *Tsc2* cKO animals, we compared the cortical phenotype of *Yap*/*Taz*/*Tsc2* triple conditional knockout (tcKO) animals with *Tsc2* cKO and wild type animals. Of note, we found that *Yap/Taz/Tsc2* conditional knockout had a rescue effect on the cortical thickness increases, cortical/hippocampal lamination defects, and the hypomyelination phenotype associated with *Tsc2* cKO. Taken together, our findings suggest that aberrant activation of Yap/Taz plays an important role in TSC pathogenesis.

Title: Investigation of a synapse-to-chromatin signaling pathway regulating the neuronal BAF complex and dendritic development

Authors: *S. GOURISANKAR[1], W. WENDERSKI[2], S. H. KIM[1], S. G. LIN[1], A. KROKHOTIN[1], J. PAULO[3], J. KWASNICK[1], N. GRAY[1], S. GYGI[3], G. CRABTREE[4]; [2]Dept. of Developmental Biol., [1]Stanford Univ., Stanford, CA; [3]Harvard Univ., Cambridge, MA; [4]Howard Hughes Med. Inst., Stanford, CA

Abstract: Human genetic studies have implicated mutations in the subunits of the neuron-specific chromatin remodeler, nBAF, in autism syndrome disorder (ASD), idiopathic intellectual disabilities (ID), and other neurodevelopmental disorders. In *Drosophila*, similar mutations produce “perfect dendritic retargeting” suggesting a fundamental role for these complexes in synaptic specificity. Sensory experience and synaptic activity shape proper neural development in part by stimulating transcription, which, in turn, is shaped by chromatin remodelers such as nBAF. While previous work has shown that nBAF is necessary for activity-dependent dendritic outgrowth and involved in activity-regulated transcription, we lack clarification of how synaptic activity regulates nBAF. Here, we use proteomic, functional genomic, and biophysical studies in murine cortical neurons to show that synaptic activity leads to rapid, global phosphorylation of the nBAF complex and changes in nBAF remodeling activity. Mutational studies show that phosphorylation of *Smarcc2*, a core nBAF subunit identified as mutated significantly in ASD and ID by large-scale human genetics studies, regulates axon targeting gene expression. Chemical inhibition studies implicate potential nBAF-kinases that link chromatin remodeling with synaptic activity. Our studies help elucidate one mechanism by which synaptic activity regulates experience-driven neurogenesis through chromatin remodeling, and has implications for nBAF-associated neurodevelopmental disorders.

Title: Characterization of PCM1 isoforms in the adolescent and adult brain

Authors: *C. CHANG[1], L. A. CREW[2], R. YOUNG[1], N. BASAZINEW[1], N. GHANI[1], H. BAKER[1], R. A. WIRT[2], R. GU[1], V. VO[1], R. TILLETT[1], J. M. HYMAN[2], E. OH[1];
[1]Nevada Inst. of Personalized Med., Univ. of Nevada, Las Vegas, Las Vegas, NV; [2]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: The pericentriolar material 1 protein (PCM1) is a component of the centriolar satellites and regulates the biogenesis and function of the centrosome and cilium in the nervous system. In response to paracrine signaling, firing patterns in neurons are modified to accommodate changes in the cellular distribution of centriolar satellite proteins at the centrosome. Here, we show that PCM1 spliced isoforms are localized to discrete cellular compartments in neurons and are expressed differentially in the adolescent and adult brain. Using mass spectrometry, we identified protein networks that complex with either the long or short PCM1 spliced isoforms and we show how each isoform can coordinate protein post-translational modifications in tubulin during the development of the brain. Deletion of the PCM1 long isoform results in the modulation of electrical activity, synchrony, and network oscillations in neurons. Electron tomography analyses of synaptic terminals in the adult hippocampus highlight how PCM1 isoform products can modify synaptic vesicle size and density. Finally, electrophysiological recordings from mutant mice demonstrate that PCM1 isoform products are necessary for theta oscillation in the hippocampus. Taken together, our data characterize a new role for centriolar satellite protein isoforms during brain development and identify a potential mechanism for ciliary proteins in human neurological disease states.

Title: Ipsc-derived neural stem cells from joubert syndrome as a novel in vitro model to elucidate ciliopathy-associated molecular mechanisms.

Authors: *J. ROSATI[1], A. D'ANZI[2], G. RUOTOLO[2], A. VESCOVI[2];
[1]Fondazione IRCCS Casa Sollievo Della Sofferenza, San Giovanni Rotondo, Italy; [2]Fondazione IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo (Foggia), Italy

Abstract: Background: Joubert syndrome (JS) is a rare autosomal recessive condition characterized by a peculiar midbrain-hindbrain malformation, known as the molar tooth sign (MTS). To date, most of the identified causative genes of JS encode proteins involved in cilia function or assembly. We focused our attention on a point mutation of AHI1 (H896R), a gene encoding a protein named Jouberin.Material and Methods. hiPSCs from a healthy donor and a JS patient were produced and fully characterized. In order to study how AHI1 mutation could affect neural differentiation at morphological and molecular level, iPS cells were differentiated in neural cells.Results. Our data show that: 1) The H896R AHI1 mutation leads to a constitutive hyperactivation of Wnt pathway, 2) this mutation causes an incorrect differentiation both in cells morphology and in the balance among neural populations during development.Conclusion. Literature data showed that WNT pathway plays a central role in the estabilishment of dorsal/ventral axis, so we had tested the expression of CNS markers in hiNSC derived from JS patients. The data show that the Joubert's neurospheres have a major expression of dorsal and posterior markers with respect to controls and a constitutive activation of WNT signaling, both canonical and non-canonical. In conclusion, our work confirmes a role for Jouberin in WNT pathway modulation. To date, the functions of primary cilia in human neural stem cells and their changes during neural differentiation remain largely vague, the next goal will be to investigate how the impairment of cilia could influence the neural development.

Title: Expression of intracellular and transmembrane sex hormone receptors during postnatal development of the rat brain

Authors: *M. PILLEROVA, M. PASTOREK, E. RENCZES, P. CELEC, L. TOTHOVA; Inst. of Mol. Biomedicine, Med. Faculty, Comenius University, Bratislava, Slovakia, Bratislava, Slovakia

Abstract: Testosterone (T) affects the structure and the functions of the developing brain. Its metabolism depends on the activity of aromatase and 5α-reductase. T and its metabolites act via intracellular androgen (AR) and estrogen (ERα, ERβ) receptors as well as via novel transmembrane androgen ZIP9 and estrogen GPER1 receptors. The aim of our study was to describe the dynamics of expression of T-related receptors in the brain during early postnatal development. RNA was isolated from the frontal cortex (FC), hippocampus (HIP), hypothalamus (HYP), and cerebellum (CER) of Wistar rats (n=68) of both sexes on postnatal days 1, 7, 14 and 21. Gene expression was analyzed using RT-qPCR with PPIA as the housekeeping gene. T was measured in plasma using ELISA. The concentration of T increased over time from 0,4-0,6 nmol/l to 1,6-2,4 nmol/l. Significant sex differences were found neither in plasma T nor in the gene expression analysis. The expression of the AR increased and peaked on PND=21 (2x-12x in compared to PND=1) in all tested regions. Similarly, ERβ increased and peaked on PND=21 (2x-4x in compared to PND=1) in all tested regions. On the other hand, ERα peaked on PND=1 (3x in compared to PND=21) and decreased in FC and HIP. In the HYP and CER, the expression of ERα increased and peaked on PND=21 (2x-10x in compared to PND=1). In the HIP, the expression of ZIP9 was 2x higher on PND=1 compared to other PNDs. In the FC, HYP, and CER, the dynamics of ZIP9 expression was without a change. Regarding GPER1 expression, in the CER, it increased and peaked on PND21 (6x in compared to PND=1). In the FC, GPER1 was 3x higher on PND=1 in comparison to other PNDs. There was no change in GPER1 dynamics in the HIP and HYP. The 5α-reductase increased over time in CER and HIP, but not HYP and FC, where no dynamics was observed. On the other hand, aromatase decreased in the CER and HYP, increased in the FC, and there was no change in its dynamics in the HIP. In conclusion, the described dynamics of expression of sex hormone receptors and T-metabolizing enzymes may indicate the likely changing signaling pathway induced by T in the developing brain of the rat. Non-classical signaling mediated by transmembrane receptors might be replaced by activation of classical intracellular sex hormone receptors depending on the brain region, but this must be proved in further studies analyzing the expression on the protein level or the activity of the particular pathways. Our findings could be useful for modeling of T-related behavioral disorders.

Title: Psychiatric-associated microRNAs are responsive to oxidative stress during neuronal differentiation

Authors: *B. KHAVARI, M. M. BARNETT, E. MAHMOUDI, M. P. GEAGHAN, A. GRAHAM, M. J. CAIRNS;
Univ. of Newcastle, Newcastle, Australia

Abstract: Oxidative stress is suggested as an environmental risk factor for neurodevelopmental and psychiatric disorders, but the underlying mechanisms are not fully understood. We previously showed that the exposure of the neuroblastoma SH-SY5Y cells to oxidative stress before (pre-treatment) or during (co-treatment) differentiation process led to significant changes in the gene expression landscape of the resultant neuron-like cells. The aim of the present study was to examine alterations in microRNA (miRNA) expression as a plausible explanation for those observations, since miRNAs are stress-responsive molecules, able to suppress gene expression at both transcriptional and post-transcriptional levels, and are involved in brain development. Using small RNA-sequencing, we detected differential expression in more than 100 miRNAs, 72 of which were reported before to be dysregulated in psychiatric diseases. Of particular interest was miR-137, which is strongly associated with the genetic risk of schizophrenia, miR-17-5p, dysregulated in several brain regions and peripheral tissues of psychiatric patients, and miR-181b-5p, whose increased expression is one of the most recurrent observations in schizophrenia. Combining the two studies results and calculating the Pearson's correlation coefficient between miRNA-mRNA pairs revealed that differentially expressed miRNAs in both pre- and co-treatment conditions were directly regulating the expression of a subset of genes with implications for critical neurobiological processes, such as neurogenesis, neuron differentiation, and synaptic signalling. In the pre-treatment regimen, miRNA-correlated genes were enriched in neurodevelopmental disorders, whereas in co-treatment condition, cardiovascular and immune diseases, which are highly comorbid with psychiatric disorders, were enriched. Collectively, our findings suggest that early exposure to oxidative stress can considerably affect neuronal differentiation process at the molecular level and possibly increase the risk of psychiatric diseases through perturbing miRNA-gene networks that have critical roles for neurodevelopment.

Title: Trp53 ablation fails to prevent microcephaly in mouse pallium with impaired minor intron splicing

Authors: *A. WHITE[1], M. BAUMGARTNER[1,2], M. F. LEE[1], K. D. DRAKE[1], G. S. AQUINO[1], R. KANADIA[1];
[1]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT; [2]Genet., Yale Univ., New Haven, CT

Abstract: The minor spliceosome is comprised of 5 small nuclear RNAs (snRNAs) U11, U12, U5, U4atac, and U6atac and is responsible for the splicing of minor introns, which are present in ~700 genes, called minor intron-containing genes (MIGs). Despite being responsible for the splicing of less than 0.5% of introns, mutations in components of the minor spliceosome have been implicated in developmental disorders. For example, minor spliceosome inhibition due to mutations in *RNU4ATAC* is linked to primary microcephaly. We have previously reported that ablation of *Rnu11,* a minor spliceosome specific snRNA, in the developing mouse pallium, inhibits the minor spliceosome resulting in microcephaly. There, cell cycle defects and p53-mediated apoptosis in response to DNA damage resulted in loss of radial glial cells (RGCs), underpinning microcephaly. To test the hypothesis that the cell death, rather than the cell cycle defects drove the observed microcephaly, we ablated *Trp53* to block cell death in the *Rnu11* cKO, to ultimately rescue microcephaly. Here, we report that *Trp53* ablation failed to rescue microcephaly in these double knockout mice (dKO). We show that the transcriptome of the dKO pallium was closer to the control compared to the *Rnu11* cKO. We found aberrant minor intron splicing of MIGs involved in cell cycle regulation, resulting in more severe impaired mitotic progression and cell cycle lengthening of RGCs in the dKO that was detected earlier than the *Rnu11* cKO. We also discovered a potential role of p53 in causing DNA damage in the developing pallium, as detection of γH2aX+ was delayed in the dKO. Thus, we postulate that microcephaly in minor spliceosome-related diseases is primarily caused by cell cycle defects and identify a core set of MIGs that are affected that may be driving the observed microcephaly.

Title: Foxp1 regulates the cell cycle in a cell type specific manner in the developing mouse cortex

Authors: *A. ORTIZ, F. AYHAN, M. HARPER, G. KONOPKA;
UT Southwestern, Dallas, TX

Abstract: Cortical development is a tightly controlled process and any deviation may increase the susceptibility to neurodevelopmental disorders, such as autism spectrum disorders (ASD). Numerous studies have identified mutations in FOXP1, a gene encoding a transcription factor enriched in the developing and mature neocortex, as causal for ASD. Our group has previously shown that loss of *Foxp1* in the mouse cortex leads to reduced cortex size, alterations in cortical lamination, and changes in relative thickness of cortical layers. However, the mechanisms underlying these changes remain unclear. My work characterizes the developmental requirement of neocortical *Foxp1* throughout early development using a cortical-specific conditional knock-out of *Foxp1* (*Foxp1* cKO). *Foxp1* expression is temporally regulated in distinct cell types throughout development. In experiments designed to measure cell cycle length in the lateral cortex of *Foxp1* cKO mice, we find that early loss of *Foxp1* results in reduced cell cycle exit of intermediate progenitors but in more rapid cell cycle exit of neuron-fated cells. This provides insight into how Foxp1 regulates cell type generation at an early stage of cortical development. The altered length of cell cycles in specific cell types provides insight into the distinct generation of neurons in *Foxp1* cKO animals to potentially explain the post-natal differences seen in cortical layers and relative cortex thickness. This adds to our ongoing work of genomic profiling, of identifying potential key driver genes, assessing how loss of *Foxp1* alters the proliferative capacity of radial glia cells and cell migration, and cell autonomous and non-autonomous effects.

Title: Hippocampal gene expression along with autism like behavior and neuroinflammation in offspring male mice from high salt diet fed parents

Authors: *K. AFROZ[1], K. ALVINA[2], N. REYES[3], K. YOUNG[1];
[2]Biol. Sci., [1]Texas Tech. Univ., Lubbock, TX; [3]Texas Tech. Unversity, Lubbock, TX

Abstract: Autism spectrum disorders (ASD) is one of the major neurodevelopmental disorders with characteristic deficit in social behavior as well as impaired learning and executive control. Several recent studies have shown a potential effect of maternal gut microbiota alteration on offspring neurodevelopment in animal models as well as in humans. As the gut microbial population is heavily modulated by dietary habits, offspring ASD has also been associated with maternal diet. Salt is a very common dietary component that has been associated with altered gut microbiota. We previously reported that male offspring from female mice fed with high salt diet (HSD) showed altered postnatal gut microbial composition and altered social behavior and hyperactivity, abnormalities that resemble ASD-like behavior in mouse models. However, the mechanisms behind these behavioral abnormalities are poorly understood.Genomic studies in ASD show networks of genes associated with deregulated synapse development, neuronal activity and altered immune function. Similarly, mouse models such as BTBR, En2-/-, Shank3, show altered gene expression in the hippocampus, including increased microglial genes. Additionally, a recent study showed that postnatal microbiota helps the functional organization of neural circuitry by regulating hippocampal synaptic gene expression and microglial functionality. Our previous data showed that offspring from HSD-fed female mice show significantly decreased level of *Lactobacillus spp*., change that has been associated with gene expression alterations in mouse brain and social behavior deficit as well as neuroinflammation. Therefore, we hypothesized that the altered postnatal microbiota in the offspring of HSD-fed mother alters expression of major hippocampal gene pathways that are associated with ASD-like behavior and neuroinflammation. To test the hypothesis, we are currently doing total transcriptome analysis of the hippocampus collected from the offspring of HSD and control fed mothers. Further, next generation RNA-sequencing is being used to obtain the differentially expressed genes (DEGs) . The ingenuity pathway analysis (IPA) software is being used to identify biological pathways, processes associated with the differentially expressed genes. In addition, to identify neuroinflammation markers in the hippocampus, we used immunohistochemistry in fixed brain samples from offspring from HSD-fed mothers. Our results will contribute to understand how environmental factors such as diet can influence brain development.

Abstract: *Fibrinogen C Domain Containing 1* (*FIBCD1*) encodes a single-pass, type II transmembrane lectin protein with an endocytic function, with no link to nervous system function yet published. Previous work has shown *FIBCD1* to recognise the chitin component of fungal cell walls and a role in the innate immune response to fungal infection. However, publicly available RNA-seq datasets and our own data show *FIBCD1* to be expressed throughout life in neurons of the human and mouse brain, particularly the hippocampus, raising the question: does *FIBCD1* have a role in neurodevelopment? By utilising knockout (KO) mouse and knockdown (KD) *D.melanogaster* models, we show that FIBCD1 functions at the interface between neurons and the brain's extracellular matrix (ECM), specifically chondroitin sulphate proteoglycans (CSPG) with sulphation at carbon 4 (CS-4S). We found that *FIBCD1* is a mediator of CSPG-neuron signalling and that the absence of *FIBCD1* leads to accumulated CS-4S and disruption to hippocampal synaptic plasticity. Finally, through whole-exome sequencing, we have identified loss of function homozygous or compound heterozygous variants in *FIBCD1* in 2 unrelated patients with severe neurodevelopmental disorder. *In vitro,* CSPG coatings inhibited attachment of *Fibcd1*-WT primary hippocampal neurons as well as inducing soma aggregation and dendrite fasciculation (in line with previous work). This was not the case for *Fibcd1*-KO neurons, indicating that *Fibcd1* is required for neuronal responses to CSPG signalling. We found that KO mice exhibited deficiencies in learning tasks, such as inhibitory avoidance, and electrophysiological recordings of hippocampal slices revealed a concordant disruption of LTP

and paired-pulse facilitation. In addition, we found an aberrant accumulation of CS-4S in the hippocampus of the KO mouse, likely due to the lack of Fibcd1's endocytic activity. We pre-treated the hippocampal slices with the enzyme Chondroitinase ABC (ChABC), to digest CSPGs, which fully rescued the deficient LTP and paired-pulse facilitation in the KO slices. Finally, we investigated if *Fibcd1*'s role is conserved among other organisms by generating *Drosophila* lines with RNAi-mediated KD of a putative Fibcd1 orthologue, *CG10359*. While full body KD was lethal, KD of *CG10359* in neurons during development resulted in perturbed neuronal morphology at the neuro-muscular junction as well as deficiencies in climbing assay performance. In summary, our study identifies *FIBCD1* as key to neurodevelopment. We show *FIBCD1* to function at the interface of hippocampal neurons and the ECM and identify *FIBCD1* as a novel candidate gene causative of neurodevelopmental disorder.

Title: Altered environmental lighting during adolescence induces neurotransmitter switching in the medial amygdala affecting anxiety-like behaviors in mice

Authors: *A. PORCU, A. NILSSON, S. BOOREDDY, D. DULCIS;
Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: Background: Anxiety and mood disorders are the most common emotional disorders in adolescents. Adolescence is a remarkable period of neural plasticity in the amygdala, a well conserved structure best known for its role in emotional behaviors. Although in many cases adaptive, the capacity for neural circuit alteration also induces a state of vulnerability to environmental perturbations. In modern societies, adolescents experience increased artificial light exposure, as 80% of adolescents in the USA reported using smartphones and tablets at night. Altered environmental light is associated with impaired mood and an increased risk of

psychiatric disorders. The medial amygdala (MeA), a sub-nucleus of the amygdala, is situated in a crucial position to link light information to brain regions regulating anxiety and risky behaviors. However, the cellular and molecular mechanisms behind the effects of light on brain function is still incomplete. We hypothesized that exposure to altered environmental lighting during adolescence affects emotional responses through a mechanism of MeA neuroplasticity.Methods: We developed a new light paradigm to mimic human adolescent light exposure in mice. This model consists of a prolonged light phase (19hrs/day), with light appearing during the biological night phase of the mice. Adolescent mice were exposed to either such light protocol or to control conditions (12hrs/day) for 4 weeks, then tested for anxiety-like behavior. Immunohistochemical analysis was performed to reveal any changes in neurotransmitter phenotype in the MeA. Chemogenetic (DREADDs)-mediated approach was used to establish a causal relationship between light-induced neurotransmitter switching in the MeA and anxiety-like behavior.Results: Exposure to altered environmental lighting increased anxiety-like responses and risky behavior in adolescent mice. The number of GABAergic and somatostatin neurons in the MeA was significantly different in adolescent mice exposed to the altered environmental lighting compared to controls. Chemogenetic inhibition of MeA GABAergic neurons interfered with light-mediated neurotransmitter switching in the MeA, and reduced anxiety states in adolescent mice.Conclusions: Our data indicate that altered environmental lighting induces changes in neurotransmitter expression in MeA neuronal populations, and that such neuroplasticity contributes to the vulnerability to anxiety and risky behaviors in adolescent mice. Overall, our study reveals potential molecular targets for antianxiety interventions and new strategies to advance mental health in human adolescents.

Title: A role for pubertal onset in changes in midbrain dopamine neuron number during adolescence

Authors: *M. G. WOODBURN, V. R. RIESGO, K. A. S. FLANIGAN, J. WILLING; Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: The ventral tegmental area (VTA) and substantia nigra (SN) of the midbrain produce the majority of dopamine in the brain, making these regions important for mood, sexual

behavior, cognition, controlled movements, and other behaviors. Cell number in the midbrain fluctuates throughout the lifespan, and recent research suggests notable changes during adolescence in terms of the number of dopamine neurons and the total number of neurons. While previous work has documented the effects of pubertal hormones, such as estrogen and testosterone, on dopaminergic functioning and cell number, there have been no studies examining changes in dopamine neurons in relation to the timing of puberty. In the present study, we collected midbrain tissue from pre-pubertal and post-pubertal adolescent rats. We aimed to assess whether cellular changes in the midbrain occur linearly across age, or whether pubertal onset may be a factor. In both males and females, we used stereological methods to document changes in dopamine neuron number, total neuron number, and the percentage of dopaminergic neurons in the VTA and SN. Our results suggest that puberty may be an important factor in the cellular maturation of the dopaminergic midbrain, which may shed light on the observed sex differences in psychiatric illnesses that tend to manifest during adolescence.

Title: Adolescent alcohol exposure increases perineuronal net density but not parvalbumin or cholinergic interneuron counts in the prefrontal cortex of adult rats.

Authors: *C. DANNENHOFFER[1], G. A. GOMEZ ACOSTA[2], V. A. MACHT[2], R. JAWAD[1], E. SUTHERLAND[1], R. P. VETRENO[3], F. T. CREWS[5], C. A. BOETTIGER[6], **D. L. ROBINSON**[4]; [1]UNC Chapel Hill, Chapel Hill, NC; [2]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [3]Sch. of Med., [4]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [5]Prof Pharmacol & Psychiat, Skipper Bowles Ctr. Alcohol, Chapel Hill, NC; [6]Psychology & Neurosci., Univ. of North Carolina, Chapel Hill, NC

Abstract: Binge alcohol exposure during adolescence results in long-lasting alterations in brain and behavior. Specifically, rodent studies show that adult animals with a history of adolescent intermittent ethanol (AIE) exposure exhibit deficits in cognitive flexibility, along with a variety of neurochemical, molecular and epigenetic alterations in brain regions underlying behavioral

choice. One well-described effect of AIE is reduced choline acetyltransferase (ChAT) expression in the basal forebrain, reflecting impaired cholinergic phenotype. As acetylcholine is critical for cognition, AIE-induced reductions in ChAT may contribute to observed cognitive deficits, but it is unclear whether cholinergic interneurons in the prefrontal cortex (PFC) are affected similarly to cholinergic neurons in the basal forebrain that project to the PFC. We also found that AIE reduced functional connectivity via resting-state MRI among PFC and striatal regions. While parvalbumin (PV)-positive interneurons are known to contribute to neural synchrony, it is unclear whether AIE impacts PV neurons. Thus, the present study addressed the hypothesis that AIE-induced behavioral and connectivity deficits are due in part to persistent alterations in expression of PV and ChAT interneurons in key prefrontal and striatal brain regions. We used immunohistochemistry to measure expression of ChAT, PV and perineuronal nets (PNN) that regulate PV neuronal plasticity. Male rats were exposed to AIE (5 g/kg/day, 2-days-on/2-days-off, IG, P25-P54) or water (CON) and brain tissue was harvested in adulthood (P80). While AIE reduced ChAT-positive cell counts in the basal forebrain, they were unchanged in the striatum or PFC. This finding indicates that cholinergic projections to the PFC likely affect AIE-induced behavioral changes rather than cholinergic interneurons. PV cell counts were also similar between AIE-exposed and CON rats in the striatum and PFC. However, we found that WFA expression, a marker of PNN, was increased in the PFC of AIE-exposed rats compared to CON (WFA expression was minimal in striatum). Finally, we used immunofluorescence to assess co-expression of PV and WFA and found that significantly more PV neurons were surrounded by WFA in AIE-exposed (approx. 40 percent) versus water-exposed rats (approx. 35 percent). These findings indicate that while PV neuron numbers are not altered by AIE exposure, their function may be altered via extracellular regulatory structures such as PNN. AIE-induced increases in PNN density surrounding PV interneurons may restrict plasticity in PFC microcircuits and contribute to behavioral deficits reliant upon frontostriatal connectivity.

Title: Late maturing neurons in juvenile mice share features of immature neurons in the human amygdala

Authors: *P. ALDERMAN[1], C. E. PAGE[1], L. TORRIJOS[2], D. SAXON[3], S. VICINI[3], J. CORBIN[4], J. GARCÍA VERDUGO[2], V. HERRANZ PÉREZ[2], S. F. SORRELLS[1];

Abstract: In the human amygdala, a center for emotional salience processing, the paralaminar nucleus contains a large population of immature excitatory neurons that undergo a delayed maturation after birth, occurring primarily during childhood and adolescence. Similar pools of immature neurons are present in multiple brain regions in many mammals; however it is not clear if any immature neurons in mice are homologous to immature amygdala neurons in humans. A mouse model of these cells would permit experimentation to investigate the development and function of this form of neurodevelopment. We examined brain regions containing immature doublecortin-expressing neurons in mice between birth and adulthood using light and electron microscopy to identify their molecular and morphological features. We identified a subset of immature neurons that express many of the same transcription factors as the immature neurons in the human paralaminar nuclei,and have similar morphology and ultrastructural features. Using unbiased stereology and the optical fractionator across postnatal ages, we find that these neurons decline in number progressively over postnatal life. Thymidine analog birthdating labels these cells when given to timed pregnant females during embryonic stages, suggesting that they are born embryonically, despite their persistent immature state. These late maturing neurons grow during critical times when cognitive functions mature, and therefore may have an important role in circuit plasticity. This work provides a foundation for better connecting investigations of mouse late maturing neurons to similar cells in humans.

Title: E-cigarette exposure during pregnancy disrupts postnatal blood-brain barrier integrity and deteriorates aspects of learning, memory and motor function

Authors: *S. RAHMAN ARCHIE, A. SIFAT, H. VILLALBA, S. SHARMA, S. NOZOHOURI, T. ABBRUSCATO;
Pharmaceut. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: Even though electronic cigarettes (e-Cig) has been perceived as a safer alternative for pregnant women, there is a growing concern related to its impact on neonates. Several studies have shown the harmful effects of prenatal tobacco smoking on postnatal health however, no such data is available in case of e-Cig exposure during pregnancy. Due to the noticeable growth in e-Cig usage during pregnancy, it has become crucial to study the impact of maternal e-cig smoking on postnatal health outcomes. Hence, in this study, we have evaluated the consequences of prenatal e-Cig use during pregnancy on postnatal development of blood-brain barrier (BBB) and on behavioral outcomes of adolescent and adult offspring. Pregnant CD1 mice (E5) were exposed to e-Cig vapor (2.4% nicotine) till postnatal day (PD) 7. Weight of the offspring was measured at different time-points till PD 90. Nicotine and cotinine concentration in plasma and brain were measured in PD 7 offspring by LC-MS/MS. The expression level of structural elements of BBB, tight junction proteins (ZO-1, Claudin-5, Occludin), astrocyte (GFAP), pericyte (PDGFRβ) and basement membrane (Laminin α1, Laminin α4) were analyzed in offspring using western blot and immunohistochemistry at PD 7, PD 23, PD 45 and PD 90. Long-term motor and cognitive functions were evaluated using open field test, novel object recognition test and morris water maze test at adolescence and adult age. Reduced body weight was observed in e-Cig exposed offspring at all time points till PD 90 compared to control ($P < 0.05$). Plasma concentration of nicotine and cotinine in PD 7 offspring were 3.215 ng/mL and 3.373 ng/mL respectively whereas in brain, these two concentrations were 43.72 ng/mL and 1.123 ng/mL respectively. Significantly reduced expression of tight junction proteins was found in male and female offspring at PD 7, PD 23, PD 45 and PD 90 ($P < 0.05$). Additionally, prenatally e-Cig exposed both male and female adolescent and adult offspring showed impaired locomotor, spatial learning, and memory function compared to control offspring ($P < 0.05$). Our findings indicate that prenatal e-Cig exposure disrupts postnatal blood-brain barrier integrity by downregulating tight junction proteins' expression and impairs motor and cognitive function at adolescence and adult age.

Title: Developmental influences on the initial subjective rewarding effects of ethanol in mice

Authors: *M. A. WALDRON[1], H. JONES[1], M. SCOPANO[1], E. M. RHINEHART[2], J. E. GRISEL[1];
[1]Bucknell Univ., Lewisburg, PA; [2]Susquehanna Univ., Selinsgrove, PA

Abstract: There is a growing recognition that adolescent exposure to addictive drugs significantly increases the risk of drug dependence later in life, in part due to the neuroadaptive changes that underlie alcohol use disorders (AUD) (Nixon & McClain, 2010). Additionally, variations in b-endorphin (βE) levels contribute to the subjective sensitivity to the rewarding effects of alcohol. Low basal levels of βE are correlated with increased risk for AUDs (Dai et al., 2005; Kiefer et al., 2006), and studies involving reduced endorphin levels demonstrate the tendency for increased ethanol intake in both rodents and humans (Grahame et al., 2000; Grisel et al., 1999; McGonigle et al., 2016). The present studies were aimed to better understand developmental contributions to the risk for disordered drinking, and especially as they might depend upon sex and βE, in order to facilitate the long-term goal of developing effective interventions for individuals at high risk for AUDs. Experiment 1 assessed the effect of adolescent pre-exposure to ethanol on adult single-exposure conditioned place preference (SE-CPP; Grisel et al., 2014), in male and female, control and βE deficient mice. Between PND 28-35, Adolescent C57BL/6J (WT) and βE deficient (KO) mice were injected once, intraperitoneally, with 1.5g/kg of ethanol or saline. Between PND 70-90, we employed a SE-CPP to investigate the impact of EtOH pre-exposure on the initial subjective rewarding effects of the drug in mice. Pre-exposure to EtOH during the adolescent period reduced sensitivity to the rewarding effects of ethanol in KO mice and increased sensitivity to alcohol-induced sedation in these mice. Pre-exposure did not affect EtOH reward or sedation in WT control mice. Experiment 2a assessed age-related differences in the initial subjective rewarding effects of 1.5 g/kg ethanol and the role of sex and βE. We tested naive adolescent (4-5 weeks) and adult (10-12 weeks) male and female, WT and KO mice. CPP was dependent on both age and βE, in that KO mice of either age, as well as adult WT, were more sensitive to the rewarding effects of ethanol; adolescent WT appeared to be insensitive to the initial rewarding effects of EtOH. Additionally, all adolescent mice failed to show alcohol-induced sedation. Experiment 2b examined the neurochemical differences in WT and KO, adolescent and adult mice from Experiment 2a. Although there were no signs of sex differences in the previous experiments, results indicated that neuronal activation to the CPP paradigm in brain regions associated with addiction was dependent on both age and sex. Taken together these results suggest that low endorphin and age differentially impact the vulnerability to AUDs.

Title: Daily Treatment with a GnRH During the Peri-Adolescent Period Delayed Puberty but Failed to Disrupt Estrous Cyclicity or Sexual Motivation in Female Rats

Authors: *F. A. GUARRACI[1], L. AVENDANO[2], M. KELLY[2], B. SENCHEREY[1], N. DHINAKER[1], L. K. DAVIS[1], H. VALDIVIA[1], C. ESTOESTA[1], B. FROHOCK[1], A. C. GORE[3]; [1]Psychology, [2]Southwestern Univ., Georgetown, TX; [3]Col. of Pharm., Univ. of Texas at Austin, Austin, TX

Abstract: The present study examined the long-term effects of suppressing puberty with a GnRH agonist on reproductive physiology and behavior in female rats. Little is known about the long-term effects of chronic GnRH agonist treatment on reproductive physiology and behavior when treatment starts prior to puberty and continues until early adulthood in animal subjects. We have recently reported that administration of the GnRH agonist leuprolide acetate (25 µg/kg) daily for 25 days (postnatal day (PD) 25-50) delayed puberty and disrupted the development of copulatory behavior and sexual motivation in male rats. However, pilot data from our lab suggest that this dose of leuprolide acetate was not high enough to significantly delay puberty in female rats. Therefore, we injected female Long-Evans rats with either leuprolide acetate at a higher dose (50 µg/kg) or 0.9% sterile saline daily for 25 days, starting on PD 25 and ending on PD 50. Vaginal opening was observed daily starting on PD 30 for signs of pubertal onset and first estrous cycle. In addition, we measured estrous cyclicity in these adult females, approximately 2 weeks after last injection of leuprolide (8-10 weeks old). Starting immediately after monitoring estrous cyclicity, females were mated on their first day in behavioral estrous using the partner preference paradigm, with and without physical contact. We found that this higher dose of leuprolide significantly delayed puberty in female rats. However, neither estrous cyclicity nor sexual motivation was significantly affected by a history of leuprolide administration. When considered with our previous findings in male rats, these results add to understanding of the developmental effects of chemically suppressing puberty.

Title: Tetrahydrocannabinol in adolescence dysregulates signaling pathway that orchestrates dopamine development

Authors: *G. HERNANDEZ[1], **T. CAPOLICCHIO**[1], M. GIROUX[2], K. ESTRADA[3], C. FLORES[4];
[1]Douglas Mental Hlth. Univ. Institute/Mcgill, Verdun, QC, Canada; [2]Douglas Res. Inst., Montreal, QC, Canada; [3]McGill Univ., Montreal, QC, Canada; [4]Dept of Psych, McGill Univ., Verdun, QC, Canada

Abstract: Cannabis is one of the most consumed substances by adolescents in North America and its regular use during this developmental period is linked to increased risk of cognitive impairment and psychopathology later in life. Yet, there is a gap in knowledge regarding the cellular and molecular processes underlying adolescent brain development and how they are influenced by exposure to drugs of abuse. Dopamine axons continue to grow from the nucleus accumbens to the prefrontal cortex throughout adolescence, remaining susceptible to environmental changes. Protracted mesocorticolimbic dopamine maturation is mediated by the Netrin-1 guidance cue receptor, DCC (deleted in colorectal cancer), whose expression is controlled by the microRNA, miR-218. Our studies in male mice have shown that stimulant drugs of abuse in adolescence dysregulate miR-218 in the ventral tegmental area (VTA), altering *Dcc* mRNA levels and inducing changes in mesocorticolimbic dopamine, consequentially impacting cognitive control in adulthood. Here we assessed whether intraperitoneal injections of tetrahydrocannabinol (THC) (0, 2.5, 5, 10 mg/kg), every other day, in early adolescence (PND 22- PND30) alters miR-218 and *Dcc* mRNA expression in the VTA in male and female mice. Exposure to the 5 and 10, but not the 2.5 mg/kg dose, downregulates miR-218, inducing a concomitant increase in *Dcc* mRNA levels. These changes seem to be absent in adolescent female mice. Furthermore, THC exposure leads to a dose-dependent reduction in body weight in males; this effect is only observed in females treated with the highest dose. Using the Go/No-Go task, we are currently examining whether adolescent exposure to THC impacts behavioral inhibition in adulthood. These results indicate that early adolescence is a vulnerable period during which exposure to THC produces changes in the molecular signaling controlling mesocorticolimbic dopamine maturation. In previous research these changes have been associated with alterations in behavioral inhibition and cognitive control. Altogether these factors may contribute to enhanced risk to addiction.

Title: Sex differences in prepubescent rats following a heterotypic stress paradigm: Are CB1 receptors contributing to post stress sociability and fear responses?

Authors: *E. PERSON[1], A. MORIN[1], V. BOISVERT[2], H. PLAMONDON[3];
[1]Psychology, [2]Univ. of Ottawa, Ottawa, ON, Canada; [3]Dept Psychol, Univ. Ottawa, Ottawa, ON, Canada

Abstract: Early adolescent stress exposure has been associated with reduced social interaction, especially in male rats, and effects on cognitive functions in both sexes. Notably, studies have suggested a role of the endocannabinoid system in memory and stress, with studies mostly focusing on male's responses. However, research support females to respond differently to stress. This study therefore aimed to investigate the sex differences in social behaviours and memory in prepubescent rats following a heterotypic stress paradigm and an acute dose of a CB1 antagonist (AM251). Female and male Wistar rats (N = 64; aged postnatal day [PND] 30) were randomly assigned to either the stress or no stress condition at the beginning of the heterotypic stress paradigm. The heterotypic stress consisted of a 10-day paradigm alternating between 30 min of restraint stress on even numbered days, and 15 min of forced swim on odd numbered days. Animals in the stress condition were stressed in the morning, while animals in the no stress condition were handled gently. Starting three days after the end of the heterotypic stress, animals were tested in the social interaction and preference tests (SIT and SP) on PND42, and in the Y-Maze passive avoidance test (YMPAT) on PND44. One hour before each test, animals in each experimental groups were injected with AM251 (1mg/kg; i.p) or received saline. Our findings indicated no significant sex differences in social recognition, although a trend was observed for the stress and the AM-251 conditions to interact in prepubescent rats. In the YMPAT, females generally took more time to exit the starting arm than males, specifically in the first trial, which could be an indication of increased anxiety in female towards novelty.

Title: Maturation of basolateral amygdala-prefrontal functional connectivity and conditioned fear during adolescence

Authors: M. AUGER, K. TSENG;
Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Basolateral amygdala (BLA) inputs to the prefrontal cortex (PFC) are thought to convey emotional information necessary for responding adaptively to threat. Anatomical studies have suggested that the density of BLA afferents in the PFC increases during adolescence, which may consequently underlie changes in fear behavior during the transition from adolescence to adulthood. Here, we investigated whether a functional refinement in BLA-PFC connectivity occurs using local field potential (LFP) recordings that assess PFC responses to BLA input in rats from postnatal day (P) 30 to adulthood. We also examined whether maturation of BLA-PFC functional connectivity is accompanied by a corresponding change in behavior during the adolescent transition to adulthood in the auditory delay fear conditioning paradigm, which is thought to require BLA input to PFC. Data revealed that the characteristic LFP facilitation observed in the adult PFC following 15 Hz BLA stimulation was not fully expressed until after P60 in naïve rats. Concurrently, the level of LFP suppression at 40 Hz does not reach maximal amplitude until P60, indicating that local PFC excitatory and inhibitory responses to BLA inputs mature through adolescence with distinct developmental trajectories. PFC LFP facilitation to 15 Hz BLA stimulation was dependent on both GluN2A and GluN2B NMDA receptor signaling, while suppression of PFC LFP responses to 40 Hz BLA stimulation requires intact PFC GABAergic transmission, and PFC GluN2A, but not GluN2B, NMDA receptors in adult rats. We observed reduced freezing in adolescent rats in comparison to adults during acquisition of the delay fear task. Reduced freezing in adolescents relative to adults was also observed during cue extinction and during a test of contextual fear memory. Collectively, our findings identify a novel feature of PFC functional refinement that may support the development of mature responding to threat during the progression from adolescence to adulthood.

Abstract: The neural circuits that support human cognition are a topic of enduring interest. Yet, the lack of tools available to map human brain circuits has precluded our ability to trace the human and non-human primate connectome. We harnessed high-resolution connectomic, anatomic, and transcriptomic data to investigate the evolution and development of frontal cortex circuitry. We first developed enhanced tools to study the development of circuits across species. We used RNA sequencing data to find corresponding ages between humans and macaques. We also transcriptionally defined neural circuits by testing for associations between gene expression and white matter maturation. We then used these tools to test whether the timeline of frontal cortex circuit maturation is extended in humans in development. We also test for cross-species variation in adult frontal cortex circuits. We found that frontal cortex circuitry development is extended in primates, and concomitant with an expansion in cortico-cortical pathways compared with mice in adulthood. Importantly, we found that these parameters varied relatively little across humans and studied primates. These data identify a collection of conserved features in frontal cortex circuits across humans and Old World monkeys. We demonstrate that integrating transcriptional and connectomic data across temporal dimensions is a robust approach to trace the evolution of brain connectomics in primates.

Title: A common reference frame for comparing cortex-wide gene expression between species

Authors: *M. ENGLUND[1], S. JAMES[2], R. T. BOTTOM[3], K. J. HUFFMAN[4], S. WILSON[2], L. A. KRUBITZER[5];
[1]Univ. of California Davis, Davis, CA; [2]Univ. of Sheffield, Sheffield, United Kingdom; [3]Neurosci., [4]Psychology/Neuroscience, Univ. of California, Riverside, Riverside, CA; [5]UC Davis, Davis, CA

Abstract: Advances in sequencing techniques have made comparative studies of gene expression a recent focus for understanding evolutionary and developmental processes. These studies have provided invaluable information about species and cell-type specific gene expression in terms of differences in gene sequence and level of expression. Yet quantitative comparisons of spatial patterns of gene expression have been extremely limited due to a lack of robust methodology. Thus, we developed a set of algorithms for quantifying and comparing spatial gene expression within and across species, which we refer to as *Stalefish, The Spatial Analysis of Fluorescent (and non-fluorescent) In-Situ Hybridization*. Here, we apply these algorithms to quantify cortex-wide expression of Id2 and RZRb mRNA in early postnatal mice and voles to determine the extent to which spatial patterns of expression of these genes is conserved between species. We found that Id2 is moderately conserved across the neocortex in mice and voles, but the extent of this conservation varies by layer and area (e.g. high conservation in caudal neocortex). On the other hand, RZRb expression is tightly conserved in somatosensory cortices (S1 and S2) between species, while expression in visual (V1 and V2) and auditory (A1) areas vary. These differences may be the result of inbreeding in mice or products of natural independent evolution that have emerged in the 35 million since the last common ancestor. We believe scientists across fields will use this newly developed tool to quantify spatial patterns of gene expression (or other histological markers) to address differences between species, developmental time-points, or experimental conditions.

Title: Evolutive origin of the RCOR genes and their interaction with LSD1

Authors: *M. OLIVARES COSTA[1], G. MERELLO OYARZUN[2], D. VERBEL VERGARA[1], M. ANDRÉS COKE[1], J. OPAZO[3];
[1]Univ. Católica, Santiago, Chile; [2]Columbia, New york, NY; [3]Univ. Austral, Valdivia, Chile

Abstract: Lysine-specific demethylase 1A (LSD1) is an epigenetic modifier that, together with the RCOR proteins, forms stable core subcomplexes recruited by several transcriptional repressors. The function and composition of the complex depends on the type of RCOR protein interacting with LSD1. Mice lacking the RCOR1 and RCOR2 proteins perinatally die and exhibit microcephaly. RCOR2 depletion resulted in reduced neural progenitor cell proliferation, neocortex thickness, and brain size. Little is known about the role of RCOR3, however, it has been proposed that it plays a compensatory role in the absence of RCOR1 or RCOR2. Due to the relevance of RCOR proteins and still lack of information about their potential different functions, we decided to evaluate the duplicative history of RCOR genes and analyze the evolutionary origin of their interaction with LSD1. Our phylogenetic analysis showed that jawed vertebrates are the only animals with three copies of the RCOR gene. We also found some species of vertebrates naturally lacking RCOR2. We have shown that the RCOR genes are onhologs because they are the product of the two duplications of the entire genome that occur in the ancestor of the vertebrates. We also predicted the ancestral sequence of the RCOR gene existing before the appearance of onhologs and evaluated a possible ancestral interaction with LSD1. Our data reveal the evolutionary origin of the RCOR-LSD1 complex and allow the selection of the best animal model for the study of the RCOR proteins.

Title: Neurodevelopmental implications of maternal and fetal inflammation at birth in the neonatal mouse

Authors: *J. M. GRAY[1], A. CASTILLO-RUIZ[1], K. MAJOR[1], T. A. HITE[2], N. G. FORGER[1]; [1]Georgia State Univ., Atlanta, GA; [2]Univ. of Texas, Austin, TX

Abstract: For placental mammals, birth is a remarkably inflammatory event for both mother and newborn, marked by a surge of inflammatory cytokines. In the present study, we investigated the role of maternal and fetal inflammation on perinatal neurodevelopment. Inflammatory responses within the body are largely mediated by Toll-like receptors (TLRs), almost all of which signal using adaptor protein myeloid differentiation factor 88 (MyD88) in both humans and murine species. The current investigation used MyD88 knockout mice (MyD88 KO), which globally lack MyD88-mediated inflammatory responses. To assess peripheral inflammation around the time of birth, we measured cytokine protein concentrations in fetal blood plasma, maternal blood plasma, and fetal milk spots using electrochemiluminescence multiplex assays, as well as in maternal uterine tissue using RT-qPCR. In fetal plasma, we observed significantly reduced levels of IL-6 (P=0.000), IL-8 (P=0.023), TNFα (P=0.003), and IL-10 (P=0.031) in MyD88 KO pups at embryonic day 18.5, regardless of maternal inflammatory status. However, IL-10 was significantly reduced (P=0.014) and IL-13 significantly increased (P=0.039) in all pups three hours postpartum born to MyD88 KO dams, regardless of inflammatory status, suggesting maternal inflammation drives offspring peripheral immune reactivity immediately after birth. We then assessed central inflammation by measuring cytokine expression in fetal hindbrain tissue using RT-qPCR and histological analysis of microglial density (Iba1) and cell death (αAC3), focusing on target brain regions sensitive to immune signaling. We observed that offspring born to MyD88 KO dams exhibit a striking reduction in cell death (PVN: P=0.010, CA1: P=0.008) and microglial labeling (PVN: P=0.020, CA1: P=0.000) at P0 in the paraventricular nucleus of the hypothalamus and CA1 Oriens of the hippocampus, indicating maternal inflammation drives perinatal microglial density and neuronal cell death. Overall, these data indicate that specific immune signals from both mother and newborn may act in tandem to drive neonatal inflammation and subsequent neurodevelopmental events throughout the perinatal period.

Title: Cellular mechanisms underlying embryonic retinal waves

Authors: *C. VOUFO[1], M. B. FELLER[2], A. TIRIAC[3];
[1]Univ. of California Berkeley, Oakland, CA; [3]Mol. and Cell Biol., [2]Univ. of California Berkeley, Berkeley, CA

Abstract: Spontaneous activity is a hallmark of developing neural systems. In the retina, spontaneous activity comes in the form of retinal waves persist from embryonic day 16 to postnatal day 14, when eye opening occurs. Though much is known about the mechanisms that mediate retinal waves during postnatal stages of development, little is known about the circuits that mediate embryonic waves. We used use two-photon calcium imaging to characterize retinal waves in the embryonic and pharmacology to assess the role of nAChR, gap junction antagonists and light stimulation on their properties. We find that waves are blocked by meclofenamic acid (50 µM) gap junction antagonist, and by the hexamethonium (100 µM), a general nAChR antagonist. Waves were still present though greatly diminished by the nAChR antagonist dihydro-ß-erythroidine (8 µM), which preferentially blocks nAChRs containing the ß2 subunit. Finally, we found that light stimulation of intrinsically photosensitive retinal ganglion cells did not generate a detectable light response but led to a small yet significant increase in wave frequency. Together these data suggest that a network consisting of ipRGCs, non-ipRGCs and cholinergic interneurons are involved in the generation Stage 1 waves.

Title: Cellular diversity in the Drosophila 3rdinstar larval ventral cord revealed by single-cell transcriptomics

Authors: *T. H. NGUYEN, R. VICIDOMINI, T. BRODY, S. D. CHOUDHURY, M. SERPE;
NICHD/NIH, bethesda, MD

Abstract: *Drosophila* ventral nerve cord (VNC), the fly equivalent of mammal the spinal cord, coordinates and integrates neural signaling from brain and periphery nervous system to produce a variety of locomotor outputs. During development, most of these locomotor outputs are executing by motorneurons (MNs), which innervate the body wall muscles. Our long-term goal is to understand how MNs develop plastic synapses, in particular what are the long-term transcriptional changes that return the circuits to steady-state functions. Here we use single cell RNA-seq to comprehensively describe the cellular diversity of *Drosophila* third instar larvae VNCs for the first time. We dissected third instar larvae VNCs, dissociated the cells and sequenced ~31,000 single cells. Using un-supervised clustering algorithms, we clustered these cells into distinct populations. We then assigned these populations to specific cell types using known markers. Through a series of reiterative processes, we first identified eight different glia subtypes, each with distinct metabolic pathways. Secondly, based on the expression of neuroblast genes, and the temporal determinant genes, we revealed a developmental trajectory leading from neural precursors to newborn neurons. We also detected novel differentially expresses genes along this trajectory. Thirdly, we identified over 40 types of clearly differentiated interneurons, each expressing unique combinations of transcription factors and neurotransmitters (*VGlut, Gad1, VAChT, DAT).* We found most of interneuron subtypes express multiple GPCRs and cell recognition molecules, suggesting that multiple sensory modalities converge onto single cells to elicit specific motor functions/behaviors. Finally, we identified a large motor neuron (MN) cluster. Within this MN population, we separated different types of MNs, including type I-b, type I-s, type II/octopaminergic and type-III/peptidergic. We also recognized different MN bundles, projecting dorsally, ventrally, or laterally. This single cell transcriptomic atlas provides a valuable resource for future studies of neurodevelopment and behavior.

Title: Convergent evolution of alternative splicing in D2 dopamine receptor genes

Authors: *M. T. PEGLAR, K. J. FRYXELL;
George Mason Univ., Fairfax, VA

Abstract: D2 dopamine receptor mRNAs are alternatively spliced (in rodents and primates) by skipping exon 6 to produce the D2S isoform, or by including exon 6 to produce the D2L isoform.

The two D2 isoforms differ in their rates of cytoplasmic vesicular processing, calcium-mediated desensitization, and their involvement in pre- vs. post-synaptic dopamine signaling. Misregulation of D2 alternative splicing is associated with human psychiatric disorders including schizophrenia, major depression, and bipolar disorder. We have shown that the peptide sequence encoded by D2 exon 6 is unique to the D2 receptor, and is conserved from lamprey to human. We have further shown that exon 6 originated (in evolutionary history) after the duplication and divergence of D2/D4 receptors, but before the duplication and divergence of D2/D3 receptors. During subsequent evolution, exon 6 was highly conserved, and in fact it was the most conserved sequence in the third cytoplasmic loop of the D2 receptors of cyclostomes, sharks and fishes, none of which undergo alternative splicing of exon 6 in the brain. Nor does alternative splicing of exon 6 occur in relatively primitive amphibians (*Xenopus*, *Notophthalmus*), reptiles (turtles), birds (ostrich), or mammals (monotremes and marsupials). Alternative splicing of exon 6 does occur in the more derived species of amphibians (bullfrog), reptiles (lizards), birds (chickens, songbirds) and mammals (placental mammals). Based on these observations, we conclude that alternative splicing of D2 exon 6 evolved convergently at least four times, and has generally marked the more derived tetrapod lineages, as if increases in alternative splicing, and/or alternative splicing of this particular exon, were generally helpful in adapting to new environments. In contrast, D3 exon 6 has not been conserved, and the D3 gene itself has also been lost or partially deleted in some vertebrate species. In those species in which D3 exon 6 was still recognizably present, alternative splicing of D3 exon 6 was rare or absent. This provides an interesting contrast between a highly conserved D2 exon 6 that convergently evolved alternative mRNA splicing, versus a poorly conserved D3 exon 6 that did not.

Title: High-throughput single neuron transcriptomics and in situ hybridization chain reaction reveal neuronal expression of both candidate and novel genes in the brain of the nudibranch mollusc Berghia stephanieae

Authors: *M. D. RAMIREZ[1], T. N. BUI[2], P. S. KATZ[1];
[1]Univ. of Massachusetts Amherst, Amherst, MA; [2]MIT, Cambridge, MA

Abstract: Identifying neuronal cell types is essential for understanding neural circuits and brain function. Single cell transcriptomics allows molecular fingerprinting of neurons at an unprecedented depth, breadth, and throughput, and also works in species lacking genetic tools to label and identify neurons. We created unbiased single neuron transcriptomes using the 10x Genomics platform for ~2000 cells from the brain and rhinophore ganglia of the nudibranch, *Berghia stephanieae*. We performed standard clustering and differential gene expression analyses to find molecular markers for computational clusters of neurons with similar gene expression profiles. Many cluster markers were understudied or unannotated genes, emphasizing that much is still to be learned from "non-model" animals. CCWamide, a recently identified peptide in the annelid *Platynereis*, appeared as a top marker for one cluster. Although CCWamide had not been previously described in any mollusc, we localized its expression to a large number of neurons throughout the cerebral-pleural ganglia of *Berghia* using *in situ* hybridization chain reaction (HCR). Temptin, known only as a reproductive pheromone in *Aplysia*, was a top marker for neuron clusters from the rhinophore ganglia (RG). Another top cluster marker for RG neurons was the enzyme nitric oxide (NO) synthase. NO signaling is thought to be important in olfactory centers in other gastropods. Many markers had no similarity with annotated sequences in public databases (e.g. NCBI). However, we found orthologs of these genes in other molluscs, suggesting they are molluscan or perhaps spiralian novelties with unknown functions for the brain. Finally, we looked for candidate genes that are important for neuron function and identification. Numerous neuropeptides, including APGWamide, small cardioactive peptide and FMRFamide were found in the transcriptomes and labeled using HCR. These genes were often co-expressed in particular sets of peptidergic neurons, and were most often not expressed in the many neurons expressing the gene for choline acetyltransferase, the synthetic enzyme for acetylcholine. Transcription factors like sox2 and brn3 marked specific clusters that we localized to unique sets of spatially segregated neurons, a pattern unlike those we found for neurotransmitters. Overall, our single neuron dataset yielded both unbiased and candidate genes that marked specific sets of neurons in this new reference species. Molecular fingerprints for all cell types in the *Berghia* brain can be established based on combinations of gene expression for these markers, enabling us to create a brain-wide neuronal atlas.

Title: Cross-species comparison of the endocannabinoid signaling system in developing neocortex

Authors: *N. MICALI, Y. M. MOROZOV, P. RAKIC;
Yale Med. Sch., New Haven, CT

Abstract: The endocannabinoid signaling (ECS) pathway plays a central role in regulating fetal neurogenesis and neural circuit formation. Dysregulations of this signaling cascade in the neurogenic phase of human neocortex development, often due to marijuana consumption during pregnancy, might affect offspring's brain development and are associated with risk for neuropsychiatric disorders. Recent evidence from our lab indicates that timing of expression and sub-cellular distribution of the cannabinoid receptors in the neocortex are different in embryonic primates versus rodents. Thus, we need to understand how ECS' role in the early steps of corticogenesis varies across species to better define the effects of its alteration during human development. In the present study, we examined ECS during early corticogenesis in mouse, rhesus macaque and human. We used electron microscopy, cell imaging, transcriptomic and bio-informatics tools to define species-specific spatio-temporal dynamics of the ECS genes across the early phases of corticogenesis. Using *in vitro* models including human iPSC derived cortical brain organoids and monkey primary neural stem cells, we interrogated the role of candidate ECS genes across radial glial cell fate progression. We defined species-specific genetic and epigenetic regulation of the ECS genes during cortical area specification and in migrating cortical neurons. This comparative research approach provides new insights into the species-specific differences of ECS function in cortical development and enhance our understanding of the implications of prenatal cannabis consumption on the onset of neuropsychiatric disorders.

Title: Region-specific dopamine D2 autoreceptor signaling drives sex-biased behavioral changes in DAT Val559 mice

Authors: *A. STEWART[1,2], F. P. MAYER[1], R. GOWRISHANKAR[1], L. B. AREAL[1], S. E. STILLEY[1], A. BODINE[1], R. D. BLAKELY[1,2];

Abstract: Virtually all neuropsychiatric disorders display sex bias, with the prevalence, age of onset, and clinical symptomology differing significantly between males and females. Here, we utilize mice expressing the dopamine (DA) transporter (DAT) Val559 variant, identified in patients with attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorder (ASD), and bipolar disorder (BPD) to investigate the critical impact of sexual dimorphism in the architecture of the DA system in phenotypes driven by chronic DA dysfunction. In males, communication between DA D2 autoreceptors (D2ARs), responsible for a negative feedback loop that suppresses vesicular DA release following neuronal activation, and DAT, the primary determinant of DA clearance, modulates DA signaling specifically in the nigrostriatal circuit, heavily implicated in DA-driven locomotor behavior. This mechanism is hyperactive in DAT Val559 males, but, in females, perturbations in D2AR-DAT coupling are seen only in the reward-associated mesolimbic circuit. Furthermore, we observed a delay in DA clearance in the dorsal striatum of male DAT Val559 mice via *in vivo* high-speed chronoamperometry whereas DAT Val559 females displayed altered DA clearance in the ventral striatum. These sex differences in DA biology are predicted to translate into a differential impact of the mutation on DA-dependent behavioral phenotypes. Indeed, we found that male DAT Val559 mice exhibit decreased interaction in a social approach paradigm and increased wins in the tube test, whereas female DAT Val559 mice show no phenotype for these measures. In the light/dark transition test, female DAT Val559 animals spent less time in the light and had an increased latency to enter the light side, suggestive of heightened anxiety. Males, conversely, spent more time on the light side. Finally, male and female DAT Val559 mice demonstrated distinct deficits in memory domains, with DAT Val559 males exhibiting decreased spontaneous alternation in the Y Maze, whereas female DAT Val559 demonstrate reduced novel object recognition. Notably, both the altered spatial working memory of DAT Val559 males and the diminished novel object recognition phenotype of DAT Val559 females could be rescued through acute administration of the D2R antagonist sulpiride, providing clear evidence that ongoing, hyperactive D2R signaling contributes significantly to the sex-biased behavioral phenotypes of DAT Val559 mice. These efforts support a model whereby sexually-dimorphic elements underlying DA signaling establish differential behavioral trajectories and determine the penetrance of neuropsychiatric disease risk factors.

Title: Impact of functional dopamine transporter coding variation on naturalistic reward-induced dopamine release in the nucleus accumbens in vivo as monitored by fiber photometry

Authors: *F. P. MAYER[1], H. PHELPS[1], H. IWAMOTO[2], A. STEWART[2], M. RABIL[1], R. D. BLAKELY[2];
[1]Dept. of Biomed. Sci., [2]Dept. of Biomed. Science, Brain Inst., Florida Atlantic Univ., Jupiter, FL

Abstract: Dopamine (DA) is a critical modulator of a wide range of processes, ranging from locomotor activity, reward and response to novelty, mood and attention. Consequently, dysfunction in DA signalling has been linked to multiple disorders that feature deficits in these processes, including attention-deficit/hyperactivity disorder (ADHD), schizophrenia, bipolar disorder and autism. At a synaptic level, the local availability of DA is dictated by coordinated processes of DA release and clearance, with the latter process overseen by the presynaptic, cocaine- and amphetamine-sensitive DA transporter (DAT, *SLC6A4*). Our lab identified the DAT Val559 coding variant in subjects diagnosed with ADHD, with others demonstrating its presence in individuals with autism or bipolar disorder. Although DAT Val559 displays normal DA uptake function in transfected cells and in synaptosomes from DAT Val559 knock-in mice, we have presented evidence that the variant supports an anomalous, DAT-dependent DA efflux process that *in vivo* alters extracellular DA levels in the striatum, leading to constitutive activation of presynaptic D2-type autoreceptors, increased surface expression of leak-prone transporters and diminished vesicular DA release. At a behavioral level, these effects alter locomotor responses to psychostimulants, waiting impulsivity and enhanced motivation for reward as well as reduced working memory. We have shown recently (Mayer FP et al., 2021) that genetically-encoded DA sensors monitored by fiber photometry *in vivo* reveal a striking pattern of DA release in the nucleus accumbens (NAc) when mice are moved from a standard testing chamber back to their home cage, providing an opportunity to monitor the impact of the DAT Val559 variant on the DAergic responses to a naturalistic reward. Our studies indicate that wild-type 9-week old male mice demonstrate the expected rise in DA levels following their transfer from the recording chamber to their home cage. In contrast, male Val559 littermates display a reduced DA rise, in both amplitude and duration. These findings provide direct evidence that the ADHD-associated Val559 variant impacts the molecular dynamics of behaviorally-induced DA release *in vivo* in the NAc. These observations may be of clinical relevance in providing further opportunities to use the paradigm for the development of treatments for disorders that feature perturbed DA signalling.

Abstract: Exploration of Michaelis-Menten kinetics of the dopamine transporter in the striatum using iontophoresis. The main objective of this study is to investigate the Michaelis-Menten (MM) kinetics for the dopamine transporter (DAT) in the striatum and the effect of psychostimulants on DAT trafficking. Traditionally, the Michaelis-Menten (MM) enzymatic model is used to determine the maximal rate of uptake (V_{max}) of dopamine (DA) by the DAT as well as provide information on the enzymatic binding activity (K_m). The MM parameters for the DAT have been examined and characterized previously, albeit under non-physiological conditions that may not be reflective of actual DAT activity. First, previous experiments determining MM K_m parameters have used homogenized tissue. The preparation of homogenized tissue is crude and disrupts ion gradients, intracellular organelles, such as mitochondria, and overall cellular function. Thus, previous estimates of MM parameters based on these conditions may be adversely affected by these non-physiological conditions. Second, voltammetry studies measuring evoked dopamine release have assumed DAT saturation for determining V_{max} without proving saturation under electrically stimulated release conditions. The assumption for DAT saturation is again based partly on K_m values from homogenized tissue studies, which estimate K_m values at ~160-200 nM. Furthermore, DAT V_{max} values from MM modeling studies correlate with release amplitude, suggesting that DATs are undersaturated and MM conditions are being violated for some of these previous studies. The validity of these parameters was investigated using exogenously application of DA (iontophoresis and puff application) in the striatum in adolescent mice. The DAT was saturated by applying exogenous DA with increasing concentrations, while measuring uptake. The V_{max} and K_m parameters were then calculated from these experiments. To quantify the effect of psychostimulants on these MM parameters, the same

procedure was conducted using increasing concentrations of cocaine and GBR12909—two drugs known to inhibit DAT activity.

Title: Characterizing the pharmacological profile of novel allosteric ligands of human dopamine transport: Potential therapy for HIV-1 associated neurocognitive disorders

Authors: *A. JIMENEZ-TORRES[1], O. MOUKHA-CHAFIQ[2], P. K. M. VENUKADASULA[2], R. HUNTER[2], T. NGUYEN[2], M. YATCHANG[2], S. ZHANG[2], C. E. AUGELLI-SZAFRAN[2], J. ZHU[1];
[1]Drug Discovery and Biomed. Sci., Univ. of South Carolina, Columbia, SC; [2]Chem., Southern Res. Inst., Birmingham, AL

Abstract: HIV-1 regulatory protein, transactivator of transcription (Tat), and cocaine synergistically dysregulate synaptic dopamine (DA) transmission by directly inhibiting DA transporter (DAT) activity, ultimately leading to dopaminergic neuron damage, which has been implicated as a mediated factor for developing HIV-1 associated neurocognitive disorders (HAND). Given the continuing presence of Tat protein in HIV patients with antiretroviral therapy, there is a pressing need to develop neuroprotective agents for preventing the progression of HAND. We have demonstrated that Tat-induced inhibition of DAT is mediated by the binding of Tat to allosteric binding site(s) on DAT and not by interacting with the DA uptake site. This provides a basis for developing compounds to attenuate Tat binding to DAT by an allosteric mechanism while having minimal influence on physiological DA transport. We have developed a series of quinazoline-based compounds that display allosteric modulatory effects at DAT, in which SRI-32743, as a novel candidate, attenuates Tat-induced inhibition of DAT-mediated DA

uptake *in vitro* and alleviates Tat-augmented cocaine reward. This study determined the structure-activity relationships of 112 analogs of SRI-32743 for identifying compounds with a balanced allosteric DAT interaction profile along with improved physicochemical and drug-like properties. SRI-32743 analogs were designed by *in silico* analysis in virtual libraries and retained the basic 7-methylimidazo[1,2-a]pyridin-6-yl moiety that is attached to the 2-position of the quinazoline ring system. Initially, we conducted the pharmacological screening for the synthesized analogs of SRI-32743 at three concentrations (10 nM and 1 and 10 µM) by assessing their inhibitory effects on [^{3}H]DA uptake and [^{3}H]WIN35-428 binding in CHO-K1 cells expressing wild-type human DAT. Compounds with over 50% inhibition at 10 µM were subjected to evaluating inhibition potencies (IC_{50} values) for DAT function and binding. Here we present the pharmacological profiles of 12 selected analogs of SRI-32743 (IC_{50} values of 3.55-17.87 µM for inhibiting [^{3}H]DA uptake and IC_{50} values of 1.29 - 35.88 µM for inhibiting [^{3}H]WIN35-428 binding) versus SRI-32743 with IC_{50} values 9.86 and 4.59 µM for inhibiting DA uptake and DAT binding, respectively. Determination of the allosteric modulatory function and capability in attenuation of Tat's effect of these selected analogs will further reveal potential for a therapeutic application in HAND.

Title: Modeling aspects of dopamine release and reuptake using fast scan cyclic voltammetry

Authors: A. C. EVERETT[1], B. E. GRAUL[1], D. B. WATTS[1], R. A. ESPAÑA[2], C. A. SICILIANO[3], ***J. T. YORGASON**[1];
[1]Brigham Young Univ., Provo, UT; [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [3]Vanderbilt Univ., Nashville, TN

Abstract: Fast-scan cyclic voltammetry (FSCV) is a highly effective electrochemistry technique for measuring rapid dopamine (DA) release and clearance, particularly in the nucleus accumbens

and dorsal striatum. The DA terminals in these areas are abundant, and DA concentrations are heavily regulated by the dopamine transporter (DAT). Historically, the Michaelis-Menten model has been a standard in measuring DAT enzymatic kinetics. However, this approach has historically used experimenter-fitted modeling and is therefore extremely subject to experimenter bias. This study presents a novel, unbiased analysis technique using the first (velocity) and second (acceleration) derivatives of evoked DA signals. Maximal upwards derivatives predict changes in DA release due to D_2 and $GABA_B$ agonist-mediated DA release inhibition. Maximal downwards derivatives are indicative of DA reuptake that is relatable to the Michaelis-Menten V_{max}, an indirect measure of DAT activity based on the number of expressed DATs. When evoked DA release in DATKO mice was subtracted from DA release in WT mice, DAT kinetics were accurately modeled. Increasingly negative velocities correlated with higher DAT activity. Critically, the Michaelis-Menten model is dependent upon an enzyme-specific constant, precluding its usage in DATKO (or similar enzymatic knockout) mice. In addition to DATKO data, the effect of two competitive, high-affinity DAT inhibitors (PTT and WF23) and the lower affinity inhibitor cocaine were analyzed to study relative effects on velocity and acceleration measures. All three inhibitors had clear effects on increasing upward velocity and decreasing downward velocity, with greatest effects on downward velocity at highest concentrations. These tools provide opportunities to study DA kinetics in situations previously inaccessible using current methodologies.

Title: Region and Sex-Dependent Developmental Plasticity of Mouse Serotonergic Innervation Arising from the ADHD and Autism-Associated DAT Val559 Mutation

Authors: *L. B. AREAL[1], F. P. MAYER[1], A. STEWART[1], R. D. BLAKELY[2];
[1]Biomed. Science, Charles E. Schmidt Col. of Med., [2]Biomed. Science, Charles E. Schmidt Col. of Med. and FAU Stiles-Nicholson Brain Inst., Florida Atlantic Univ., Jupiter, FL

Abstract: Disruptions in dopamine (DA) and serotonin (5-HT) signaling are believed to contribute to multiple neuropsychiatric disorders. The rare DA transporter (DAT) coding variant Val559, previously identified in subjects with Attention-Deficit/Hyperactivity Disorder (ADHD), autism spectrum disorder and bipolar disorder, promotes anomalous, DAT-dependent DA efflux. Mice engineered to express the Val559 mutation exhibit altered responses to the psychostimulants amphetamine and cocaine and display heightened impulsivity and reward motivation. We have previously shown that the loss of locomotor responses to cocaine in DAT Val559 mice involves a serotonergic plasticity since genetic elimination of cocaine binding at SERT restores cocaine actions, and locomotor activation occurs when animals are treated with a cocaine analog with reduced SERT action. Since increased levels of 5-HT have been found in the striatum and cortex of DAT Val559 mice, we hypothesized that the Val559 mutation induces a compensatory neuroplasticity that involves changes in serotonergic axon density. Immunofluorescent staining for 5-HT was performed with brain sections from DAT Val559 and littermate WT mice at 3 weeks and 7 weeks of age. 3D reconstruction and fiber tracing analysis revealed an increase in serotonergic axonal branching, length and volume in the dorsal striatum of 7-week-old DAT Val559 male mice, compared to WT. These changes were not observed in the dorsal striatum of DAT Val559 mice at 3 weeks of age, nor were changes found in the ventral striatum of 3- or 7-week-old mice. Consistent with these findings, microdialysis experiments showed increased baseline 5-HT extracellular levels in the dorsal striatum of DAT Val559 mice and increased 5-HT release induced by d-fenfluramine was revealed by fiber photometry in this region. Interestingly, 7-week-old female DAT Val559 mice showed increased 5-HT axon density in the medial prefrontal cortex, whereas no change was seen in males in this region. Consistent with this observation, head twitch responses induced by 2,5-dimethoxy-4-iodoamphetamine (DOI), known to be reliant on cortical 5-HT signaling, was observed in females but not in males. The present data reveals a functional, developmental and region-dependent alteration of serotonergic innervation arising in the context of the DAT Val559 mutation, pointing to the adolescent period as a critical developmental stage for the emergence of DA-dependent serotonergic plasticities. Furthermore, these results suggest that an altered interplay between DA and 5-HT during development may contribute to the sex-dependence of risk and trajectory of neuropsychiatric disorders.

Title: Voluntary aerobic exercise protects against chronic ethanol-induced changes to kappa-opioid receptors

Authors: *D. Z. OTTESON[1,2], J. BRUNDAGE[1], B. M. WILLIAMS[1], J. A. SAUNDERS[1], J. T. YORGASON[1], K. B. BILLS[2,1], S. C. STEFFENSEN[1];

Abstract: Exercise has long been prescribed as adjunctive treatment for alcohol-use disorder (AUD) despite the underlying mechanisms remaining largely uncharacterized. Mu-opioid receptors (MORs), delta-opioid receptors (DORs) and kappa-opioid receptors (KORs) are the three types of opioid receptors expressed in the brain which are part of the mesolimbic dopamine system and have long been thought to drive alcohol withdrawal symptoms. They attenuate dopamine (DA) release in the nucleus accumbens (NAc) and are known to sensitize following chronic ethanol exposure. The objective of this study was to evaluate the effect of exercise in conjunction with chronic ethanol on opioid receptor expression and DA release in the NAc. To answer this question, we used fast scan-cyclic voltammetry (FSCV), immunohistochemistry (IHC) and a behavioral assay, specifically the drinking-in-the-dark (DID) paradigm, which measures self-administration of ethanol in mice. Using FSCV, we found that a regiment of aerobic exercise was protective against ethanol-induced sensitization of KORs compared to non-exercised controls. Exercised mice displayed significantly lowered DA release upon exposure to KOR agonist u50488 using FSCV and reduced levels of KOR expression on DA neurons in the ventral tegmental area and NAc using IHC. Additionally, we found that aerobic exercise had no significant effect on DA release following superfusion of MOR agonist DAMGO; however aerobic exercise increased DA release following superfusion of DOR agonist DPDPE. Using IHC, we found that aerobic exercise was protective against ethanol-induced sensitization of DORs compared to non-exercised controls. Furthermore, in our DID model, aerobic exercise decreased seeking behavior compared to non-exercised controls. The findings in this study confirm that exercise is an effective adjunctive treatment for AUD and helps to illuminate the underlying mechanisms behind the protective effects of exercise on ethanol-induced changes to KORs.

Title: SARS-CoV 2 spike protein-derived peptides inhibit the alpha 7 nicotinic acetylcholine receptor and are counteracted by a positive allosteric modulators of alpha 7

Authors: *J. FARLEY, J. B. ANDERSON;
PNS & PBS, Indiana Univ., Bloomington, IN

Abstract: Based on clinical observations of low prevalence of smoking among hospitalized COVID-19 patients and identification of snake "toxin-like" amino acid (aa) sequences in the spike protein of SARS-CoV-2, Changeux et al 2020 *C R Biol* and Farselinos et al 2020 *J Toxicol* (C & F) proposed that the hyper-inflammation of severe COVID-19 reflects dysfunction of the "cholinergic anti-inflammatory pathway" (CAP). In seminal CAP work, Tracey et al (2002, 2012) found that vagal nerve release of acetylcholine (ACh) suppressed activation of NF-κB and production of proinflammatory cytokines in α7 nicotinic ACh receptor- (α7 nAChR-) expressing macrophages. C & F proposed that SARS-CoV-2 spike protein (allowing viral entry into cells via ACE2) also binds and inhibits several nAChRs. The most critical of these in peripheral immune cells may be α7 Rs, activated on macrophages and T-cells by ACh, leading to decreased release of inflammatory cytokines. An important implication *ex hypothesi* that nAChRs are targets for spike proteins is that nAChR-activators/modulators may be useful in battling COVID-19. But we are unaware of any direct evidence that spike protein(s) bind and inhibit activation of α7, or other nAChRs. We tested a recombinant SARS CoV-2 (L strain) spike protein construct that included most of the S1 region (Gln14-Arg685 and a c-mFc tag). *Xenopus* oocytes expressing murine α7 R and exposed to this protein (100 nM concentration, 5-8 m) showed ~73% inhibition of peak α7-current evoked by 500 μM ACh. dH2O-exposed control oocytes (n=9) had a peak current (mean ± sem) of 262.4 ± 88.3 nA; the value for spike-protein treated cells (n=8) was 71.4 ± 32.3 nA ($p < .05$). Subsequent tests of 1 nM of this protein also produced significant ~59% inhibition of peak current. Controls (n=8) had peak current of 2565.8 ± 1100.6 nA; the value for S1 protein-treated cells (n=8) was 1064.7 ± 430.0 nA ($p < .005$). We also found that ~5 m exposure to 100 uM genistein (gen), a positive allosteric modulator of α7, counteracted inhibition by 1 nM spike protein. Gen-alone treated cells (n=3) had a peak current of 5553.4 ± 2287.4 nA. Cells exposed to both 1 nM S1-protein + gen (n=6) had peak current of 3870.7 ± 552.0 nA. ANOVA for these 4 treatments [$F(3,19) = 9.3$, $p < .0005$] and Tukey HSD tests indicated significant differences between: control vs. gen-exposed cells, and S1-protein exposed cells vs. S1-protein + gen exposed cells. Notably, gen abolished the S1-protein inhibition of α7 current. Tests of additional S1-protein constructs (e.g., Val16-Gln677) suggest that aa 375-390 are critical for inhibition. As C & F noted, spike protein-nAChR interactions may contribute to COVID-19 pathophysiology in immune and nervous systems.

Title: Nicotine enhances SARS-CoV-2 glycoprotein functional modulation of the alpha7 nicotinic acetylcholine receptor

Authors: *B. C. V. O'BRIEN, M. M. WELTZIN;
Chem. and Biochem., Univ. of Alaska Fairbanks, Fairbanks, AK

Abstract: SARS-CoV-2 has been proven to enter cells via targeting of its spike glycoprotein to angiotensin converting enzyme 2 (ACE2). Interestingly, the SARS-CoV-2 glycoprotein contains a region with similar sequence homology to other neurotropic virus glycoproteins, including rabies and HIV, and the neurotoxin domain found in snake toxins and protoxins. Such toxins and viral glycoproteins have been proven to interact with nicotinic acetylcholine receptors (nAChRs). Data collected from multiple countries has indicated smoking as a factor to decrease risk of SARS-CoV-2 related hospitalization, and that smokers who are admitted tend to experience increased disease progression and worse outcomes. We hypothesize that the SARS-CoV-2 spike glycoprotein neurotoxin domain interacts with nAChR subtypes, and that nicotine may enhance this interaction in a concentration dependent manner. To test our hypothesis, in *Xenopus laevis* oocytes, we expressed the most common nAChR subtypes, and their associated isoforms, that are potentially involved in SARS-CoV-2 infection. Using two-electrode voltage clamp electrophysiology, concentration response profiles were generated to test how the glycoprotein peptide affected response to acetylcholine in the absence and presence of physiologically relevant concentrations of nicotine. Our results show that the SARS-CoV-2 glycoprotein peptide interacts with nAChRs in a subtype specific manner. Further, the SARS-CoV-2 glycoprotein peptide has a bimodal effect on alpha7 nAChRs, including potentiation of agonist responses at low concentrations of peptide, and inhibition at higher peptide concentrations. Pre-incubation with nicotine at concentrations found in smokers blood enhanced the amount of potentiation and inhibition induced by the SARS-CoV-2 glycoprotein peptide. Our findings provide clues as to the reason for lower prevalence of hospitalized smokers as well as their tendency to see worse outcomes once hospitalized. In addition, we have identified the a7 nAChR, which is found in the brain, immune cells, and in respiratory epithelial cells, as a potential new therapeutic target for the treatment of SARS-CoV-2.

Title: Cmpi is a high-affinity, high-efficacy agonist at the α4:α4 acetylcholine binding site of (α4)3(β2)2 nicotinic acetylcholine receptor.

Authors: F. DEBA[1], E. PEREDIA[1], K. MUNOZ[2], G. AKK[3], ***A. K. HAMOUDA**[1];
[1]Fisch Col. of Pharm., Univ. of Texas At Tyler, Tyler, TX; [2]Texas A&M Col. of Pharm., Kingsville, TX; [3]Dept. of Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: The extracellular domain of the (α4)3(β2)2 nicotinic acetylcholine receptor (nAChRs) harbors two high-affinity ACh binding sites located in the two α4:β2 intersubunit interfaces and a low-affinity ACh binding sites located in the α4:α4 intersubunit interface. In this study, we used ACh, cytisine, and nicotine that bind at both the α4:α4 and α4:β2 interfaces, TC-2559 as a ligand that binds at the α4:β2 but not the α4:α4 interface, and CMPI as a ligand that binds at the α4:α4 but not the α4:β2 interface to investigate the interplay between these two classes of binding sites and their effect on channel gating. We recorded whole-cell currents of *Xenopus laevis* oocytes expressing (α4)3(β2)2 nAChR elicited in response to application of these ligand (alone or in combination at various concentrations). The electrophysiological data were analyzed in the framework of a modified Monod-Wyman-Changeux (MWC) allosteric activation model. Our results indicate that CMPI is a high-affinity, high-efficacy agonist at the α4:α4 ACh binding site. CMPI binds at the α4:α4 interface with a higher affinity than ACh, cytisine or nicotine. In addition, the gating efficacy of CMPI at the α4:α4 site is equivalent to that of ACh, while CMPI weak direct activation is accounted for by a single binding site mediating its action. As such, CMPI enhances channel gating triggered by agonist occupancy at the α4:β2 ACh binding sites by providing ligand occupancy at the α4:α4 ACh binding site which is otherwise not occupied at all by agonist or only occupied at very high agonist concentrations. The data presented here enhance our understanding of the functional contributions of ligand binding at the “non-canonical” α4:α4 subunit interface to (α4)3(β2)2 nAChR channel gating.

Title: Ligand-binding promotes functional expression of human α9/α10 nicotinic acetylcholine receptors in Xenopus laevis oocytes

Authors: *A. J. HONE[1,2], J. M. MCINTOSH[1,2];
[1]Sch. of Biol. Sci., Univ. of Utah, Salt Lake City, UT; [2]Veterans Affiars Med. Ctr., Salt Lake City, UT

Abstract: Nicotinic acetylcholine receptors (nAChRs) containing α9 and α10 subunits have been implicated in neuropathic pain and inflammation. Separately, these receptors are expressed in hair cells of the cochlea where they modulate auditory processing. Cone snails are venomous marine mollusks that hunt worms, other mollusks, and fish. Some cone snails have α-conopeptides as components of their venom and may use these peptides to disorient fish prey by inhibiting α9 nAChRs expressed by hair cells of the lateral line sensory organ. α-Conopeptides are useful pharmacological tools for characterizing the expression of nAChRs in neurons and other cell types. Unfortunately, poor heterologous expression has hindered in depth pharmacological characterization of human α9/α10 subtypes. However, recently it was shown that transmembrane proteins of the inner ear, involved in human deafness, in concert with nAChR ligands are capable of promoting the expression of α9α10 nAChRs. *Xenopus* oocytes are routinely used for expressing nAChRs; previous reports have shown acetylcholine elicits robust functional responses when cRNAs for both α9 and α10 subunits are co-injected but little or no response when only α9 subunit cRNA is injected and no response when only α10 subunit cRNA is injected. We used a battery of α-conopeptides and other nAChR ligands to further examine the effects of ligand-binding on the functional expression of α9/α10 receptors and show that robust expression can be obtained by pre-exposure to select compounds. Furthermore, differential ligand effects were found for oocytes expressing α9 homomers vs. those expressing α9α10 heteromers. The results of these studies will help facilitate pharmacological characterization and drug discovery of therapeutic ligands for α9/α10 nAChRs.

Title: Functional expression of nicotinic receptor isoforms on distinct categories of pyramidal neurons within layer 5 of the mouse medial prefrontal cortex

Authors: *A. PATEL[1], A. NGUYEN[1], P. PALETTA[2], E. CHOLERIS[2], C. D. BAILEY[1];
[1]Dept. of Biomed. Sci., [2]Dept. of Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Nicotinic acetylcholine signalling within the rodent medial prefrontal cortex (mPFC) is important for higher-order cognitive functions. Nicotinic receptors (nAChRs) are present on pyramidal neurons within layer 5 of the mPFC. These neurons form the primary signalling output from the mPFC and may be categorized as either regular-firing or initial burst-firing, based on threshold responses to positive current injection. We sought to complete a detailed characterization of nAChR function and neuron morphology for these neuron categories in young postnatal mice (P15-20) of both sexes, using whole-cell electrophysiology combined with biocytin filling and retrograde labelling. Pharmacological experiments using receptor isoform-selective antagonists identified a striking specificity for the postsynaptic function of the two major nAChR isoforms, in that regular-firing neurons respond to the α4β2* nAChR exclusively whereas burst-firing neurons respond to either the α7 nAChR exclusively or to a combination of α4β2* and α7 nAChRs. Comparison of the neuron categories determined that regular-firing neurons are more excitable due to their greater membrane resistance and smaller post-firing afterhyperpolarization, and receive a lower frequency of spontaneous excitatory postsynaptic currents (EPSCs). Morphological analysis determined that regular-firing neurons have more apical dendrite matter distal to the soma and more basal dendrite matter proximal to the soma. Retrograde labelling revealed that projections to the thalamus are made exclusively from regular-firing neurons that contain the α4β2* nAChR, projections to the contralateral mPFC are made exclusively from burst-firing neurons that contain the α7 nAChR only, and projections to the nucleus accumbens are made exclusively from burst-firing neurons that contain both α4β2* and α7 nAChRs. These novel findings suggest a detailed receptor isoform-based mechanism by which nicotinic signalling is regulated within the main output layer of young postnatal mPFC, which may influence the development and function of cognitive circuits involving this brain region.

Title: Functional changes in prefrontal cholinergic synapses during adulthood: an optophysiological investigation

Authors: *S. K. POWER[1], S. VENKATESAN[1], E. K. LAMBE[1,2,3];
[1]Dept Physiol., [2]Dept Obstetrics & Gynaecology, [3]Dept Psychiatry, Univ. of Toronto, Toronto, ON, Canada

Abstract: Cholinergic modulation of the prefrontal cortex is essential for attention and executive function. During attention, basal forebrain neurons projecting to the prefrontal cortex release acetylcholine, exciting deep-layer pyramidal neurons. This cholinergic synapse is complex and has been hypothesized to change with age, though this has not been studied functionally. Broad cholinergic alterations have been reported with human aging, such as decreases in nicotinic binding and cholinergic enzymes and fibers. These differences are hypothesized to underlie behavioural declines in attention, cue detection, and executive function in aging adults; however, their integrated impact on cortical cholinergic signalling is not well understood. Here, we use optogenetics and whole cell electrophysiology to investigate functional properties of prefrontal cholinergic synapses across a broad age range in adulthood. We use brain slices from transgenic mice expressing excitatory opsin in cholinergic basal forebrain neurons whose axons project to the cortex and release acetylcholine when stimulated with light. We demonstrate that pyramidal neurons in the adult brain show age-related changes in the properties of their responses to optogenetically-released acetylcholine. Direct excitation of cholinergic receptors on pyramidal neurons declines with age, with deficits arising most noticeably in the nicotinic component of these responses. Ongoing experiments are probing the age-sensitivity or resilience of specific presynaptic and postsynaptic components of the synapse with an eye to improving treatment targets. To this end, we are investigating age-dependence in the sensitivity of functional cholinergic signalling to specific allosteric modulators and other interventions. The goal of understanding the impact of age on synaptic mechanisms of cholinergic transmission is to improve treatments for cognitive impairment and better understanding of cognitive resilience.

Title: Speculation on how RIC3 assists alpha7 nicotinic receptor pentameric assembly

Authors: R. H. LORING[1], K. AGARWAL[2], M. GUPTA[2];
[1]Pharmaceut. Sci., [2]Biotech., Northeastern Univ., Boston, MA

Abstract: We know little about how transmembrane proteins fold and assemble even though they form the majority of neurotransmitter receptors. Alpha7 nicotinic acetylcholine receptors (a7R) are unique (so far) among Cys-loop receptors in having a "latch" (Noviello et al., Cell, 184:1, 2021), an amphipathic alpha-helix (AH) at the C-terminal which is preceded by a Ser-Ala-Pro (SAP) motif. Although the latch sequence is **not** conserved in invertebrates, the SAP motif **is** conserved among a7-like receptors including *C. elegans* ACR-16. RIC3 (Resistance to inhibitors of cholinesterase 3) assists pentameric assembly of a7-like receptors across species evolution including ACR-16. Recent structural data suggest a groove forms within single a7R subunits between the latch, transmembrane (TM) domain 4 (including the helix that starts in the cytoplasmic loop-the CyM4AH), and another amphipathic helix located after M3 on the cytoplasmic side of the membrane (the cytoplasmic helix or CAH). **Hypothesis:** The structure of RIC3 is unknown but includes at least one TM helix which possibly fits into the groove of single a7R subunits, which we hypothesize aids in the assembly of a7Rs. One unknown is whether the rest of the cytoplasmic loop linking CAH to CyM4AH covers the groove, but this loop is not well resolved for any Cys-loop receptor, suggesting that it is very flexible. Z.Z. Wang proposed (Wang et al., J. Neurosci. 24:12625, 2009) that RIC3 pulls a7R subunits together by interactions between pairs of RIC3 coiled-coil domains and additional unidentified interactions between the RIC TM helix and a7R subunits. Selected alanine substitutions in CyM4AH (Castillo et al., J. Biol. Chem. 280:27062, 2005) blocks RIC3's ability to assemble a7Rs and these a7R wild-type amino acid side chains mostly project into the groove. Upon a7R assembly, the groove is blocked by overlap of CyM4AHs and by the loop between M3 and CAH from the neighboring subunit, requiring RIC3 to leave during the assembly process. **Method:** Chimeras made by replacing a7R TM domains with 5HT3 receptor helices assemble in HEK cells without any RIC3. We are looking for a7R amino acid substitutions that allow assembly (measured by alpha-bungarotoxin binding) while restoring RIC3 activity. **Preliminary results:** Replacing the chimeric 5HT3 M4 C-terminal with the SAP-latch sequence substantially blocks pentameric assembly. **Future directions:** Can RIC3 reverse the effects of the SAP-latch substitution if 5HT3 amino acid side chains that project into the groove are replaced with those of a7Rs?

Title: Study of the structural determinants involved in the potentiation of the a9a10 cholinergic nicotinic receptor by extracellular calcium.

Authors: *S. GALLINO[1], P. CRAIG[2], J. BOFFI[1], P. PLAZAS[3], B. ELGOYHEN[1,3];
[1]INGEBI-CONICET, Buenos Aires CABA, Argentina; [2]Univ. de Buenos Aires,, Inst. de Química Biológica, Facultad de Ciencias Exactas y Naturales (IQUIBICEN, UBA/CONICET), Buenos Aires, Argentina; [3]Facultad de Medicina, Univ. de Buenos Aires, Inst. de Farmacología, Buenos Aires CABA, Argentina

Abstract: The α9α10 nicotinic cholinergic receptor (nAChR) mediates the inhibitory synapse between medial olivocochlear efferent neurons and outer hair cells of the cochlea. The inhibition results from calcium (Ca^{2+}) entry through the α9α10 nAChR, and the subsequent activation of a small-conductance SK2 Ca^{2+}-dependent potassium channel. The α9α10 nAChR plays a key role in auditory neural circuits at the post-hearing onset. Hence, a deep understanding of the modulatory effects of this cholinergic receptor in auditory circuits would be extremely useful for the development of new translational strategies towards hearing loss and hyperacusis.The α9α10 nAChR is a pentameric cation-permeable ion channel that is composed of α9 and α10 subunits. Each nAChR subunit comprises a large extracellular amino-terminal domain, four transmembrane domains (TM1-TM4), a long cytoplasmic loop between TM3 and TM4 and a C-terminal domain. Expression of rat α9 and α10 nAChR subunits in *Xenopus laevis* oocytes yields functional α9 and α9α10 receptors, but not α10 homomeric nAChRs. One of the functional differences between α9 and α9α10 nAChRs is the modulation of their ACh-evoked responses by extracellular Ca^{2+}. While α9 nAChRs responses are blocked by Ca^{2+}, ACh-evoked currents through α9α10 nAChRs are potentiated by Ca^{2+} in the micromolar range and blocked at millimolar concentrations.In order to identify the structural determinants responsible for Ca^{2+} potentiation, we generated several chimeric and mutant α10 subunits, expressed them in *Xenopus* oocytes and performed electrophysiological recordings under two electrode voltage clamp. Our results suggest that the TM2-TM3 loop of the α10 subunit contains structural determinants responsible for the potentiation of the α9α10 nAChR by Ca^{2+}. Moreover, we identified α10 E 45 and E 175 as possible key residues of two potential Ca^{2+} binding sites involved in this potentiation.
These studies are being complemented with molecular dynamics simulations of the interaction of

Ca^{2+} with different nAChRs models (α9 and α10 homomeric receptors, and α9α10 heteromeric receptor in grouped or alternated subunit spatial arrangements) to help in the structural interpretation of the experimental results obtained.

Title: Efficiency: an agonist attribute that links binding and gating

Authors: *D. C. INDURTHI[1], A. AUERBACH[2];
[1]Univ. at Buffalo, Buffalo, NY; [2]Univ. At Buffalo, Buffalo, NY

Abstract: Agonists are evaluated by a concentration-response curve (CRC), with a midpoint (EC_{50}) that indicates potency and a high-concentration asymptote (r_{max}) that indicates efficacy. The low-concentration asymptote indicates constitutive activity and is agonist-independent. A third agonist attribute, efficiency (η; eta) is the fraction of binding energy that is applied to the conformational change that activates the receptor. We show that η can be calculated from EC_{50} and the asymptotes of a CRC for muscle nicotinic acetylcholine receptors (AChR) derived from either single-channel or whole-cell responses. For 20 agonists the distribution of η values is multimodal with population means at 55% (including TMA), 51% (including ACh, nornicotine and DMPP), 42% (including epibatidine and cytisine) and possibly 35% (including varenicline). Agonist potency and efficacy are related by η, which otherwise appear to be unrelated. The value of η decreases with increasing volume of the agonist's head-group. Many binding site mutations have only a small effect on ACh efficiency except for αY190A (35%), αW149A (60%) and those at αG153 (42%, including one that causes CMS). If η is known, EC_{50} and r_{max} can be calculated from each other. Hence, an entire CRC can be estimated from the response to a single agonist concentration, and efficacy can be estimated from CRCs that have been normalized to 1. Given η, the level of constitutive activity can be estimated from a single CRC. Efficiency is the missing link between affinity and efficacy.

Title: Stochastic population oscillations in type 2 networks of type inhibitory interneurons require neurons to be biased in a deeply subthreshold regime at low firing rates

Authors: *R. BARAVALLE, C. C. CANAVIER;
Cell Biol. and Anat., LSU Hlth., New Orleans, LA

Abstract: The leaky integrate and fire (LIF) model has been particularly useful in explaining the irregular firing of cortical neurons. An important candidate mechanism for the generation of gamma oscillations, the stochastic population oscillator is based on networks of LIF model neurons in the fluctuation driven regime. The network is amenable to a 1D Fokker Plank analyses assuming a fixed spike threshold and a random walk in the membrane potential plus a drift towards an effective subthreshold membrane potential. Pyramidal neurons in general have type 1 excitability, meaning they function as integrators and can fire arbitrarily slowly, so this is likely a good approximation. However, PV+ FS interneurons known to play an important role in gamma oscillations have type 2 excitability and cannot support repetitive firing below an abrupt cutoff frequency. Spiking in these neurons likely arises via a subcritical Hopf bifurcation. At subthreshold values of the membrane potential near the bifurcation, an unstable limit cycle surrounding the stable rest potential forms the spike “threshold”. This threshold may be crossed not only by depolarization, but also by hyperpolarization causing post-inhibitory rebound. Moreover, once the threshold is crossed the angular velocity of the vector field may allow multiple cycles (spikes) before the potential becomes “subthreshold”, enabling a phenomenon called stuttering. Therefore, it is not clear that the 1D Fokker Planck analyses that apply to type 1 neurons strictly apply to type 2 neurons nor whether the range of dynamic activity exhibited by networks of type 2 neurons is the same as type 1 neurons. Near the bifurcation a 2D Fokker Planck analysis may be required. The activity of networks of inhibitory LIF neurons has been characterized in the 2D parameter space of current noise intensity and synaptic conductance strength (Brunel and Hansel Neural Comput 18: 1066-1110, 2006) at a constant average firing rate, which eliminated bias current as a parameter. We have sampled the 3D parameter space including bias current for the Izhikevich cubic integrate and fire model with type 2 parameters. We show that type 2 neurons can exhibit a stochastic population oscillation, but only when sufficiently subthreshold that the vector field near the Hopf bifurcation or the saddle node of periodics is not sampled and with individual neuron firing rates much lower than the frequency of the oscillation. These results hold for nested gamma nested evoked by sinusoidal theta drive rendering this an unlikely mechanism for hippocampal theta nested gamma.

Title: Fast spiking interneurons generate gamma oscillations in the medial entorhinal cortex in the absence of excitatory cell input

Authors: *B. D. WILLIAMS[1], F. R. FERNANDEZ[1], C. C. CANAVIER[2], J. A. WHITE[1]; [1]Dept. of Biomed. Engin., Boston Univ., Boston, MA; [2]Dept. of Cell Biol. and Anat., Lousiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Many cells in layer II of the medial entorhinal cortex (mEC) exhibit spatially tuned firing rates that generate a grid-like ('grid cells') pattern when traversing an open field. Grid cell firing rates are modulated by a theta (4-12 Hz) frequency network-wide oscillation. Further, higher frequency gamma (40-140 Hz) oscillations are nested within the slower-wave theta oscillation and are believed to help synchronize grid cell spike output (Hafting et al., 2008; Reifenstein et al., 2012). Two different (but not mutually exclusive) mechanisms have been proposed to generate gamma oscillations. In the pyramidal-interneuron network gamma (PING) model, excitation of pyramidal cells activates local interneurons which provide inhibitory feedback to the pyramidal cells. Alternatively, the interneuron network gamma (ING) model proposes that inhibition between interneurons can lead to synchronous inhibition. To address the potential network mechanisms of theta-nested gamma, we used intracellular recordings in slices to measure excitatory and inhibitory post synaptic currents in stellate, pyramidal, and fast spiking cells during optogenetic stimulation. No differences were observed in the gamma frequency, theta phase or maximum power of the inhibition-driven gamma oscillations among the main cell types in the mEC. Excitation-driven gamma oscillations were observed in fast spiking interneurons, but not excitatory cells, consistent with the low degree of recurrent excitatory connections (Fuchs et al., 2016). Importantly, inhibition-driven gamma oscillations persisted after AMPA/kainate receptors were pharmacologically blocked, contrary to a similar study (Pastoll et al., 2013), but consistent with local field potential recordings in mEC (Butler et al., 2018). In support of the ING model, preliminary data indicates that inhibition-driven gamma oscillations can be observed when exclusively activating PV+ interneurons with optogenetic drive. These results suggest that a fast-firing inhibitory network is sufficient for generating gamma oscillations in the mEC. Therefore, both PING and ING mechanisms likely contribute to theta-nested gamma oscillations in the mEC. References: [1] Hafting et al. *Nature* (2008)

Title: Simulated optogenetic theta stimulation is sufficient to evoke nested gamma in a biophysically realistic model of a fast spiking interneuronal network in the medial entorhinal cortex

Authors: G. VIA[1], F. R. FERNANDEZ[2], B. D. WILLIAMS[2], J. A. WHITE[2], *C. C. CANAVIER[1];
[1]Cell Biol. and Anat., LSU Hlth., New Orleans, LA; [2]Biomed. Engin., Boston Univ., Boston, MA

Abstract: Theta nested gamma oscillations in the hippocampal formation are thought to enable temporal codes with distinct items encoded by each gamma cycle. In vitro experiments have recently shown that exclusively activating PV+ interneurons with optogenetic drive at theta frequency drive is sufficient to evoke nested gamma in the medial entorhinal cortex (MEC) in the absence of excitation (see companion poster BD Williams et al.). In order to better understand how an interneuronal network gamma (ING) model can account for these results, we thoroughly characterized variability of MEC PV+ fast spiking interneurons and their connectivity. Variability in the electrophysiology was characterized in the input resistance, membrane time constant, resting potential, excitability and frequency/current (F/I) curves. We constructed a population of one compartment models with a leak conductance, a capacitance, a voltage-gated Na+ channel, and two voltage-gated K+ channels, Kv1 and Kv3. The passive properties (leak reversal, capacitance, leak conductance) were adjusted in a biophysical range. However, this was not sufficient to capture the full variability in the F/I curve. Variability in the conductance and half activations of the active currents was required to fit the population envelope of F/I curves in terms of slope, rheobase and the cutoff frequency below which these neurons cannot sustain firing. Imposing a linear correlation between the Kv3 and NaV peak conductance values and their half activation voltages helped constrain the models in a

physiological range. 100 model neurons were connected sparsely and randomly according to the experimental data with a probability of 0.6 via inhibitory synapses with delays uniformly distributed in (0.6,1.0) ms, a log-normal distribution of peak conductance, and rise and decay times of 0.4 and 2.3 ms, respectively. The short-term depression exhibited at PV+ to PV+ synapses (Fernandez et al. SFN Global Connectome poster P071.02, online, 2021) was incorporated into the network. In accordance with Pastoll et al 2013 (*Neuron* 77:141-154), during the peaks of theta the interneurons were above threshold in the mean driven regime. Despite the multiple dimensions of heterogeneity in the network, simulated sinusoidal activation of channel rhodopsin robustly evoked gamma oscillations, in accordance with our experimental observations. Moreover, as in Fernandez et al. 2021, a simulated stellate cell population spike during the rising phase of theta greatly increased gamma amplitude, suggesting that although ING is sufficient for theta-nested gamma oscillations, excitation synergistically amplifies the oscillation.

Title: Frequency-, phase-, and task- specific functional connectivity across primate anterior cingulate and prefrontal cortex and striatum

Authors: *K. BANAIE BOROUJENI[1], T. WOMELSDORF[2];
[2]Dept. of Psychology, [1]Vanderbilt Univ., Nashville, TN

Abstract: Neural circuits in the fronto-striatal network are recurrently connected. This network structure suggests that interconnected neurons activate near-simultaneously with small time-lags between activations. Time-lags of activations should indicate the direction of spike-transfer and hence neural communication, but so far studies in primates quantified time-lags of spiking activation mostly indirectly using the local field potential. To surmount this limitation, we developed and applied a novel technique that delineates the time-lagged functional connectivity based solely on spiking activity across network. We, first, validated with biophysically plausible network modelling a novel technique to characterize time-lagged connectivity based on single neuron spike-triggered modulation of multiunit activity. We then applied the technique to simultaneously recorded spiking activity from the lateral prefrontal cortex (LPFC), anterior

cingulate cortex (ACC), and anterior striatum in two rhesus monkeys while they were engaged in an adaptive learning task. We found that spike-triggered functional connectivity profiles overall match anatomically expected connectivity profiles. The strength and sign of functional connectivity was significantly modulated by the frequency and the phase of transient oscillatory events. Spikes in ACC and LPFC occurring during transient oscillatory bursts had stronger impact on each other and the striatal circuit. This oscillatory gain on spike-efficacy was in the beta band in LPFC to the striatum, and in the theta band in ACC to the LPFC. These findings are likely functionally important as we found stronger functional connectivity for neuron-multiunit pairs that were tuned to the reward outcomes during learning. These results elucidate frequency-, phase-, and task- specific modulation of spiking co-variation, and thus depict principles of neural communication in the fronto-striatal network during adaptive learning behavior.

Title: Parsing mechanisms that support theta rhythm in a hippocampal CA3 model

Authors: *P. CANFIELD[1], M. STROUD[1], V. GUNTU[1], A. M. HUMMOS[2], S. S. NAIR[1]; [1]Electrical & Computer Engin., [2]Informatics Inst., Univ. of Missouri, Columbia, MO

Abstract: We report a computational model of the CA3 region of a rodent hippocampus to characterize the relative contributions of the intrinsic physiological mechanisms to the generation of the intrinsic CA3 theta rhythm. In the network model, the CA3 module receives non-rhythmic excitation from the entorhinal cortex (EC) and from the dentate gyrus (DG) modules. The DG module also receives input from EC as in our previous model (Hummos et al., 2017). Specifically, we extend our previous studies and parse the intrinsic physiological theta-generating mechanisms into resonant and synchronizing types and show that such a categorization can help predict the mechanisms that would interfere or possibly substitute for another, in the generation of the theta rhythm. A mechanism is termed resonant if it produces rhythms via the intrinsic dynamics of components participating in the mechanism, e.g., slow inhibition, spike-frequency adaptation, slow neuronal currents, and rhythmic external input. And it is termed synchronizing if it support rhythm coordination, e.g., non-rhythmic external excitation, inhibitory feedback, and recurrent excitatory connections. Some of the intrinsic mechanisms were found to participate in both functions. We found that pyramidal cell adaptation

interferes with theta rhythms produced by slow inhibition and that fast inhibition can substitute for rhythm generation or interfere with it through slow inhibition, depending on the level of neuromodulation (via acetylcholine). These results could help reconcile conflicting reports about the effects on rhythm generation by the inactivation of specific circuit components. We find that the effects of component removal can only be characterized in the context of the mechanisms present and on the neuromodulatory state of the system.

Title: Linking Oscillating Cell Assemblies and Population Vectors in a Model Neocortical Circuit

Authors: *Z. CHEN[1], D. DOPP[3], D. B. HEADLEY[4], S. S. NAIR[2];
[2]Electrical & Computer Engin., [1]Univ. of Missouri Columbia, Columbia, MO; [3]Univ. of Missouri, Columbia, MO; [4]Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Rhythmic activity is closely linked to neuronal processing within and across brain regions. The microcircuit mechanisms that subserve such rhythms via intrinsic and extrinsic inputs are being studied actively. Neocortical circuits exhibit both beta and gamma rhythms which are through to be caused by distinct subcircuits involving different type of interneurons. Another approach to study the microcircuit mechanisms is via population vectors. However, it is not clear how rhythmically oscillating cell assemblies and population vectors are related, and how they influence each other.
We report a 1000-cell biophysical computational model of a neocortical circuit to investigate how different patterns of population activity recruit specific beta and gamma generating micro-circuits. Our preliminary results with a 1000-cell network model (Feng et al., 2020) indicated that stable afferent ensembles recruit beta while varying ensembles recruit gamma oscillations. Previous work on gamma and beta oscillations have emphasized the resonant properties of interneuron networks as being instrumental in rhythm generation. Our preliminary model indicated that this is only part of the reason for the emergence of brain rhythms. The frequency of the rhythm is largely determined by the resonance of the recurrent principal cells/interneuron network. However, whether that network is activated, and the persistence of that activity,

depends upon the slower temporal dynamics of the principal cell ensembles that supply the excitation to fuel the rhythm. Our preliminary model did not have specific layers and had only one type of pyramidal cells. The revised network model includes all pertinent layers in the neocortex with their predominant cell types. Model single cell characteristics as well as network features such as cell numbers, connectivity, synaptic and short- and long-term plasticity characteristics were calibrated using biological reports.
One direction that on-going work explores is how random extrinsic drive engages the population vectors. This is performed by varying either the drive intensity or the ensemble recruited. Another direction explores activation of different ensembles and how the population vector trajectory on the intrinsic manifold transitions between different ensembles.

Title: Generation of oscillatory LFP bursts in different model brain regions

Authors: *M. STROUD[1], Z. CHEN[2], S. S. NAIR[3];
[1]Univ. of Missouri, Columbia, Harrisburg, MO; [2]Electrical Engin. and Computer Sci., [3]Electrical & Computer Engin., Univ. of Missouri Columbia, Columbia, MO

Abstract: Generation of oscillatory LFP bursts in different model brain regions Matthew Stroud, Ziao Chen, Feng Feng, Satish S. NairElectrical Engineering & Computer Science Dept., University of Missouri, Columbia, MO
Abstract A recent physiologically constrained biophysical network model of the rodent amygdala produced gamma (30-80 Hz) bursts as transient, several cycle-long bursts, via the PING mechanism involving principal cells (PNs) and fast-spiking interneurons (ITNs). Moreover, the model local field potential (LFP) mimicked the fine structure of gamma rhythmogenesis seen *in vivo* (Feng et al., 2019). We developed a similar 1000-cell model of a structurally different rodent region, the layered neocortex, to explore the dynamics that engender two prevalent types of bursts seen in the LFP from neocortex: beta, and gamma. The present study compares the dynamics related to burst generation between the nuclear-structured amygdala with randomly projecting axons, and the layer-structured neocortex with axons aligned in the same direction.
Specifically, this comparative study investigates how the interactions between the stochastic

extrinsic afferents and the intrinsic dynamics, including short-term synaptic plasticity, impact both the generation and the characteristics of bursts. We will also explore the formation of cell assemblies underlying the bursts as well as the capabilities and limitations of reduced order models and approaches such as mean-field models and population-averaging, in predicting the genesis and characteristics of bursts. Preliminary amygdala model results of average populational activity rates of afferents, PNs and ITNs after aligning by cycle phase showed cross-correlations with the gamma-band filtered LFP along expected lines but with a larger time lag with afferents: approximately one gamma cycle (~17 ms) for afferents, half gamma cycle (~8 ms) for PNs and a quarter of gamma cycle (~5 ms) for ITNs. These early results provided insights into both the temporal lags in correlations and possible interaction dynamics, which are being analyzed presently. A next step is to also compare these characteristics with those seen in the neocortical model to explore how a layered architecture might affect the generation of similar bursts.
In that model, the afferents were modeled as two separate components. One set comprised distinct uncorrelated Poisson spike trains, with only one impinging a cell via an excitatory synapse with synaptic weight drawn from a log normal distribution. The other set was modeled as uncorrelated point-conductances on the soma, with both excitatory and inhibitory components that had log-normally distributed weights.

Title: Cholecystokinin basket cell (CCK+BC) and parvalbumin basket cell (PV+BC) interactions are crucial elements for theta rhythm generation in a novel biophysical model of the rodent hippocampus.

Authors: *A. CHATZIKALYMNIOU[1,2], F. K. SKINNER[1,2];
[1]Krembil Res. Inst., Toronto, ON, Canada; [2]Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: In the hippocampus, the 3-12 Hz local field potential (LFP) theta oscillation is strongly correlated with spatial navigation, episodic memory, and rapid-eye-movement (REM) sleep. Understanding the origin of theta rhythms could shed light on the encoding and retrieval of cognitive information. However, how the large variety of cell types form a theta-generating network remains unknown. We use a novel CA1 hippocampus model of unprecedented

biological detail to uncover the generation mechanism of theta rhythms. The model contains detailed representations of eight inhibitory cell types and pyramidal cells and is constructed based on experimentally derived connectivity. We find that a 400 μm thick, isolated segment (slice) represents the minimum network that can produce these activities. Guided explorations of this computationally tractable model reveals that theta rhythms are initiated by the pyramidal cells whose net input drive is strongly correlated with the resulting theta frequency. This implies that the intrinsic properties of the pyramidal cells are theta frequency controllers. Returning to the full hippocampus model, we study the role of inhibition to the generation of theta rhythms. Of the eight inhibitory cell types in the model, abolishment of three types, the PV+BCs, bistratified cells (BiCs) and CCK+BCs, is particularly disruptive to theta. With respect to PV+BCs and BiCs, we find that these cell types reset the theta rhythm by mediating the sharp termination of pyramidal cell theta bursts. The CCK+BCs on the other hand are found to be prominent controllers of the PV+BC excitability. Specifically, a comprehensive grid search of the nine postsynaptic weights from the different cell types onto the PV+BCs shows that small changes to the CCK+BC-PV+BC postsynaptic weights can induce drastic alterations to the PV+BCs' firing rates. Consequently, theta rhythmicity relies on balanced activation of both CCK+BCs and PV+BCs which, if disrupted, drives the network out of the theta oscillatory regime. In conclusion, our models can be used to identify cellular-specific pathways underlying theta and theta-gamma modulations in behaving animals. In turn, this opens up avenues for clinical translation where theta (and gamma) rhythms are pathologically modulated.

Title: Stimulation response is shaped by the brain's collective dynamical state

Authors: *S. BENITEZ STULZ[1], G. RABUFFO[1], G. DUMONT[2], B. S. GUTKIN[2], D. BATTAGLIA[1];
[1]INS, Univ. Aix-Marseille, Marseille, France; [2]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

Abstract: Neuronal populations within local regions frequently undergo oscillatory modulations of their activity. The oscillations of distant populations coupled by long-range connections can phase lock at different stable phase differences. The flexible change of these phase locking

patterns between brain regions has been hypothesized to modulate communication and functional interactions between them. A tool which has proved useful to model and predict the behavior of coupled oscillating populations is the phase response curve (PRC). The PRC is a local transformation function that determines the phase-dependent response of an oscillator to any given input. More precisely, the PRC quantifies the phase advancement or delay of the oscillation in a stimulated region, changing as a function of the phase at which a brief stimulation pulse is applied. Such phase shifts can persist after stimulation and may even lead to a modified functional connectivity of the stimulated region with other regions. However, the notion of PRC has been formulated for isolated oscillating systems. On the contrary, brain regions are part of a broader system, interacting with many other regions via a structural connectome. The oscillatory dynamics of large-scale brain networks is collective in nature and the behavior of individual regions composing them can strongly differ from the behavior of these regions in isolation. The phase-shifting effects produced by a local pulse perturbation may thus not depend uniquely on the phase of the ongoing local oscillation, as assumed by the PRC framework, but also on the state of the ongoing whole-brain dynamics. If this was the case, predictions of the phase-shifting effects induced by stimulation based on conventional PRCs may radically deviate from reality. Here, we construct computational models of whole-brain dynamics and tune them to produce complex dynamics with switching between spontaneously occurring functional connectivity states. These functional connectivity states are characterized by distinct cores of strongly integrated regions and different sets of stable phase lags between oscillating regions. We then measure the "effective PRC" of selected brain regions in different functional connectivity states by quantify the phase-shifting effects of the stimulation in a phase-dependent manner in each state. We find that these effective PRCs not only differ strongly from the conventional PRCs in the uncoupled regions, but also differ across functional connectivity states. Our results suggest that it is crucial to consider the collective dynamical state of a network, such as the brain, when predicting the effect of stimulation.

Title: Low-level algorithmic decomposition of neural circuit functions

Authors: N. VOGES[1], A. BROVELLI[1], ***D. BATTAGLIA**[2];
[1]INT, Aix-Marseille Univ., Marseille, France; [2]INS, Aix-Marseille Univ., Marseille, France

Abstract: Cognitive functions must arise from the coordinated activity of neural populations distributed over large-scale brain networks. However, it is challenging to understand how specific aspects of neural dynamics translate into operations of information processing, and, ultimately, cognitive function. An obstacle is that simple circuit behaviors -such as self-sustained or propagating activity and nonlinear summation of inputs- do not directly give rise to high-level functions, even if they do, nevertheless, implement simple transformations of the information carried by neural activity. In other words, they already map to low-level processing operations, that can be used within more complex functional computations.
Here we show that distinct neural circuit functions, such as stimulus representation, working memory or selective attention stem from different combinations and types of low-level processing operations. To prove this hypothesis, we combine approaches from information theory with computational simulations of canonical neural circuits involving one or more interacting brain regions and emulating well-defined cognitive functions.
More specifically we track the dynamics of information emergent from neural activity dynamics, using suitable quantitative metrics to detect where and when information is actively buffered ("active information storage"), transferred ("information transfer") or non-linearly merged ("information modification"), as different possible modes of low-level processing. We thus find that neuronal subsets maintaining representations in working memory or performing attention-related gain modulation are signaled by their boosted involvement in operations of, respectively, active information storage or synergistic modification.
Thus, information dynamics metrics, beyond detecting *which* network units participate in cognitive processing, also promise to specify *how* they do it, i.e. through which type of primitive computation, a capability that could be exploited for the parsing of actual experimental recordings.

Title: Sexually dimorphic effects of astrocyte-specific superoxide dismutase deficiency on cognitive function

Authors: *S. LOGAN[1,2], R. Y. NAGARAJA[3], M. BAIER[4], H. YARBROUGH[4], A. MASINGALE[1], M.-P. AGBAGA[3];
[1]Rehabil. Sci., [2]The Oklahoma Ctr. for GeroScience and Healthy Brain Aging, [3]Cell Biol., [4]Biochem. and Mol. Biol., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Cognitive decline is a debilitating aspect of aging and neurodegenerative diseases such as Alzheimer's disease that is closely associated with mitochondrial dysfunction, increased reactive oxygen species (ROS) and accumulation of damaged macromolecules that are hallmarks of cellular aging. The purpose of this study was to investigate the effects of increased mitochondrial oxidative stress specifically in astrocytes, using tamoxifen-inducible astrocyte-specific knockout of SOD2 (*aSOD2-KO),* on neuronal function and cognitive performance. We reduced astrocyte levels of mitochondrial superoxide dismutase (SOD2) to induce mitochondrial oxidative stress in both males and females at 5-6 months of age and learning and memory was assessed using the PhenoTyper and radial arm water maze at 15 months of age. We show that aSOD2-KO impairs hippocampal-dependent spatial working memory. Male aSOD2-KO mice showed decreased cognitive flexibility in the Reversal phase in the PhenoTyper and the radial arm water maze. No significant differences were observed in the females. aSOD2-KO males further showed decreased hippocampal long-term potentiation, while paired-pulse facilitation was unaffected. Levels of D-serine were also reduced in aSOD2-KO males and in primary cultured astrocytes treated with MitoPQ. Furthermore, when challenged with NMDA toxicity, aSOD2-KO males demonstrated increased neuronal death in the hippocampus and hypothalamus compared to age-matched controls. These results suggest that post-synaptic mechanisms may underlie the associated cognitive dysfunction with increased oxidative stress in astrocytes possible through reduced D-serine availability and impaired glutamate handling. Thus, targeting astrocytic mitochondrial function may be an avenue for therapy for age-related cognitive impairment.

Abstract: Germline mutations in RAS signaling pathway are associated with various developmental disorders such as Noonan syndrome, neurofibromatosis, Cardio-facio-cutaneous syndrome (CFCS) and so on, collectively called RASopathy. Mutations in *BRAF* gene encoding a downstream effector of RAS account for majority of CFCS. Most of CFCS patients display severe degrees of cognitive impairments such as intellectual disability, but the neurobiological basis of their cognitive abnormalities remains largely unknown. Here, we investigated how the aberrant BRAF signaling affects cognitive functions using conditional knock-in mice harboring CFCS-associated *BRAF* mutations. Expressing the mutant BRAF under control of Nestin-, but not αCaMKII- or vGAT-CRE, resulted in severe hippocampal memory deficits in mice. Intriguingly, we found that the mutant *BRAF* increased the number of reactive-like astrocytes in multiple experimental systems including mutant mice, cultured mouse astrocyte, and human cortical organoid, suggesting that the mutant BRAF and subsequently activated ERK signaling renders astrocytes being in reactive-like status. Importantly, astrocyte-specific expression of the mutant BRAF in adult was sufficient to induce cellular and behavioral deficits in mice. Our study demonstrates that the reactive-like astrogliosis may underlies the severe cognitive deficits in CFCS.

Title: Dementia-linked TDP-43 dysregulation in astrocytes impairs memory, antiviral signaling, and chemokine-mediated astrocytic-neuronal interactions

Authors: *A. LICHT MURAVA[1], S. M. MEADOWS[2], F. PALAGUACHI[1], S. C. SONG[4], Y. BRAM[5], C. ZHOU[3], R. E. SCHWARTZ[5], R. C. FROEMKE[4], A. L. ORR[1], A. G. ORR[2]; [1]Brain and Mind Res. Inst., [2]Brain and Mind Res. Institute, Weill Cornell Grad. Sch., [3]Brain and Mind Res. Institute, Tri-Institutional MD-PhD Program, Weill Cornell Med., New York, NY; [4]New York Univ. Sch. of Medicine, Skirball Inst., New York, NY; [5]Dept. of Med., Div. of Gastroenterology and Hepatology, Weill Cornell Med., New York, NY

Abstract: Dysfunction in transactive response TAR DNA-binding protein 43 (TDP-43) is linked to cognitive deficits in diverse neurodegenerative disorders, including frontotemporal dementia (FTD), amyotrophic lateral sclerosis (ALS), and Alzheimer's disease (AD). The effects of TDP-43 pathology in different cell types, including astrocytes, are not clear. In this study, we investigated whether astrocytic TDP-43 is dysregulated in human brain and how this dysregulation affects behavior, gene expression, and neural cell functions. Our results show that astrocytic TDP-43 is mislocalized in postmortem human hippocampal tissue from AD cases. To assess the effects of widespread or hippocampus-specific dysregulation of astrocytic TDP-43 in complementary systems, we generated three novel astrocyte-specific mouse models of TDP-43 dysfunction. Consistently, these mouse models indicated that astrocytic TDP-43 dysfunction causes progressive hippocampus-dependent memory loss, but not motor deficits. Manipulation of astrocytic TDP-43 also increased hippocampal levels of interferon (IFN)-inducible chemokines CXCL9 and CXCL10, and altered cell-autonomous antiviral signaling and defense against viral pathogens. Moreover, expression of CXCR3, the shared receptor for CXCL9 and CXCL10, was increased selectively in hippocampal presynaptic terminals. Acute or chronic stimulation of presynaptic CXCR3 modulated neuronal activities and presynaptic vesicles. Overall, our findings shed new light on TDP-43 dysregulation in astrocytes and its potential contributions to disease-related impairments in cognitive and immune-related functions. We report a novel chemokine-mediated astrocytic-neuronal pathway that is likely downstream of aberrant antiviral immune signaling in astrocytes that affects presynaptic release and neuronal activities. Together, these results implicate astrocytic TDP-43 dysregulation in the pathogenesis of dementia and point to chemokine signaling and CXCR3 as potential therapeutic targets for alleviating cognitive decline.

Title: Bmp4 regulates lipid metabolism and unfolded protein response in astrocytes

Authors: S. A. KESSLER[1], A. K. LINDEN[2], T. L. MCGUIRE[1], *C.-Y. PENG[1];
[1]Northwestern Univ., IL, IL; [2]Northwestern Univ., Chicago, IL

Abstract: Alzheimer's disease (AD) is the most prevalent and debilitating conditions affecting elderly populations. Aging and the *ε4* allele of Apolipoprotien E (ApoE) are known as the greatest risk factors of the disease, yet molecular mechanisms connecting the two factors are unknown. Previous research has indicated that the levels of Bone Morphogenetic Protein 4 (BMP4) increase dramatically as individuals age, and we hypothesize that such increases in BMP4 expression play a role in APOE mediated lipid metabolism and cellular stress response correlated with AD pathogenesis in astrocytes, which produce the majority of APOE in the brain. To determine the effects of BMP signaling on endoplasmic reticulum (ER) stress associated unfolded protein response (UPR) and lipid droplet (LD) formation in astrocytes, primary murine astrocytes were treated with BMP4, Noggin (a BMP antagonist), GSK26066414 (a UPR pathway inhibitor) in the presence or absence of Brefeldin A or Tunicamycin-induced ER stress for 24 hours. Following treatment, the levels of GRP78, a UPR marker, and APOE were evaluated by western blot, and the levels of APOE, GRP78, and lipid droplet formation were evaluated by immunocytochemical staining. The results indicated that, not only can BMP4 induce UPR in astrocytes, which is accompanied by an increase in the formation of LD, but the induction of the astrocytic UPR is dependent on BMP signaling as Noggin treatment reduce UPR and LD formation under ER stress conditions. In addition, upregulation of APOE by BMP signaling activation takes place independent of the UPR activation. We will also present findings from parallel experiments using APOE deficient astrocytes to determine whether APOE is necessary for BMP mediated UPR and LD phenotypes. Together, these studies will elucidate the role of BMP signaling in the context of astrocytic responses to the AD pathological cascades.

Title: Three dimensional analysis of astrocyte phenotype in a rat model of alcohol use disorder

Authors: *S. P. GUERIN[1], K. NIXON[2];
[1]Univ. of Texas at Austin, Austin, TX; [2]Pharmacol. & Toxicology, The Univ. of Texas at Austin, Austin, TX

Abstract: Individuals with Alcohol Use Disorder (AUD) commonly experience cognitive impairments which result from structural and functional changes in the brain. Heavy alcohol consumption can cause both neuronal cell death and changes to glial phenotype with some data suggesting that females exhibit higher expression of markers typically upregulated in reactive astrocytes. In a rat model of AUD, increases in the expression of reactive astrocyte marker vimentin were observed in multiple brain regions, most dramatically in the hippocampus, after 7 days of abstinence from alcohol dependence in male rats. However, little is known about the effects in female rats and the expression of other markers commonly upregulated in reactive astrocytes have yet to be defined in this model. Therefore, adult female and male rats (PND 65-70; ~240g males, ~350g males) were subjected to a four-day binge ethanol paradigm of alcohol dependence. Ethanol (25% w/v in Vanilla Ensure Plus) was administered to animals 3 times per day for 4 days, while control animals were administered an isocaloric diet. Doses of ethanol were adjusted based on an intoxication behavior scale which resulted in an average dose of 9.5 ± 1.0 g/kg/day for males, and 10.1 ± 0.6 g/kg/day for females. Blood ethanol concentrations of 360.8 ± 63.1 mg/dl for males, and 344.9 ± 33.6 mg/dl for females were recorded. Withdrawal behaviors were observed starting 10 hours after the last dose for 17 hours. Model parameters were statistically similar between males and females. 7 days following the final dose, animals were transcardially perfused, brains were removed and postfixed, and sectioned in 12 series of 40µm sections. Fluorescent immunohistochemistry for GFAP, an intermediate filament protein that labels the proximal portion of astrocyte processes, and S100B, a calcium binding protein, were used to identify populations of astrocytes. Z-stack images of labeled cells in the hilus of the hippocampus were taken using a laser scanning confocal microscope. Imaris software was utilized to create three dimensional models of individual GFAP and S100B volumes, surface areas, and to reconstruct visible astrocyte processes. There were no significant differences between male ethanol and control groups in either S100B or GFAP immunoreactivity. Two-way ANOVA revealed a main effect of Sex in multiple measures of GFAP morphology such as GFAP sphericity and volume. These results suggest that the phenotype of reactive astrocytes following ethanol dependence is unique compared to other pathologies and may exhibit sex differences consistent with reports on female susceptibility to alcohol's damaging effects.

Title: The role of astrocytes in spinal muscular atrophy motor neuron synaptic defects

Authors: *E. WELBY[1], L. BERG LUECKE[2], R. L. GUNDRY[2], A. D. EBERT[1];
[1]Cell Biology, Neurobio. and Anat., Med. Col. of Wisconsin, Milwaukee, WI; [2]Cell. and Integrative Physiol. Dept. and Div. of Cardiovasc. Med., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Spinal muscular atrophy (SMA) is a neurodegenerative disease characterized by the loss of lower spinal motor neurons. Evidence suggests that survival motor neuron (SMN) protein deficiency in other cell types can contribute to SMA pathology. We and others have demonstrated astrocytes derived from SMA patient induced pluripotent stem cells (iPSCs) show SMN-dependent intrinsic defects, including increased production and secretion of microRNA-146a which contributes to motor neuron cell loss. Our recent work shows elevated levels of microRNA-146a are still detected in SMA patient cerebral spinal fluid post-nusinersen treatment and may negatively impact iPSC-derived motor neuron functionality *in vitro*. Motor neuron peripheral and central synaptic defects have been described in SMA, but it remains to be fully determined how human glial cells contribute to synapse pathogenesis. Since astrocytes are known to play an important regulatory role in synapse development and function, we are investigating novel disease mechanisms involving astrocyte-mediated motor neuron synaptic defects in SMA. Differential gene expression analysis of our iPSC-derived astrocyte RNA seq data demonstrates a significant down-regulation of genes associated with synaptic transmission and plasma membrane cell projections in SMA patient iPSC-derived samples. Using the SurfaceGenie prediction tool, we verified many of these down-regulated genes are likely to encode cell surface proteins associated with ion gradient regulation, neurotransmitter uptake, and synaptic formation and integrity. We therefore hypothesize that SMA astrocytes may lack important synaptic-related cell surface genes and their encoding proteins, which could contribute towards motor neuron synaptic defects. Using cell surface capture mass spectrometry, we have identified cell surface proteins present in healthy and SMA patient-derived astrocyte samples. We are currently validating and quantifying protein candidates of interest using a targeted mass spectrometry approach. We will assess if candidate proteins are implicated in synaptic defects by applying super resolution microscopy and multi-electrode array (MEA) techniques to our iPSC-derived motor neuron astrocyte co-cultures. Thus far, initial MEA recordings reveal reduced motor neuron weighted mean firing rate and bursting activity when co-cultured with SMA patient-derived astrocytes. Identification of novel astrocyte cell surface proteins implicated in motor neuron synaptic defects could be targeted in future therapies for SMA.

Title: Morphological and Distribution changes of Astrocytes in Alzheimer's Disease and Down Syndrome

Authors: *L. VAZQUEZ[1], A. C. MARTINI[1], M. J. PHELAN[1], E. HEAD[1,2,3,4];
[1]Dept. of Pathology and Lab. Med., [2]Inst. for Memory Impairments and Neurolog. Disorders, UCI, Irvine, CA; [3]Dept. of Neurol., [4]Dept. of Pharmacol. & Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Down syndrome (DS) or Trisomy 21 is the most common genetic cause of intellectual disability. People with DS express excessive amounts of the amyloid precursor protein (APP) gene on the triplicated chromosome 21, leading to an enhanced production of the beta-amyloid found in Alzheimer's Disease (AD). The majority of people with DS develop sufficient AD neuropathology by the age of 40; however, clinical symptoms of AD arise approximately a decade later. Neuroinflammation is a factor that has proven to be critically involved in AD development, and it holds a distinct pattern in people with Down syndrome and AD pathology (DSAD) compared to AD. Astrocytes are the most abundant glial cells in the brain, yet much is still unknown regarding their role and morphological differences in DSAD. Although astrocytes were categorized into two main subtypes known as A1 (neurotoxic) and A2 (neuroprotective), recent studies found these cells to be extremely heterogeneous and diverse, not adopting a single binary classification but rather a much more complex phenotype. These states may vary at different ages, cerebral areas, and neuropathological conditions. The goal of the present study is to characterize the varying distributions, morphologies, and states of astrocytes in the frontal cortex and posterior cingulate cortex of people with DS, DSAD and AD along the lifespan. With a combination of immunostaining markers, and morphological as well as quantification analysis using ImageJ, the heterogeneity of astrocytes will be assessed. These results will provide valuable insight into the roles of astrocytes in the development of AD in people with DS.

Title: Protein Kinase A Expression and Activity in Alzheimer's Disease

Authors: *P. R. KANDIMALLA, S. SAHAY, N. D. HENKEL, R. E. MCCULLUMSMITH; Univ. of Toledo, Toledo, OH

Abstract: Since neurocognitive disorders are estimated to impact one in every ten American seniors, Alzheimer's disease (AD) has and will continue to have a prominent presence in our communities. Given that more than 140 clinical trials have failed to alter the progression or cure AD, a deeper understanding of the pathophysiology of this neurocognitive disorder is needed. Protein Kinase A (PKA) is a class of enzymes with a wide range of cellular homeostatic functions and is primarily involved in the cAMP-PKA signaling pathway. Past research has shown that the cAMP-PKA signaling pathway is dysregulated in AD. Using the PamGene12 Kinome Array on postmortem DLPFC brain, we identified PKA as an overrepresented "hit" on the array compared to age-matched, control (CTL) samples. We hypothesize that PKA expression (at the transcript, protein, and enzymatic activity levels) will be significantly higher in AD than that of mild cognitive impairment (MCI) and CTL samples. We will quantify changes in the expression of the PKA catalytic subunits (PRKACA and PRKACB) and its regulatory subunits (PRKAR1A, PRKAR2B, PRKAR2A, PRKAR1B, and PKIA) in the DLPFC and the hippocampus of our subjects (Male/Female CTL, n = 22/sex; Male and Female AD, n = 22/sex; Male and Female MCI, n = 22/sex). We will also quantify PKA protein levels using Western blotting protocols. Lastly, we will measure PKA activity in the same AD and control samples. This will be performed with an H89 inhibitor to normalize our quantifications. We expect our findings to support our hypothesis that PKA expression and activity is perturbed in AD compared to MCI and CTL samples.

Title: Assessment of the Active Kinome in Hippocampal Subfields

Authors: *E. S. SHEDROFF, N. D. HENKEL, P. PULVENDER, A. S. IMAMI, A. W. JOYCE, W. G. RYAN, V, K. ALGANEM, R. E. MCCULLUMSMITH;
Univ. of Toledo Col. of Med. Neurosci. & Neurolog. Disorders, Toledo, OH

Abstract: This study will use a functional proteomic approach to examine the active kinome in the hippocampus. The active kinome is the global activity of all protein kinases in a system. The hippocampus is subject to dynamic change based on regulatory needs within the system and can therefore contribute to neuroplasticity at a cellular level. The hippocampus has distinct subfields (DG, CA1, CA2, CA3, CA4) and plays a major role in learning and memory. The hippocampal subfields are discrete and have distinct anatomy. Thus, we hypothesize that each subfield has a unique active kinome profile. Differential protein kinase regulation may be essential for molecular plastic changes within the brain. This plasticity is vital for cognitive ability.
By identifying the protein kinase activity in each hippocampal subfield, comparisons can be made between subkinomes to better understand signaling pathways associated with memory and learning within the brain. The subfields will be isolated via laser capture microdissection (LCM) and run on the PamGene kinome array. Analysis of the array data will be performed using bioinformatic pipelines. Bioinformatic analyses will identify the kinase activity profiles enriched in different hippocampal subfields . The pipelines used in kinomic analysis are Upstream Kinase Analysis (UKA) and Kinome Random Sampling Analyzer (KRSA). Additionally, pathways will be visualized using Bayesian Network Modeling (KINNET). Hippocampal subfield specific pathways will also be generated. The key kinases investigated and the pathways they belong to will then be compared and contrasted between subfields to paint a clearer picture of how they communicate with one another. These studies will extend our knowledge of signalling mechanisms in the hippocampus and provide a roadmap for interrogating the hippocampus in discrete subfields.

Title: Connectomic analysis of whole brain network via glucose metabolism in the 5xFAD mouse

Authors: *R. M. SILVOLA[1], M. VERONESE[4], S. PERSOHN[2], A. A. BEDWELL[2], K. ELDRIDGE[2], R. SPEEDY[2], P. R. TERRITO[3];
[1]Clin. Pharmacol., [2]STARK NEUROSCIENCES, [3]NEUROSCIENCE, Indiana Univ. Sch. of Med., Indianapolis, IN; [4]King's Col., London, United Kingdom

Abstract: Alzheimer's disease (AD) is the leading cause of dementia worldwide, yet no effective strategies to prevent, slow, or reverse the disease exist. The number of people in the US affected by AD is expected to reach 13.8 million by 2050 and incur a financial burden of $9.12 trillion over this timeframe, thus highlighting a critical need for the development of novel diagnostic methods to better characterize onset and progression of disease. To address this gap, we adapted a novel connectomic analysis of mouse brain circuits and studied changes in glucose metabolism across time (ages), sexes, and genotypes in the 5xFAD model and littermate controls.Using ^{18}F-FDG PET/MRI and a published network analysis method, we conducted connectomic analyses in 5xFAD mice (n=64) and littermate controls (n=65) across 28 brain regions. Hierarchical modularization analysis was performed using adjacency matrices constructed by cross-correlations to yield primary and secondary modules, which were statically compared across age, sex, and genotype. Preliminary network analysis of the control group (male, WT, 4mo) revealed two primary modules within the whole brain network which were further partitioned into four secondary sub-modules of 5-10 brain regions/module. Upon reviewing brain regions within each sub-module for associated function(s), we noted module 1.1 represented predominately sensory (S) related function, modules 1.2 and 2.1 were mostly learning (L), while module 2.2 had a mixture of motor, perception, and sensory (MPS) associated brain regions. Statistical analysis of the four sub-modules were analyzed with age, sex, and genotype as the primary factors. Modules 1.1 (S) and 2.2 (MPS) showed a significant sex dependent effect for 12mo 5xFAD mice, significant effect of age in both sexes of WT mice between 4mo and 12mo, but only male 5xFAD mice had a significant effect between 6mo and 12mo. Interestingly, genotype was significant in strictly male 4mo mice for modules 1.1 (S), 2.1 (L), and 2.2 (MPS).These data illustrate the enhanced capacity of the new connectomic analysis approach to identify AD-related patterns both spatially and temporally using 18F-FDG PET data. Moreover, they replicate clinical manifestations of subjects with the same familial AD mutations, encouraging additional mechanistic studies to elucidate the mechanisms and etiology of this network connectomic phenomenon.

Title: Plcg2 is associated with the inflammatory response and is induced by amyloid plaques in alzheimer's disease

Authors: *E. J. MESSENGER[1], A. P.-Y. TSAI[1], C. DONG[1], P. B.-C. LIN[4], B. T. CASALI[1], M. MOUTINHO[4], Y. LIU[1], A. OBLAK[2], B. T. LAMB[4], G. E. LANDRETH[3], S. J. BISSEL[1], K. NHO[1];

Abstract: Alzheimer’s Disease (AD) is a neurodegenerative disorder and the leading cause of dementia. It is characterized by amyloid beta (Aβ) plaque deposition, intracellular tau tangles, and microgliosis. Accumulating evidence from genetic studies suggest the importance of phospholipase C gamma 2 (PLCG2), an intracellular phospholipase that, in the brain, is found in microglia and an important downstream effector of immune receptors, in late-onset AD (LOAD) pathophysiology. However, the role of PLCG2 in AD is still poorly understood. Using bulk RNA-Seq (N=1,249) data from seven brain regions from the Accelerating Medicines Partnership-Alzheimer’s Disease Consortium (AMP-AD), we observed significant upregulation of PLCG2 expression in the parahippocampal gyrus, superior temporal gyrus, and inferior temporal gyrus in LOAD patients and a significant positive correlation of PLCG2 expression with amyloid plaque density. These findings from the human brain were recapitulated in the 5xFAD amyloid mouse model, which showed disease progression-dependent increases in Plcg2 expression with increased amyloid pathology. Furthermore, using bulk RNA-Seq data, we performed differential expression analysis by comparing cognitively normal older adults (CN) with high and low PLCG2 gene expression levels. Notably, genes related to inflammation and the inflammatory response were significantly altered between high and low PLCG2-expressing CN adults. These findings from human brain were recapitulated in mouse by generating mice with inactivated Plcg2 and by performing differential expression analysis comparing wild-type (WT) mice to mice lacking Plcg2 (Plcg2 inactivation), indicating that this model is appropriate to study PLCG2 as it relates to human disease. Additionally, PLCG2 co-expression network analysis of human MCI and AD microglia via single-cell RNA-Seq identified pathways closely

related to the inflammatory response, including regulation of I-kappa B/NF-kappa B signaling and response to lipopolysaccharide. These findings reinforce the importance of PLCG2 in the inflammatory response and suggest PLCG2 as an important mediator of the inflammatory processes underlying AD pathology. In conclusion, our results provide further evidence that PLCG2 plays an important role in AD pathophysiology and may itself be a potential target or be an important component of the pathways targeted in microglia-focused AD therapeutics.

Abstract: Alzheimer’s disease (AD) and other neurodegenerative diseases are typified by a robust microglial-mediated immune response. Genetic studies have demonstrated that variants in microglial genes are linked to risk for AD. Phospholipase C gamma 2 (PLCG2), whose variants confer altered risk for AD, is a critical signaling element for various immune receptors and is a key regulatory hub gene for immune signaling.GWAS studies demonstrated that the P522R variant (rs72824905) of PLCG2 was associated with reduced AD risk (OR= 0.68, p=5.83-10), and this variant is a functional hypermorph. Significantly, we identified a novel SNP

(rs617749044) associated with elevated AD risk (OR=1.164; p=0.047) encoding the PLCG2 M28L variant. However, a comprehensive analysis of PLCG2, whose genetic variants confer both protection and risk for AD, has yet to be explored in mouse models of AD.To investigate the impact of PLCG2 AD risk variants on microglia biology and disease pathology, we have generated mice bearing either the M28L risk or the P522R protective PLCG2 variant, all crossed onto the 5XFAD amyloidogenic murine model of AD.We provide data demonstrating that in individuals with AD, there is increased expression of PLCG2 in the brain, a finding that is recapitulated in 5XFAD mice. We show that PLCG2 variants program microglial phenotypes in 5XFAD mice, affect plaque pathology, and drive distinct transcriptional phenotypes of microglia in the presence of amyloid pathology. Compared to 5XFAD mice, behavioral analysis of 5XFAD; P522R mice demonstrated an improved performance in the Y maze assay, reflecting a restriction of cognitive decline. Our data suggest that the M28L variant had accelerated and exacerbated disease-related pathology. Conversely, the P522R variant appeared to attenuate disease severity and progression through an increased immune response program and enhance the clearance of amyloid plaques.Together, our findings provide evidence that PLCG2 plays an important role in AD pathophysiology, indicating PLCG2 as a potential new therapeutic target for AD.

Title: Late-onset AD risk mutation PICALMH458R prevents plaque generation in 5xFAD mice

Authors: *J. PHAN[1], K. M. TRAN[1], D. I. JAVONILLO[1], C. D. CUNHA[1], S. FORNER[1], S. KAWAUCHI[2], A. J. TENNER[1,3,4], F. LAFERLA[1,3], G. MACGREGOR[2,5], K. GREEN[1,3]; [1]Inst. for Memory Impairments and Neurolog. Disorders, [2]Transgenic Mouse Facility, [3]Neurobio. and Behavior, [4]Mol. biology and Biochem., [5]Dept. of Developmental and Cell Biol., Univ. of California, Irvine, Irvine, CA

Abstract: Alzheimer’s disease (AD) is an age-related neurodegenerative disorder characterised by the presence of amyloid-beta plaques and intraneuronal neurofibrillary tangles in the aged

brain. To understand the processes that drive late-onset AD genome-wide association studies (GWAS) have uncovered many risk loci. One of these is within the phosphatidylinositol-binding clathrin assembly protein (PICALM) gene, and a coding mutation has been identified (H458R) which conveys increased risk. CRISPR/Cas9 endonuclease-mediated genome editing was used to introduce the equivalent missense mutation in the C57BL/6J mouse genome (H465R). To explore how this risk mutation influences the development of AD relevant pathologies we crossed PicalmH465R mice with the 5xFAD mouse model of AD, to generate 4 groups (WT, PicalmH465R homozygous (HO), 5xFAD, and 5xFAD x PicalmH465R HO) and aged them to 4 months age, when plaque loads are being established. Coronal brain sections were immunolabeled with Thioflavin-S to visualize dense-core plaques in the hippocampus subiculum and cortex. No plaques were observed in wild-type C57BL/6J mice and PicalmH465R mice, as expected. PicalmH465R x 5xFAD mice exhibited significant reduction in plaque density in both brain regions compared to 5xFAD mice, as well as reductions in plaque volumes. Microglia numbers mirrored plaque load, with reduced microgliosis in 5xFAD x PicalmH465R mice compared to 5xFAD mice, due to the reduced plaque load. No changes in microglia and plaque interactions were seen. Soluble and insoluble Ab40 and Ab42 were measured in cortical and hippocampal brain homogenates. Similar to the observed plaque load, hippocampal insoluble fractions of 5xFAD x PicalmH465R have reduced levels of Aβ40 and Aβ42 compared to 5xFAD mice. A decrease was also observed in Aβ40 in 5xFAD x PicalmH465R cortical insoluble solution but no significant differences in Aβ42. Notably, soluble Abeta levels in the hippocampus were increased in 5xFAD x PicalmH465R mice, but decreased in the cortex, compared to 5xFAD mice. In summary, the results indicate PicalmH465R variant induces diminished Ab plaque burden in 5xFAD mice.

Abstract: Background: GWAS variants associated with late-onset Alzheimer's disease (LOAD) are enriched in noncoding regions of the genome, with a large proportion of functional variants falling into enhancers. Yet, identifying causal enhancers and the cell types in which they are active remains challenging. Functional conservation between human and mouse can reveal key transcriptional and chromatin state dynamics linked to enhancer function. **Methods:** We developed a novel multi-tier approach to assess functional enhancer conservation by leveraging chromatin, ChIA-PET and transcriptomic data sets from human and mouse to provide a comprehensive catalog of LOAD enhancers. Further, ATAC-seq data from human and mouse was integrated to predict cell-type specific effects of the prioritized regulatory elements. Then, two deep learning approaches (DeepSEA, TReNA) were implemented to identify regulatory variants in enhancers that are predicted to disrupt expression of nearby candidate genes. Finally, the top-conserved disease-associated variants were used to create five novel enhancer mouse models as part of the MODEL-AD initiative. **Results:** Heritability analysis across multiple neurodegenerative disease traits revealed a specific enrichment of LOAD GWAS variants within lowly conserved enhancer elements active in microglia. We also identified a significant enrichment of an oligodendrocyte and microglia signature (FDR $p < 0.5$) across conserved LOAD enhancers. Among microglia specific enhancers, binding sites of transcription factors (TF) linked to inflammation and microglia activation (SPI1, RUNX1, NFKB) were over-represented while oligodendrocyte enhancers showed an enrichment for a TF (MYC) associated with cell proliferation. By integrating transcriptome data from post-mortem brains, we found that microglia enhancers harboring SPI1 binding sites are linked to increased expression of genes mediating an inflammatory response across species. Our TReNA approach identified variants in *PTK2B* which alter binding sites for two TF (RARA,CUX2) that showed a high correlation with *PTK2B* expression. To functionally follow-up on our findings, we created enhancer deletion and knock-in models for LOAD variants in five well-known GWAS loci (*ADAMTS4*, *BIN1*, *PTK2B*, *SCIMP*, *EPHA1*). These variants are predicated to mediate the expression of nearby candidate genes in a cell type-specific manner. We provide initial functional characterization for our novel models based on brain RNA-seq data. **Conclusion:** Our findings provide not only a translational catalog of cell type-specific LOAD enhancers but also a novel set of five mouse models to study their effects *in vivo*.

Title: Incorporating genetic diversity to improve alignment of mouse models to human Alzheimer's disease

Authors: *K. J. ELK, A. UYAR, D. GARCEAU, D. BEDNARCZYK, R. O'ROURKE, K. KOTREDES, M. SASNER, G. W. CARTER, G. R. HOWELL;
The Jackson Lab., Bar Harbor, ME

Abstract: A growing body of research is revealing the benefits of incorporating genetically diverse mouse strains to better model human Alzheimer's disease (AD). For instance, mouse models of AD on genetically distinct wild-derived mouse strains demonstrated robust differences in immune response to amyloid and neurodegeneration, better representing the phenotypic spectrum of AD than previous models. To further investigate the importance of genetic diversity, we are generating AD-relevant mouse models on at least ten Collaborative Cross (CC) strains, a recombinant inbred mouse panel created from eight highly diverse founder strains. To date, C57BL/6J (B6J) mice homozygous for humanized APOE4 allele and carrying mutant APP and PS1 transgenes (APPswe, PS1de9) have been crossed to five CC strains that were selected to maximize variation in AD-relevant genes, including *Trem2* and *Cd33*. Cohorts of male and female B6JCCnF1.APOE4.APP/PS1 mice and controls (6/sex/strain/Tg-genotype) were aged to 8 months (a midpoint for amyloid deposition in B6.APP/PS1 mice) and brain hemispheres were processed for transcriptional profiling by RNA-seq and multiple neuropathological assessments (including amyloid deposition, neurodegeneration, and glial activation) via immunohistochemistry (IHC). Data were assessed for strain-, genotype- and sex-specific variation. RNA-seq analysis revealed up-regulation of neuroinflammation related pathways (lysosome, complement and coagulation cascades) in all CC strains as an effect of mutant APP and PS1 transgenes in presence of APOE4 allele. On the other hand, we observed significant CC strain- and sex- specific variation in immune (Fc gamma R-mediated phagocytosis) and metabolic (glycosphingolipid biosynthesis) response to amyloid pathogenesis. Alignment with human AD signatures revealed high strain- and sex- specific variation in correlation with synaptic signaling, cell cycle and DNA repair related gene modules. Preliminary IHC data revealed marked differences in amyloid deposition across the CC strains. For instance, in the presence of the amyloid drivers, B6J/CC037F1 and B6J/CC006F1 exhibited elevated levels of parenchymal plaque compared to B6J. Also, vascular amyloid, indicative of cerebral amyloid angiopathy (CAA), varied across the strains, independent of parenchymal amyloid load, with B6J/CC037F1 and B6J/CC002F1 showing the highest levels of CAA. Assessments of neurodegeneration and glial activation are in progress. Overall, this study further supports the incorporation of genetically diverse mouse strains, including CC strains, to better model complex neurodegenerative disorders such as AD.

Abstract: Selecting an optimal mouse model for target validation experiments and preclinical testing of compounds remains a major barrier to the progression of basic research discoveries through the Alzheimer's disease (AD) drug development pipeline. There are numerous challenges that contribute to the inability to identify ideal model systems, including lack of standardized phenotypic measures, lack of mice that fully replicate features of late-onset human disease, and licensing requirements, among others. To address these issues, the Model Organism Development and Evaluation for Late-onset Alzheimer's Disease (MODEL-AD) consortium has generated dozens of new mouse models of late-onset, sporadic AD that are available without restriction to the research community. These strains were developed using a variety of strategies to model AD, including introduction of human AD genetic variants, AD risk gene knockouts, and knockins of humanized AD related genes. All MODEL-AD models have been characterized using a rigorous, standardized phenotypic pipeline across multiple timepoints, and all data is freely available through the AD Knowledge Portal. To facilitate evaluation of these models by interested researchers, we have developed the MODEL-AD Explorer (https://modeladexplorer.org/). The Explorer currently hosts pathology and gene expression data from 15 unique models. The pathology explorer presents quantification of amyloid plaques, microglia, astrocytes, and dystrophic neurites based on immunostaining as well as soluble and insoluble amyloid-beta levels in brain tissue. A second explorer allows exploration of gene expression data for a subset of models and can be used in two ways: 1) viewing all differentially

expressed genes for selected mouse models as a function of age and sex or 2) comparing differential expression of selected genes across models, sexes, and ages. A third explorer shows the extent to which gene expression changes in mouse models mimic expression changes in humans with AD. Once users identify a model of interest based on phenotypic evaluation, they can visit the Jackson Laboratory website to learn more about each strain. The MODEL-AD Explorer will continue to grow to house phenotypic data from additional MODEL-AD developed models as well as new data modalities.

Title: Phenotypic characterization of UCI MODEL-AD mice using RNA-seq

Authors: *M. GANTUZ, H. Y. LIANG, N. REZAIE, G. BALDERRAMA-GUTIERREZ, C. MODEL-AD, A. MORTAZAVI;
Univ. of California, Irvine, Irvine, CA

Abstract: Phenotypic characterization of UCI MODEL-AD mice using RNA-seqAuthors: Magdalena Gantuz, Heidi Y. Liang, Narges Rezaie, Gabriela Balderrama-Gutierrez,MODEL-AD Consortium, Ali MortazaviThe development and characterization of new Alzheimer’s Disease (AD) mouse modelsare critical for the understanding the progression of the pathology and as a platform for theevaluation of new drugs. The UCI MODEL-AD project focuses on the development of late-onsetAD (LOAD) mouse models based on human GWAS data. We evaluate each new modeldeveloped in our group by performing a comparative transcriptomic analysis of cortex andhippocampal tissues in order to relate changes in expression to other phenotypic changes.As part of our standard pipeline, we test each new GWAS variant model at the age of 4months crossed with 5XFAD mice to regular 5XFAD mice and GWAS variant-only mice.Differential gene expression analysis allows us to quantify the impact of the variant on thepathology. We discuss the result of several of our latest models data. RNA

transcriptomeanalysis combined with phenotypic characterization is fundamental to the identification of themost appropriate LOAD mouse model.

Title: Impact of Non-Pharmacological Chronic Hypertension on a Transgenic Rat Model of Cerebral Amyloid Angiopathy (rTg-DI)

Authors: *A. STANISAVLJEVIC[1,2], J. M. SCHRADER[1,2], X. ZHU[1,2], J. GUILMAIN[2], A. HANKS[1,2], M. MAJCHRZAK[1,2], J. K. ROBINSON[1,2,3], W. E. VAN NOSTRAND[1,2];

Abstract: Cerebral Amyloid Angiopathy (CAA), a common comorbidity of Alzheimer's disease (AD), is a small vessel disease characterized by deposition of fibrillar amyloid β (Aβ) in and around blood vessels of the brain, neuroinflammation, cognitive impairment and dementia. Hypertension, another prominent small vessel disease, has been found to increase risk of dementia and may worsen associated pathologies but clinical data regarding its effects in CAA patients is controversial. Studies have reported that hypertension can worsen CAA related intracerebral hemorrhage (ICH), have little to no effect or even lessen CAA related ICH. To understand effects of hypertension on pathologies of CAA, we bred rTg-DI transgenic rats, a model of CAA, with spontaneously hypertensive, stroke prone rats (SHR-SP) producing rTg-DI/SHR-SP and non-transgenic SHR-SP littermates (n= 6-7 including males and females). Also utilized in this study were rTg-DI rats and non- transgenic (WT) littermates (n= 6-7 including males and females). Blood pressure measurements and behavioral testing were completed at 7 months of age before euthanization and brain tissue collection. Results showed that both rTg-DI/SHR-SP and SHR-SP littermates exhibit elevated blood pressures. However, behavioral testing showed no changes between rTg-DI/SHR-SP and rTg-DI rats. Forebrain tissue was assessed for known pathologies of CAA including vascular amyloid load, vessel occlusions, microbleeds, and microglial cell activation. Vascular amyloid load in cortex, thalamus and surface pial vessels was significantly increased in rTg-DI/SHR-SP rats compared to rTg-DI rats. However, the number of thalamic vessel occlusions were no different between rTg-DI and rTg-

DI/SHR-SP rats. Further, no difference in microbleeding was observed between SHR-SP, rTg-DI, and rTg-DI/SHR-SP animals. Our findings suggest that hypertension causes modest impacts on CAA pathologies in 7 month-old rats and provide a non-pharmacological model to further study hypertension and CAA as co-morbidities for cerebral small vessel disease.

Title: WSB/EiJ — A genetic context to determine vascular contributions to cognitive decline and dementia

Authors: *G. HOWELL[1], *G. HOWELL[1], H. YANG[1], K. KEEZER[1], A. UYAR[1], G. CARTER[1], M. SASNER[1], H. H. PATEL[3], A. E. WALKER[4], P. R. TERRITO[5], K. D. ONOS[2]; [2]Res., [1]The Jackson Lab., Bar Harbor, ME; [3]Univ. of California San Diego, San Diego, CA; [4]Univ. of Oregon, Eugene, OR; [5]Radiology and Imaging Sci., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Vascular contributions to cognitive decline and dementia (VCID) are now widely appreciated but the underlying genetic causes remain elusive. Current studies relevant to VCID use mouse models focused on environmental risk factors such as diet-induced obesity. To complement these approaches, we are taking advantage of mouse genetic diversity to understand the mechanisms underlying VCID.
We performed a strain survey using amyloid drivers APP^{swe} and $PSEN1^{de9}$ (*APP/PS1*). *APP/PS1* transgenes were backcrossed from C57BL/6J (B6) to founder strains of the Collaborative Cross (129S1/SvlmJ, NOD/ShiltJ, NZO/HILtJ, WSB/EiJ, CAST/EiJ and PWK/PhJ), NSG (NOD-skid-gamma), and DBA/2J. Cerebral amyloid angiopathy (CAA) was used as a VCID-relevant phenotype that is largely absent in B6.*APP/PS1* mice. CAA is found in 85-95% of AD cases, positioning CAA as one of the strongest vascular contributors to age-related cognitive decline. Of the nine strains assessed, WSB showed the greatest propensity and amount of CAA. To understand the increased susceptibility to CAA, cohorts of male and female WSB.*APP/PS1* and

WSB mice were aged from 4 to 18 months (mos). Vascular amyloid deposits were observed as early as 8 mos in cortical and leptomeningeal vessels. These vascular amyloid deposits colocalized with GFAP-positive astrocyte processes but were devoid of microglia and collagen. Brain transcriptional profiling comparing WSB.APP/PS1 to WSB mice at multiple ages identified genes relating to vascular health including basement membrane, endothelial function, and blood vessel formation. These genes were not differentially expressed in similar studies performed in B6 mice, supporting our hypothesis that WSB are prone to CAA due to inherent vascular-dependent dysfunction. Supporting our hypothesis, Prussian blue staining revealed the presence of microbleeds in aged WSB mice – even in the absence of amyloid. To validate these findings, the middle cerebral artery is being isolated from aging WSB mice and endothelial cell function assessed. Preliminary data suggest that deficits in mitochondria function may underlie vascular dysfunction. High-resolution respirometry indicated a significant depression of mitochondria respiration in the hippocampus from 4 mos WSB.*APP/PS1* mice, prior to observed CAA.
We are also exploring the utility of WSB as a preclinical model for VCID using more clinically relevant genetic (humanized amyloid and tau, allelic series of apolipoprotein E) and environmental (high fat/high sugar diet) risk factors. We are also using WSB to improve the face validity of other complex neurodegenerative disorders, including retinal vasculopathies and glaucoma.

Title: Two-photon imaging identifies blood-brain barrier alterations in a murine Alzheimer’s disease model

Authors: A. HANAFY[1,2], P. STEINLEIN[1,3], I. PAULUßEN[3], N. S. VANA[3], A. LAMPRECHT[1], D. DIETRICH[3];
[1]Pharmaceutics, Inst. of Pharmacy, Univ. of Bonn, Bonn, Germany; [2]Pharmaceutics and Pharmaceut. Technol., Fac. of Pharmacy, Pharos Univ. in Alexandria, Alexandria, Egypt; [3]Neurosurg., Univ. Hosp. Bonn, Bonn, Germany

Abstract: Since the identification of Alzheimer's disease (AD) a century ago, inconclusive data have been suggesting three hypotheses of pathogenesis involving the blood-brain barrier (BBB): disrupted tight junctions (TJ), decreased functionality of efflux transporters and increased activity of receptor for advanced glycation end products (RAGE), as drawn from different BBB models that favor controllability and accessibility over biological validity. In this study, a newly established BBB model was used to investigate the validity of these hypotheses in transgenic *Tg2576* AD mice. This model utilizes a novel controlled micropipette-based local perfusion of capillaries in acute brain slices, while monitoring the cellular transport of test compounds in real-time with high resolution two-photon (2P) microscopy. Acute cortical brain slices were isolated from age-matched wildtype and transgenic *Tg2576* mice, and placed in a submerged chamber of a 2P microscope. A blood vessel was pierced with a dye-filled pipette and ejected under 100 mmHg pressure. The TJ integrity was functionally and structurally assessed by quantifying the extravascular leakage and membrane diffusion of injected dyes and 3D reconstructed focused ion-beam scanning electron microscopy (FIB-SEM). The functionalities of two ATP-binding cassette (ABC) transporters, ABCB1 and ABCC1, and RAGE receptor were evaluated as well. Compared to wildtype mice, the paracellular diffusion of tetramethylrhodamine was doubled in Tg2576 capillaries, while the membrane diffusion of FM1-43 probe from the luminal to abluminal side of endothelial cells was 2.3-fold higher. FIB-SEM analysis revealed scarcer and shorter TJ in *Tg2576* capillaries. Based on the endothelial accumulation of calcein dye under sole or combined inhibition of ABCB1 and ABCC1 transporters, their efflux activity in *Tg2576* capillaries decreased by 30% and 85%, respectively. Surprisingly, exogenous β-amyloid endothelial uptake from blood to brain was 60% lower in *Tg2576* capillaries compared to wildtype mice, regardless of RAGE inhibition by FPS-ZM1. The results may imply TJ disruption possibly due to partial disassembly of the transmembrane domains of TJ proteins. The reduced efflux activity of ABCB1 and ABCC1 transporters could account for the poor β-amyloid clearance from AD capillaries. However, as opposed to the often-reported data, RAGE receptor is not overly activated in *Tg2576* capillaries.

Title: Primary cerebrovascular cilia are involved in blood pressure and Alzheimer's disease manifestations through ciliary muscarinic acetylcholine receptors.

Authors: K. V. FORERO[1], W. M. MESSER, Jr[1], ***W. ABOUALAIWI**[2];
[1]Pharmacol. and Exptl. Therapeut., Univ. of Toledo, Toledo, OH; [2]Pharmcology and Exptl. Therapeut., Univ. of Toledo/College of Pharm. and Pharm, Toledo, OH

Abstract: Cilia dysfunctions manifest a broad range of symptoms, including hypertension (HTN) and cognitive and memory dysfunction - symptoms also observed in Alzheimer's disease (AD). We demonstrated that the inability of primary cilia to sense and transmit fluid shear stress can lead to nitric oxide (NO) deficiency and cause vascular HTN. It is well documented that decreased biosynthesis of NO contributes to cerebral amyloid angiopathy in AD patients through increased deposition of beta amyloid (Aβ). Disruption of cholinergic neurotransmitter pathways, which are important for cognition, memory and learning abilities has been reported in AD patients. Muscarinic acetylcholine receptors (mAChRs) are also expressed throughout the cardiovascular system and can regulate BP. However, the connection between cilia and mAChR signaling in the brain has never been investigated before. Supported by our recent discovery of the mAChRs (M1 and M3) localization to primary cilia, we propose a **bold idea to look at the pathophysiological roles of cerebrovascular ciliary receptors in BP and AD.** We generated vascular-specific *AChM3R* and *Tg737* (important for ciliogenesis) knockout mouse lines. These mice developed high BP. We formulated the hypothesis that *ciliary mAChRs in the cerebrovascular endothelial cells contribute to AD progression through diminished NO biosynthesis*. We used human brain endothelial cells (HBECs) to show that AChM3R, its downstream effector PIP2, and eNOS localize to primary cilia. We also discovered that mAChR-specific activation (with CDD-0102A) increases cilia length in HBECs and cilia formation in cilialess *Tg737* cells and was also associated with an increase in eNOS activity (p-eNOS). We set out to determine if Aβ affects primary cilia structure and potentially leads to cilia sensory dysfunction and impaired ciliary AChM3R signaling. We showed that exposure to 2.5 μM synthetic human Aβ42 resulted in significant reduction in primary cilia length and ciliation percentage. We further demonstrated that upon RNAi-mediated knockdown of Tulp3, a significantly decreased trafficking of AChM3R to the cilia was detected with no effect on its plasma membrane localization. To further confirm if ciliary AChM3R localization is necessary for its activity, we treated our cilialess *Tg737* cells with AChM3R agonists (cevimeline) or antagonist (difenidol) and assayed for AChM3R activity using the arachidonic acid release assay. Interestingly, AChM3R activity did not change in cilialess *Tg737* cells following cevimeline or difenidol treatment. The proposed studies offer advanced scientific understanding of primary cilia in cerebrovascular and cognitive disease.

Title: Abeta peptides disrupt the barrier integrity and glucose metabolism of human induced pluripotent stem cell-derived brain microvascular endothelial cells

Authors: *S. RAUT[1], L. CUCULLO[1], A. AL-AHMAD[2];
[1]Oakland Univ. William Beaumont Sch. of Med., Rochester, MI; [2]Pharmaceut. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., Amarillo, TX

Abstract: Amyloid beta peptides are important components of Alzheimer's disease and cerebral amyloid angiopathy, and they have been linked to negative effects on the blood-brain barrier (BBB) in *in vivo*. The physiological and molecular mechanisms by which these peptides affect the brain vasculature, however, are unknown. The goal of this work was to see how Aβ peptides affected the cellular response of iPSC-derived brain microvascular endothelial cells (BMECs). In this model, changes in barrier function, efflux transporter activity, glucose absorption, and metabolism were evaluated. Although iPSC-derived BMECs sustained prolonged exposure (<72 hours) to a high level of Aβ peptides including Aβ42, such cells also suffered from a loss of barrier integrity, coupled with reduced glucose uptake and impaired bioenergetics activity. Overall, our research demonstrates the capacity of iPSC-derived BMECs to replicate features seen in other models and reveals that Aβ peptides may undermine the BBB via different targets. Our previous investigation, which used iPSC-derived BMECs from two patients with a Familial type of Alzheimer's disease, found a similar altered bioenergetics profile. To summarize, this study shows that iPSC-derived BMECs generated using the Shusta technique can exhibit behavior and cellular response similar to that shown in the literature employing somatic cells or in vivo models.

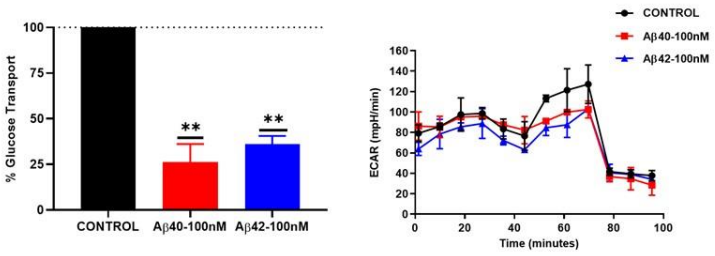

Figure 1. Aβ peptides impact glucose transporters expression and transport and impact cellular energetic profile.

Title: Increased levels of SARS CoV-2 ACE2 receptors in an age-dependent manner in Alzheimer’s and Huntington’s mouse models

Authors: *J. LOEWEN, S. UPPALA, E. ORLOV, H. MORTON, N. SAWANT, M. VIJAYAN, H. REDDY;
Texas Tech. Univ., Lubbock, TX

Abstract: Abstract: The purpose of our study is to assess the levels of angiotensin-converting enzyme 2 (ACE2) in mouse models of Alzheimer's disease and Huntington's disease. The SARS CoV-2, commonly known or COVID-19, has been the cause of a global outbreak since the first reported case in China in late 2019. The virus is spread directly person-to-person via respiratory droplets and utilizes receptors such as the angiotensin-converting enzyme 2 (ACE2) to enter host cells. SARS CoV-2 is most known for the severe respiratory distress it can cause, most often affecting individuals who are older as well as those with other comorbidities, such as Alzheimer's, Huntington's, diabetes, and obesity. Additionally, neurological manifestations have also been reported in those infected with Covid-19. These include neurodegenerative disorders which also have correlations to the ACE2 levels, also suggesting a connection to increased susceptibility to SARS CoV-2. Our initial investigation makes use of mice models, specifically the cerebellum, to understand the correlation between age and ACE2 levels. It is believed that there is an upregulation of the ACE2 receptor levels with age and age-related neurological diseases such as Alzheimer's and Huntington's. **Methods:** Using brain tissues from 2-, 6-12- and 20-month-old wild-type (WT) and also age-matched transgenic mouse models of Alzheimer's disease (APP and Tau) and Huntington's disease (BACHD and HD-knockin), we measured levels of ACE2. Results: We found age-dependent significantly increased levels of ACE2 in WT, APP, Tau BACHD and HD-knockin mice. Our comparative analysis of 1) WT to APP, 2) WT to Tau, 3) WT to BACHD mice revealed that ACE2 levels were increased in APP, Tau, BACHD and HD-knockin mice. These observations suggest that ACE2 levels increased with disease progression in Alzheimer's disease and Huntington's disease in an age-dependent manner. **Conclusions:** Our study findings suggest that age and neurodegenerative diseases result in increased susceptibility to acquiring Covid-19.

Title: Branched-chain amino acid (BCAA) restriction improves cognition and systemic metabolism in APP/PS1 mouse model for Alzheimer's disease

Authors: *M. SIDDIK[1], H. SHAH[1], R. GANNABAN[1], V. HEGDE[1], A. C. SHIN[2];
[2]Nutritional Sci., [1]Texas Tech. Univ., Lubbock, TX

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by accumulated amyloid (Aβ-42) plaques, neurofibrillary tangles, and diminished neurotransmitters in the brain. Recently, our lab has shown high circulating branched-chain amino acids (BCAAs) in both AD humans and animals, most likely due to impaired BCAA degradation. High BCAAs can potentially lead to neurotransmitter imbalance, reduction in nerve growth factor, glutamate-induced excitotoxicity, and insulin resistance through mammalian target of rapamycin. Importantly, all these consequences represent the key pathological features of AD, making BCAAs a potentially significant contributor to this disease. Therefore, we tested if restriction of dietary BCAAs can ameliorate AD pathogenesis in transgenic AD mice. 10-12 months old WT or APP/PS1 mice were placed on either a chow diet (CD) or a CD with 50% BCAA restriction for two months. The BCAA-restricted diet was adjusted for all other amino acids to make it iso-caloric and iso-nitrogenous compared to the CD. For assessing cognitive function, Y-maze and novel object recognition (NOR) tests were used at baseline and after BCAA restriction. Animals were sacrificed after 5 hours of fasting, blood and tissues were collected for analysis. Baseline and post-restriction blood glucose, insulin, and BCAAs were also measured. To evaluate changes in neuropathological hallmarks of AD following dietary BCAA restriction, cortical protein expression of pTau and Aβ-42 were measured by western blot.BCAA restriction lowered plasma insulin levels in APP/PS1 mice compared to chow-fed animals, indicating a possible improvement in insulin sensitivity. This phenomenon was further supported by a reduction in blood glucose. While there was no difference in NOR results between groups, AD mice on a BCAA-restricted diet showed improved cognition as evidenced by a higher % of spontaneous alternations in Y-maze compared to both their baseline and chow-fed group. Surprisingly, we did not observe any changes in the amount of Aβ-42 in the cortex upon BCAA restriction. Our findings suggest that two months of BCAA restriction is able to lower fasting blood glucose, insulin, and improve cognition in AD mice. Considering that a pre-diabetic glucose dysregulation and insulin resistance are associated with AD development, our results suggest a possibility that BCAA restriction may improve cognitive function partly via correcting the metabolic impairments. To understand the underlying mechanisms for the improved cognition, we plan to examine neurotransmitter synthesis, autophagy, and mitochondrial and oxidative stress markers in the brain.

Title: Exposure to combustion-derived air pollution may induce prolonged neuroinflammation

Authors: *S. H. PRADHAN[1], M. GIBB[2], C. M. SAYES[1];
[1]Envrn. Sci., [2]Inst. of biomedical studies, Baylor Univ., Waco, TX

Abstract: Combustion-derived air pollution is a multi-layered environmental toxin which is becoming a global health concern due to rapid urbanization. Air pollution contains mixtures of pro-inflammatory stimulants such as fine and ultra-fine particulate matter ($PM_{<2.5}$), gases (CO and NOx), and metals (Mn). Inhalation of these compound are linked to systemic damage through the peripheral circulatory system from the lungs. This systemic damage implicates the central nervous system, due to co-morbidity of disease link to environmental air pollution. In particular air pollution is linked to neuroinflammatory effects as well as prolonged damage with neurodegeneration. This specific study looks at an *in vitro* model of an inhalation exposure to combustion-air pollution, specifically for diesel particulate matter (DPM) on alveolar macrophages and collecting the post-exposure serum to induce activation of microglial cells. For this study, alveolar macrophages were exposed to aerosolized DPM in an acute exposure (24-hour incubation) and tested for the expression of MCP-1, IL6, and TNF-α. Once release of cytokines and chemokines was confirmed, post-exposure serum was collected from cultured alveolar macrophages and introduced to a healthy culture of microglial cells (HMC3) over 72-hours and tested for activation (HLA-DR and CD14 expression). Lipopolysaccharides (LPS; 10ng/mL) was used as a positive control to stimulate activation of microglial cells. Once activation was confirmed cells were tested for ROS generation and neurotoxic cytokine expression.
Microglial cells, through a feedback loop with surrounding neurons, release neurotoxic pro-inflammatory markers, these include, IL1β, IL6, TNF-α and CD86 and cause internal damage to neurons. Results indicated high expression of ROS measured through H2O2 and observed with confocal fluorescence microscopy. There was moderate expression of IL1β, IL6, TNF-α and CD86 through exposure. This confirmed activated microglial cells release inflammatory markers which could implicate the indirect pathway of exposure (through lungs) to the brain as a method of inducing neuroinflammation and possibly neuronal cellular damage.

Title: Establishment and comparison of microglia/astrocyte/neuron co-cultures derived from rodent spinal cord and cortical preparations for the study neuroinflammatory processes in vitro

Authors: *D. AMADIO[1], C. NODIN[1], M. SVEDMAN[1], J. SJOHOLM[1], S. ILLES[2]; [1]Cellectricon AB, Mölndal, Sweden; [2]Inst. of Neurosci. and Physiol., Gothenburg Univ., Gothenburg, Sweden

Abstract: Increasing evidence supports inflammation in the central nervous system (CNS) as a major player in the pathogenesis of human neurodegenerative disease. Microglia, the resident macrophages of the central nervous system, have a central role in maintaining cellular homeostasis; in contrast, microglial dysfunction has been linked to CNS disease progression. To best study microglia in a CNS physiologically relevant context, an *in vitro* cell culture systems comprised of microglia, astrocytes and neurons should be used, with the aim to dissect the cellular effect of microglia on neuronal activity and the cross-talk along the neuroinflammatory axis. In this study, we aim to develop two different systems that will allow the *in vitro* study of neuroinflammatory processes in complex primary rodent cell culture in the two different components of the CNS: brain and spinal cord. We have optimized two *in vitro* co-culture systems comprised of microglia, astrocytes and neurons in both mouse cortex and rat spinal cord. These can be used to investigate the role of (activated) microglia in the pathogenesis and progression of neurodegenerative disorders. We characterized the established models by using high content imaging and analysis. In addition, we further assessed neuronal function using Cellectricon's proprietary optical electrophysiology platform, and we finally examined the effect of LPS stimulation on microglia and neuronal function. The optimized microglia/astrocyte/neuron models permit robust survival of microglia *in vitro* in the presence of astrocytes and neuronal cells, and microglia survival can be further modulated by controlling culture conditions. Remarkably, we show that these co-culture systems have a healthy neuronal network and preserved neuronal activity as indicated both by electric field stimulation evoked responses and spontaneous activity patterns. We have also highlighted the difference between the two models (mouse cortex vs rat spinal cord) using the optimized co-culture condition and how they responded differently to culture stimulation *in vitro*. Given the results obtained in this study, the presented models are excellent tools suitable to study neuroinflammation *in vitro*, showing that a functionally active neuronal network can be achieved under culture condition that also permits robust microglia survival. Furthermore, the models are established in a high density 384-well format and are thus well suited for usage in medium throughput screening applications e.g. to study neuroinflammation in neurodegeneration and neuropathic pain.

Title: Perturbators of microglia functions with ageing: Identification of osteopontin through single cell and spatial RNA sequencing

Authors: *Y. DONG, R. W. JAIN, B. M. LOZINSKI, C. D'MELLO, F. VISSER, S. GHORBANI, V. YONG;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Oxidized phosphatidylcholine (OxPC) species formed in multiple sclerosis (MS) lesions are proinflammatory and neurotoxic. Microglia depletion exacerbates OxPC mediated neurodegeneration, suggesting they are important for OxPC clearance (Dong et al., Nature Neurosci 2021). Since aging alters microglia transcriptomic signatures and functions, we aimed to determine if and how microglia responding to OxPC mediated neurodegeneration becomes dysfunctional due to aging by comparing OxPC-induced lesions in the spinal cords of 6-week and 52-week-old mice. Histology and immunofluorescence showed OxPC-induced lesions in spinal cord white matter was more severe in 52-week compared to 6-week-old mice with greater total lesion volume and axonal loss, and reduced oligodendroglial counts. Single cell RNAseq of live cells sorted from homogenized spinal cords identified multiple distinct microglia/macrophage clusters and there was upregulation of aging signatures such as interferon signaling and antigen presentation genes in the healthy 52-week spinal cord compared to the 6-week samples. Moreover, microglia/macrophages in the 52-week spinal cord significantly upregulated genes associated with neuroinflammation such as *Spp1*, *Ifitm3*, *Cd74*, and *Lgals3* compared to 6-week spinal cords after OxPC injection. Tissue sections were also examined by spatial RNAseq which showed aging associated transcriptional changes that were enriched in the OxPC lesion compared to the normal white or grey matter. Both single cell and spatial RNAseq revealed the upregulation of liver x receptor (LXR) activated genes by microglia in response to OxPCs and LXR activation by the agonist GW3965 attenuated OxPC mediated neurodegeneration in both 6-week and 52-week-old mice. Moreover, in vitro and in vivo experiments demonstrated altering the levels of the aging-upregulate gene *Spp1* (osteopontin) significantly impacted the severity of OxPC mediated neurodegeneration, at least in part by altering microglia/macrophage functions. Thus, aging is associated with significant transcriptomic changes by microglia and macrophages in the spinal cord, which were further altered after aging exacerbated OxPC mediated neurodegeneration. These findings also highlighted pathways associated with LXR activation and osteopontin signaling that may regulate neurodegeneration and MS progression with aging.

Title: Dna damage induced neuroinflammation in neurodegenerative disease

Authors: *F. SONG[1], J. MA[1], J. AW[2], D. C. LEUNG[3], K. HERRUP[1];
[1]Univ. of Pittsburgh, Sch. of Med., PITTSBURGH, PA; [2]The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [3]Div. of Life Sci., Hong Kong Univ. of Sci. and Technol., Clear Water Bay, Hong Kong

Abstract: DNA damage induced neuroinflammation in neurodegenerative disease Fiona Song, Jack Ma, Jacqueline AW, Danny Leung, Karl Herrup
Cytoplasmic DNA (cytoDNA) is a strong immune stimulus that protects the cell against invasion by DNA viruses. Intriguingly, cytoDNA is also found in the absence of viral infection in conditions such as cancer, immune system disorders and neurodegeneration. As we showed previously, in mouse microglia, ATM deficiency and compromised DNA repair lead to a substantial accumulation of cytoDNA. This has pro-inflammatory consequences in microglia, where cytoDNA primes an antiviral response via the cGAS/STING pathway and activates the AIM2 containing inflammasome which cleaves and activates cytokine precursors such as pro-IL-1β. Together, these two responses create a pro-inflammatory response with neurotoxic consequences. We have extended these studies to learn the life history of microglial cytoDNA. We found that blocking nuclear export with Leptomycin B dramatically reduced cytoDNA demonstrating that it is actively exported from the nucleus by a CRM1-dependent mechanism. Deep sequencing of cytoDNA purified from ATM-deficient microglia highlighted two important features of its origins. First, mitochondrial DNA contributes less than 1% to the total amount of cytoDNA. Second, the cytoDNA exported from the nucleus comes predominantly from transcriptionally inactive, intergenic regions, in particular, AT-enriched repetitive elements at the nuclear periphery. RNA sequencing of ATM-deficient microglia revealed a significant upregulation in pathways involved in autophagy-lysosomal function, and the concomitant

downregulation of the c-MYC proto-oncogene. The c-MYC response is consistent with its role as a negative regulator of TFEB, a master regulator of lysosome biogenesis genes. We validated this connection by showing, both *in vivo* and *in vitro*, the decrease ofthat MYC and phospho-MYC decrease in *Atm*$^{-/-}$ mice brain. In microglia, ATM dysfunction induced the accumulation of cytoDNA which coupled was associated with the perinuclear aggregation of lysosomes as well as TFEB-mediated lysosomal biogenesis. In the aggregate, our findings suggest that with the inhibition of ATM the cellular balance of cytoDNA production and digestion is compromised triggering a complex response of the innate immune system. This identifies cytoDNA as a potential target for modulating the immune response that contributes to many neurodegenerative diseases.

Sch., Charlestown, MA; [5]Anesthesiol. and Critical Care, Penn Medicine, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Cognitive dysfunction is common after anesthesia and surgery in geriatric patients and is often attributed to systemic inflammation and CNS immune responses. Microglia, the immune cells of the brain, have been implicated based largely on immunohistochemical and morphological measures of activation, but one clinical study suggests microglia are hypoactive postoperatively. We hypothesized that surgery induces upregulation of proinflammatory mediators in microglia that is age-dependent and persistent. Old (20 mo; n = 8 M, 8 F) and young (3 mo; n = 9 M, 10 F) C57Bl/6J mice were anesthetized with isoflurane (1.2% in 30% O2, 70% N2), given bupivacaine (0.25%, s.c.) at the incision site and meloxicam (0.1 ml of 0.5 mg/ml, s.c.) for analgesia, and underwent a 15 min laparotomy with bowel manipulation. The

wound was closed with suture and mice remained under anesthesia for 2 h, then recovered for 4 h until sacrifice. Age-matched controls (9 M, 8 F old; 9 M, 10 F young) had no surgery and received carrier gas for 2 h but were otherwise treated identically. Additional old male mice (n = 9 surgery, 10 control) received the same treatment and recovered for 48 h before sacrifice. Plasma was collected at sacrifice for measurement of IL6, CCL2, IL1B, and TNFa by Luminex assay. We isolated microglia from hippocampus and hemisphere by FACS (Ly6C- CD11b+ Fcrls+), extracted RNA, and measured expression of *ApoE, Tgfbr1*, *Clec7a*, *Il6*, *Il1β*, and the housekeeping gene *Gapdh* via qPCR. C_t values were normalized to the young control mean ($2^{-\Delta\Delta Ct}$). Results were analyzed by 2-way ANOVA with an alpha of 0.05. At 6 h, plasma IL6 and CCL2, but not IL1b and TNFa, were elevated old but not young mice. Microglia from the hippocampus and hemisphere of old mice had higher *ApoE*, *Clec7a*, and *Il1β*, and lower *Tgfbr1* than those from young mice. Surgery increased microglial *Il6* and *Tgfbr1* for both age groups. There was an interaction of age and surgery only for *Clec7a*, a marker of phagocytic microglia; surgery decreased microglial *Clec7a* only in old mice. By 48 h after surgery, there were no differences in the expression profiles of microglia between control and surgery mice. Using validated molecular markers to isolate microglia, we confirmed age-differences in these cells as demonstrated previously. Our data indicate that abdominal surgery in mice may transiently decrease the phagocytic activity of microglia but does not produce sustained microglial-dependent neuroinflammation in the aged brain.

Title: Imaging of microglial activation in mice with acetaminophen-induced acute liver injury: a dual tracer microPET evaluation of neuroinflammation

Authors: Q. ZENG[1], *J. CARRION[1], **S. PALANDIRA**[1], L. TURECKI[1], A. FALVEY[1], D. HERSCHBERG[1], K. J. TRACEY[1,2], *V. A. PAVLOV[1,2];
[1]The Feinstein Inst. for Med. Research, Northwell Hlth., Manhasset, NY; [2]Donald and Barbara Zucker Sch. of Med. at Hofstra/Northwell, Hempstead, NY

Abstract: Acute liver injury that progresses into acute liver failure (ALF) is a life-threatening condition with increasing incidence and cost of care. Brain dysfunction and neurological

complications have also been documented in ALF and this *hepatic encephalopathy* is a central diagnostic criterion for ALF. Among other factors in the brain, neuroinflammation has been shown to significantly contribute to the development of hepatic encephalopathy. Non-invasive evaluation of neuroinflammation is important for strategizing new diagnostic and therapeutic approaches in ALF targeting the brain. Here we utilized Micro Positron Emission Tomography (microPET) with [^{18}F]-Fluoro-2-deoxy-2-D-glucose (^{18}FDG) and ^{11}C-Peripheral Benzodiazepine Receptor ([^{11}C]PBR28) to evaluate brain microglia activation (indicating neuroinflammation) during murine acetaminophen (APAP)-induced acute liver injury. Male C57Bl/6 mice (13-15-week-old) were fasted overnight and injected i.p. with APAP (600 mg/kg) or vehicle (saline). Imaging was performed at 24h and 48h after APAP (n=9) or vehicle (n=8) administration. [^{11}C]PBR28 (~0.5 mCi) was injected via the tail vein followed by 60-min dynamic imaging acquisition and 10-min transmission scan on a Siemens Inveon MicroPET. Subsequently, ^{18}FDG (0.5 mCi) was injected i.p. with a 10 mins static scan acquired following 40 mins uptake. Brain images were reconstructed using 3D-OSEM with attenuation correction and aligned into standard anatomical space using individual^{18}FDG-templates within Pixel-Wise Modeling Software (PMOD 4.0). Statistical analysis was done using Statistical Parametric Mapping. MicroPET analysis revealed no significant differences between the two groups of animals at 24h, although significantly elevated serum aspartate aminotransferase (AST) levels (P=0.0001) following administration of the same APAP dose vs vehicle confirmed the presence of liver injury. At 48h significantly increased [^{11}C]PBR28 binding (P<0.05 vs controls) was determined in the cortex (granular insular cortex), dorsal striatum (caudate putamen), and other brain areas. These brain alterations were associated with significantly increased serum AST levels (P=0.0001) at 48h. In conclusion, these results demonstrate the presence of microglial activation (neuroinflammation) using microPET at 48h after the onset of APAP-induced acute liver injury. These findings support further development of non-invasive PET-based evaluation of neuroinflammation in the context of hepatic encephalopathy in preclinical and clinical settings of acute liver injury and ALF. This study was funded in part by NIH/NIGMS.

Title: Alteration of M1/M2 ratio of microglial cells from the developing brain exposed to perinatal injuries

Authors: *M. MENGUS[1,2], R. IMANE[1], S. TREMBLAY[1,2];
[1]Res. center of CHU SAINTE-JUSTINE, Montréal, QC, Canada; [2]Univ. de Montréal, Montréal, QC, Canada

Abstract: Background: Extreme preterm infants are exposed to multiple inflammatory stressors over their neonatal period including perinatal cerebellar hemorrhage (CBH) and postnatal infection, known as two major risk factors for neurodevelopmental impairments. Given microglia involvement in inflammatory functions across the central nervous system, they may play a central role in the pathogenesis of cerebellar injury in developing brains.
Methods: Conditional transgenic mice dependent on diphtheria toxin intracerebellar injection to deplete *CX3CR1*-positive cells (mononuclear phagocytes including microglial cells) were bred and exposed to CBH at P2 combined or not with early inflammation (LPS). Using this transgenic mouse model allows microglial cells depletion prior to cerebellar insult. Microglia phenotypic changes across time will be analyzed by flow cytometry.
Results: Our preliminary data showed that prior to insult at postnatal day 2, the predominant phenotype of activated microglial cells is M2 pro-repair (48,74% *n*=3-6) compare to M1 pro-inflammatory phenotypes (0,88%; *n*=3-6) analyzed by flow cytometry from whole brain tissue (*n*=8-9). Two weeks after being exposed to diverse perinatal insult combination (postnatal day 15), mouse pups showed a significant change of their M1/M2 ratio compare to controls. We observed an increase of M1 phenotype (7,51%; *n*=4-7) after LPS-exposure compare to controls (1,66%; *n*=4-6). We measured also a significant decrease of activated microglial cells expressing M2 phenotype from all insult groups: LPS (8,90%; *n*=4-7*;**P=0.0025*), CBH-LPS (12,53%, *n*=4-7,***P=0.0025*) and CBH alone (26,30%, *n*=2) compare to controls (35,04%, *n*=4-6).
Conclusions: Perinatal insult exposure lead to changes in M1/M2 ratio from microglial cells over time, which may translate to altered immune responses induced by future stressors exposure.

Title: Transcriptional profile of microglia and neuroinflammatory mediators associated with depressive-like behavior in chronic epileptic rats

Authors: *C. ESPINOSA-GARCIA[1], A. ROJAS[1], G. N. NEIGH[3], L. B. WOOD[4], S. BITARAFAN[4], H. XIAO[2], S. RANGARAJU[2], R. DINGLEDINE[1];
[1]Pharmacol. and Chem. Biol., [2]Neurol., Emory Univ., Atlanta, GA; [3]Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA; [4]Parker H. Petit Inst. for Bioengineering and Biosci., Georgia Inst. of Technol., Atlanta, GA

Abstract: Epilepsy is a chronic neurological disease characterized by recurrent seizures. Epileptic patients frequently develop psychiatric comorbidities such as depression. Depression and epilepsy are associated with elevated brain inflammation, including microglial activation and pro-inflammatory cytokine production. Specific cellular transcriptional and cytokine profiles could provide insight into inflammatory pathways involved in the pathogenesis of epilepsy and comorbid depression. To better understand how seizures cause cellular and molecular changes in the epileptic brain that may lead to depression, we examined transcriptional changes in microglia and inflammatory mediator expression from chronic epileptic rats. **Methods:** Status epilepticus (SE) was induced in adult male rats with pilocarpine (380 mg/kg, s.c.); non-seizure controls received saline. After 60 min, SE was interrupted with diazepam. Depressive-like behavior was assessed by the sucrose preference test (SPT) and the forced swim test (FST) each month after SE. At 6 months after SE, a 24 h-video was recorded to evaluate the intensity of epilepsy measured as the number of spontaneous seizures. Next, rats were deeply anesthetized and perfused with PBS, brains were removed, longitudinally bisected, one hemisphere was used for cellular and molecular analysis and the other for histology and immunohistochemistry. CD11b+ microglia were isolated from cortices using magnetic activated cell sorting (MACS). Microglial gene expression was analyzed with the nCounter Neuroinflammation Panel (nanoString). Neuroinflammatory mediators were measured in cortical homogenates using a multiplexed Luminex assay. Ventricle enlargement was quantified in Nissl-stained coronal sections using the NanoZoomer slide scanner. Iba1 and GFAP markers were used to assess glial activation. **Results:** Transcriptomic analysis revealed alterations in expression of several genes, upregulation of complement C3 was the most relevant change in microglia isolated from SE rats. The chemokine RANTES was upregulated in cortical homogenates from SE rats compared to controls. SE rats displayed a persistent lower sucrose consumption, indicative of anhedonia. No differences were observed in FST immobility time. Among the 16 pilocarpine-treated rats, at least ten had one or more spontaneous seizures. Several SE rats exhibited enlarged lateral ventricles, indicating severe neuronal loss. Iba1 was upregulated in hippocampal CA3. Our findings confirm activated microglia and neuroinflammation persist in the chronic phase of the disease, and suggest potential therapeutic targets for epilepsy and comorbid depression.

Title: Decoding hand, wrist, and forearm movements using a wearable neural interface in chronic stroke survivors.

Authors: *E. MEYERS[1], D. GABRIELI[1], L. WENGERD[2], N. TACCA[1], M. DARROW[1], D. FRIEDENBERG[1];
[1]Battelle Mem. Inst., Columbus, OH; [2]Ohio State Univ., Columbus, OH

Abstract: Prosthetics and orthotics have been recognized for decades as a potential means to restore hand function and independence to individuals living with impairment due to stroke. However, current practices are insufficient, and the majority of stroke survivors are left with long-term dysfunction of the arm and hand. A promising method for controlling upper limb assistive devices is to infer movement intention from muscle activity using electromyography (EMG). Here, we present a wearable neural interface called the NeuroLife® Sleeve which is like a compression sleeve worn on the forearm with embedded electrodes to record high-resolution surface EMG. In this IRB-approved study, we recorded EMG activity using the sleeve in eight chronic stroke survivors (less than 6 months after stroke) with a range of upper extremity motor impairment (Upper Extremity Fugl-Meyer: 7-38). In the study sessions, participants followed along with cues on a computer monitor and attempted 12 hand, wrist, and forearm movements during three separate 2-hour sessions. We demonstrate decoding of 12 movements, including multiple functional grasps, with an overall accuracy of 82% in simulated real-time situations. Furthermore, we present feedback from stroke survivors who tested the system which highlights the user-centric design of the sleeve, including being simple to don and doff, comfortable, portable, and lightweight. Lastly, the sleeve is in a form factor such that it can be used in the home without an expert technician, can be donned by a user or caretaker, and can be worn comfortably for multiple hours. Taken together, the NeuroLife Sleeve represents a platform technology to record and decode forearm muscle activity for the eventual control of assistive devices in a form-factor designed to meet user needs. Disclaimer: This is an investigational device, it's not commercially available, and it has not been cleared or approved by the FDA. Results discussed are from research studies performed.

Title: Global Network Structure Deficits Persist in Forearm Surface Electromyography Graphs of Chronic Stroke Survivors

Authors: *D. GABRIELI, E. MEYERS, M. DARROW, L. WENGERD, D. FRIEDENBERG; Battelle Mem. Inst., Columbus, OH

Abstract: Stroke is one of the leading causes of long-term disability and can result in lasting cognitive and motor impairment. Emerging technologies utilizing high-density surface electromyography (EMG) have shown great promise in non-invasively quantifying differences in neuro-muscular activation. However, these technologies have been limited by hardware ease-of-use and frameworks to assess the muscular coordination for functional motion. Here we utilize the Battelle Neurolife® Sleeve, a 160-electrode wearable garment, to assess the EMG activity of six chronic stroke participants with limited hand function (1-6 on Chedoke-McMaster Stroke Assessment hand subscale) while attempting functional movements of the hand, fingers, and wrist. We build movement specific, functional network graphs between EMG electrodes located across the forearm and assess the differences between stroke subjects and a set of able-body controls. We find that both global efficiency and local clustering metrics are altered in stroke subjects, compared to able body controls. Additionally, network metrics were indicative of the level of impairment, with greater deficits shown in subjects with moderate or severe hand impairment when compared to mild-impairment or able body subjects. Our research indicates that topological differences assessed through complex network theory can provide a novel, quantifiable assessment for neuro-muscular coordination deficits in subjects with chronic stroke.

Title: Battelle | Efficient Mapping of Motor Points Using a High-Density Electrode Array

Authors: *I. W. BAUMGART, C. F. DUNLAP, S. COLACHIS, IV, L. WENGERD, M. DARROW, E. MEYERS;
Battelle Mem. Inst., Ohio, OH

Abstract: Functional electrical stimulation (FES) has been shown to facilitate the recovery of motor function following spinal cord injury and stroke by promoting neuroplasticity and reducing spasticity. FES is standardly administered at motor points (MPs), which are points on the skin surface where the current applied to achieve muscle contraction is minimized. Although muscle contraction can be achieved by placing stimulating electrodes in many configurations over the muscle of interest, electrodes placed over MPs can decrease the current necessary to achieve contraction, decrease discomfort, and decrease fatigue. The location of MPs has been described in literature, but identification in the clinic can be difficult and time consuming, especially when trying to identify motor points for many functional movements. Here, we present a method for the efficient identification of motor points for multiple functional movements using machine learning techniques and Battelle's high-density electrode array sleeve. We first reduce the dimensionality of the problem by using "region of interest" electrodes constituting deformable clusters of electrodes in the high-density array. We then use machine learning techniques such as genetic algorithms and Bayesian optimization to identify and map MPs. We show that this method reduces the overall calibration time of multiple functional movements compared to trained manual calibration. We also evaluate the consistency of these calibrations between subjects and between sessions with the same subject. Finally, we discuss the challenges in using this automated approach in stroke populations.

Title: Maximizing Hand Function of Chronic Stroke Survivors Using a Low Profile Functional Electrical Stimulation Sleeve

Authors: *L. WENGERD, E. MEYERS, M. DARROW, D. FRIEDENBERG;
Battelle Mem. Inst., Columbus, OH

Abstract: The inability to grasp and manipulate objects is a common outcome of stroke that results in devastating effects on functional independence and quality of life. Functional electrical stimulation (FES) has proven to be an effective rehabilitation tool to decrease motor impairment in adult stroke survivors, yet current systems are limited in usability and functionality. Here, we present the NeuroLife® Sleeve, a breakthrough technology that addresses the shortcomings of current FES systems to restore hand and forearm function to adult stroke survivors. NeuroLife is a low-profile orthosis, comparable to a compression sleeve, with 160 high-definition electrodes and a portable stimulator to stimulate forearm muscles and evoke finger, wrist, and hand movements during functional activities. In this IRB-approved research study, we used the sleeve to elicit various functional hand movements in three chronic stroke survivors (>6 months) with moderate-to-severe motor impairment (Upper Extremity Fugl-Meyer Assessment: 19-31) limiting their ability to complete functional tasks. Each participant wore the NeuroLife Sleeve to provide stimulation as they attempted various hand, wrist, and forearm movements. Participants showed a significant improvement in carrying out functional hand movements, as demonstrated by the ability to grasp and release objects and improvement in clinical assessment scores. One participant demonstrated a decrease in time completing a portion of the 9-Hole-Peg Test from 2 minutes and 42 seconds down to 19 seconds (an ~850% improvement), while another improved his score on the Action Research Arm Test (ARAT) by 6 points in one session (MCID: 5.7 points). Our research indicates the feasibility of the NeuroLife Sleeve as a rehabilitation tool or functional orthosis to maximize functional independence of adult stroke survivor with upper extremity motor impairment. © 2021 Battelle Memorial Institute. Title: Ultraflexible Neural-Thread enabled chronic quantification of neurovascular coupling in a mouse stroke model

Authors: *H. RATHORE[1,2,3], F. HE[1], B. NOBLE[2,1], L. LUAN[3,2,1];
[1]Rice Neuroengineering Initiative, Rice Univ., Houston, TX; [2]Applied Physics, Applied Physics Grad. Program, Smalley-Curl Institute, Rice Univ., Houston, TX; [3]Electrical and Computer Engin., Dept. of Electrical and Computer Engineering, Rice Univ., Houston, TX

Abstract: Neurovascular coupling (NVC), the close spatial and temporal relationship between neural activity and hemodynamics, has a central role of regulating the cerebral blood flow and maintaining normal brain function. However, the quantitative relationship between changes in hemodynamics and neural activity, particularly the spatiotemporal variations within the evoked brain region, remains murky. More importantly,although a broad spectrum of neurological and cerebrovascular diseases are known to affect neurovascular coupling, the changes In the coupling function and its longitudinal time evolution with the progression of the disorder remains largely unknown. Here, we integrate large-scale ultra-flexible Neural-Threads (NET) with functional optical imaging for simultaneous mapping of laminar neural activity at multiple locations, cerebral blood flow, and oxygenation. This novel multimodal neural platform enables quantification and spatiotemporal tracking of NVC over chronic periods. Using mouse models and whisker stimulation paradigms, we determine the cortical-depth specific NVC transfer function in normal brain states and how the functional form changes with time and location after artery-targeted strokes. The results reveal the pathological evolutions of neurovascular interaction after stroke and helps further our understanding on the interpretation of neuroimaging techniques that infer neural activity from hemodynamic responses.

Title: Immediate effect of stretching spastic elbow under Intelligent control for stroke survivors

Authors: *S. RAO[1], M. HUANG[1], S. G. CHUNG[2], *L.-Q. ZHANG[1];
[1]Univ. of Maryland, Baltimore, MD; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Upper limb problems, including muscle spasticity, contracture, and weakness, are common after stroke. Elbow joint is one of the frequently and chronically affected structures with a manifestation of reduced range of motion (ROM) and weakness, which significantly impacts activities of daily living. Therefore, management of upper limb motor impairment has been identified as a top priority by stroke survivors, caregivers, and clinicians. The purpose of this study was to assess the immediate effects of strenuous dynamic stretching of elbow joint performed with help of an intelligent stretching device in chronic spastic stroke survivors. The intelligent stretching device could provide intensive and repetitive stretching to the spastic elbow

joint in sagittal plane (i.e., flexion and extension) to its extreme positions safely, with control of the stretching velocity and resistance torque to increase ROM, reduce spasticity and joint stiffness. Eight chronic stroke survivors (52.6±8.2 years old, 5 males/3 females) completed a single hourly intervention session. Elbow passive and active ROM, strength, passive stiffness (quantifying the non-reflex component of spasticity) and instrumented biceps tendon tapping test (quantifying the reflex component of the spasticity) were measured before- and after-stretching. Post stretching, there was a significant increase in active ROM of elbow flexion($p=0.021$) and extension ROM($p=0.026$). Also, elbow AROM and the spastic elbow flexors showed a trend of an increase in their strength. The intelligent stretching had a short-term positive influence on the passive movement ROM. Thereby may potentially be used to stretch spastic elbow joints repeatedly and regularly and subsequently help reduce upper limb impairments post stroke.

Title: Evaluation of objective methods for measuring ipsilateral motor potentials evoked by transcranial magnetic stimulation in stroke survivors with severe upper limb paresis

Authors: *A. MOHAN[1], X. LI[1], E. B. PLOW[1], J. S. KNUTSON[2], M. WIDINA[1], B. ZHANG[3], D. A. CUNNINGHAM[2];
[1]Biomed. Engin., Lerner Res. Inst., Cleveland, OH; [2]MetroHealth Rehabil. Inst., Cleveland, OH; [3]Case Western Reserve Univ., Cleveland, OH

Abstract: Introduction: Ipsilateral motor evoked potentials (iMEPs) elicited using transcranial magnetic stimulation (TMS) are often used to measure excitability of (uncrossed) ipsilateral pathways to paretic muscles. Evidence indicates ipsilateral pathways may serve as alternate resources to support recovery in stroke survivors lacking sufficient (crossed) ipsilesional substrate. However, there are no widely accepted methods for defining the presence or absence of iMEPs. Both manual and semi-automatic (objective) methods are used in the literature without clear, common guidelines. Here, we investigate the percent agreement of published objective methods against the manual method. A high agreement between the objective and manual methods would provide precision to the manual methods and could minimize the time and

human effort required for the analysis.Methods: Six chronic stroke survivors with severe upper limb hemiplegia (Upper Extremity Fugl-Meyer (UEFM) median = 18, range = 2.75), characterized by lack of 10-degree extension in wrist and fingers, underwent iMEP testing using TMS. IMEPs were collected from the paretic biceps brachii (BB) by delivering suprathreshold TMS (30-40 pulses) to contralesional motor areas. Participants were asked to maximally contract the paretic BB and the non-paretic triceps brachii simultaneously while turning their neck to the paretic side, a method that elicits more and larger iMEPs. Two experienced investigators subjectively measured the presence and absence of iMEPs (manual method), which involved identifying an MEP waveform in the ipsilateral biceps muscle 3-10ms after the appearance of an MEP waveform in the contralateral (non-paretic) biceps muscle. Seven objective methods based on standard deviation (SD) and mean consecutive differences (MCD) were used to measure the presence or absence of iMEPs. Reliability (percent agreement) of the objective methods was compared against the manual method.Results: Percent agreement of iMEP presence or absence between the two raters was 87.3%, indicating strong agreement. Of the objective methods, iMEP detection using criterion threshold of background mean electromyography (EMG) + 1SD and background mean EMG + 2SD yielded the best percent agreement with the manual method (73.3% and 70.9% respectively), indicating moderate agreement.Discussion: There is room for improvement for current objective methods to meet the percent agreement based on the manual method. Future work to improve the objective method (e.g., patient-specific feature detection and optimization) are being explored.

Title: Determining the influence of movement speed and distance on the accuracy of upper limb proprioceptive estimates

Authors: *D. T. TULIMIERI, J. A. SEMRAU;
Kinesiology and Applied Physiol., Univ. of Delaware, Newark, DE

Abstract: Intact proprioception is required for accurate movement of the upper limbs. Compared to motor function, little is known about the effects of stroke on proprioception. This is because

current clinical assessments largely fail to directly assess proprioception. Recently, to mitigate this problem, robotic tools have been implemented to objectively measure proprioception. Previously, we have found that ~60% of individuals with stroke have impaired proprioception. Here, we build upon previous work to determine the influence of perceived movement characteristics on the estimation of proprioceptive information for upper limb movements. We hypothesized that proprioceptive accuracy will decrease as a function of parameter magnitude from a "typical" reaching movement, and that these effects will be amplified as a function of age and/or neurologic injury (i.e., stroke). Twenty-nine controls (N=20 young adults, N=9 older adults) and 3 stroke participants performed a bi-manual proprioceptive matching task. Here, the robot passively moved one of the participants arms (passive arm) and they were instructed to mirror-match the speed, length, and direction of movement with the opposite arm (active arm). Each robotic movement was defined by two parameters, speed and length. We assessed movements at 7 speeds (0.1-0.4m/s) and 5 distances (7.5-17.5cm). Participants completed 10 trials per combination, for a total of 350 trials. We determined proprioceptive accuracy using previously validated measures of position sense and kinesthesia including Initial Direction Error (IDE) and Peak Speed Ratio (PSR). IDE was defined as the angular deviation between the passive and active movements. PSR was defined as peak speed of the active arm divided by peak speed of the passive arm. Preliminary results demonstrated that proprioceptive errors significantly increased in older adults and stroke participants. Within groups, we found that these errors scaled as a function of movement speed and/or length for multiple parameters. We observed similar linear trends for the three groups, where IDE increased and PSR decreased with movement speed, and IDE decreased and PSR increased with movement distance. Notably, we observed that both age and stroke had an effect on the overall level of IDE and PLR accuracy, with stroke participants displaying the highest level of proprioceptive errors. Our results suggest that the characteristics of the reference movements used in a proprioceptive task (here, speed and distance) can influence the overall level of perceptual accuracy. Further, these difference in error are likely magnified in older individuals and individuals with stroke.

Title: Stroke related changes in spinal reflex of multiple forearm muscles using high-density electromyography

Authors: *E. BEDOY[1], K. LEITHOLF[1], E. CARRANZA[1], E. GUIROLA[1], N. VERMA[3], I. LEVY[1], G. F. WITTENBERG[2], E. PIRONDINI[1], D. J. WEBER[3];
[2]Neurol., [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Muscles work in coordination and are recruited differentially depending on the task being performed. These muscle activation patterns are thought to be encoded in the spinal cord. Stroke often produces clear changes in the function of spinal cord circuits, including reflexes, despite the injury being in the brain. Because the spinal cord is not directly injured by stroke, there is the possibility of some level of motor recovery by reversing the changes that occur in the spinal circuit. Therapy for motor control may be improved by having a better understanding of how the spinal circuit changes after neurological injury. We developed a non-invasive approach to test for stroke-induced changes in the spinal circuit by electrically stimulating peripheral nerves to measure reflex responses in forearm muscles. The electrical activity of activated muscles was measured by multiple high-density electromyography (HD-EMG) electrodes to capture the pattern of co-recruitment across multiple muscles. The subjects maintained hand postures used for functional tasks (i.e. power grip, hand opening) to facilitate spinal reflexes in muscles that are recruited preferentially for each task. The study was repeated for both forearms of able-bodied volunteers and stroke patients for comparison. We hypothesized that H-reflexes in extensor muscles will either be absent or the ratio of flexor/extensor H-reflex size will be increased significantly in the affected arm compared to the unaffected arm of stroke patients and both arms of able-bodied subjects during hand opening. We also hypothesized that larger ratios or absence of extensor reflexes are correlated with lower Fugl-Meyer scores and hand opening force. Finally, we hypothesized that H-reflexes in the flexor forearm muscles will be absent or significantly smaller in the affected arm compared to the unaffected arm of stroke patients and both arms of able-bodied subjects during power grip and that these results are negatively correlated with Fugl-Meyer scores. The results give us insight into the spinal circuit of stroke patients with motor impairment. Future work can investigate how to utilize spinal reflex recruitment patterns for personalized motor rehabilitation using electric stimulation targeting the spinal cord, peripheral nerves or muscles directly.

Title: An Integrated Augmented Reality (AR) Encephalography (EEG) System for Detecting and Measuring Post-Stroke Spatial Neglect

Authors: *J. MAK[1], D. KOCANAOGULLARI[2], X. HUANG[5], M. SHIH[3], E. S. GRATTAN[3], E. SKIDMORE[3], G. WITTENBERG[4], S. OSTADABBAS[5], M. AKCAKAYA[2];
[1]Bioengineering, [2]Electrical and Computer Engin., [3]Occup. Therapy, [4]Neurol., Univ. of Pittsburgh, Pittsburgh, PA; [5]Electrical and Computer Engin., Northeastern Univ., Boston, MA

Abstract: Visual spatial neglect (SN) is a post-stroke syndrome that manifests as inattention to contralesional stimuli. Current clinical assessments such as the Behavioral Inattention Test (BIT) consists of simple pen-and-paper tests that do not adequately capture the extent or severity of SN, account for compensatory body movements, or yield consistent results. Our overall goal is to develop an objective method to detect and assess SN. To achieve this, we have developed a system that integrates augmented reality (AR) with electroencephalography (EEG) system for SN detection and measurement. In this setup, the displayed task follows the user's head movements and can be easily adaptable for rehabilitative purposes. We have implemented two computerized versions of the Starry Night Test for the Microsoft Hololens AR headset: a Clicker-Based Assessment to measure the ground-truth field-of-view (FOV) via reaction times to visual targets appearing among distractors, and an EEG-Based Assessment to evaluate the neural response to those targets using 14 electrodes. Five patients with SN and five without SN (WSN), identified using BIT scores (five male, five female, ages 27 to 80), performed the Clicker-Based Assessment followed by the EEG-Based Assessment. In this preliminary exploratory analysis, we first aimed to identify spectral features for optimal neglect detection. Reaction times from the clicker assessment were divided into fast and slow responses. A power ratio was calculated for five frequency bands (delta (0-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), beta (13-30 Hz), and gamma (30-45 Hz)) for each response as the power in the 400ms post-stimulus over that in the 200ms pre-stimulus. Two-way ANOVAs with Tukey HSD post-hoc tests of the power ratios of the fast responses at each electrode found statistically significant differences between SN and WSN groups primarily in the frontoparietal regions in the theta, alpha, and beta frequencies. Furthermore, a logistic regression analysis of the fast responses found that the right frontoparietal electrodes in the alpha band were most informative for separating SN from WSN. Similar analysis using the slow responses did not reveal significant results, suggesting that fast responses offer more information for class separation. Next, we estimated the FOV by classifying targets as fast or slow with common spatial pattern with linear discriminant analysis. For each participant, cross validation was conducted in estimating individual FOVs, resulting in high accuracies for all participants. These early results suggest that our system may be able to accurately detect and measure the extent of SN.

Ctr., Boston, MA

Abstract: Introduction. In chronic pain, a positive patient-clinician relationship is associated with higher patient satisfaction and treatment efficacy. In this study, we investigated brain-to-brain connectivity between patients and clinicians during an experimentally controlled augmented (empathetic) compared to limited (business-like) clinical interaction and assessed whether the context contributes to chronic pain relief and analgesia. **Methods.** We recorded simultaneous EEG (hyperscanning, 18 dyads, 64 channels each subject) from low back pain patients and acupuncturists during an evoked pain task with treatment and no-treatment trials. Brain data were reconstructed (algorithm eLORETA) on 17 Regions of Interest defined by our previous fMRI study (Ellingsen et al. 2020) and directed statistical connectivity networks were obtained by comparing Granger Causality-based estimates for treatment and no-treatment, separately for the augmented and limited group. **Results.** Patients in the augmented group, compared to the limited group, rated therapeutic alliance and clinician warmth significantly higher (Fig 1a). Pain intensity decreased after the treatment, irrespective of clinical context (Fig 1b). EEG analysis suggested that in Theta band (linked with empathy for pain in prior studies), inter-brain network density within social mirroring and pain/sensorimotor brain regions was altered when clinician treated evoked pain. The number of significant clinician-to-patient connections was higher in the no-treatment condition, while the number of patient-to-clinician connections were greater during treatment (Fig 1c). **Conclusion.** Both behavioral and brain-to-brain response across the patient/clinician dyad reflect clinical interaction context. Using an EEG hyperscanning approach we were able to identify inter-brain networks whose density and

directionality were modulated by the clinical context and by the presence of the pain treatment, highlighting new brain mechanisms underlying therapeutic alliance in chronic pain therapy.

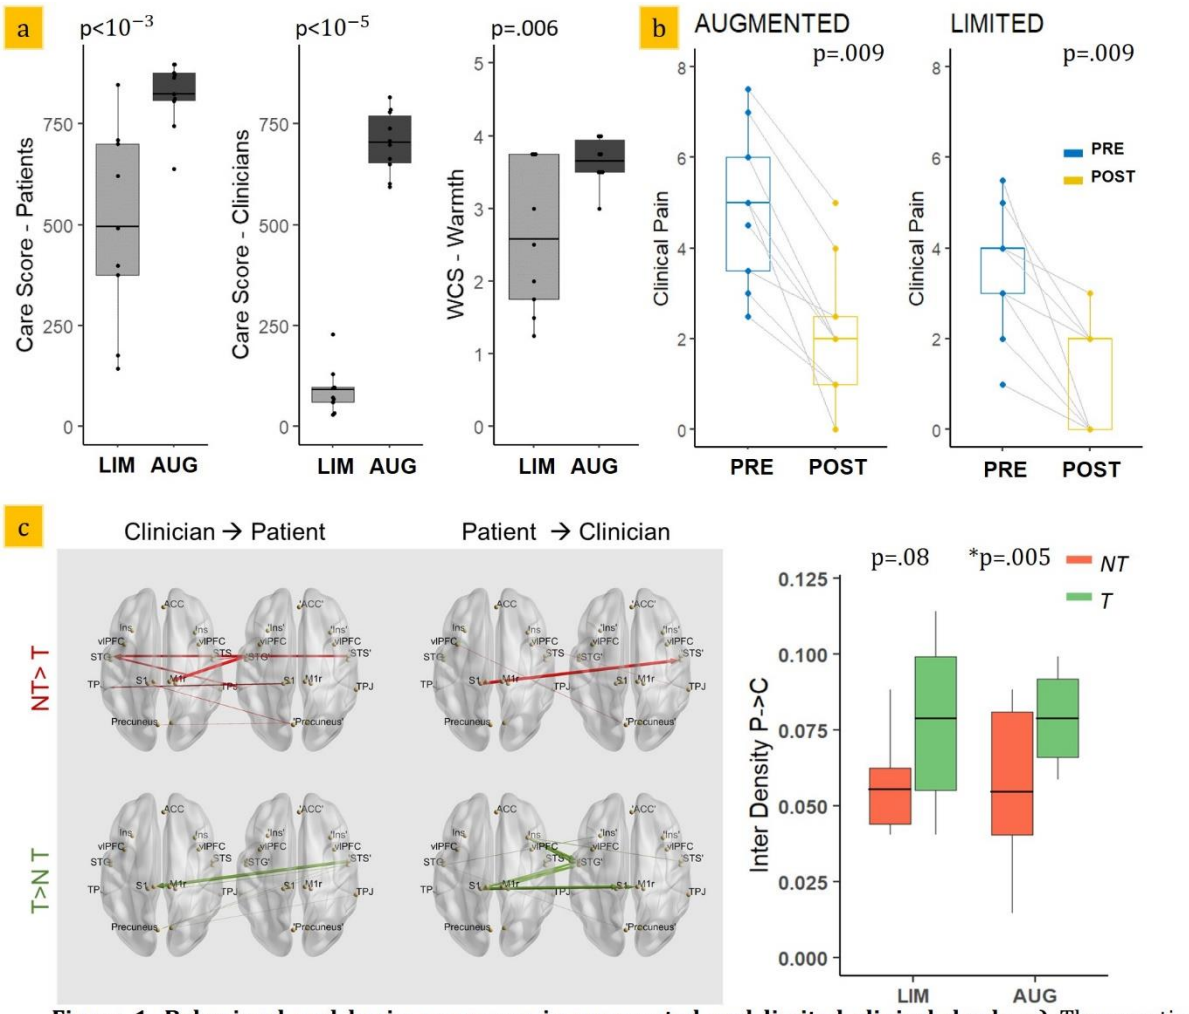

Figure 1. Behavioral and brain responses in augmented and limited clinical dyads. a) Therapeutic alliance (CARE score) and perceived warmth were rated as higher in the augmented group compared to the limited. **b)** Clinical pain assessed before (PRE) and after (POST) low back pain treatment significantly decreased regardless of the clinical context. **c)** Inter-brain network obtained from EEG data in Theta band. The number of connections directed from the clinician to the patient was higher when the clinician was forced to watch the patient in pain with no treatment (NT). In contrast, the number of inter-brain connections from patient to clinician was higher during the treatment trials (T).

Abstract: Isolated rapid eye movement (REM) sleep behavior disorder (iRBD) is a prodromal stage of Parkinsonism characterized by abnormal behaviors and loss of normal muscle atonia during REM sleep. Most iRBD subjects develop Parkinson's disease (PD) or dementia with Lewy bodies (DLB) with a median conversion time of 7 years. At PD onset, 30 to 60% of the dopaminergic neurons in the substantia nigra pars compacta (SNc) are already lost. These SNc neurons contain neuromelanin (NM) that can be detected using NM-sensitive magnetic resonance imaging (MRI).
In this study, we investigated the SNc NM neurodegeneration in iRBD, compared to PD patients and healthy volunteers (HV).
Participants were scanned at 3T MRI using 3D T1-w and NM images as part of the ICEBERG study (ClinicalTrials.gov: NCT02305147). Two experts performed SNc manual segmentations. Automatic SNc segmentations were performed using our proposed artificial intelligence (AI) framework, NigraNet that is a modified U-net architecture. NigraNet was trained on 54, validated on 6, and tested on the remaining 186 images. SNc volumes (Vol), corrected volume (C_{vol}=Vol/total intracranial volume) to normalize for the head size, signal-to-noise ratio, and contrast-to-noise ratio were obtained. A one-way general linear model analysis of variance adjusted for age and sex and post-hoc t-tests were performed. Receiver operating characteristic (ROC) analysis was computed for the diagnostic performance. Dice similarity coefficient was computed to compare the NigraNet and manual segmentations.
We analyzed 246 participants including 47 iRBD (MDS UPDRS OFF score: 11.7 ± 6.5), 144 PD (MDS UPDRS OFF score: 29.6 ± 7.9, disease duration: 1.5 ± 1.0 years) and 55 HV (MDS

UPDRS OFF score: 5.6 ± 5.3).We demonstrated that all the NM-based SNc measurements significantly differed between the three groups with C_{vol} of 0.16 ± 0.04 for iRBD, 0.14 ± 0.04 for PD, and 0.20 ± 0.04 for HV ($p<0.001$). We obtained significantly lower values in PD than in both iRBD and HV, and in iRBD than in HV except for SNR that did not differ between iRBD and HV. Using NigraNet, ROC analyses allowed differentiating iRBD and HV using C_{vol} with areas under the curve (AUC) of 0.79 and differentiating PD and HV using C_{vol} with AUC of 0.85. The SNc Manual segmentation results were also similar. There was high reproducibility with a DICE of 0.80 between NigraNet and manual SNc segmentations.
We demonstrated reduced neuromelanin content in iRBD with changes being at an intermediate level between values in HV and PD patients. Hence, NM MRI, coupled with our fast and user-independent NigraNet, has the potential to be the future biomarker for clinical trials of disease-modifying treatments.

Title: Linking day-to-day fluctuations in chronic pain to neural correlates of pain anticipation and clinical outcomes of cognitive behavioral therapy

Authors: *M. BARTON-ZUCKERMAN[1], A. GRAHL[1], A. LAZARIDOU[2], M. PASCHALI[2], J. LEE[1], M. BERRY[1], L. ISARO[2], A. ANZOLIN[1], K. ISENBURG[1], R. EDWARDS[2], V. NAPADOW[1];
[1]Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA; [2]Pain Mgmt. Center, Brigham and Women's Hosp., Chesnut Hill, MA

Abstract: Previous studies suggest that greater day-to-day fluctuations in clinical pain predict better outcomes following interventions. Specifically, patients with greater fluctuations in pain at baseline experience greater placebo effects. However, the neural correlates of this phenomenon are largely unknown. In this longitudinal neuroimaging study, we assessed the influence of daily reported pain variability on brain response to nociceptive stimuli and clinical outcomes following behavioral therapy. Female fibromyalgia (FM, N=78) patients used a diary to report average daily pain severity for seven days before and after an 8-week intervention of cognitive behavioral therapy (CBT, N=49) or a matched education control intervention (EDU, N=29). Pain fluctuation was calculated using the standard deviation of all diary entries completed before intervention for each subject. Before the intervention, patients also completed an evoked pressure pain paradigm during whole-brain fMRI (Siemens 3T MRI, TR/TE=1250/33ms, voxel size 2mm3 isotropic, SMS MB acc. factor 5). This included six cuff stimulations of either non- or moderately painful pressures (calibrated to a 0 or 40 out of 100 intensity on a visual analogue scale). Clinical outcomes included the Pain Catastrophizing Scale (PCS), a specific target of CBT. We found that greater day-to-day clinical pain fluctuations at baseline were associated with lower ratings of evoked pressure pain during the MRI ($r = -0.23$, $p = 0.049$). Additionally, greater day-to-day clinical pain fluctuations were also associated with greater post-therapy improvement in pain catastrophizing for the CBT group (Mean = -7.5, SD = 8.2, $r = -0.32$, $p = 0.02$) but not education control (Mean = -5.2, SD = 9.6, $r = 0.29$, $p = 0.17$). Furthermore, greater day-to-day clinical pain fluctuations were negatively correlated with BOLD fMRI responses during the anticipation period prior to evoked pressure in the CBT+EDU sample. Specifically, this association was seen in several nociception-processing areas (e.g., primary sensory cortex, insula, and cerebellum). Our results support previous literature which suggests that greater clinical pain fluctuations may boost clinical treatment effects by influencing expectations of pain. This highlights the potential predictive importance of assessing daily diaries for chronic pain characterization and suggests that greater fluctuations in pain may reflect a more malleable pain experience leading to optimistic expectations during pain processing and better clinical outcomes.

Title: Fmri hyperscanning in chronic pain: neural and behavioral correlates of the patient-clinician relationship

Authors: *A. GRAHL[1], A. ANZOLIN[1], M. BARTON-ZUCKERMAN[1], K. ISENBURG[1], J. LEE[1], D.-M. ELLINGSEN[2,1], C. JUNG[1,3], J. GERBER[1], J. KELLEY[4,5], I. KIRSCH[5], T. KAPTCHUK[5], V. NAPADOW[1,6,7];
[1]Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Boston, MA; [2]Dept. of Psychology, Univ. of Oslo, Oslo, Norway; [3]KM Fundamental Res. Div., Korea Inst. of Oriental Med., Daejeon, Korea, Republic of; [4]Endicott Col., Beverly, MA; [5]Program in Placebo Studies & Therapeut. Encounter (PiPS), Harvard Med. Sch., Boston, MA; [6]Dept. of Radiology, Logan Univ., Chesterfield, MO; [7]Dept. of Anesthesiol., Brigham and Women's Hosp., Boston, MA

Abstract: The quality of a clinical encounter is fundamental to shape patients' trust and build a collaborative relationship. Using synchronized real-time dual-brain approaches, insights into the patient's neural activity paired with the clinician's cognitive processes elucidate modulators of the patient-doctor relationship. Previous research suggests that a warm-empathic (*Augmented*) compared to a neutral, business-like (*Limited*) patient-clinician relationship can improve clinical outcomes. This longitudinal hyperscan fMRI study evaluates the influence of the clinical relationship on a course of therapy for chronic pain patients, and includes behavioral, neural, and clinical outcomes. FMRI hyperscanning and an evoked pressure pain-treatment-paradigm was applied. Seventeen women with fibromyalgia (mean age=41.41, SD=12.20), randomly assigned to either an *Augmented* (N=8) or a *Limited* (N=9) patient-clinician dyadic interaction style (trained acupuncturists), were scanned (2 synchronized Siemens 3T MRI scanners; TR/TE=1250/33ms; SMS MB acc. factor 5; voxel size $2mm^3$; 2x358 volumes) before and after 6 biweekly electro-acupuncture (EA) treatment sessions. Moderately painful cuff pressures, either treated or not treated with EA (8 trials each) by the acupuncturist, were applied to patients' left leg. Importantly, patients and clinicians were able to interact via a live video connection while being scanned simultaneously. The quality of the patient-clinician relationship and clinical outcomes were assessed (e.g. therapeutic alliance – THA, warmth – W, pain catastrophizing – PCS). As rated by patients, pooled therapeutic alliance and clinicians' warmth in the *Augmented* group ($mean_{THA}$=43.21, SD=2.40; $mean_{W}$=4.00, SD=0.0) were significantly higher than in the *Limited* group ($mean_{THA}$=22.79, SD=13.15; $mean_{W}$=2.54, SD=1.10; $t_{THA}(15)=4.31$, $p<0.001$; $t_{W}(15)=3.74$; $p=0.002$). PCS was significantly reduced after the intervention ($t(15)=3.79$; $p=0.002$) in the A*ugmented* (Δ-7.88) but not the *Limited* group (Δ1.44). Brain imaging analysis focused on social mirroring areas such as the temporo-parietal junction. Future analyses will link clinical outcomes and therapeutic alliance differences between the groups with brain and behavioral concordance metrics. Our preliminary results are highlighting the importance of investigating variable interaction quality during longitudinal clinical therapies and its influence on clinical outcomes and brain processing of nociceptive signaling. Hopefully, the results will inform future chronic pain treatment approaches how to harness the positive effects of the patient-clinician relationship.

Title: Imaging Cortical Circuitry During General Anesthesia-Induced Analgesia

Authors: *J. A. P. WEINRICH[1], C. LIU[1], C. ANDOLINA[1], M. E. JEWELL[2], M. BERNSTEIN[1], A. I. BASBAUM[1];
[1]Anat., UCSF, San Francisco, CA; [2]Anat., Univ. of California San Francisco, San Francisco, CA

Abstract: INTRODUCTION: Many volatile general anesthetics (VGA) block the experience of pain by inducing unconsciousness, however, a select few can provide analgesia in conscious, responsive patients. Despite advances in our understanding of the effects of general anesthetics on regional measures of brain activity (fMRI, EEG), little is known about the mechanisms through which VGAs produce analgesia. In the present studies in the mouse, we investigated the influence of non-analgesic (isoflurane) and analgesic (nitrous oxide) anesthetics on the activity of neurons in the anterior cingulate cortex (ACC), a region that encodes affective/emotional features of the pain experience. Our objective is to uncover the neural circuit mechanisms through which general anesthetics alter the perception of pain. **METHODS:** In adult mice, we monitored the spontaneous activity of hundreds of individual ACC neurons before, during, and after the inhalation of isoflurane or nitrous oxide. To visualize neural activity, we used virally delivered genetically encoded fluorescent reporters of neural activity (GCaMP6f) expressed ubiquitously or within molecularly distinct neural subtypes. Changes in GCaMP6f fluorescence were captured via Inscopix miniscopes. **RESULTS:** Consistent with previous studies demonstrating that the global activity of the cerebral cortex is decreased during general anesthesia, we find that the rate of spontaneous neural activity decreases with increasing concentrations of isoflurane. Surprisingly, and in sharp contrast, during inhalation of nitrous oxide, we observed a significant increase in spontaneous activity of ACC neurons. Additionally, after dissecting the effects of general anesthetics on functionally distinct neurons within the ACC (i.e., excitatory vs subtypes of GABAergic inhibitory neurons), we demonstrate that inhibitory

interneurons exhibit increased susceptibility to isoflurane, while nitrous oxide preferentially increases activity in excitatory neurons. **CONCLUSIONS:** We conclude that non-analgesic and analgesic general anesthetics differentially alter neural activity in the ACC, a region of the brain that is a major contributor to the pain percept. In both patients and animals, decreases in ACC activity are generally associated with analgesia. Therefore, our finding that nitrous oxide, an analgesic, increased ACC activity, and that isoflurane, which is non-analgesic, decreases ACC activity, was unexpected. Our findings suggest that the analgesic potential of a general anesthetic results from the preferential modulation of the activity of particular subtypes of neurons rather than an overall reduction of neural activity.

Title: Stay or go? Neuronal activity in medial frontal cortex during a voluntary tactile preference task in head-fixed mice.

Authors: *A. KEYES, Y.-C. KIM, P. BOSCH, Y. USACHEV, G. ALDRIDGE;
Univ. of Iowa, Iowa City, IA

Abstract: The decision to move is influenced by sensory, attentional, and motivational cues. One such cue is the quality of the tactile input, with noxious or unpleasant sensations causing an animal to move away from the cue. Processing of painful and unpleasant sensation in the cortex involves multiple brain regions, although the specific role of the brain areas involved in voluntary, rather than reflexive movement away from unpleasant stimuli is not well understood. Here, we focused on the medial subdivision of secondary motor cortex, which is proposed to link sensory and contextual cues to motor action, and tested its role in controlling voluntary movement in the context of an aversive tactile cue. We designed a novel, 3D-printed tactile platform consisting of innocuous (grid) and mildly noxious (spiked) surfaces (50:50 % of total area), which enabled monitoring neuronal activity in the medial frontal cortex by two-photon

imaging during a sensory preference task in head-fixed mice. We found that freely moving mice spent significantly less time on a spiked-surface, and that this preference was eliminated by administration of a local anesthetic. At the neuronal level, individual neurons were differentially modulated specific to the tactile surface encountered. At the population level, the neuronal activity was analyzed in relation to the events where mice chose to “stop-on” or “go-from” a specific tactile surface and when they “switched” surfaces without stopping. Notably, each of these three scenarios showed population activity that differed significantly between the grid and spiked tactile surfaces. Collectively, these data provide evidence that tactile quality is encoded within medial frontal cortex. The task pioneered in this study provides a valuable tool to better evaluate mouse models of nociception and pain, using a voluntary task that allows simultaneous recording of preference and choice.

Title: Evaluation of hippocampal subfields volume relationship to disability, catastrophizing and anxiety in chronic low back pain patients

Authors: *M. SEAN[1,2,4], G. LÉONARD[3,5], P. TÉTREAULT[1,2,4];
[2]Anesthesiol., [3]Sch. of rehabilitation, [1]Univ. de Sherbrooke, Sherbrooke, QC, Canada; [4]Med. Imaging Axis, Ctr. de Recherche du CHUS, Sherbrooke, QC, Canada; [5]Axe autonomisation, Ctr. de recherche sur le vieillissement, Sherbrooke, QC, Canada

Abstract: Chronic pain is an important public health problem, specifically chronic low back pain (CLBP). Limbic brain structures and more importantly the hippocampus is known to be involved in the transition from an acute to a chronic pain condition. Investigating hippocampal subfield properties and their relationship to pain, quality of life and comorbid conditions in CLBP could reveal the interplay between hippocampus function and behavioral phenotype. In this exploratory study, we aimed to use Magnetic Resonance Imaging (MRI) to establish baseline values of bilateral whole hippocampus and three of its subfields and their relationship to the impact of pain on daily activities (Pain Outcome Questionnaire - POQ), catastrophizing (Pain Catastrophizing

Scale - PCS) and anxiety (State and Trait Anxiety Inventory - STAI-S/T) in healthy subjects and individuals with CLBP. So far, 21 participants (10 healthy subjects and 11 CLBP subjects) were recruited to acquire brain structural data using T1 MRI and psychometrics data. MRI data were analyzed using the automated pipeline HIPS from volBrain (volbrain.upv.es) that produce volumetric values (raw and normalized to intracranial volume) of three hippocampus subfields: CA1-3, CA4-Dentate Gyrus and the subiculum. In healthy subjects, Spearman's correlation (adjusted for age and sex) showed a correlation between STAI-T score and bilateral subiculum fields normalized volume (right: r=0.78; p=0.02 and left r=0.84; p=0.009), but not in the CLBP subjects. No correlations were observed with the STAI-S in both groups. In the CLBP group, a correlation was observed between PCS score and right hippocampus normalized volume (r=0.82; p=0.007). Also, there was a correlation between PCS score and bilateral CA1-3 fields normalized volume (right: r=0.96; p<0 .001 and left: r=0.74; p=0.02). There was no correlation with either CA4-DG or subiculum fields. Finally, there was a correlation between the POQ score and the right CA1-3 field normalized volume (r=0.91; p<0.001). These results are supported by the literature where PCS was linked with hippocampus subfields impairments. Also, our results suggest that the correlation obtained with the right hippocampus was mainly driven by the CA1-3 field as no other subfields was correlated to PCS. To conclude, these results contribute to the refinement of our understanding of chronic low back pain phenotype and hippocampus abnormalities. Furthermore, we are currently collecting longitudinal data on these participants to evaluate stability of these findings.

Title: Classification of trigeminal pain using artificial intelligence and multimodal brain imaging

Authors: *T. H. LATYPOV[1,4], M. C. SO[5], P. S.-P. HUNG[1,4], M. R. WALKER[4], S. TOHYAMA[6], F. RUDZICZ[2,7,8], M. HODAIE[1,4,3];
[1]Inst. of Med. Sci., [2]Computer Sci., [3]Dept. of Surgery, Univ. of Toronto, Toronto, ON, Canada; [4]Krembil Res. Inst., Univ. Hlth. Network, Toronto, ON, Canada; [5]Fac. of Hlth. Sci., McMaster Univ., Hamilton, ON, Canada; [6]A.A. Martinos Ctr. for Biomed. Imaging, Harvard Med. Sch., Boston, MA; [7]Vector Inst. for Artificial Intelligence, Toronto, ON, Canada; [8]St Michael's Hosp., Unity Hlth. Toronto, Toronto, ON, Canada

Abstract: Hypothesis
Trigeminal neuralgia (TN) is a severe type of chronic facial pain characterized by frequent

electric shock-like pain episodes. TN is one type of pain syndrome, which at present is defined based on clinical grounds. MR imaging can provide *in vivo* insights into the pathophysiology of chronic facial pain disorders and can assist with diagnostics. A large amount of MRI data cannot be easily analyzed using conventional statistical methods but benefit modern artificial intelligence (AI) tools. We hypothesize that AI-driven analysis of MR imaging can define subtypes of facial pain with greater accuracy than current conventional methods. The main objective of this study is to create an AI model capable of defining types of facial pain based on MR imaging data.

Methods

T1 and Diffusion-Weighted Imaging (DWI) data from 435 chronic facial pain and 118 healthy subjects have been analyzed. Cortical thickness, surface area, and thalamic volume measures were extracted from T1 data using Freesurfer. DWI data distortion correction and estimation of Diffusion Tensor Imaging (DTI) scalar volumes had been performed in FSL. DTI Scalar volumes transformed to the MNI template space and regional intensity measures were extracted using the Johns Hopkins University White Matter Atlas. Processed data was used to train Random Forest (RF) and Logistic Regression (LR) models to distinguish between different types of chronic facial pain and healthy control data.

Results

Classical TN can be distinguished from healthy controls with accuracies up to 95% with area under the curve (AUC) ~ 0.93 and 0.99 for RF and LR, respectively. Classifying between trigeminal neuropathic pain vs. healthy controls is up to 91% accuracy, on average (AUC~0.92 and 0.97 for RF and LR respectively). Both classifiers identified sets of important grey and white matter-based predictive metrics which were significantly different across compared groups ($p<0.05$). These include changes in temporal gyri grey matter, diffusivity changes in fornix, cingulum, and corpus callosum, and volume reduction of the pulvinar nucleus. Classifying between Classical TN vs Trigeminal Neuropathic pain is relatively inaccurate (with the accuracy of 51% and AUC of 0.55); however, comparing the important features revealed two grey matter structures (ipsilateral insular and contralateral orbital cortex) with significant univariate differences ($p<0.05$).

Conclusions

Our findings represent the first instance of an AI-driven diagnosis of pain type, which opens the pathway for a greater level of objectivity for the assessment of pain conditions.

Abstract: Background & Aims: Migraine is a highly prevalent chronic pain disorder. Interoception, the sensing of signals originating from within the body, is processed in insular cortex and may be altered in patients suffering from episodic migraine. The association between brain mechanisms of interoceptive awareness and clinical characteristics of migraine pathology has not been fully explored. We used functional MRI to explicitly investigate this association. **Methods**: 18 patients with episodic migraine (17 F, 1 M, mean age ± SD: 41.3 ± 13.1 yrs) were enrolled in an ongoing treatment study. All patients completed a novel interoceptive awareness task (**Figure 1A**) during BOLD fMRI acquisition in a 3T scanner (TR=2s, 3.125x3.125x3.6mm). During the task, patients were asked to focus their attention on and rate the intensity of sensation for two interoceptive conditions (visual cues: “heart” and “lungs”), as well as two exteroceptive conditions (“sight” and “sound”). Participants completed survey measures related to migraine symptoms, interoception, and trait mindfulness for at least 30 days prior to their scan. Participants also completed daily headache diaries to log migraine frequency, duration, and pain intensity. Bonferroni corrected Pearson correlations were calculated between insula BOLD response to interoception and each clinical and survey measure. **Results**: BOLD fMRI response for the interoception - exteroception task contrast included two clusters overlapping with mid-insula, bilaterally (**Figure 1B**). Significant inverse associations were observed between insula response and the Self-Compassion Scale ($r = -0.65$, $p = 0.003$), Freiburg Mindfulness ($r = -0.68$, $p = 0.002$), and number of migraine days in the 30 days prior to scan ($r = -0.64$, $p = 0.004$) (**Figure 1C**). **Conclusions**: Patients with episodic migraine showed robust insula response during a novel interoceptive awareness task, and this response was inversely correlated with recent migraine frequency, and measures of both trait mindfulness and self-compassion.

Figure 1. A) Task design including interoception conditions (visual cues for "Heart" and "Lungs") and matched exteroception conditions ("Sound" and "Sight").
B) Whole-brain results (n=18) from INT - EXT contrast ((Heart+Lungs)-(Sound+Sight)). BOLD response values used for correlations with clinical and survey measures were extracted from voxels of intersection between the whole-brain results (red-yellow) and the anatomical insula mask (green).
C) Correlation between BOLD response in insula cortex and number of migraines reported within 30 days prior to MRI scan.

Title: A theory of cortical map formation in the visual brain

Authors: *S. NAJAFIAN[1], E. KOCH[2], K. L. TEH[3], J. JIN[1], H. RAHIMI[1], Q. ZAIDI[1], J. KREMKOW[3], J. M. ALONSO[1];
[1]Suny Optometry, NYC, NY; [2]Biol. and Biol. Engin., Caltech, Pasadena, CA; [3]Neurosci. Res. Ctr., Charité-Universitätsmedizin Berlin, Berlin, Germany

Abstract: The cerebral cortex receives multiple afferents from the thalamus that become organized in topographic maps for different sensory modalities. Each sensory map represents the multiple dimensions of a stimulus in a complex pattern that varies across species for reasons unknown. Here we introduce a general theory of map formation that explains the natural diversity of visual cortical maps while replicating past and new measurements of multidimensional visual topography in different species. The theory develops maps through the sorting of thalamic inputs by type followed by synaptic adjustment through afferent co-activation and visual experience. Map diversity emerges from variations in the shape and size of the cortical domains representing the same stimulus position, which depend on the afferent sampling of sensory space (receptive-field tiling) and cortical space (axon-arbor tiling). We test the theory with a computational model that simulates visual maps and quantitatively compare them with experimental measurements. The model accurately simulates the orientation maps from three different species published in the scientific literature: macaque, cat, and tree-shrew (Figure 1). It reproduces the differences in orientation map geometry and pinwheel density across species (compare Figure 1a and c), the tendency for iso-orientation lines to run orthogonally to the ocular dominance borders in macaques and cats, the tendency of same-sign pinwheels to be farther apart than different-sign pinwheels, and the differences in average pinwheel distance and orientation periodicity across species (compare Figure 1b and d). The model also replicates the combined topography for multiple stimulus dimensions measured with multielectrodes in cat visual cortex for spatial position, ocular dominance, ON-OFF polarity, orientation preference/selectivity, homogeneity of orientation preference, spatial-frequency resolution and low-pass filtering. Because brain pathways use similar mechanisms for axon sorting and pruning, the theory may extend to other areas of the mammalian brain.

Title: Biased distribution of fitted parameters in space reveals robust, yet spurious, angular tuning maps in the early visual cortex

Authors: *K. MORAVKOVA, J. FABIUS, A. FRACASSO;
Inst. of Neurosci. and Psychology, Glasgow, United Kingdom

Abstract: Extending conventional modelling frameworks with the use of neurophysiologically-informed parameters is routinely performed in the field of computational neuroscience. This approach builds on the assumption that multitude of small-scale organisational principles of brain function can be recovered at coarse-scale if the employed measurement is sensitive enough to capture such features. While modelling single-unit receptive fields with the use of Gabor filter functions has uncovered some of the key organisational principles of neuronal tuning in the visual cortex, whether this benefit could be obtained at the scale of functional magnetic resonance imaging (fMRI) has not yet been explored via a forward-modelling framework. Here we extended the population receptive field (pRF) modelling approach, a method routinely used to characterise visually-evoked responses in humans, by implementing pRFs with Gabor filter configurations. Thus, we were able to estimate additional tuning properties (angle, phase, spatial frequency) at a single voxel level. The model revealed a coarse-scale organisation of angular tuning within the early visual cortex. This result was selective for Gabor filter pRF configurations with an asymmetric shape, a relationship which is in line with findings previously reported in monkey neurophysiology (see Figure 1). However, when we reapplied the model to a dataset of pRFs with uniformly randomly distributed configurations in space (i.e. lacking any coarse-scale pattern), we observed the same coarse-scale organisation, highlighting a non-neural origin of the observed result. This result is thus a cautionary case highlighting the potential caveats of extending the pRF modelling framework with assumptions grounded in neurophysiology. We believe these results underscore the continuing necessity to retest robust results with simulated datasets, irrespective of their consistency with theory.

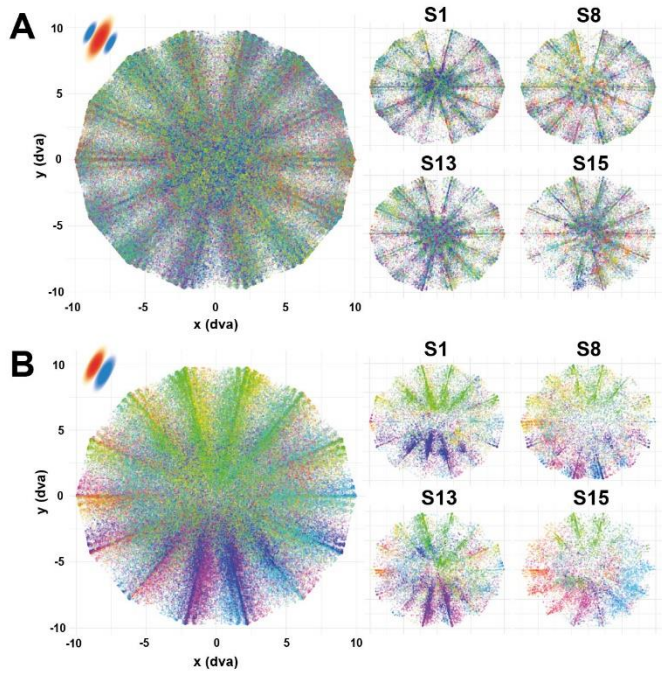

Figure 1: Coarse-scale angular tuning maps are dependent on the phase of the fitted Gabor filter pRF.

The plots show the results collapsed across all selected early visual areas (V1, V2, V3, V4, V3A, V3B). The colour represents the angular tuning of the Gabor filter pRF at the specified x and y coordinate. On the left, the plot shows data collapsed across all 18 participants. On the right, the single-participant-level angular tuning maps are shown for a subset of participants.

A: Data filtered to capture only Gabor filter pRFs with a symmetrical shape (defined by the phase parameter).

B: Data filtered to capture only Gabor filer pRFs with an asymmetrical shape (defined by the phase parameter).

The data shows a clear distinction between the coarse-scale angular tuning observed in space for the Gabor filter pRFs with symmetrical and asymmetrical shapes. While Gabor filter pRFs with symmetrical shapes show random distribution of angular tuning, the asymmetrical Gabor filter pRFs show spatially localised clusters of angular tuning, following the full range of 0-360 degree sensitivity across the visual cortex.

Title: A model for the development of binocular congruence in primary visual cortex

Authors: M. SOMARATNA, *A. W. FREEMAN;
Univ. of Sydney, Sydney, Australia

Abstract: INTRODUCTION. A recent study has provided insight into the development of binocular congruence. Chang et al. (*Neuron*, 107, 338, 2020) compared the interocular difference in preferred orientations of cortical neurons: the preferences differed substantially at the age of eye opening but matched well after visual experience. How does experience turn the monocular preferred orientations towards each other? We investigated this question by adding a second eye to an existing model (Freeman, *J. Neuroscience*, 41, 89, 2021). METHODS. The model has multiple on- and off-centre subcortical channels driven by each eye. All channels converge onto excitatory neurons in layer 4 of primary visual cortex. Development in the model occurred through Hebbian plasticity in the geniculocortical synapse and proceeded in two phases. In the first phase, which simulated the period before eye opening, stimulation of cortical neurons was assumed to be due to waves of retinal activity and was therefore monocular. The second phase simulated visual experience and the stimulus here was binocular. In the interests of physiological plausibility, the model was based on the known characteristics of the cat's X-cell pathway. RESULTS. Cortical responses before development were very weak because signals from neighbouring on- and off-channels cancelled each other when they converged at the cortex. Hebbian development increased response amplitude by spatially segregating on- and off-input. The segregation took the form of oriented bands and, because stimulation was monocular, the preferred orientation from stimulation via one eye was uncorrelated with that for the other eye. Binocular stimulation in the second phase of development remedied this mismatch. Where signals of one sign in one eye cancelled signals of the opposite sign at the same visual field location for the other eye, one eye was favoured and the fellow eye down-regulated. The result was an interocular match in orientation preference similar to that seen in empirical measurements. Further, the histogram of preferred binocular disparity across all neurons reflected empirical findings. Finally, a substantial fraction of cortical neurons in the fully developed cortex were dominated by a single eye: strong monocularity was seen in those neurons for which the monocular orientation preferences at the end of the first phase were close to orthogonal. This suggests that ocular dominance is a by-product of monocular stimulation before eye opening. CONCLUSIONS. Hebbian plasticity in geniculocortical synapses can explain the two-phase development of binocular congruence seen in the laboratory.

Title: Brain network mechanisms of visual shape completion

Authors: *B. P. KEANE[1], D. M. BARCH[3], R. D. MILL[4], S. M. SILVERSTEIN[2], B. KREKELBERG[4], M. W. COLE[4];
[1]Psychiatry, Neurosci., Brain/Cog. Sci., [2]Psychiatry, Neuroscience, Ophthalmology, Univ. of Rochester, Rochester, NY; [3]Dept Psychol & Psychiatry, Washington Univ., Saint Louis, MO; [4]Ctr. for Mol. & Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Visual shape completion recovers object shape, size, and number from spatially segregated edges. Despite being extensively investigated, the process's underlying brain regions, networks, and functional connections are still not well understood. To shed light on the topic, we scanned (fMRI) healthy adults during rest and during a task in which they discriminated pac-man configurations that formed or failed to form completed shapes (illusory and fragmented condition, respectively). Task activation differences (illusory-fragmented), resting-state functional connectivity, and multivariate patterns were identified on the cortical surface using 360 predefined parcels and 12 functional networks composed of such parcels. Brain activity flow mapping (ActFlow) was used to evaluate the likely involvement of resting-state connections for shape completion. We identified 36 differentially-active parcels including a posterior temporal region, PH, whose activity was consistent across 95% of observers. Significant task regions primarily occupied the secondary visual network but also incorporated the frontoparietal, dorsal attention, default mode, and cingulo-opercular networks. Each parcel's task activation difference could be modeled via its resting-state connections with the remaining parcels ($r=.62$, $p<10^{-9}$; see Figure), suggesting that such connections undergird shape completion. Functional connections from the dorsal attention network were key in modeling task activation differences in the secondary visual network. Dorsal attention and frontoparietal connections could also model activations in the remaining networks. Taken together, these results suggest that shape completion relies upon a sparsely distributed but densely interconnected network coalition that is centered in the secondary visual network, coordinated by the dorsal attention network, and inclusive of at least three other networks. Additional neuroimaging results from schizophrenia and bipolar patients will also be considered using the methods described.

Title: Using brain-optimized deep neural networks to investigate hierarchical computation in human visual areas V1-V4

Authors: G. ST-YVES[1], E. J. ALLEN[2], Y. WU[3], K. N. KAY[4], *T. NASELARIS[5,6];
[1]Neurosci., [2]Psychology, [3]Cognitive Sci., [4]Ctr. for Magnetic Resonance Res., Univ. of Minnesota Twin Cities Campus: Univ. of Minnesota Twin Cities, Minneapolis, MN; [5]Neurosci., Univ. of Minnesota, Minneapolis, MN; [6]Ctr. for Magnetic Resonance Res., Minneapolis, MN

Abstract: Visual areas V1, V2, V3, and V4 are often characterized as instantiating hierarchical computation. It has been hypothesized that the defining feature of this hierarchy is compositional dependence, i.e., each area applies a transformation to the outputs of the preceding area. Recently, task-optimized deep neural networks (DNNs) have been shown to yield impressively accurate predictions of brain activity in V1-V4, and for most networks, V1-V4 align with network layer depth. This result has been construed as evidence that V1-V4 are compositionally dependent. To carefully assess this interpretation, we analyzed the Natural Scenes Dataset, a massive dataset consisting of fMRI measurements of human brain activity (7T, 1.8-mm resolution) in response to up to 30,000 natural scene presentations per subject. We used this dataset to optimize DNNs to predict responses in V1-V4. In such brain-optimized networks, features distribute across layers in any way that improves the prediction of brain activity. This allows us to assess whether the alignment of V1-V4 with layer depth is a general property of DNNs that accurately predict brain activity. We found that when a single DNN is trained to jointly predict activity in V1-V4, alignment emerged in the sense that bottom layers of the DNN were more important for predicting activity in a given area than the areas above it in the hierarchy (e.g., bottom layers were more important for predicting activity in V1 than in V2-V4, and so on). Conversely, top layers were more important for predicting activity in a given area than the areas below it. Interestingly, when four distinct networks were independently trained to predict each of areas V1 through V4, there was no evidence for this type of alignment with layer depth. For example, the bottom layers in the network trained to predict V1 were less important than the bottom layers in the network trained to predict V4. Importantly, jointly and independently trained networks yield equivalent prediction accuracy. From these findings, we conclude that there is considerable flexibility in how to implement stimulus transformations that accurately predict brain activity in V1-V4. Some stimulus transformations are consistent with compositional dependence while others are not. We suspect that compositional dependence--without additional qualification--is too general a property to adequately explain the nature of the visual representations encoded in V1-V4.

Title: Interpreting models of neurons in visual area V4 via structural compression

Authors: *R. ABBASI-ASL[1], B. YU[2];
[1]UCSF, San Francisco, CA; [2]UC Berkeley, Berkeley, CA

Abstract: V4 is a large cortical area located between the primary visual cortex (V1) and higher visual areas in the inferior temporal lobe. Due to V4 neurons' highly non-linear responses, functions of neurons in V4 are less understood compared to other areas in the ventral visual pathway such as V1, V2, and IT. Recently, models based on convolutional neural networks (CNNs) have shown promise in predicting the activity of V4 neurons. More importunately, interpreting these CNN-based models has opened new doors to understand neural functions. However, these interpretations are based on models with hundreds of convolutional filters. Therefore, it is challenging to present a sparse set of filter bases for neurons via these models. To address this, we propose two algorithms to remove redundant filters in CNN-based models of V4 neurons. CAR compression prunes filters in a CNN based on their contributions to the image classification accuracy. Similarly, RAR prunes filters based on their contribution to the neural response prediction accuracy. Both CAR and RAR give rise to a new set of simpler accurate models for V4 neurons. These models achieve almost similar (for CAR) or higher (for RAR) accuracy compared to the original model. Using the compressed models, we are able to characterize each V4 neuron with a sparse set of filters. We show that V4 neurons are modeled via curvature or texture filters, as well as other more complicated filters. Our results present one of the first efforts to bridge between large-scale convolutional models of neurons and interpretable sparse networks.

Title: Topographic deep neural networks predict the functional organization of the primate ventral visual pathway

Authors: *E. MARGALIT[1], H. LEE[4], J. J. DICARLO[4,5], K. GRILL-SPECTOR[2,6], D. L. K. YAMINS[2,6,3];
[1]Neurosciences Grad. Program, [2]Psychology, [3]Computer Sci., Stanford Univ., Stanford, CA; [4]Brain and Cognitive Sci., McGovern Inst. for Brain Res., Cambridge, MA; [5]Ctr. for Brains, Minds and Machines, MIT, Cambridge, MA; [6]Wu Tsai Neurosciences Inst., Stanford, CA

Abstract: The primate ventral visual pathway is organized into functional maps, including pinwheel-like arrangements of orientation-tuned neurons in primary visual cortex (V1) and patches of category-selective neurons in higher visual cortex. While deep convolutional neural networks (DCNNs) trained for object recognition accurately predict neural representations throughout the ventral pathway, they have no spatial layout for features at a given retinotopic location and are thus unable to predict the rich topographic organization of visual cortex. Here, we close this gap by first assigning each DCNN unit a position in a 2D cortical sheet, then training the network to minimize a cost function with two components: one encouraging accurate object recognition, and another favoring correlated responses among nearby units in each model layer (Figure 1A, 1B). We find that training with this composite spatial loss produces brain-like topographic maps in both early and later model layers (Figure 1B). Early layers contain smooth orientation preference maps with pinwheels, clusters of units preferring the same spatial frequency, and color-preference domains resembling V1 “blobs”. In a later layer of the same model, we observe clusters of category-selective units, e.g., face patches, whose spatial organization largely matches that found in primate higher visual cortex. Our model thus leverages local response correlations, which have been linked to theories of wire-length minimization, to accurately predict neuron responses and functional organization throughout the ventral visual pathway. In support of the wire-length minimization hypothesis, we find that our topographic DCNN would require shorter connections than a standard DCNN to support connections between similarly-tuned neurons within early (38% reduction) and later (31% reduction) model layers (Figure 1D). These results suggest that the functional organization of visual cortex can be explained by two constraints: the need to perform object recognition and pressure for local populations of neurons to have correlated responses.

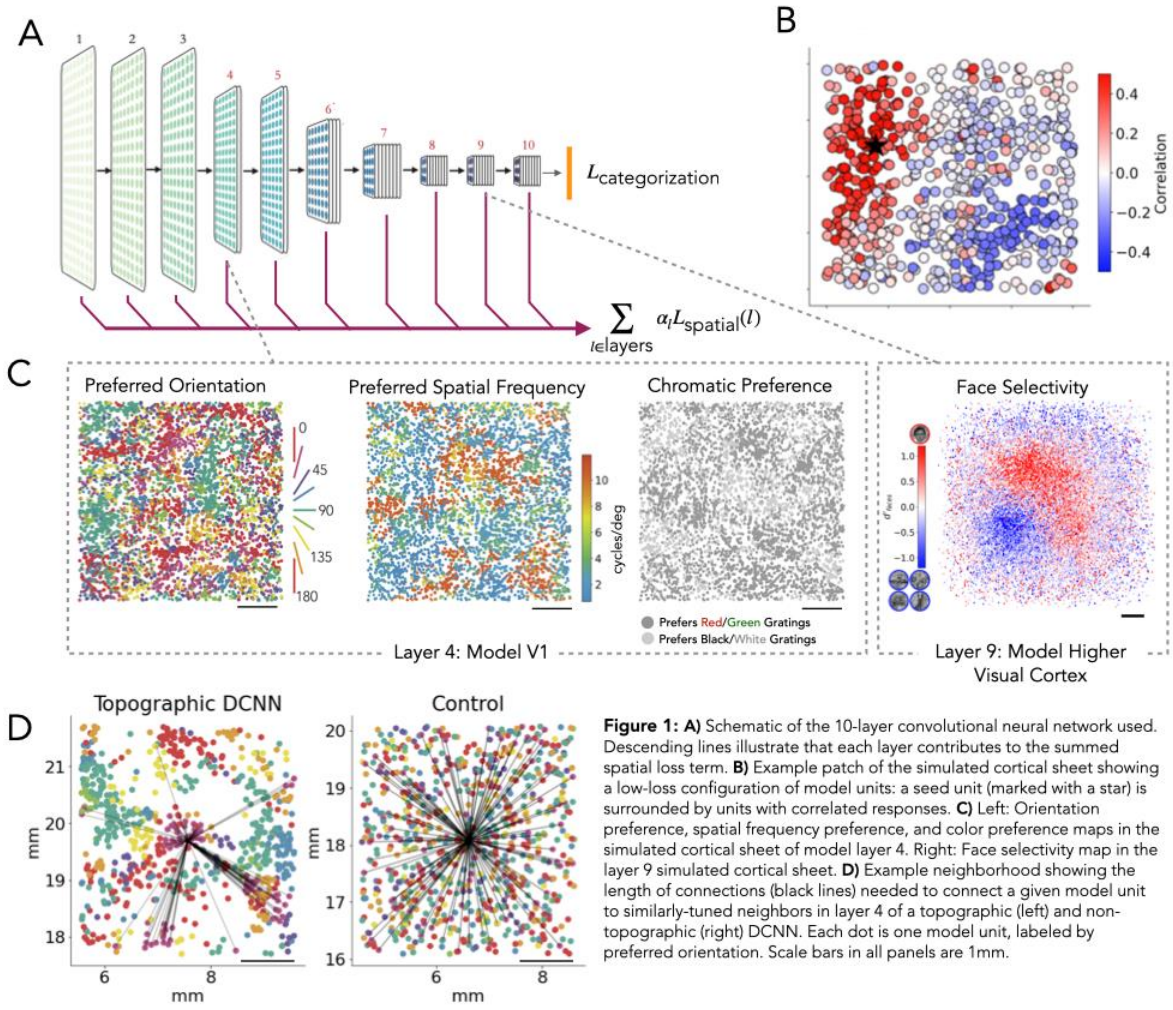

Figure 1: A) Schematic of the 10-layer convolutional neural network used. Descending lines illustrate that each layer contributes to the summed spatial loss term. **B)** Example patch of the simulated cortical sheet showing a low-loss configuration of model units: a seed unit (marked with a star) is surrounded by units with correlated responses. **C)** Left: Orientation preference, spatial frequency preference, and color preference maps in the simulated cortical sheet of model layer 4. Right: Face selectivity map in the layer 9 simulated cortical sheet. **D)** Example neighborhood showing the length of connections (black lines) needed to connect a given model unit to similarly-tuned neighbors in layer 4 of a topographic (left) and non-topographic (right) DCNN. Each dot is one model unit, labeled by preferred orientation. Scale bars in all panels are 1mm.

Title: Modularity and saccade influence in cortical vision networks: an fMRI and graph theory approach

Authors: *G. TOMOU[1], B.-R. BALTARETU[1], A. GHADERI[2], J. CRAWFORD[3];
[2]Ctr. for Vision Res., [1]York Univ., Toronto, ON, Canada; [3]Ctr. for Vision Res., York Univ., North York, ON, Canada

Abstract: Considerable regional evidence has accumulated for dorsal-ventral modularity in the visual system, but it is not clear how these modules function at the whole brain network level, or how these networks are influenced by naturally occurring saccades. We addressed these questions using graph theory analysis of fMRI data collected during a task where participants had to remember, then discriminate between two different object features. Seventeen participants judged whether a remembered object changed shape or orientation with or without an intervening saccade. BOLD activation from 50 cortical nodes was used to identify local and global network properties, which indicated greater inter-connectivity and efficiency of information transfer during saccades. A network modularity analysis revealed three sub-networks during fixation: a bilateral dorsal sub-network linking areas involved in visuospatial processing and two lateralized ventral sub-networks linking areas involved in object feature processing. Importantly, when horizontal saccades across the remembered object required visual comparisons between hemifields, the two lateralized ventral sub-networks became functionally integrated into a single bilateral sub-network. Comparisons of betweenness centrality between conditions identified several significant hub regions in occipital, parietal, and frontal cortex involved in linking distant network nodes during saccades. These results provide support of a ventral and dorsal stream distinction in human perception and show how hemispheric sub-networks are modified to functionally integrate information across saccades.

Title: Sensory Plasticity Driven by Single Neurons in the Mouse Cortex

Authors: *R. AOKI[1], J. G. ORLANDI[2], A. BENUCCI[3];
[1]RIKEN Ctr. for Brain Sci., Wako City, Saitama, Japan; [2]Lab. for Neural Circuits and Behavior, RIKEN Ctr. for Brain Sci., Wakoshi, Japan; [3]RIKEN Ctr. For Brain Sci., Wakoshi, Japan

Abstract: Brain circuits acquire, implement, and update computations through the dynamics of recurrently connected neurons. The recurrent dynamics is enabled by the plasticity of the strength of these circuit connections, with diverse cellular and molecular mechanisms controlling the variability and changes in connectivity strength across neurons, as highlighted in several studies; however, the principles coordinating population-level changes for network computations remain largely elusive. Here, we found that optogenetic stimulation centered on a cortical cell—the *target* cell—could coordinate activity changes across hundreds of cells in the network in which it was embedded —the *surround*—and shifted the population encoding toward the feature preferentially encoded by the target cell. In particular, the repeated pairing of target cell (30 msec) -surround (10 msec, 1 msec delay, 5 pulses in 0.1 Hz) stimulation in the primary visual cortex of awake mice resulted in long-term, enhanced neuronal responsiveness to the stimulus feature—a specific orientation—preferred by the target cell. Moderately visually responsive cells showed the greatest magnitude of enhancement (0.05 ± 0.03, z-score, $n = 25$ experiments, $p < 0.002$, hierarchical bootstrapping), where the strongly visually responsive cells were mostly unperturbed ($p = 0.50$). Spontaneous responses were also affected, such that population activity became more aligned to the subspace defined by the visual modes (Explained variance: 19 ± 1 % for *before*, 21 ± 1 % for *after*, $p = 0.003$, $n = 25$), and cells similarly tuned to the target cell became more likely to participate in spontaneous neuronal assemblies ($p = 0.264$ for *before*, $p = 0.011$ for *after*). Our results reveal a surprising form of plasticity in adult cortical networks that is sensitive to the activation of targeted neurons and shows differential plasticity in weaker and stronger neural encoders, which highlights a mechanism that balances plasticity and stability of sparse feature representations. Our work also provides a proof of principle for technologies aiming to sculpt brain computations with spatially localized activations.

Title: Functional diversity of frontostriatal circuits along the anterior-posterior striatal axis

Authors: *K. CHOI[1], E. PIASINI[2], L. VARGAS[3], E. DÍAZ-HERNÁNDEZ[3], M. SUBRAMANIYAN[1], M. V. FUCCILLO[1];
[1]Neurosci., [2]Computat. Neurosci. Initiative, [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Frontostriatal circuits have been extensively implicated in the cognitive control of behavioral output for both social and appetitive rewards. The incredible diversity of prefrontal cortical function is strongly dependent on its synaptic target, with cognitive control of motor output mediated by connectivity to the dorsal striatum. Given evidence for a functional divergence along the anterior-posterior axis of the dorsomedial striatum, we investigated how distinct frontostriatal sub-circuits contribute to neural computations essential for action selection. Neural circuit tracing revealed largely segregated prefrontal populations defined by anterior/posterior dorsomedial striatal target. We probed the functional relevance of this organization via neural recordings and manipulations during a feedback-based choice task. In vivo calcium imaging revealed a largely non-overlapping distribution of task-relevant neural coding, with prelimbic-anterior dorsomedial striatum (PL-ADMS) circuits uniquely signaling action-related behavioral events and responses to negative outcomes while prelimbic-posterior dorsomedial striatum (PL-PDMS) neurons encoded internal representations of value and integrated choice-positive outcome signals. Consistent with this divergent prelimbic neural coding based on striatal target, optogenetic inhibition of PL-ADMS strongly impacted behavioral control in response to negative outcomes while PL-PDMS signals impaired task engagement and strategies following positive outcomes. Together these data suggest a distributed model of action control for prefrontal neurons defined by A/P striatal target.

Title: Data driven linkage between network connectivity and dystonic behavior in writer's cramp dystonia

Authors: *N. BUKHARI-PARLAKTURK[1], M. FEI[2], M. DEREZINSKI-CHOO[2], J. VOYVODIC[2], S. DAVIS[2], A. MICHAEL[2];
[1]Duke Univ., Chapel Hill, NC; [2]Duke Univ. Sch. of Med., Chapel Hill, NC

Abstract: Background: Dystonia is a network level brain disorder with limited understanding of interactions between functional networks. Prior studies have used a data driven approach to demonstrate abnormalities both between and within functional networks. However, these studies were focused on the "off" or resting disease state of task-specific dystonia and did not study functional networks when engaged in clinically relevant dystonic disease state. As a result, it remains unclear if the abnormal networks in the "off" disease state are also abnormal during the "on" disease state of task-specific dystonia. Furthermore, no study to date has demonstrated how changes in these functional networks correlate with manifestation of dystonic behavior. Methods: 12WC and 12 age-matched HV performed 3 motor tasks in fMRI: writing, sequence tapping and finger flexion-extension. Group independent component analysis was used to identify 11 functional networks. The functional networks were then correlated with the time course of the 3 motor tasks to identify highly correlated networks and determine group differences in network activation patterns. Differences in functional network connectivity was then evaluated between the two groups. Lastly, functional network connectivity was correlated with behavioral measures of dystonia.Results: Our analysis showed decreased functional connectivity between the basal ganglia and left sensorimotor network during the on-dystonia disease state. Behavioral analysis demonstrates positive correlation between writing legibility and functional connectivity of the cerebellum to basal ganglia and negative correlation of writing legibility and functional connectivity of the cerebellum to the orbitofrontal network. We also demonstrate a significant group difference in recruitment of the right sensorimotor network during dystonic behavior. Conclusions: Our analysis supports a global network disorder in which the basal ganglia and cerebellum play key roles. Based on our findings, we also propose a unifying mechanism of network disorders that may provide insight on primary disease and compensatory network changes. Our study is the first to link network changes during task performance to behavioral manifestations of a task-specific dystonia.

Title: Direct projections from the external globus pallidus to thalamus and brainstem differentially impact behavior

Authors: *Z. GU[1], J. TANG[1], S. ROSENBERG[1], A. CHAKRAVARTHY[1], V. PAIXAO[2], L. HAMMOND[1], D. PETERKA[1], R. COSTA[1];
[1]Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY; [2]Champalimaud Neurosci. Program, Champalimaud Fndn., Lisbon, Portugal

Abstract: The external globus pallidus (GPe) is a key component of the basal ganglia system, yet its neuronal heterogeneity and contribution to action control have remained elusive. In the textbook model of basal ganglia function, the GPe comprises a single, homogenous population of neurons that serves as a simple relay in the striatopallidal pathway to inhibit movements. Using a combination of anterograde and retrograde tracings, we first found that GPe neurons are highly heterogenous: different subsets of GPe have distinct projection patterns, including previously uncharacterized subpopulations that project to the thalamus and brainstem. Second, axon-specific calcium imaging demonstrated that the activity of parafascicular thalamic nucleus-projecting (GPe→Pf) and pedunculopontine nucleus-projecting (GPe→PPN) GPe neurons are differentially modulated, such that GPe→Pf is strongly modulated during the performance of a learned lever pressing task while GPe→PPN is more modulated during locomotion. Third, optogenetic activation of GPe→PPN projection impeded locomotion, while manipulation of GPe→Pf had a strong effect on the execution of lever press. Therefore, our study provides anatomical, physiological, and functional evidence to support that GPe is an output nucleus of the basal ganglia, questioning the classical prokinetic versus antikinetic dichotomy of direct and indirect pathways. Our data strongly suggest a new model of basal ganglia function, in which striatopallidal pathway can either promote (via the novel GPe projections to thalamus and midbrain) or inhibit (via the classical subthalamic nucleus/STN to internal segment of the globus pallidus/GPi and the substantia nigra pars reticulata/SNr) movements depending upon the output channel(s). Supporting this notion, we further demonstrated that optogenetic activation of GPe→PPN projection blocks locomotion evoked by striatopallidal pathway stimulation in an open field exploratory task. Together, our data suggest that the striatopallidal pathway can function as direct output pathways via GPe projections to brainstem and thalamus to facilitate locomotion and learned action respectively.

Abstract: Previous reports have shown that both cannabidiol (CBD) and CID16020040 blocks the GPR55-mediated effects of LPI. In addition, the expression of GPR55 mRNA in the basal ganglia (BG) has been described by *in situ* hybridization, especially in the striatum and external *globus pallidus* (GPe). These nuclei form the indirect pathway of BG are overactived in animal models of Parkinson's disease, leading to inhibition of GPe neurons and hypokinetic states. Because of this, the aim of the present work was to study the effect of GPR55 receptor inhibition in the GPe on fine motor skills of hemiparkinsonian rats in free movement. Male Wistar rats were used weighing 250-300 g to which 6-hydroxydopamine (6-OHDA) was administered in the nigrostriatal pathway [16 µg / 2 µL] by stereotaxic surgery. The staircase test was used to determinate the motor asymmetry of the experimental subjects in the 15th -19th days post-surgery and, later, at 20th days, a guide cannula was placed in the GPe to directly administer CBD [10 µM], CID160 [10 µM] and, LPI [10 µM]. Once the cannula was introduced, the drugs were administered at 28th, 29th, and 30th days and fine motor skills were assessed in staircase model. The results obtained show that the rats lessoned with 6-OHDA plus the intrapallidal injection with CBD or CID160 achieved a significant greater increase in the expert use of the forelimb contralateral to the lesion with 6-OHDA, but not with intrapallidal administration with LPI. While, an improvement was observed in the experimental groups that were administered CBD and CID160 of rats injured with 6-OHDA on fine motor skills: pronation, grasp and supination. In summary, our results suggest that the inhibitory effects of CBD and CID160 on the GPR55 receptor in the GPe of hemiparkinsonian rats reverse motor impairment possibly by regulating GABAergic neuronal activity.

Title: The basal ganglia direct pathway supports motor control via GPe axon collaterals

Authors: *M. LABOUESSE[1], A. TORRES-HERRAEZ[1], J. VILLARIN[1], J. GREENWALD[1], X. SUN[1], A. TANG[1], M. ZAHRAN[1], S. LAM[2], J. BONAVENTURA[2], F. DE CARVALHO[1], C. LACEFIELD[1], M. MICHAELIDES[2], S. CHAN[3], O. YIZHAR[4], C. KELLENDONK[1];

Abstract: In the classical model of the basal ganglia (BG) two segregated and functionally opposing pathways connect its input, the striatum with its midbrain outputs the substantia nigra reticulata (SNr) and entopenduncular nucleus (EP). Direct pathway spiny projection neurons (dSPNs) project to the SNr and EP while indirect pathway iSPNs project to the GPe. However, many recent studies have challenged both the functional dichotomy and the anatomical organization delineated by the classical BG model. For instance, all major BG nuclei send at least a subset of arborized axons collateralizing into one to four BG target regions. These axon collaterals could help shape BG information flow in space or time by sending copies of the same signals to distinct brain regions. Axonal “bridging” collaterals arising from dSPNs are a prominent example: axonal fibers arising from SNr-projecting tracts, yet targeting the GPe, the classical projection area of iSPNs. They generate half the density of GPe terminals produced by iSPNs, but their significance for behavior is still unknown. Here, we use *in vivo* optical and chemogenetic tools combined with deep learning approaches to dissect the roles of bridging collaterals in motor function. We found that dSPNs projecting to the SNr send synchronous motor-related information to the GPe via axon collaterals. We then found that inhibition of native activity in dSPN GPe terminals impaired motor activity and function via regulation of pallidostriatal Npas-1 neurons. We propose a model by which dSPN GPe collaterals act in concert with the canonical terminals in the SNr to support motor control by inhibiting Npas1 signals going back to the striatum.

Title: Functional characterization of genetically defined subtypes of nigrostriatal dopamine neurons

Authors: *M. AZCORRA[1], R. AWATRAMANI[2], D. A. DOMBECK[3];
[1]Neurobiology/Neurology, Northwestern Univ., Evanston, IL; [2]Neurol., Northwestern Univ., Chicago, IL; [3]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Recent single cell studies have identified several molecularly distinct subtypes of midbrain dopamine neurons (Poulin et al. 2016), with different cell body locations, projection patterns, and vulnerability in Parkinson's Disease models. But whether this genetic division relates to the function of the neurons remains unanswered. Here, we characterized the activity of several of these subtypes in the mouse during dopamine related behaviors, such as locomotion, reward consumption, and response to aversive stimuli. We used intersectional genetic strategies to label the individual dopaminergic subtypes with the calcium indicator GCaMP6f, and recorded changes in fluorescence using one-photon fiber photometry. We found that, beyond the previously identified morphological differences, nigrostriatal dopamine subtypes have distinct functional signaling patterns. For example, locomotion related calcium transients correlated mostly with accelerations in some subtypes, but mostly with decelerations in others. These results could explain previous incongruences in dopamine signaling patterns found during recordings of undefined dopamine neuron subtypes during movements (Howe et al. 2016, Dodson et al. 2016, Da Silva et al. 2016 Coddington et al. 2018), and have implications for the research and treatment of dopamine related disorders.

Title: Striosome circuitry and constraint on locomotor vigor with respect to an unlearned valence differential

Authors: *S. HAWES[1], **B. OLDHAM**[1], B. LIANG[2], D.-T. LIN[3], H. CAI[4];
[1]Natl. Inst. on Aging, Bethesda, MD; [2]Natl. Inst. On Drug Abuse, Baltimore, MD; [3]Behavior Neurosci., NIH NIDA IRP, Baltimore, MD; [4]Neurogenetics, Natl. Inst. Aging, Bethesda, MD

Abstract: Survival demands that safe and unsafe contexts are met with different locomotor profiles, yet whether striatal microcircuitry links contextual valence to spontaneous locomotor vigor is unresolved. Using a SepW1-Cre “Patch” model, we test for striosome contributions to spontaneous locomotion using ablation, calcium-imaging and chemogenetics in the context of a modified Light/Dark box test. We find that locomotor speed reflects the unlearned, external valence differential present in this test, and that striosomes gate valence-oriented speed selection. We also investigate circuit anatomy through regional synaptic density quantification in striatal output nuclei transfecting a cre dependent synaptophysin infused GFP. We observe denser direct pathway innervation in the internal pallidum, with more diffuse indirect pathway synapse formation. We provide a more intricate understanding of striosomes regulation of anxiogenic locomotor response, as well as patch circuit architecture that leads to complex striosome-related behavior.

Title: The role of the striatum in the formation of cortical attractor dynamics

Authors: *A. STETSENKO, T. Z. KOOS;
Rutgers, State Univ. New Jersey, Newark, NJ

Abstract: A recent study on working memory in the anterior lateral motor cortex (ALM) suggests that working memory is supported by discrete attractor dynamics [Inagaki et al., Nature 566(7743) 212-217, 2019]. However, it is not well understood which brain regions are involved in these dynamics. It is known that specific areas of the striatum are activated during the performance of tasks involving working memory [Akhlaghpour et al., Elife, 5, e19507, 2016]. In the current study, we explore the possibility that the striatum, and more broadly the basal ganglia, are integral parts of this attractor network. We use a working memory task that requires mice to give an appropriately chosen licking response (left or right reward port licking) 2 seconds after the termination of the discriminative auditory cue. We perform calcium imaging of task-related activity of pyramidal neurons in the ALM and examine the effects of bilateral and/or unilateral optogenetic manipulation of striatal activity. The optogenetic stimuli are timed to the beginning of the delay period. We observe effects of the manipulation on both the behavioral performance of the animals (more discrimination errors, i. e. left instead of right lick and vice versa) and on neuronal activity in the ALM (changes in the activity of the task selective and nonselective neurons). These results suggest the normal functioning of the basal ganglia is necessary for the performance of this task. And the basal ganglia may specifically contribute to the emergence or maintenance of the task-selective cortical attractor states. More specifically, we hypothesize that the striatum supports the maintenance of activity corresponding to the correct choice and suppresses the activity corresponding to the incorrect choice.

Title: Smart Dura: A monolithic functional surface array for chronic neural interfacing with non-human primates

Authors: *S. MONTALVO VARGO[1], T. BELLOIR[2], I. KIMUKIN[1], D. J. GRIGGS[2], J. REDDY[1], Z. AHMED[1], S. FISHER[2], A. YAZDAN-SHAHMORAD[2], M. CHAMANZAR[1]; [1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Univ. of Washington, Seattle, WA

Abstract: A neural interface that can be safely implanted for long-term recording and stimulation is highly desired for chronic monitoring of the brain's function and designing effective therapeutics. Despite the recent developments in surface micro-electrocorticographic (μECoG) arrays for rodents, the design of a stable, chronic interface for non-human primate (NHP) brain still remains elusive. In previous work, to keep the craniotomy open for successive acute experiments using surface ECoG arrays, artificial dura was introduced as a passive cap made of polydimethylsiloxane (PDMS) to cover the surface of the exposed brain in between the experiments. Since PDMS can be made optically transparent, artificial dura also provides optical access to the brain tissue.

Here, we are capitalizing on our previous work and demonstrate a novel neural interface design combining a chronic, transparent and flexible architecture inspired by the artificial dura that monolithically incorporates a high density of electrophysiological recording electrodes. Using thin-film microfabrication on flexible polymer substrates maintains the cranial pressure and minimizes tissue damage and at the same time reduces the chance of tissue infection. Our novel neural interface, called smart dura, can replace the native dura and provide neural recording and stimulation capabilities with high spatiotemporal resolution. Our current design features a honeycomb lattice for symmetrical recording and a channel count of 32 and 64 electrodes over a large area of NHP cortex (300mm^2). The resolution of our lithographic technique enables increasing the number of channels to 512 in each single thin-film layer. The transparent smart dura allows for a hybrid modality with external optical stimulation or imaging to augment the electrical recording and stimulation capability of smart dura. With 20-40 μm diameter electrodes, electrochemical impedance spectroscopy (EIS) measurements confirmed an average impedance of <1MΩ at 1 kHz for electrodes, thus enabling electrophysiological recording of multi-units and local field potentials with acceptable signal-to-noise ratio. We will discuss the details of our design, the microfabrication method and the in-vivo validation of the smart dura in the somatosensory cortex of macaques.

Title: Chronic electrophysiological performance of L1CAM coated Utah arrays in non-human primate model

Authors: *D. SHI[1,3], A. B. SCHWARTZ[3,2], X. T. CUI[1,3];
[1]Dept. of Bioengineering, [2]Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: By stimulating or recording from the microelectrodes chronically implanted in the brain, Brain-Computer Interface (BCI) technology can be used to restore lost sensations and motor functionalities. However, the performance of the intracortical electrodes will degrade significantly over time partially due to the inflammatory tissue response to those neural implants. As a biomimetic coating on the electrode surface, the neuroadhesive molecule L1CAM has demonstrated great potential in attenuating the foreign body response (FBR), promoting neuronal health and proximity. Application of the coating has prolonged chronic electrophysiological performance up to 16 weeks in rodent models (Asiyeh Golabchi et al., 2020). Here, we evaluated the chronic recording performance of the L1-coated 10-by-10 Utah arrays implanted in the motor cortex of Rhesus monkeys (n=3). After the non-human primate (NHP) subjects recover from the Utah array implantation surgery, two minutes of baseline neural activity was recorded every week. Manual unit clustering task was performed in the 3D PCA space using the Offline Sorter (Plexon). Some of the electrophysiological data from both L1-coated and un-coated arrays were assigned to a blinded operator to establish the manual unit sorting baseline. Next, "MountainSort" was chosen as a fully automated method for sorting the entire electrophysiology data set (Jason Chung et al., 2017). MountainSort input parameters (detection threshold, detection sign, etc.) were carefully tuned to be comparable to the manual sorting baseline and kept consistent throughout the sorting process. L1-coated arrays showed significantly higher unit amplitude (169.8±127.1 μV, p=0.0032, Welch's t-test) than the un-coated control arrays (84.52±49.05 μV) for the first five months and retained a higher trend than the un-coated arrays for another 15 months. This result reinforced existing evidence supporting the beneficial effect of L1CAM in improving chronic recording performance. Aside from neuronal recording data, monthly electrochemical impedance spectroscopy (EIS) data showed that coated arrays have overall lower impedance than the uncoated control arrays. Ongoing immunohistochemical analysis of the brain tissue and Utah array explants will provide a more comprehensive understanding of the biological and material factors affecting the chronic interface and uncover the mechanism of action of the L1CAM coating in primates. The ability of L1CAM coating to improve neural recording yield and longevity will benefit both BCI technologies and neuroscience studies relying on chronic recordings.

Title: Tracking the migration of free-floating microdevices injected into the brains of rodents using Magnetic Resonance Imaging

Authors: *A. KHALIFA[1], J. WEIGAND-WHITTER[1], C. FARRAR[1], A. EISAPE[2], S. CASH[1]; [1]Massachusetts Gen. Hosp., Boston, MA; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Free-floating implantable neural interfaces are an emerging powerful paradigm for mapping and modulation of brain activity. Wirelessly powered microdevices are being miniaturized to improve safety, longevity, and spatial resolution in a wide range of biomedical applications. Some of them have reached a point where they can be injected whole into the central nervous system. However, these intracortical microdevices are faced with two vital questions. 1) How can they be injected into the brain rapidly in an essentially arbitrary location? 2) Will the implants migrate over time? To answer the first question, we have built a simple injection tool that allows for precise, fast, and minimally invasive insertion into the central nervous system. To validate the needle injectable tool and the presented delivery approach, we evaluate the spatial precision and rotational alignment of the microdevices injected into agarose and brain with the aid of tissue clearing techniques and MRI. To answer the second question, we tracked microdevices injected in different areas of the brain of five rats over 5 months using a 9.4T MRI scanner. We then present immunohistology data to assess the damage caused by the injection tool and the chronic immune reaction to the microdevices. By virtue of its simplicity, we show that the proposed injection method can be used to inject microdevices of all sizes and shapes (340 × 330 × 250 µm; 300 × 200 × 80 µm, 200 × 200 × 250 µm) and will do so in a fast (< 70 sec per microdevice) and minimally-invasive manner. Furthermore, MR images show that microdevices smaller than 0.01 mm^3 remain anchored in the brain at the targeted injection over 5 months. Based on CD68 (microglia) and GFAP (astrocytes) immunoreactivity to the microdevice, we hypothesize that glial scar formation is preventing the migration of chronically injected microdevices in the brain. The findings of this research show a promising future for these next-generation types of intracortical electrodes in animal models.

Title: Unsupervised Channel Compression Methods in Neural Prostheses Design

Authors: *A. ALOTHMAN[1], P. TOSTADO[2], Z. ARNEODO[3], T. GENTNER[4], V. GILJA[5]; [1]Electrical and Computer Engin., [2]Dept. of Bioengineering, [3]Biocircuits Inst., Univ. of California San Diego, San Diego, CA; [4]Psycholgy, [5]Electrical and Computer Engin., UCSD, La Jolla, CA

Abstract: High-performance brain machine interfaces (BMIs) require scaling recording channel count to enable simultaneous recording from large populations of neurons. Unfortunately, proposed implantable neural interfaces have power requirements that scale linearly with channel count, introducing a critical constraint on the number of channels that can be recorded simultaneously. To facilitate the design of interfaces with reduced power requirements, we develop an unsupervised-learning-based compressed sensing strategy. This strategy suggests novel neural interface architectures which compress neural data by methodically combining channels of single-unit spiking activity. We develop a compression strategy that models the neural population activity as being generated from a lower dimensional set of latent variables and aims to minimize the loss of information in the latent variables due to compression. This strategy assumes that the low-dimensional latent variables effectively describe the activity of a high-dimensional population of neurons. Previous work demonstrated that low-dimensional latent variables can describe neural variability effectively and enable better performance in online BMIs than features based on high-dimensional neural observations (Kao et al. 2015). Neural population dynamics, as described by low-D latent variables, can be accurately estimated from unsorted multi-units (Trautmann et al. 2019). That study connects unsorted multi-units activity to the theory of random projections and compressed sensing. Multi-units can be emulated as a random projection of single units and as demonstrated these random projections can be used to infer low-D latent variables without the need to measure the activity of every single unit. This provides motivation to study whether informed mixtures of single-unit features, based on designed compression methods, can yield high accuracy estimates of low-D latent variables with even lower numbers of channels. We introduce two evaluation metrics to assess the latent variables inferred from compressed features to quantify the loss of information. We measure the accuracy with which the activity of held-out neurons can be estimated and the accuracy with which the behavior can be estimated. We apply these methods to data collected from the RA region in a zebra finch in a free vocal behavioral experiment (Tostado, SfN 2021) and compare the compression strategy to a random projections strategy. Our initial results suggest that the

compression strategy can reach the similar prediction error of the activity of held-out neurons to random projections with a 50% reduction in dimensionality.

Title: The effect of subthalamic nucleus deep brain stimulation and volume of tissue activated on sequential memory-guided reaching encoded with peripheral vision versus proprioception

Authors: F. J. DAVID[1], *Y. RIVERA[2], T. ENTEZAR[4], M. MUNOZ[1], Q. DRANE[1], G. PAL[5], L. V. METMAN[6], S. SANI[6], J. ROSENOW[7], A. S. KURANI[8], D. M. CORCOS[3]; [2]Physical Therapy and Human Movement Sci., [3]Dept. of Physical Therapy/Human Movement, [1]Northwestern Univ., Chicago, IL; [4]Univ. of Illinois Urbana Champaign, Champaign, IL; [5]Rush Univ. Med. Ctr., Chicago, IL; [6]Rush Med. Ctr., Chicago, IL; [7]Northwestern Med., Chicago, IL; [8]Dept. of Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Peripheral-visual and proprioceptive inputs are used to encode spatial locations as well as plan and execute movements to sequentially memorized locations. These inputs recruit the basal ganglia-thalamo-cortical network which degenerates in Parkinson's disease (PD). Previously, we studied the effect of anti-Parkinsonian medication on sequentially memory-guided reaching amplitude, velocity, and error when encoded with either peripheral vision or proprioception. Medication had no effect on reaching amplitude, improved velocity but did not normalize to healthy controls (HC), and reduced error further from HC levels. Here, we studied the effect of subthalamic nucleus deep brain stimulation (STN DBS) on sequential memory-guided reaching. We asked 2 questions: 1) How does STN DBS affect sequential memory-guided reaching amplitude, velocity, and error when encoded with peripheral-vision vs

proprioception, and 2) does the VTA intersection with the STN (VTA-STN overlap) predict sequential memory-guided reaching amplitude, velocity, and error in each of the 2 experimental paradigms? Participants with PD who underwent bilateral STN DBS (n=15, m=15) and HC (n=13, f=2) performed 2 memory-guided reaching tasks: 1) encoding targets through peripheral vision and 2) through proprioception. During the peripheral-visual paradigm, participants encoded 3 sequential LED targets to memory, and then reached to the memorized locations as accurately as possible, using peripheral vision. The proprioceptive paradigm was similar, except participants were blindfolded throughout the task and an experimenter guided their relaxed arm to 3 target locations for encoding. Trials were conducted in total darkness over 2 days for participants with PD and 1 day for HC. Participants with PD performed the tasks off medication while ON and OFF bilateral STN DBS. We estimated VTA-STN overlap using Lead DBS. Dependent outcomes were reaching amplitude, velocity, and error. In contrast to our medication findings, STN DBS significantly increased reaching amplitude and velocity towards HC in both paradigms, but did not normalize these values. STN DBS had no effect on peripheral-visual reaching error and caused proprioceptive error to move closer to HC. VTA-STN overlap did not predict any reaching outcome. These findings suggest that the mechanism of action of STN-DBS differs from medication and VTA-STN overlap did not drive this improvement. Future research should determine the mechanism by which VTA of non-STN areas cause this improvement.

Title: Reducing convolutional neural network architectures for selective peripheral nerve recording on implantable devices

Authors: *Y.-C. HWANG[1,4], R. GENOV[2], J. ZARIFFA[1,4,3,2];
[1]Inst. of Biomed. Engin., [2]Edward S. Rogers Sr. Dept. of Electrical and Computer Engin., [3]Rehabil. Sci. Inst., Univ. of Toronto, Toronto, ON, Canada; [4]KITE Res. Inst., Toronto Rehabil. Inst. – Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Background: Closed-loop control of functional electrical stimulation involves using recorded nerve signals to make decisions regarding nerve stimulation in real-time. Surgically implanted devices that can implement this strategy have significant potential to restore natural movement after paralysis and improve the quality of life of individuals living with spinal cord injury. Discriminating between recorded signals from different neural pathways can provide information about the body's state and external inputs, which can then be used to decide on the most appropriate form of stimulation to deliver. Our previous work demonstrated the use of a convolutional neural network (CNN), ESCAPE-NET, to discriminate spatiotemporal signatures produced by different neural pathways. Despite state-of-the-art performance, this approach required too much data storage, power and computation time for implementation on hardware that is small enough to be surgically implanted in patients and fast enough for real-time decision making. **Objective:** This study aimed to minimize resource consumption while maintaining performance accuracy for machine learning techniques that can distinguish between neural pathways in high-density multi-contact nerve cuff electrode recordings. **Methods:** Several CNN architectures were evaluated using a dataset of rat sciatic nerve recordings previously collected using 56-channel (7 x 8) spiral nerve cuff electrodes. The CNNs were trained to classify individual, natural compound action potentials (nCAPs) elicited by ankle dorsiflexion, plantarflexion or heel prick. Reduced-complexity CNN architectures have been explored and designed using techniques such as dropout and fully convolutional networks (FCN). **Results:** Reduced ESCAPE-NET using dropout was 16x smaller than the original architecture and operated with 2.4x fewer floating-point operations per second (FLOPS), performing with 80.6% accuracy compared to a baseline of 80.7%. Reduced ESCAPE-NET using FCNs was 420x smaller than the original and operated with 3.5x fewer FLOPS, performing with 77.8% accuracy compared to a baseline of 80.7%. **Conclusion:** These reduced versions of ESCAPE-NET require significantly fewer resources with minimal accuracy loss, and thus will be more easily incorporated into a surgically implantable device that performs closed-loop control of stimulation in real-time. Beyond the impact on people with paralyzed limbs and spinal cord injury, this selective peripheral nerve recording technology has applications in the control of

prosthetic limbs and neuromodulation interventions for diseases such as chronic pain, diabetes, or incontinence.

Title: Iterative Learning Control and Balance Control for Walking in a "Muscles-First" Motor-Assisted Hybrid Neuroprosthesis

Authors: S. HNAT[1], R.-D. REYES[1], M. NANDOR[2], N. MAKOWSKI[3], M. AUDU[1], R. TRIOLO[1], *R. QUINN[2];

Abstract: Paralysis due to spinal cord injury (SCI) can limit mobility and result in secondary health impacts such as muscle atrophy and bone density loss. While commercial powered exoskeletons can restore mobility to individuals with SCI, we have developed a "Muscles-First" Motor-Assisted Hybrid Neuroprosthesis (MAHNP) to better counteract disuse atrophy. MAHNP stimulates the user's muscles to complete movements via functional neural stimulation (FNS) while electric motors assist as needed. Conventional orthotics are used for the trunk and shank, while each joint features its own separate power module with a brushless DC motor, electromagnetic solenoid brake, and harmonic drive transmission. MAHNP can be adapted for the user's anthropometry, with the power units connected by aluminum tubing with customizable limb length and pyramid adaptors that allow 15° of fitment adjustment in the sagittal and coronal planes. FNS is administered through implanted and/or surface electrodes capable of exciting hip, knee, and ankle flexion/plantarflexion and trunk flexion. We developed a biologically-inspired iterative learning controller (ILC) that swing the legs in a ballistic fashion. The control algorithm was tested using an anatomically realistic 3D musculoskeletal model of the lower leg and pelvis suitably modified to account for exoskeletal inertia. The model was developed and tested with the OpenSim biomechanical modeling suite. Preliminary data demonstrate controller efficacy via

swing-leg simulations and its ability to learn to balance muscular and motor contributions to improve performance and accomplish consistent stepping. In particular, the controller took 15 iterations to achieve the desired outcome with 0.3% error. Additionally, to automatically maintain balance while wearing MAHNP, we developed a method for estimating COM kinematics (typically used as feedback for balance controllers) using only body segment accelerations using a COM Estimation Algorithm. The algorithm was trained by minimizing the mean-squared-error between COM displacements measured by a gold-standard motion capture system and acceleration signals obtained from ten body-mounted IMUs on five able-bodied participants during unexpected and volitional destabilizing perturbations. We have tested the ILC on a participant with SCI wearing MAHNP and have begun balance control implementation in able-bodied participants wearing actuated ankles. Preliminary results suggest MAHNP 1) can improve with each step by maximizing muscle recruitment and 2) has the appropriate hardware (ankle plantarflexion torque and angular velocity) for maintaining balance.

Title: Exploring vibrotactile and intracortical microstimulation feedback on sensory embodiment and expectations

Authors: L. E. OSBORN[1], ***A. C. G. CREGO**[1], B. P. CHRISTIE[1], D. A. D'ALMEIDA[1], D. P. MCMULLEN[3], C. FIRESTONE[4], F. V. TENORE[5], M. S. FIFER[2];
[2]Res. and Exploratory Develop., [1]Johns Hopkins Applied Physics Lab., Laurel, MD; [3]Neurol., Johns Hopkins Univ. Dept. of Neurol. and Neurosurg., Baltimore, MD; [4]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [5]Johns Hopkins Univ. APL, Laurel, MD

Abstract: Artificial sensory feedback can provide useful information to users of external devices, such as prosthetic limbs. For prosthesis users, restored sensory information is useful for improving grasping function and enhancing perceived levels of device embodiment (i.e., defined here as integrating the device into one's internal body representation). Qualitative surveys are used to capture broad perceptual experiences pertaining to changes in embodiment. This integration relies on multiple factors, including perceived agency, ownership, and the sensory

stimuli of the system. In this study, we explored the role of artificial tactile feedback in promoting embodiment of a virtual robotic hand shown on a monitor. We provided either vibrotactile stimulation or intracortical microstimulation (ICMS) to the hand of a human participant who was implanted with microelectrode arrays in the primary somatosensory cortex (S1) and the motor cortex (M1). In the experiment, a virtual sphere made contact with a virtual robotic hand while the participant observed and received artificial stimulation in the same location as the touch occurring on the virtual hand. After an initial training period of 60 trials with simultaneous virtual touch and stimulation, we randomly introduced stimulation dropout trials at an effective rate of 1:15. The experiment was repeated for both vibrotactile stimulation on the thumb and ICMS to S1 regions mapped to the thumb. In initial exploratory sessions, the participant reported they were able to feel as if the tactile sensation was originating as a result of the virtual touch event, despite the virtual hand being spatially incongruent and physically located beyond the body. Using button presses to indicate a perceived tactile sensation, the participant had a false positive rate (i.e., pressed the button during a dropout trial) on 70% of the ICMS dropout trials and 53% of the vibrotactile stimulation dropout trials; however, after approximately half of those false positive trials the participant realized the absence of sensory information and reported having incorrectly pressed the button. Despite the absence of sensory stimulation, the behavioral response indicating perceived tactile sensation suggests the development of sensory expectations and embodiment of the external system. This work has implications for better understanding artificial sensory feedback in modulating levels of system embodiment. By quantifying the relationship between sensory events of an external system and user perception, we can develop intuitive stimulation paradigms that more readily promote human-machine teaming.

Title: Spatial and cellular transcriptomic mapping of the songbird brain provides context for the origin of vocal learning circuits

Authors: *D. P. MERULLO, G. KONOPKA, T. F. ROBERTS;
Neurosci., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Songbird brains contain specialized regions with well-characterized connectivity for learning and producing complex vocalizations. Most of these song regions reside in the dorsal ventricular ridge (DVR), the largest portion of the avian forebrain. Molecular, anatomical, and electrophysiological specializations distinguish these song regions from surrounding portions of the DVR, suggesting that song learning may have arisen in parallel with the development of unique cell-types and/or through the re-organization and specialization of pre-existing cell-types within the DVR. To unambiguously characterize the cell-types of the DVR, we performed single-nuclei sequencing inside and outside of song regions of adult male zebra finches. We integrated all data and performed an unbiased clustering analysis to identify globally distinguishable cell-types. We report that glial cells and inhibitory GABAergic neurons are common to all DVR regions examined, showing no distinctions across neuroanatomical subdivisions or within song-specialized regions. However, the excitatory glutamatergic neurons are specific to sub-fields of the DVR, including the nidopallium and arcopallium. Nonetheless, the glutamatergic neuron classes in song regions do not differ from those in adjacent portions of the DVR, despite numerous gene expression differences. This indicates that each excitatory projection cell-type in a song region has a counterpart in the surrounding portions of the DVR. To further examine organizational principles and specializations of the DVR and other regions of the songbird brain, we performed spatial transcriptomics on whole sagittal tissue slices in adult male zebra finches. This technique maps the entire transcriptome while preserving spatial coordinates (but not at single-cell resolution). Using spatial coordinates as anchors, we computationally mapped differential gene expression patterns throughout the brain. Preliminary analysis reveals that spatial transcriptomic profiles clearly define anatomical sub-regions of the avian pallium and subpallium. While song regions largely conform to the transcriptional profiles of their adjacent regions, molecular specializations can be used to distinguish their borders from surrounding DVR fields. By integrating spatial and cellular transcriptional data, we aim to provide a general resource and framework for understanding the cell-type composition of the avian brain and the sub-regions responsible for orchestrating complex suites of behavior, like song learning. Our current results indicate that neurons within song regions largely reflect the cell-types found within the broader DVR.

Title: An analysis of vocalization-associated molecular pathways and gene networks within the basal ganglia of mouse and finch Parkinson's disease models

Authors: C. A. MEDINA[1,2], S. J. MUNGER[1], M. CORENBLUM[3], J. L. ECKHARDT[1], L. MADHAVAN[2,3,4,5], J. E. MILLER[1,2,3,5,6];

Abstract: Parkinson’s Disease (PD) is the most prevalent neurodegenerative disorder worldwide that affects motor control. Limb motor symptoms include loss of balance, resting tremor, and rigidity that present during the later stages after significant neurodegeneration has occurred. Unlike limb motor symptoms, vocal motor symptoms such as a soft, monotonous voice and changes in speaking rate can occur earlier in the disease progression. Human studies suggest that deterioration of basal ganglia function linked with limb deficits are also linked with this worsening vocal quality. However, very little is known about the molecular mechanisms of basal ganglia dysfunction that underlie the early vocal changes in contrast to later stage limb deficits. Prior research showed that driving overexpression of the causally-related PD gene wild-type human *SNCA* - which encodes for the neuronal protein alpha-synuclein (αsyn) - with the Thy-1 promoter in mice leads to quieter and shorter ultrasonic calls along with deterioration in vocal structure. Interpreting these findings, however, is difficult given the lack of understanding regarding the neurobiological mechanisms involved in mouse vocalizations. In contrast, the neurobiology of vocal control in zebra finch is well-characterized and strongly resembles human speech pathways from the molecular through systems level. Recently, we showed that viral-mediated overexpression of human αsyn in a vocal-dedicated central brain circuit that includes the basal ganglia causes deterioration of finch song - it becomes quieter, shorter, and they sing less. Here, we leverage both the Thy1-αsyn mouse and our viral-mediated finch PD model to identify differentially expressed genes, molecular pathways, and genetic networks that are perturbed within the basal ganglia under vocalizing and quiet behavioral states. We first compared mouse ultrasonic vocalizations to finch song using the machine learning program DeepSqueak. Secondly, we conducted bulk mRNA-seq of the basal ganglia from vocalizing and quiet finch and mice to identify genetically conserved vocal pathways using differential gene expression (DGE) and Weighted Gene Coexpression Network (WGNCA) analyses on control

mice and finches. DGE was used to identify individual gene targets or molecular pathways, and WGCNA was used to construct vocalization-associated gene networks. Lastly, vocalization-associated genetic networks from control animals were compared to networks derived from both Parkinsonian models. Our experiments represent the first comparative transcriptomic study conducted to isolate vocalization-associated genetic networks within a disease framework.

Title: Micro RNA miR-9 regulates Area X neuron structures in zebra finches

Authors: *H. JARRELL[1], Z. HUANG[2], Y. DING[3], Z. SHI[2], X. LI[4];
[2]Neurosci., [1]LSUHSC, New Orleans, LA; [3]Neurosci., Tulane, New Orleans, LA; [4]Neurosci. Ctr., LSU Sch. of Med., New Orleans, LA

Abstract: Male juvenile zebra finches learn to sing in a manner parallel to young humans learning to speak. Area X, the avian basal ganglia, plays important roles in song related sensory-motor learning and performance in zebra finches. We have recently shown that expression of miRNA miR-9 is regulated in Area X during song development and that overexpression of miR-9 in Area X of juveniles leads to impairments in vocal learning and performance. We have also shown that miR-9 regulates FOXP2 (a gene associated with speech and language development) and many FOXP2 downstream genes that are important for neuronal structure development and plasticity. These observations prompted us to hypothesize that miR-9 modulates neuronal structure in Area X. In this study, we examined miR-9's role in modulating dendritic and spine structure of the spiny neurons in Area X of juvenile and adult zebra finches. We made a lentiviral vector that expresses miR-9 and a fluorescent marker, mCherry. We stereotaxically injected the miR-9 expressing lentivirus into the Area X of one hemisphere and a control virus into Area X of the contralateral side of 27 (±3) day old juveniles. We sacrificed the animals at 60 days (juvenile) and 100 days of age (adult), imaged virally labeled spiny neurons, which were identified by DARPP-32 staining. We traced three-dimensional neuronal dendritic structures, and quantified dendritic length, dendritic complexity and spine structures of spiny neurons. We found that miR-9 overexpression in juvenile Area X reduced dendrite length and dendrite complexity and reduced spine density of spiny neurons. In addition, miR-9 downregulated DARPP-32, a key

molecule in dopamine signaling. These changes were long lasting and persisted into adulthood. These results provide strong evidence for miR-9's role in regulating basal ganglia neuronal structure. Since the basal ganglia is key to many neurological and psychiatric disorders in humans, dysregulation of miR-9 may contribute to these disorders as well.
Key words – basal ganglia, Area X, medium spiny neurons, dendrite, spines, zebra finches

Title: Area X Marks the Spot: Cell-Type-Specific Gene Expression Signatures of Sensorimotor Learning in the Zebra Finch

Authors: *E. COOKE[1], S. A. WHITE[2];
[1]UCLA, Los Angeles, CA; [2]Integrative Biol. & Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: The courtship song of the zebra finch (*T. guttata*) is a complex, quantifiable, and highly motivated behavior that provides the opportunity to study neural mechanisms underlying sensorimotor learning and performance. Young male birds learn their songs during partially overlapping sensory and sensorimotor learning stages in development, during which songs from an adult tutor are internalized and then imitated with increasing fidelity. The brain regions required for song learning, including song-dedicated basal ganglia Area X, have highly convergent gene expression patterns to human forebrain regions involved in speech learning. In Area X, the language-linked transcription factor FoxP2 is expressed in a tightly regulated manner necessary for optimal song learning: expression levels are high at the start of the morning and subsequently decrease over the next 2 hours proportionally to the amount a bird sings, while song variability increases. Our previous work used weighted gene co-expression network analysis (WGCNA) to identify transcriptional expression patterns involved in song learning and production; notably, genes in a module linked with singing were found to overlap heavily with human datasets from individuals with autism and language impairment in a follow-up meta-analysis (Lombardo et al, 2018). However, as the WGCNA was done using bulk sequencing data, it is unknown which cell type(s) are regulated following singing. Droplet-based single cell RNA sequencing with the 10XGenomics platform allows for investigation into cell-type-specific changes in gene expression between singing and non-singing siblings. This data aids our understanding of how distinct cell types within the basal ganglia circuit contribute to motor learning, and specifically which basal ganglia cell types are differentially regulated after singing,

in and outside of the sensorimotor learning phase. We additionally apply a deconvolution analysis to our previous bulk dataset based on newly reported Area X cell types from frozen nuclei tissue, to reinforce our findings.

Title: Molecularly-defined cell types of the zebra finch deep cortical layer analogs

Authors: *A. NEVUE[1], C. V. MELLO[2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ. Sch. of Med., Portland, OR

Abstract: Songbirds learn their songs via tutor imitation and possess a specialized brain circuitry to support this behavior. Despite considerable knowledge on the anatomical, physiological, and molecular properties of the songbird vocal circuitry, especially in zebra finches, our understanding of how song nuclei relate to their surrounding brain regions in terms of their cellular type composition is limited. The robust nucleus of the arcopallium (RA) is a particularly prominent and extensively studied vocal nucleus in zebra finches. It is the major forebrain vocal output nucleus and it plays important roles in encoding acoustic features of song. RA is located in the intermediate arcopallium (AI), a brain region thought to contain avian analogs of projection neurons of deep layers of motor and sensory cortices in mammals. We have previously reported that RA shares a large portion of gene expression specializations with the adjacent dorsal intermediate arcopallium (AId), a portion of the AI that has been linked to somatic motor function. However, the extent to which the shared molecular profile of RA and AId reflects a shared cell type composition is largely unknown. Defining the cell types in the intermediate arcopallium (AI) can give insights into the function and evolution of RA as a specialized nucleus for vocal-motor control. To determine the cell types present in AI, we microdissected a core portion of the AI that includes RA, AId, and the adjacent ventral AI (AIv), an auditory region, in adult male zebra finches. We isolated nuclei and performed single nuclei RNA sequencing on the 10x Genomics platform, and performed follow-up *in situ* hybridizations to verify the spatial distribution of genes of interest. We identified cell class clusters associated with neuronal (54% of total nuclei) and non-neuronal (46% of total nuclei) cells. While

excitatory cells (*SLC17A6+*) were non-differentially distributed throughout the AI, some subclasses were specific to the individual nuclei, most prominently an RA-specific class of excitatory cells labeled by the androgen-related gene *SRD5A2*. GABAergic cells (*GAD2+*), in contrast, were fewer in number in RA compared to AId and AIv, with suggestive evidence of subclasses based on classical inhibitory neuron-related genes such as *PENK*, *NPY*, and *LAMP5*, although most of these were largely distributed throughout the AI. Future work will further characterize the cell types of the AI to gain insights into the specialized vs shared properties of its component nuclei, and of the genes that define specific cell types within these nuclei.

Title: Establishing behavioral relevance to molecularly defined GABAergic interneurons within a songbird premotor circuit

Authors: *E. HOZHABRI[1,2], A. CORREDERA ASENSIO[1], M. ELMALEH[1,2], P. W. FRAZEL[1], J. DIMIDSCHSTEIN[3], G. J. FISHELL[4], M. A. LONG[1];
[1]Neurosci. Inst., NYU Sch. of Med., New York, NY; [2]New York Univ., New York, NY; [3]Broad Inst., Cambridge, MA; [4]Neurobio., Harvard Med. Sch., Boston, MA

Abstract: GABAergic interneurons enrich the computational power of neural circuits, with different subpopulations often proposed to play distinct roles within a network. In the mammalian brain, separate categories can be defined based on their morphological, physiological, molecular, and connectivity profiles. Although these classes have been well-characterized in sensory cortices, the roles of distinct inhibitory cell types in the production of complex motor behaviors are still poorly understood. To address this issue, we investigated the role of GABAergic interneurons within the zebra finch song production pathway, which has the distinct advantage of a complex, but highly tractable, behavior mediated by a set of well-characterized brain regions. In a key premotor locus, called HVC, inhibition mediated by local circuit interneurons plays several distinct roles in song learning and production. Furthermore, we and others have characterized heterogeneity within the HVC interneuron population. However, the degree to which these diverse profiles mediate distinct roles within the HVC circuit remains unclear.
We begin to address this issue by characterizing molecularly defined interneurons across a range

of behaviors. We first explored the genetic diversity of HVC interneurons using single-nuclei transcriptomics and found distinct clusters of HVC interneurons consistent with recently published findings (Colquitt et al., 2021). We then categorized electrophysiological responses of HVC interneurons in different behavioral contexts using chronically implanted silicon probes. To link these observations, we used *in vivo* 2-photon targeted recordings of HVC interneurons labeled with GFP under the control of the mDlx enhancer (Dimidschstein et al., 2016) followed by post hoc immunolabeling with antibody markers for major transcriptomically defined interneuron subclasses. Using this approach, we have begun to relate specific physiological roles of interneurons with their molecular designations.

Title: Neurogenetic Mechanisms for Vocal Learning, Practice, and Performance

Authors: *M. FARIAS-VIRGENS[1], T. DEACON[3], S. A. WHITE[2];
[2]Integrative Biol. & Physiol., [1]Univ. of California Los Angeles, Los Angeles, CA; [3]Univ. of California at Berkeley, Berkeley, CA

Abstract: We have previously used zebra finches (ZF; *Taeniopygia guttata*) to uncover hundreds of genes whose brain co-expression patterns are correlated with vocal learning (e.g., the pupil's song spectral and sequential similarity to its tutor's song) and performance (e.g., amount of singing and song stereotypy - rhythmic, repetitive, fixed, predictable). Gene co-expression in young birds' brains, which are actively engaged in song learning, can be correlated with both learning and singing-related variables. Noticeably, gene modules correlated with song learning are broadly distributed across the songbird basal ganglia, comprising both the song-

dedicated nucleus Area X of the basal ganglia and the adjacent, more generalist, region of the ventral striatopallidum (VSP), while singing-related gene modules are uniquely found in Area X. At later ages, when ZFs have passed the vocal learning phase and are instead engaged in song maintenance and performance, learning modules are disassembled and co-expression exclusive to singing persists, which may characterize a transcriptional dynamic underlying the closure of a critical period in which the bird can change its song. We now build upon this work by assessing the extent to which these spatiotemporal patterns of co-expression of behaviorally relevant gene modules found in the ZF are preserved in the Bengalese finch (BF: *Lonchura striatta domestica*), a songbird species with a remarkably more complex song, in which transitions between vocal units are weakly fixed, introducing variability in song sequencing. For this, we have collected song and transcriptomic data from Area X and VSP of young and adult male BFs. Additionally, to analyze a bird's ability to adaptively modulate its vocal variability and identify the associated transcriptional changes, we compared male BFs singing in natural contexts known to elicit differences in song stereotypy. In BFs, a species in which only males learn to sing, social context modulates song variability: it is typically reduced when a male sing to females (FD; female directed) relative to when he sings alone (UD; undirected). Accordingly, within our adult cohort, song and brain transcriptomic data were collected from male BFs after a period of continuous singing either alone or in the presence of a female. Results from our work illuminate context-dependent and spatiotemporal transcriptional networks in the avian basal ganglia that contribute to motor learning and reinforcement and have the potential to highlight specializations related to complex communication both in birds as well as in our own species.

Title: Seasonal changes in neurogenesis and indicators of stress in European starlings (Sturnus vulgaris)

Authors: S. D. T. AITKEN[1], M. M. SOLLOWS[1], A. OPREA[1], C. A. BARBER[3], ***L. S. PHILLMORE**[2], B. M. B. PARKS[1];
[1]Psychology and Neurosci., [2]Dalhousie Univ., Halifax, NS, Canada; [3]Biol., St. Mary's Univ., Halifax, NS, Canada

Abstract: During breeding season, male songbirds, like the European starling, sing stereotyped, complex songs to attract mates, and females use these complex songs to judge male fitness. Following breeding season males vocalize less frequently and their songs become more variable. Accompanying these changes in vocal behaviour are changes in neurogenesis, the process by which neurons are born, differentiate, migrate, and are incorporated into neural circuits in the brain. We examined seasonal differences in neurogenesis in three brain regions associated with vocal learning, performance, and discrimination: HVC, caudomedial nidopallium (NCM) and caudomedial mesopallium (CMM). We captured male and female starlings in spring and fall and counted neurons in these regions using an endogenous marker of neurogenesis, doublecortin. We also examined seasonal differences in stress using two blood measures: plasma corticosterone levels and heterophil/leukocyte ratio. Male birds had more HVC neurogenesis in fall than in spring, and female birds had more HVC neurogenesis than males. We also found a positive relationship between corticosterone levels and neurogenesis in HVC and NCM, suggesting that stress may modulate aspects of neurogenesis in specific auditory brain regions.

Title: A novel classification method to quantify adult neurogenesis using doublecortin (DCX) in songbirds

Authors: *B. M. B. PARKS[1], C. A. STADNYK[1], R. M. W. GIBBS[1], S. D. T. AITKEN[1], A. V. KINGBÉDÉ[2], S. MOORE[2], M. F. GUIGUENO[2], L. S. PHILLMORE[1];
[1]Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada; [2]Biol., McGill Univ., Montréal, QC, Canada

Abstract: The microtubule-associated protein doublecortin (DCX) has been long used as an immunohistochemical marker of neurogenesis during development in rodents and was proposed as a marker of neurogenesis in songbirds by Boseret et al. (2007), and later by Balthazart et al. (2008) and Balthazart and Ball (2014). Boseret et al. (2007) described four distinct cellular morphologies arising from DCX immunolabeling in the songbird brain, however the number of cell types and their descriptions are not standardized across the literature using DCX to quantify adult neurogenesis in songbirds. Several studies published since Boseret et al. (2007) have

created new or updated categorization schemes and new nomenclature to classify DCX-stained (DCX+) cells in the songbird brain, making it difficult to compare results across studies. We therefore aimed to create a more standardized classification scheme to describe and quantify types of DCX+ cells in the songbird brain. We created a database of individual DCX+ cell images (n=328) shared with us by various laboratories, comprised of eight species, both males and females, from two brain regions (HVC and hippocampus). We then had observers (n=10) with varying levels of experience and expertise categorize images of these cells into three categories (multipolar, fusiform, and round), using examples and definitions amalgamated from several studies. Overall, 87.5% of cell images could be categorized into one of the three categories with agreement of eight or more observers, the overall inter-rater reliability was 91.8%, and there was no difference in reliability between raters with different experience. Our next step is to repeat the categorization task with experienced and new naïve observers using more accurate definitions. These definitions are based on quantification of a variety of morphological characteristics (e.g., soma shape, number of processes, amount of branching) in cells that were categorized reliably by 9 or 10 observers. Overall, our findings seem to show that our three categories are sufficient to classify DCX+ cells and quantify adult neurogenesis in adult songbirds.

Title: Characterization of interneuron glucocorticoid receptor expression in the murine hippocampus

Authors: *A. P. CHORDIA[1], K. L. KRAUS[2], C. L. LASARGE[1], S. C. DANZER[3]; [1]Dept. of Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Med. Scientist Training Program, Univ. of Cincinnati, Cincinnati, OH; [3]Dept. of Anesthesia, Cincinnati Children's Hsptl Med. Cntr, Cincinnati, OH

Abstract: Despite the pervasive impact of stress on psychiatric and neurological disease, much of the circuit- and cell-mechanisms responsible for the limbic regulation of the stress response remain unknown. The hippocampus has become a significant target of stress research in recent

years because of its role in cognitive functioning and neuropathology. Based on preclinical data, the hippocampus is thought to inhibit the stress response and play a crucial part in the hypothalamic pituitary adrenal (HPA) axis. Hippocampal excitatory neurons (dentate granule cells, CA1 and CA3 pyramidal cells) express glucocorticoid receptors (GRs) and can therefore respond directly to serum glucocorticoids. Whether hippocampal interneurons also express GRs, however, is not known. Hippocampal interneurons play a major role in the regulation of neuronal activity, exerting tight inhibitory control over excitatory neurons, and consequently, hippocampal function. Based on the GR expression profiles among interneurons of other limbic brain regions involved in the HPA axis regulation, such as the prefrontal cortex, we hypothesize that hippocampal parvalbumin (PV) and cholecystokinin (CCK) interneurons express GR, whereas somatostatin (SST) interneurons do not. Using immunohistochemistry (IHC), confocal imaging, and Imaris image analysis software, we quantified colocalization for GR, PV and CCK immunolabeling. We confirmed antibody specificity for PV interneurons by also measuring GR immunolabeling in a transgenic mouse line which expresses eGFP among PV interneurons. Both PV and CCK interneurons were found to co-express GRs by immunohistochemistry. Studies are ongoing to determine whether hippocampal SST interneurons express GR. Elucidating the relationship between GR and interneuron populations within the hippocampus is crucial to better understand which cell populations represent direct targets of glucocorticoids and their role in stress-related illness.

Title: Distinct representations of a novel anxiogenic environment in the ventral hippocampus

Authors: *J. E. BERRY[1], J. C. JIMENEZ[3], S. LIM[1], N. MANFRED[1], K. M. OGBU[1], F. STEFANINI[2], S. FUSI[2], R. HEN[1];

Abstract: The ability to recognize dangerous situations and environments is crucial for survival, but overestimating risk can lead to pathological avoidance of normal activities, potentially leading to anxiety disorders. Many studies over the past several decades have begun to identify the brain regions underlying threat detection and anxiety behavior. In particular, the ventral hippocampus has emerged as a critical structure for emotional behaviors, including innate anxiety. Recent work from our lab and others has shown that ventral CA1 pyramidal neurons encode information about anxiety, and these CA1 neurons preferentially target downstream structures such as hypothalamus and medial prefrontal cortex. However, the neural representation of anxiogenic environments in the initial stage of the trisynaptic circuit— the dentate gyrus— is unknown. Here, we use Dock10-Cre and Drd2-Cre mouse lines to gain optical access to granule cells and mossy cells, respectively, in the ventral dentate gyrus. Calcium activity was recorded during free exploration of the elevated plus maze (EPM) and open field test (OFT). Single cell activity and population coding were analyzed for mossy cells, granule cells, and CA1 pyramidal neurons. We found that anxiety-related activity was present in granule cells and vCA1, however mossy cells encoded novelty and spatial position. These findings support the notion that different features of an anxiogenic environment are encoded by different cell types, and that anxiety information is present at the earliest stage of the trisynaptic circuit.

Title: Chromatin footprints in the ventral hippocampus in a double-hit model of heterotypic acute stress

Authors: *S. G. CARADONNA[1], M. R. PAUL[2], K. BULLOCH[3], B. S. MCEWEN[1], J. MARROCCO[1];

Abstract: Stress induces allostatic responses, whose limits depend on both genetic background and the nature of the challenges. Acute stress generally assembles immediate adaptive responses, although, depending on the intensity of the stressors and individual differences, maladaptive responses may occur and persist through the lifespan and even intersect with later adverse events, as in the case of post-traumatic stress disorder. We investigated affective behavior and genome-wide chromatin accessibility in the ventral hippocampus in a double-hit model of acute stress in adult male and female mice in which heterotypic stressors, acute restraint stress (ARS) and acute swim stress (AS), were applied within a 7-day interval period from each other. Six days after ARS, ARS males showed decreased anxiety-like behavior compared to controls in the light-dark box test, whereas ARS females exhibited no behavioral changes. Using ATAC-sequencing, we then investigated whether there existed sex differences in the epigenetic reprogramming that underlined differences in the behavioral outcome observed one week after ARS and assessed the epigenetic signatures when AS, a second-hit stressor, was applied 7 days after ARS. We found that 1034 gene transcripts were differentially regulated between males and females prior to stress. AS alone induced chromatin reorganization in 3007 gene transcripts in males and 854 transcripts in females 40 minutes after the end of stress, while ARS modulated 2092 transcripts in males and 583 transcripts in females 7 days after stress. When both stressors were combined, the number of differentially regulated transcripts compared to AS or ARS alone was significantly increased in females, which showed 1909 open transcripts, while males showed 2797 modulated transcripts, a number akin to ARS alone. Notably, commonalities in differentially regulated transcripts in AS alone, ARS alone, or with ARS combined with AS accounted for only 0.76% in females and 5.76% in males, indicating that each stressor and the double-hit stress, all induced unique changes in chromatin modification. Together, we found that distinct acute stressors induce allostatic signatures in chromatin reorganization that i) can be observed within minutes after the end of stress, ii) persists one week after the stressor, iii) shows transcripts that are unique to the double-hit acute stress, and iv) differs in males and females.

Title: Distinct forebrain circuits from the subfornical organ regulate fear (IL cortex) or physiological homeostasis (BNST).

Authors: *K. M. J. MCMURRAY[1,2], A. KALATHILL[1], R. SAH[1,2];
[1]Pharmacol. & Systems Physiol., Univ. of Cincinnati, Cincinnati, OH; [2]DVA, Cincinnati, OH

Abstract: PTSD associates with dysregulated fear/threat responding. Prior fear-related research has focused on responses to externally evoked threats. Yet mounting evidence suggests PTSD patients are highly sensitive to homeostatic threats such as CO_2 inhalation. CO_2 inhalation triggers acidosis and evokes anxiety- and fear-associated defensive behaviors in clinical and preclinical models. Pre-deployment CO_2 sensitivity in veterans associates with later trauma-induced PTSD symptoms, suggesting CO_2 sensitivity pre-dates development of PTSD. Investigating the relationship between homeostatic threats like CO_2 inhalation and externally evoked threats will improve our understanding of PTSD vulnerability. We recently developed a mouse model examining the effect of CO_2-inhalation on later PTSD relevant behaviors and found CO_2 exposure increased later footshock-evoked fear extinction deficits. These effects associated with reduced neuronal activation within the infralimbic (IL) cortex and increased activation in the bed nucleus of the stria terminals (BNST), two regions mediating threat and fear responses. This suggests a convergence of homeostatic CO_2-sensing nodes and forebrain fear nodes, yet the distinct circuits mediating these effects are unknown. We previously reported the subfornical organ (SFO) as a key homeostatic site regulating CO_2-evoked fear. Here, we identified direct SFO projections to both IL and BNST by AAV tract tracing. Using an intersectional chemogenetic (DREADD) approach we tested the hypothesis that inhibiting SFO-IL or SFO-BNST projections during CO_2-inhalation attenuates defensive responding during CO_2-inhalation and delayed CO_2-associated fear extinction deficits. We found inhibiting the SFO-IL, but not SFO-BNST circuit during CO_2 inhalation reduced CO_2-evoked defensive behaviors, and later attenuated CO_2 potentiation of contextual conditioned fear and improved extinction. Given a role of the SFO in maintaining physiological homeostasis via adaptive behaviors like drinking, we determined if inhibiting these circuits affected water consumption. We found inhibition of SFO-BNST, but not SFO-IL projections affected consumption. These data suggest SFO projections have discrete roles in behavioral regulation: the SFO-IL circuit regulates fear associated with homeostatic threat CO_2, while the SFO-BNST circuit regulates adaptive behaviors for homeostatic maintenance. Collectively, these data highlight SFO-IL projections as a key circuit facilitating the convergence of homeostatic threat sensing and long-term fear memory that may contribute to PTSD vulnerability.

Title: An insular cortex-bed nuclei pathway engages passive avoidance behavior in aversive and non-aversive contexts

Authors: *D. C. HINZ[1], T. D. SKOG[3], R. LINGG[3], J. T. LUNA[2], S. A. ROMIG-MARTIN[1], J. J. RADLEY[3];
[1]Dept. of Psychological and Brain Sci., [2]The Univ. of Iowa, Iowa City, IA; [3]Dept. of Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: For many years the insular cortex (IC) has been appreciated to be a key site for the integration of somatosensory and viscerosensory information. More recent work has demonstrated that in rodents the role of IC extends to promoting adaptive responses to stressful or threatening contexts that favor avoidance or anxiety-like behaviors. However, less consideration has been given to whether IC integrates behavioral with neuroendocrine features under these and in other aversive contexts. Our previous work implicates the anteroventral bed nuclei of the stria terminalis (avBST) in the inhibition of medial prefrontal cortical influences over passive behavioral and hypothalamo-pituitary-adrenal (HPA) responses to stress. Based on these studies, we examined the role of the IC-avBST pathway in HPA and behavioral responses in tests of stress coping and avoidance. Using an intersectional viral expression strategy, the projection from the IC-avBST was transfected with the excitatory DREADD, hM3Dq, or reporter-only virus in rats. Using the shock probe defensive burying test (SPDB) to measure active (escape, defensive burying) and passive (immobility) coping in response to a noxious shock, we found that chemogenetic activation of the IC-avBST pathway (0.1 mg/kg CNO, i.v.) significantly decreased defensive burying (by 51%, $p < 0.05$) without affecting other active or passive behaviors relative to CNO-injected and vehicle-injected controls. Interestingly, although SPDB provoked a reliable increase in HPA output, chemogenetic activation of the IC-avBST pathway failed to modulate this response, as based on radioimmunoassay for corticosterone from blood samples collected over repeated intervals before and after SPDB. Follow-up studies using two additional approach-avoidance tests (elevated plus maze and novelty suppressed feeding test) each revealed that chemogenetic activation of IC-avBST pathway (0.3 mg/kg CNO, i.p.) shifted behavior toward a more passive avoidant phenotype. Taken together, these data show that increasing activity in the IC-avBST pathway promotes a shift toward passive avoidance behavior. The divergent effects of IC-avBST and prefrontal-avBST pathways on passive avoidance suggests a more complex role of avBST in promoting behavioral adaptations to stress than previously envisaged.

Abstract: Stress disorders in humans are believed to be due in part to a maladaptive shift in behavior from active toward passive coping strategies as well as increases in glucocorticoid stress hormones and sympathetic tone. While disturbances in medial prefrontal cortex (mPFC) function likely account for this behavioral shift, the basic neurobiological mechanisms underlying this switch are not well understood.To address this question, we employed an intersectional viral optogenetic approach in rats to investigate the role of a mPFC-periaqueductal gray (PAG) pathway in coping behaviors and glucocorticoid stress hormone output. The projection from the rostral prelimbic mPFC to the ventrolateral PAG was transfected with an adeno-associated virus serotype 5 (AAV5) expressing either a Cre-inducible, light-sensitive chloride ion pump *halorhodopsin*, light-sensitive cation channel *channelrhodopsin*, or reporter-only virus. A Cre recombinase-containing, retrogradely transported AAV2 was injected in the ventrolateral PAG to selectively induce opsin expression in PAG-projecting mPFC neurons. Using the shock probe defensive burying test to naturalistically measure active (escape, defensive burying) and passive (immobility) coping behaviors in response to a noxious shock, we found that pathway inactivation given throughout the period of behavioral observation significantly increased the time rats spent immobile (by 65%, $p<.05$) and produced a downward trend in defensive burying of the probe using the bedding material ($p=.07$), while photostimulation attenuated immobility ($p<.05$) without affecting burying. Interestingly, neither manipulation produced a significant effect on blood plasma corticosterone levels before or after shock as tested using radioimmunoassay. As the ventrolateral PAG has been previously implicated in defensive freezing behaviors, our data implicate a novel, long-projection from the mPFC capable of directly inhibiting passive coping in response to stressors. Our results suggest that this diminished activity in this pathway may contribute to understanding behavioral passivity in stress-related psychiatric illnesses.

Title: Adult stress exposure does not alter posterior parietal synaptic architecture, sensory processing or working memory.

Authors: *G. LUR, A. Y. FLORES, **S. B. PARK**;
Univ. of California Irvine, Irvine, CA

Abstract: Synapse loss in key brain regions is thought to underlie stress-induced cognitive impairment. Our group has previously shown that repeated exposure to multiple concurrent stressors (RMS, consisting of physical, auditory, and visual stimuli) during adolescence reduces both excitatory and inhibitory synapse density in the mouse posterior parietal cortex (PPC). We linked this synapse loss to deficits in working memory. Whether these findings depended on the specific pre-juvenile timing of RMS exposure (postnatal day 30-40) was unclear. Thus, here we test the effect of the same stress exposure in young adult male mice (postnatal day 70-100). Using immunofluorescence staining, we found no effect of adult RMS on excitatory or inhibitory synapse density in the PPC. Basic behavioral tests (light-dark box and Y-maze) showed no effect of adult RMS on anxiety, motivation, or navigation. A sophisticated, head-fixed behavioral paradigm indicated that adult RMS did not disrupt working memory performance either. Our previous work showed that adolescent RMS specifically disrupted sensory inputs to the PPC. Here, we employed two-photon calcium imaging to assess parietal sensory processing pre- and post-stress. We did not find a notable difference in sensory responsiveness of PPC neurons when comparing adult RMS exposed and control mice. Together, these data suggest that developmental timing critically influences the synaptic, circuit and behavioral outcomes of adverse experience. In our case specifically, stress exposure during the critical period for PPC development - i.e. early adolescence - has a marked effect on parietal circuitry and behavior. In contrast, the adult PPC appears to be robust against relatively mild stress like our RMS paradigm.

Title: Cortex-wide dynamics of norepinephrine release in resting state

Authors: *D. M. ASHBY[1], A. MCGIRR[2];
[1]Hotchkiss Brain Inst., [2]Psychiatry, Univ. of Calgary, Calgary, AB, Canada

Abstract: Resting state brain activity is characterized by ongoing fluctuations in neuronal activity that have widespread organization at multiple spatial and temporal scales. In mice, genetically encoded calcium sensors are proxies of neural activity, and allow the interrogation of large-scale population activity. At the cellular level this neuronal activity is bidirectionally related to neurotransmitter and neuromodulator release and clearance dynamics. The development of protein biosensors designed to measure specific neurotransmitters and neuromodulators enables the investigation of their dynamics on a sub-second timescale, as well as the relationship of these fluctuations to neuronal calcium activity at the mesoscale. Using combined imaging of the norepinephrine sensor GRAB_NE1m and the red-shifted calcium indicator jrGECO1a, we describe cortical mesoscale dynamics of norepinephrine release in awake head-fixed mice. AAV9-GRAB_NE1m was injected in three bilateral cortical sites in Thy-1 jrGECO1a mice, allowing combined imaging over a large expanse of the dorsal cortical surface (approximately 8x8mm) through a chronic intact skull preparation. After recovery and head-fixation training, GRAB_NE1m and jrGECO1a were simultaneously imaged using a dual camera setup with strobed excitation of GRAB_NE1m (470nm) and jrGECO1a (567nm), in addition to red and green wavelengths for hemodynamic signal correction. In spontaneous resting state, we find evidence for spatial and temporal dynamics in the cortical release of norepinephrine associated with neuronal calcium fluctuations.

Title: Transcutaneous auricular vagus nerve stimulation modulates brainstem functional connectivity and gastric peristalsis in functional dyspepsia

Authors: *H. FISHER[1], R. SCLOCCO[1,4], R. STALEY[1,2], K. HAN[5,1], A. MENDEZ[2], J. COLL-FONT[3,1], C. NGUYEN[3,6,1], B. KUO[2], V. NAPADOW[1,4];

Hosp., Boston, MA; [4]Radiology, Logan Univ., Chesterfield, MT; [5]Korean Inst. of Oriental Med., Daejeon, Korea, Republic of; [6]Med., Harvard Med. Sch., Charlestown, MA

Abstract: Functional dyspepsia (FD) patients experience upper gastrointestinal (GI) symptoms possibly related to gastric motor or sensory dysfunction. The nucleus tractus solitarii (NTS) receives and integrates afference from visceral organs including the GI tract and projects to regions involved in central autonomic regulation and pain processing. This processing of afferent visceral sensation may be modulated by transcutaneous auricular vagus nerve stimulation (taVNS). We hypothesize that altered NTS connectivity to higher brain regions in FD will be associated with motor and sensory dysfunction during a meal challenge, and that tVNS can modulate both the motor function of the gut and gastric mechanosensory processing in the brain. FD (N=12) and healthy control (HC) (N=14) subjects were assessed at two MRI visits, one with active respiratory-gated taVNS and one with sham (no current applied). Subjects consumed their maximum tolerable amount of a 470ml food-based MR-contrast pudding. Post meal, subjects were alternately scanned with stomach MRI and brain fMRI at 3T (3x each). Peristaltic propagation velocity in the antrum was calculated using cross-sectional area time series, as previously published (Sclocco et al. 2021). Average BOLD fMRI timeseries were extracted from a left NTS region and used to generate seed-to-voxel whole-brain functional connectivity maps, which were contrasted between groups and conditions, correcting for multiple comparisons (FSL FLAME1+2, cluster forming threshold $z > 2.3$, FWE cluster size $p < 0.05$). With no taVNS stimulation (sham visit), FDs displayed lower average peristaltic velocity compared to HCs (t-test: HC=5.58 +/- 1.68, FD=3.76 +/- 0.76mm/s, p=0.003). For FD, there was a trend toward significance for higher peristaltic velocity during active taVNS compared to sham (t-test: sham=3.76 +/- 0.76; active=5.03 +/- 1.65mm/s; p=0.09). Additionally, for FD there was a trend toward a significant increase in peristaltic velocity over time, i.e. between the first and last stomach MRI scans for active, but not sham, taVNS visit (t-test: Δsham=-0.02 +/- 2.22, p = 0.98; Δactive=1.24 +/- 2.32mm/s; p=0.08). Relative to HCs, FDs demonstrated increased NTS functional connectivity to pre-supplementary motor area, ventrolateral prefrontal cortex, and left anterior insula when no stimulation was applied. For FD patients, active taVNS decreased NTS connectivity to subgenual anterior cingulate cortex. Our results reveal altered stomach motility and NTS cortical connectivity in FD which are both modulated by active taVNS. Understanding both sensory and motor effects of taVNS will inform applicability of this therapy for FD patients.

Abstract: Background: The vagus nerve contains thousands of afferent and efferent fibers for communication between the brain and peripheral organs, including the heart, lungs, stomach, intestine, and pancreas. Vagus nerve stimulation (VNS) is a potential therapy for cardiac, respiratory, gastrointestinal (GI), and metabolic diseases. Cervical VNS has been used to treat epileptic seizures but it is difficult to activate specific pathways with this approach because of the complex mixture of nerve fibers at the cervical level. Here, we placed nerve cuff electrodes on the abdominal vagus nerve to target GI fibers; moreover, we implanted electrodes on the GI serosal surface to record myoelectric responses. Our objective was to determine the VNS parameters producing retching, vomiting, and other adverse behavioral responses for future development of VNS therapy to treat obesity and GI motility disorders while avoiding off-target effects, such as emesis and GI myoelectric dsyrthymia. Methods: All animal experiments were approved by the University of Pittsburgh IACUC. Ferrets were surgically implanted with nerve cuff and GI planar electrodes. Cuffs were placed on the ventral or dorsal abdominal vagus trunks. Planar electrodes were placed on the ventral serosal surface of the stomach at four sites from antrum to fundus and in the proximal and distal duodenum. Following recovery, animals were tested using 10 and 30 Hz VNS on separate days. We used a sweep of parameters on each test day: (1) pulse widths of 0.1 and 0.5 ms; and (2) amplitudes of 0.5, 1, 2, and 3 mA. VNS was applied in combinations of pulse width and amplitude with increasing charge for 10 min for each

trial followed by 10 min of no stimulation. Results: Results show that both short and long pulse widths and both stimulation frequencies produced retching and emesis, with stimulation amplitudes of 1 to 3 mA, depending on the individual animal. There were also dysrythmic myoelectric responses produced by VNS before and after retching and emesis. Conclusions: These results demonstrate the range of VNS parameters sufficient to produce retching, emesis, and dysthymic GI myoelectric responses in the ferret. Future studies will need to confirm these findings using different stimulation sequences and conditions, such as with food intake, to tailor VNS for the treatment of obesity and GI motility disorders.

Abstract: Gastric motility is regulated by neural innervation of gastric smooth muscle by the intrinsic enteric nervous system and indirectly by vagal innervation. However, the relationship between vagal and enteric neural circuits and their influence on gastric electrical and mechanical activity has not been characterized or modeled in detail. This study developed a mathematical model of the stomach incorporating the effects of efferent vagal innervation on gastric slow waves, herein referred to as the “Virtual Stomach”.
The model includes an anatomically-based network for the endings of the gastric branches of vagal efferents, spatial distributions of enteric neurons and enteric neuron axonal projections, based on experimental data from rats and guinea pigs. The current network contained approximately half the realistic number of enteric motor neurons. Neuron spiking simulations were conducted in NEURON 7.8 using a leaky integrate-and-fire artificial cell model, with parameters derived from experimental literature. The results of this simulation were coupled to a

biophysical simulation of gastric slow waves through rule-based changes to biophysical model parameters. The spatiotemporal spiking characteristics were quantified by counting the number of spikes in 1 mm^2 square bins and reported as the mean ± standard deviation across bins. P-values are reported for paired t-tests between inhibitory and excitatory spiking activity. The influence of spiking on the activation of gastric slow waves was investigated qualitatively.
The border between the corpus and fundus regions experienced a greater difference between the number of excitatory and inhibitory spikes than the corpus (1730 ± 655 vs 541 ± 406 spikes s^{-1} mm^{-2}). Inhibitory and excitatory spiking frequency was similar in the corpus (3600 ± 452 vs 3550 ± 564 spikes s^{-1} mm^{-2}; $p = 0.33$), however in the antrum, excitatory spiking frequency was greater (5130 ± 693 vs 4100 ± 838 spikes s^{-1} mm^{-2}; $p < 0.01$). In the gastric smooth muscle model this manifested as multiple sites of slow wave origin, at regional boundaries, with the more frequent distal pacemaker entraining the entire simulation region.
The formation of slow wave origin sites in the slow wave model is likely due to changes in the density of enteric motor neurons across the border region and the different direction of excitatory and inhibitory enteric motor neuron axonal projections. The model proposed here provides a platform for further examination of the effects of neuronal network geometry and stimulation parameters on gastric slow waves through coupling with biophysical multiscale models of gastric electrophysiology and biomechanical contractions.

Title: Sparc- comprehensive model of colonic motility

Authors: *B. B. BARTH, W. M. GRILL;
Duke Univ., Durham, NC

Abstract: One in five adults in the US suffer from functional gastrointestinal and motility disorders (Talley, 2008). Peripheral nerve stimulation provides a treatment option for patients

whose symptoms are refractory to dietary changes and pharmacological treatment (Payne et al., 2018). Sacral nerve stimulation (SNS) is an FDA-approved therapy for fecal incontinence, but SNS has failed to treat slow-transit constipation in clinical trials despite supporting evidence from animal models (Dinning et al., 2015). The mechanisms of SNS are unknown, and the stimulation parameters or "therapeutic dose" are chosen non-systematically (Carrington et al., 2014). Our objective is to develop a comprehensive model of colonic motility that can enable systematic assessment of the effects SNS parameters on colonic motility (Barth et al., 2017). The computational colonic motility model consists of a spatially-distributed network of biophysically-realistic point cells in NEURON with Python (Hines et al., 2009), and connections constructed in NetPyNE (Dura-Bernal et al., 2019). The cells of the network include neurons, categorized into 9 functional populations and 21 population subsets, enterochromaffin cells, enteric glial cells, 2 populations of smooth muscle fibers, and 4 populations of interstitial cells of Cajal. The 21 subsets are derived from the single-cell atlas of the mouse enteric nervous system (Drokhlyansky et al., 2020). We model the colon as a closed pressure vessel with deformable walls and use Stokes equations to model computational fluid dynamics in the lumen of the colon and pellet propagation. We use particle swarm optimization to calibrate model parameters, including neural mechanosensitive mechanisms, synaptic weights, and the likelihood of connection between two cells of given populations. The model propagates fecal pellets at a velocity proportional to their diameter, consistent with findings in the isolated mouse colon (Heredia et al., 2013). Pellets 1, 1.5, 2, 2.5, and 3 mm in diameter propagate at 0.05, 0.05, 0.21, 0.76, and 0.80 mm / s, compared to target velocities of 0.29, 0.40, 0.55, 0.72, and 0.91 mm / s (Heredia et al., 2013). The comprehensive model of colonic motility provides a platform to examine pathological mechanisms and explore novel therapeutics including modeling pharmacological effects and electrical stimulation.

Title: SPARC: Neurons in the nucleus tractus solitarius respond to gastric electric stimulation with orientation selectivity

Authors: *J. CAO[1], X. WANG[1], T. L. POWLEY[2], Z. LIU[3,1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Purdue Univ., W Lafayette, IN; [3]Purdue Univ., West Lafayette, IN

Abstract: Background: The nucleus tractus solitarius (NTS) in the brainstem receives sensory information from the stomach primarily relayed through the vagus. The vagal afferent nerves innervate the stomach with structurally and functionally specialized receptors. As one type of sensory receptors, intramuscular arrays (IMAs) align themselves with circular and longitudinal muscle fibers and presumably encode and transmit muscle activity to the NTS as well as its downstream nuclei. In this study, we aimed to characterize the functional specialization of gastric neurons in NTS, by evaluating their responses to selective activation of circular and longitudinal IMAs given gastric electrical stimulation (GES) in different orientations and amplitudes. **Methods:** We designed the stimulation paradigm according to the distribution and layout of IMAs in the rat stomach. Two stimulating targets were specified in the distal forestomach. One was on the greater curvature and with dense longitudinal IMAs; the other was on the ventral stomach and with dense circular IMAs. To either location, GES was applied with different electrode pairs, generating short (0.3ms) and weak (0.6 to 1mA) current stimuli in four possible directions. During GES, multi-unit activity (MUA) in NTS was recorded with a 32-channel silicon probe and then decomposed into single-unit activity (SUA) by spike sorting. For both SUA and MUA, the post-stimulus firing rate and peri-stimulus time histogram (PSTH) were evaluated as a function of current orientation and stimulation targets of GES in seven rats. **Results:** Both multi and single-unit responses were highly selective to the orientation of GES. The largest response occurred when the current flowed in the same direction as IMAs. For GES targeting longitudinal IMAs, the preferred orientation was longitudinal, pointing from distal to proximal stomach. For GES targeting circular IMAs, the preferred orientation was circular, pointing from the less curvature to the greater curvature. This orientation selectivity was also consistent across different stimulus amplitudes (0.6, 0.8, and 1 mA). **Conclusion:** Our results suggest that gastric neurons in NTS may encode the orientation-specific activity of the stomach relayed by the ascending vagal pathway. This finding indicates that the orientation of GES is critical to the effective engagement of vagal afferents and should be considered in light of the structural phenotypes of vagal terminals in the stomach.

Title: Sparc: gastric emptying of liquids initiated by neural stimuli -- a compartmental modeling approach

Authors: S. FERNANDES[1], *M. V. KOTHARE[1], B. MAHMOUDI[2];
[1]Dept. of Chem. and Biomolecular Engin., Lehigh Univ., Bethlehem, PA; [2]Emory Univ., Atlanta, GA

Abstract: Introduction The stomach in the Gastrointestinal (GI) tract is responsible for the storage, breakdown, and transport of food to the duodenum for digestion. Previously, finite element methods and computational fluid dynamics (CFD) techniques have been reported that model this complex function involving interacting neural and smooth muscle cell (SMC) activity, deformable wall boundaries and the resulting pulsating flow. Invariably, these models are computationally expensive. We use a compartmental modeling approach that is computationally cheaper and suitable for designing model-based closed-loop controllers as neurostimulation-based therapy for treating GI disorders.**Methods** The stomach is divided into seven compartments: Fundus, Upper Corpus (pacemaker), Lower Corpus, Proximal/Middle/Terminal Antrum and Pyloric sphincter. Each compartment is modeled with a set of ordinary differential equations with respect to time. The stomach is stimulated at the pacemaker region which results in slow waves in the SMC. A simplified set of equations captures the electro-chemo-mechanical coupling of smooth muscle contractions. The muscle wall of the stomach is modeled as a hyper-viscoelastic material. The muscle contractions give rise to peristalsis in the gastric walls which influences the velocity of gastric fluid flow resulting in emptying of stomach. The velocity profile for peristalsis is modeled using Shapiro’s model. The fundus acts as a pressure bubble which also influences gastric emptying. The equation for the pressure bubble is derived from Bernoulli's equation for fluids. The time taken for gastric emptying depends on the volume of gastric contents in the stomach, the nutrient content, and the viscosity. When chyme from the pyloric sphincter enters the duodenum, a feedback signal may be sent to the pyloric sphincter to inhibit the chyme flow to the duodenum to prevent overloading if the liquid is high in calorie content. This feedback signal is also incorporated in the model. The resulting model is solved using differential equation solvers in MATLAB.**Results/Conclusions** The model computes membrane voltage from SMC, intracellular calcium concentration, stress and stretch values during the SMC contraction, fluid velocity and volume of the stomach during gastric emptying. These results are then compared and validated against other simulations: (1) the CFD study of liquid gastric emptying (Li, Gin (2020)); (2) FEM viscoelastic SMC model (Panda, Buist (2021)); (3) experimental data from Vella, Camilleri (2017) on mechanical and hormonal response to nutrient ingestion.

Title: SPARC: a 3D anatomical and molecular map of cardiac vagal motoneurons

Authors: *E. HORNUNG, S. ROBBINS, S. ACHANTA, A. SRIVASTAVA, A. MOSS, J. SCHWABER, R. VADIGEPALLI;

Abstract: The pioneering work of many in the single cell transcriptomics field has begun to illuminate the diversity of cell types in the brain. However, cardiac-projecting vagal motoneurons of the Dorsal Motor Nucleus of the Vagus (DMV) are relatively understudied. By combining principles of neuroscience and single cell transcriptomics, we begin to explore the transcriptomic phenotypes of cardiac-projecting DMV neurons. Neuromodulatory co-transmission is an emerging discipline of neuroscience, and the work of the Allen Institute suggests transcriptomics of neuropeptides and corresponding receptors may characterize cell types. We find that DMV neurons are not solely cholinergic, but simultaneously catecholaminergic and GABAergic, including those that project to the heart. These findings challenge the conventional neuronal nomenclature. We propose inputs determine phenotype, and work done on the Mouse Brain Atlas supports this premise, suggesting a transcriptomic diversification, less region-specific, results from interaction with the environment. We present here a characterization of DMV cell types by input-output transcriptomics. Remote ischemic preconditioning (RIPC) is an invasive cardioprotective physiological intervention. The literature shows the DMV is required for the cardioprotective effect of RIPC. We combine high throughput transcriptomics, 3D anatomical mapping, and neural tracing in 12 week old Sprague Dawley male and female rats to interrogate the phenotypes of DMV neurons. To distinguish potential mechanisms of cardioprotection, we highlight the functional significance of several transcripts for secreted proteins in cardiac-projecting DMV neurons. We have spatially mapped the location and molecular phenotypes of these single cells in the DMV and Nucleus Ambiguus (NA). The cardiac-projecting neurons of the DMV extend approximately 2.5 mm rostrocaudally. The cardiac-projecting neurons of the left DMV are particularly prominent caudally, while the cardiac-projecting neurons of the right DMV are particularly prominent rostrally. A unique phenotype, with transcriptomic markers of strong cardioprotective potential, is present at the rostrocaudal position of left DMV previously shown to affect ventricular contractility. There is consistency between our findings from three spatial transcriptomics techniques. Based on this, we propose a 3D anatomical and molecular map of cardiac vagal motoneurons.

Title: Unilateral vagotomy in rats blunts respiratory responses to vagal afferent stimulation

Authors: *G. C. HOFMANN[1], D. D. KLINE[2], E. M. HASSER[2];
[1]Area Pathobiology/Dalton CRC, [2]Biomed. Sciences/Dalton CRC, Univ. of Missouri, Columbia, MO

Abstract: The nucleus tractus solitarii (nTS) of the brainstem is the initial site of integration of sensory input from the cardiorespiratory system, including afferents from the vagus nerve carrying sensory input from the heart, lungs, and gut. The nTS is an important site of neuroplasticity in health and disease. Such plasticity is dependent upon a variety of factors, including neuronal and astrocytic activity, with the latter regulating glutamate signaling. We have shown that unilateral transection of the vagus nerve to decrease afferent input to the nTS results in morphologic changes in brainstem glia, including augmented astrocyte branching. Vagal nerve transection also decreases nTS synaptic transmission studied in vitro. The influence of vagotomy on in vivo cardiorespiratory function via afferent-driven glutamatergic signaling and astrocytes is unknown. We hypothesized that chronic vagotomy blunts cardiorespiratory responses to vagal afferent stimulation via altered glutamate signaling. Male Sprague-Dawley rats (6-wk, N=13) were randomly assigned to vagotomy, sham (surgery without nerve transection), or control (no surgery) groups. Right cervical vagus nerve transection caudal to the nodose ganglion was performed. One week after surgery, rats were anesthetized with Inactin, ventilated, and instrumented to measure heart rate (HR), blood pressure (BP), splanchnic sympathetic and phrenic nerve (SSNA and PhrNA, respectively) activity, and for cervical vagal nerve stimulation. Intact vagus nerves were transected acutely to prevent efferent stimulation. Left and right vagus nerves were stimulated (20 sec, 0.2mA, 10Hz, 0.5ms pulse width) and responses recorded for 3 minutes. Vagal nerve stimulation in sham and control groups decreased PhrNA frequency and amplitude (apnea). However, unilateral vagotomy blunted the decrease in PhrNA ($p<0.05$) due to stimulation of the severed (right) vagus compared to right-sided stimulation of controls and shams, and compared to left-sided (intact) stimulation. Increases in HR, BP, and SSNA to stimulation were similar among groups as well as between their ipsi- and contralateral sides. Preliminary experiments in which glutamate was nanoinjected into the right

nTS showed a trend towards blunted BP and HR responses after vagotomy compared to shams. The blunted responses to both physiological glutamate release (stimulation) and exogenous glutamate administration may indicate that vagotomy alters glutamate activity via postsynaptic or astrocytic mechanisms. Additional experiments are needed to determine the mechanisms of altered nTS response to changes in afferent input in cardiorespiratory health and disease.

Title: Vagus nerve stimulation mitigates cardiac hypertrophic remodeling in rats with pressure overload

Authors: T. BANKS[1], **A. FARRAND**[1], C. COOPER[1], M. HERNDON[1], A. HEBERT[1], B. KENKNIGHT[2], *E. BEAUMONT[1];

Abstract: Vagus Nerve Stimulation (VNS) is currently being investigated in the clinic for treatment of heart failure. Cardiac dysfunction in heart failure with reduced ejection fraction (HFrEF) is thought to be due in part to a chronic neuroinflammatory state as measured by increased pro-inflammatory cytokines in key autonomic brain nuclei. While the primary mechanism of action for VNS remains unknown, VNS exhibits anti-inflammatory properties ranging from reduced activation of glia and macrophages to a reduction of pro-inflammatory cytokine production both in the periphery and in the central nervous system. Therefore, the purpose of this study is to provide insight into VNS treatment for HFrEF via a pressure overload (PO) rat model. The PO was induced by constricting the aorta ~30-50% under anesthesia. Following the PO procedure, half of the rats underwent surgical implantation of VNS devices with a bipolar lead connected to the left cervical vagus nerve. Rats were separated into control (n=8), PO (n=6), and PO + VNS (n=12) treatment groups. We initiated VNS therapy for 2 months upon reaching a 20% decrease in left ventricular relative ejection fraction (EF, p=0.0031 compared to baseline). These PO + VNS rats were compared to age matched PO and Controls. Regular echocardiography, electrocardiogram readings and weights were recorded at baseline

and at regular intervals throughout the study for all rats. Brains were preserved and sectioned for immunohistochemical staining, and hearts were removed and weighed at termination for a final heart to body weight ratio measurement. Our findings thus far indicate that while PO reduced EF ~40% at termination (p=0.0348 compared to study midpoint, p=0.0179 compared to baseline), VNS treatment resulted in a restoration of EF back to control levels (p<0.0001 compared to study midpoint, no significant difference compared to baseline). Further, the heart/body weight ratio increased for PO rats compared to control (p=0.0386) and PO + VNS rats (p=0.0319). This demonstrates that VNS therapy mitigates physiological markers of heart failure. To assess potential mechanisms of action, neuroinflammatory markers including glial density and activation are being examined in key nuclei relevant to heart failure including both the nucleus of the solitary tract and the paraventricular nucleus of the hypothalamus. These changes will provide insight into the role of neuroinflammatory mechanisms for VNS effects in this PO model.

Title: Sparc: gastric myoelectrical activity is intrinsically synchronized with fmri activity in the rat brain

Authors: J. CAO[1], X. WANG[2], U. SCHEVEN[2], ***Z. LIU**[2];
[1]Biomed. Engin., [2]Univ. of Michigan, Ann Arbor, MI

Abstract: SPARC: Gastric Myoelectrical Activity isIntrinsically Synchronized with fMRI Activity in the rat Brain Jiayue Cao[1], Xiaokai Wang[1], Ulrich scheven[2], and Zhongming Liu[13*]

[1]Biomedical Engineering,[2]Mechanical Engineering,[3]Electrical Engineering, and ComputerScience, University ofMichigan, Ann Arbor, Michigan, United States
Background: Stomach-brain interactions are essential to interoceptive feeling and can influence cognition andemotion. However, the central neural circuits underlying stomach-brain interactions are poorlyunderstood. Recent studies tackle this problem and use simultaneous recordings of functionalmagnetic resonance imaging (fMRI)and electrogastrogram to report the phase-coupling betweenbrain activity and gastric pace-making activity. In this study, we investigated the stomach-braininteraction using a more direct measurement from the stomach, the gastric myoelectrical activity(GMA),and mapped brain regions with fMRI signals coupled to both phase changes and powerfluctuations of GMA.
Method: We implanted two pairs of electrodes on the medial (corpus)and distal (antrum)stomach torecord GMA in four rats. Each rat underwent two fMRI experiments simultaneously with GMArecording in the fasting and postprandial states. The relationship between GMA and fMRIsignals was assessed in terms of both phase and power coupling. The phase-coupling wascalculated as the coherence between fMRI and GMA at the gastric pace-making frequency; thepower-coupling was evaluated as the correlation between fMRI and GMA power fluctuations.
Results: This study confirmed the phase-coupling between the stomach and the brain in rats in bothfasting and postprandial states. The phase-coupling occurred in a broad set of brain regions,including the somatomotor cortex, visual cortex, and basal ganglia. The coupling was strongerwith gastric activity from the corpus than the antrum. In addition, the power fluctuations ofGMA were also correlated with fMRI activity in the brain, such as the anterior cingulate cortex,insular cortex, and somatomotor cortex. The power correlation was stronger in the postprandialstate than the fasting state and with the corpus than the antrum.
Conclusion: This study confirms that brain fMRI activity is synchronized with both the phase and power ofgastric myoelectric activity, more so for the corpus than the antrum. The results suggest that thebrain monitors the stomach for both gastric rhythms and contractional power and may contain atopographic mapping of the stomach function.

Title: Proliferation of putative GABA/glutamate co-releasing terminals in the primate habenula

Authors: *L. RIOS[1], C. TAN[2], A. HAJEISSA[1], V. NARLA[1], K. GLEASON[1], C. A. TAMMINGA[3], S. SHABEL[1];
[2]Psychiatry, [1]UT Southwestern Med. Ctr., Dallas, TX; [3]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: The lateral habenula (LHb) responds to aversive stimuli, and its hyperactivity is hypothesized to contribute to depression. Most of the central nervous system uses a balance of excitatory and inhibitory transmission from separate inputs to control neural activity. However, multiple inputs to the lateral habenula co-release GABA with glutamate in rodents; the balance of GABA and glutamate at these synapses may regulate LHb responses to aversive stimuli and mood. Here, we investigated whether the magnitude and topography of co-release of GABA and glutamate in the LHb is conserved in primates. Our data indicate substantially increased co-labeling of GAD (the synthesizing enzyme for GABA) and VGLUT2 (vesicular glutamate transporter), as well as VGAT (vesicular GABA transporter) and VGLUT2, in synaptic terminals in the monkey and human LHb, consistent with increased co-release of GABA and glutamate from individual terminals onto primate LHb neurons. We also found an expanded topography of co-release in the primate LHb, perhaps partly due to expansion of the LHb in primates. Thus, co-release of GABA with glutamate may be a mechanism for regulation of LHb activity and mood that proliferated during primate evolution.

Title: Looking at both sides: a scoping review of neurochemical asymmetries in animal models of depression

Authors: *F. B. ALMEIDA[1,2], R. L. FIORE[2], R. GOMEZ[4], M. S. NIN[1,4,5], H. M. T. BARROS[1,2,3];
[1]PPG Ciências da Saúde: Farmacologia e Toxicologia, [2]Laboratório de Neuropsicofarmacologia, [3]Dept. de Farmacociências, Univ. Federal de Ciências da Saúde de Porto Alegre (UFCSPA), Porto Alegre, Brazil; [4]PPG Ciências Biológicas: Farmacologia e Terapêutica, Univ. Federal do

Rio Grande do Sul (UFRGS), Porto Alegre, Brazil; [5]Dept. de Farmacologia, Univ. Federal do Rio Grande (FURG), Rio Grande, Brazil

Abstract: Many clinical studies have demonstrated an asymmetry in cortical function of depressed individuals, contrasting with a symmetrical activity observed in non-depressed controls. However, the relationship of this functional asymmetry with the neurochemistry that drives the underlying mechanisms of depression is not clear. In this sense, preclinical studies that investigate the hemisphere-specific role of neurochemical markers in depressive-like behaviors and antidepressant action could shed light on this matter. Thus, we conducted a systematic scoping review to map the preclinical literature on depression that investigated hemisphere-specific levels of neurochemical markers related to animal models of depression and antidepressant treatment. We searched four different databases (PubMed, EMBASE, PsycInfo and LILACS) for relevant papers that were subsequently screened for eligibility, and a final number of 23 articles were included. Our results show that animal models of depression used were based on stress (either prenatal, on early-life or on adulthood), congenitally depressed rat lines, or were pharmacologically induced. Several different antidepressants were used as pharmacotherapies, but other classes of substances such as neurosteroids and hypertensives were also administered. The array of neurochemical markers assessed was highly heterogeneous, with dopamine, serotonin, brain-derived neurotrophic factor (BDNF) and subunits of the $GABA_A$ receptor appearing with the higher frequencies. For each neurochemical marker, studies were of significantly different experimental designs to derive generalizable conclusions, but experiments in which laterality was analyzed as a factor in ANOVA statistics were mapped and quantified. Approximately one third (32%) of all experiments that were analyzed this way showed an interaction with the laterality factor, demonstrating a significant impact of hemisphere for the measurement of neurochemical markers. Our results underscore the importance of considering cerebral laterality when measuring neurochemical markers relevant for depression, while pointing to potential issues with the design of neurochemical analysis and with publication/reporting bias in the field. More research of this kind is needed to allow for cross-study comparison of inter-hemispheric neurochemical data in animal models of depression.

Title: Activation of a novel α_{2A}AR-spinophilin-cofilin axis determines the effect of α_2 adrenergic drugs on fear memory reconsolidation

Authors: S. SAGGU[1], Y. CHEN[1], H. WANG[1], C. COTTINGHAM[1], S. ZHANG[2], C. AUGELLI-SZAFRAN[2], K. JIAO[1], X.-Y. LU[3], *Q. WANG[1];

Abstract: Posttraumatic stress disorder (PTSD) after the pandemic has emerged as a major neuropsychiatric component of post-acute COVID-19 syndrome, yet the current pharmacotherapy for PTSD is limited. The use of adrenergic drugs to treat PTSD has been suggested; however, it is hindered by conflicting clinical results and a lack of mechanistic understanding of drug actions. Our studies, using both genetically modified mice and human induced pluripotent stem cell-derived neurons, reveal a novel α_{2A} adrenergic receptor (α_{2A}AR)-spinophilin-cofilin axis in the hippocampus that is critical for regulation of contextual fear memory reconsolidation. In addition, we have found that two α_2 ligands, clonidine and guanfacine, exhibit differential abilities in activating this signaling axis to disrupt fear memory reconsolidation. Stimulation of α_{2A}AR with clonidine, but not guanfacine, promotes the interaction of cofilin, an actin binding protein, with the dendritic spine scaffolding protein spinophilin to induce cofilin activation at the synapse. Spinophilin-dependent regulation of cofilin is required for clonidine-induced disruption of contextual fear memory reconsolidation. Our results inform interpretation of differential clinical observations of these two drugs on PTSD, and suggest that clonidine could provide immediate treatment for PTSD symptoms related to the current pandemic. Furthermore, our study indicates that modulation of dendritic spine morphology may represent an effective strategy for the development of new pharmacotherapies for PTSD.

Title: Reciprocal control of obesity and anxiety-depressive disorder via a GABA and serotonin neural circuit

Authors: *Q. WU[1], G. XIA[2], Y. HAN[2], F. MENG[3], Y. HE[1], D. SRISAI[4], R. D. PALMITER[5], Y. XU[1];
[2]Pediatrics, [1]Baylor Col. of Med., Houston, TX; [3]Neurol., The Univ. of Texas At Austin, Austin, TX; [4]Mol. Physiol. & Biophysics, Vanderbilt Univ., Nashville, TN; [5]Univ. of Washington, Seattle, WA

Abstract: The high comorbidity between obesity and mental disorders, such as depression and anxiety, often exacerbates metabolic and neurological symptoms significantly. However, neural mechanisms that underlie reciprocal control of feeding and mental states are largely elusive. Here we report that melanocortin 4 receptor (MC4R) neurons located in the dorsal bed nucleus of the stria terminus (dBNST) engage in the regulation of mentally associated weight gain by receiving GABAergic projections from hypothalamic AgRP neurons onto α5-containing $GABA_A$ receptors and serotonergic afferents onto 5-HT_3 receptors. Chronic treatment with a high-fat diet (HFD) significantly blunts the hyperexcitability of AgRP neurons in response to not only hunger but also anxiety and depression-like stimuli. Such HFD-mediated desensitization reduces GABAergic outputs from AgRP neurons to downstream $MC4R^{dBNST}$ neurons, resulting into severe mental dysregulation. Genetic enhancement of the $GABA_AR$-α5 or suppression of the 5-HT_3R within the $MC4R^{dBNST}$ neurons not only abolishes HFD-induced anxiety and depression, but also robustly reduces body weight by suppression of food intake. To gain further translational insights, we revealed that combined treatment of zonisamide (enhancing the $GABA_AR$-α5 signaling) and granisetron (a selective 5-HT_3R antagonist) alleviates mental dysfunction and yields a robust reversal of diet-induced obesity by reducing total calorie intake and altering food preference towards a healthy low-fat diet. Our results unveil a neural mechanism for a reciprocal control of appetite and mental states, which culminates in a novel zonisamide-granisetron cocktail therapy for potential tackling the psychosis-obesity comorbidity.

Title: Acute stress reduces effort-related motivation in male and female rodents

Authors: *E. ERRANTE, O. I. AKINBO, L. MATUSZEWICH;
Northern Illinois Univ., Dekalb, IL

Abstract: Motivational dysfunction is present in a variety of disorders, including major depressive disorder, schizophrenia, and Parkinsonism (Demyttenaere et al., 2005) and can negatively impact social functioning, employment, and treatment response (Tylee et al., 1999). Outside stressors and stress hormones have been shown to contribute to depressive episodes in humans and depressive-like behaviors in rodents, including reducing motivated behaviors (Hammen, 2005; Sinha et al., 2018). One approach of examining motivation in both humans and animals is to assess effort-related decision making procedures, as the subject is given a choice between high effort/reward and low effort/reward options (Errante et al., 2021; Shafiei et al., 2012; Treadway et al., 2012). Despite prior research consistently showing sex differences in the

prevalence of depression and depressive-like behaviors in humans, little research has examined the effects of stress on effort-related decision making behaviors in female rats. Thus, the current study investigated the impact of acute stressors or the stress peptide hormone CRF on effort-related choice procedures in both sexes. Male and female rodents were trained on a fixed ratio 5/chow choice feeding procedure for a highly valued sucrose pellet reward or to approach and consume freely available lab chow in an operant chamber. Once responding was stable, rats experienced an acute stressor (Group 1: restraint stress, yohimbine, and food restriction) or a systemic manipulation of CRF (Group 2: CRF peptide, restraint stress, and CRF antagonist antalarmin with restraint stress). Baseline performance in the effort-related decision making task was similar across both sexes ($p > 0.05$). Exposure to restraint stress for 1 hour or yohimbine in group 1 resulted in lower levels of lever pressing in both male and female rodents ($p < 0.05$). In group 2, restraint stress also resulted in lower levels of lever pressing in both male and female rodents ($p < 0.05$); however, antalarmin did not attenuate this response. Further, CRF did not negatively alter performance. Collectively, the current project suggests that stress negatively alters
motivation in both male and female rodents equally; however, more work needs to be done in order to fully understand this phenomenon to improve treatment for mental illnesses associated with motivation.

Title: Leveraging evolution to unravel the neuro-molecular basis of psychiatric disorders in the human amygdala

Authors: *J. HAN[1,2], H. A. HOFMANN[2,1,3];
[1]Inst. for Cell. & Mol. Biol., [2]Dept. of Integrative Biol., [3]Inst. for Neurosci., The Univ. of Texas at Austin, Austin, TX

Abstract: The toll of psychiatric disorders is staggering, with an estimated 51.5 million adult sufferers in the US alone! The development of effective interventions has been hampered by the fact that the underlying molecular mechanisms are still not well understood. Because the complex phenotypes of human mood disorders, in particular, cannot be readily recapitulated in non-human animals, any animal model of a psychiatric disorder is necessarily limited in its applicability to the human condition. Nevertheless, numerous studies have shown that abnormalities of the subpallial amygdala - an evolutionarily ancient forebrain region critical to

decision-making and emotional responses - are associated with psychiatric disorders. However, this research cannot explain why certain gene expression modules are susceptible to dysregulation in specific mood disorders or how unique these processes might be to humans. We hypothesized that gene expression modules dysregulated in psychiatric disorders have been gained in the lineage leading to humans. We used phylogenetic comparative transcriptome analyses to understand how evolution has shaped neuromolecular pathways in the (medial) amygdala that may leave us vulnerable to psychiatric disorders. We first collected and normalized publicly available transcriptome datasets of (medial) amygdala (n=351 individuals) for 12 vertebrate species, representing mammals, birds, reptiles, and teleosts. Next, we reconstructed ancestral amygdala transcriptomes for vertebrates, amniotes, mammals, and primates, which allowed us to identify evolutionary conserved "core transcriptomes" of the medial amygdala and its putative non-mammalian homologs. We found that <2% of the genes expressed in the human amygdala transcriptome have been gained compared with the ancestral transcriptome of the common ancestor of primates, suggesting that most dysregulated in psychiatric disorders are not human-specific. We then identified the gene co-expression modules that are either evolutionarily conserved or have evolved *de novo* in the lineage leading to humans and again found that most of these modules are evolutionarily ancient. Finally, few gene co-expression modules dysregulated in different psychiatric disorders are uniquely human and instead display deep evolutionary roots. Our novel approach illuminates the surprising evolutionary origins of the molecular mechanisms underlying complex (social) behavior and their vulnerability to dysregulation in various psychiatric disorders.

Title: Auditory cocaine-cue orienting behavior in rats: role of locus coeruleus

Authors: *M. A. PRESKER[1], S. A. TOMBOKAN[1], G. S. ASTON-JONES[2];
[1]Rutgers - The State Univ. of New Jersey, Piscataway, NJ; [2]Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: Enhanced behavioral reactivity to and altered neural encoding of drug-associated cues is a primary feature of addiction that contributes to relapse, a primary therapeutic target.

Plasticity in attention and sensory systems may underlie altered drug-cue reactivity in cocaine (COC) addiction. The locus coeruleus (LC) is a noradrenergic brainstem nucleus that projects widely throughout the neocortex and modulates attention and sensation. Although LC is important for drug-cue memories and stress-induced drug seeking, it is not clear what role LC plays in encoding drug-cue salience. We developed a behavioral paradigm to examine the effect of an auditory COC cue on a natural reward operant behavior (nosepoking for water). Rats learned to self-administer water and then underwent classical conditioning to associate one tone with COC (20mg/kg, ip) and another with saline. After conditioning, the effect of the tone on responding for water and stimulus orienting was measured. Behavior was recorded by operant chambers equipped with photodiodes and video cameras. Preliminary results indicate that the COC tone exerted significantly different behavioral control over both responding for water and stimulus orienting compared to the saline tone. This behavioral activation correlates with a significant increase in LC activity measured by Fos expression. Furthermore, the COC tone functioned as a conditioned reinforcer and supported the acquisition of a novel operant response (lever press). Ongoing experiments employ chemogenetic inhibition to test the role of LC in the ACQUISITION (conditioning) and EXPRESSION (tone testing) of the drug-tone association, respectively. TH-cre+ rats (N=36) received virus injections to express the inhibitory hM4Di DREADD receptor or GFP in LC (n=18 each). Next, rats trained on the water task and were split into ACQUISITION and EXPRESSION groups, counterbalanced by virus and behavior. ACQUISITION rats were conditioned and tested as described, except they were pre-treated with CNO (1mg/kg, ip) to inhibit LC during COC tone conditioning. EXPRESSION rats were conditioned normally except they were pretreated with CNO prior to tone testing sessions. All behavior was analyzed between subjects, to determine effects of LC inhibition by hM4Di, and within subjects, to determine cue specificity. Preliminary findings indicate that a COC cue can control attention and natural reward motivated behavior, and that LC encodes aspects of these responses. Ongoing experiments will test the causal role of LC in the acquisition and expression of this response, potentially indicating a new avenue for addiction treatment.

Title: The orexin/hypocretin system drives affective behaviors associated with acute abstience from oxycodone.

Authors: *J. E. FRAGALE, V. A. STIRITZ, K. A. NEWMAN, M. H. JAMES, G. S. ASTON-JONES;
Brain Hlth. Inst., Rutgers, The State Univ. of New Jersey, Piscataway, NJ

Abstract: Opioid use disorder (OUD) is a chronic and relapsing disorder that has become a national emergency.Misuse of prescription opioids, like oxycodone, is a major contributing factor to the current crisis.Although the rewarding properties of prescription opioids are important for initial drug use, aversivewithdrawal states are believed to better explain the compulsive nature of addiction. Orexins (hypocretins)are neuropeptides produced in the hypothalamus that are important for physical withdrawal; however,less is known regarding the role of orexins in affective withdrawal symptoms. Here, we establish an animalmodel of negative affect associated with acute abstinence from oxycodone, and investigate thecontribution of the orexin system. Male Sprague Dawley rats were treated with non-contingentoxycodone (n=16) or saline (n=16) for 21 days and assessed for evidence of depression and anxiety-likebehaviors during acute abstinence. Compared to saline-treated rats, oxycodone rats showed decreasedsaccharin preference, increased anxiety-like behavior on the elevated plus maze, and reduced mobilityduring the forced swim test (independent samples t-tests, $p<0.001$). Other withdrawal signs such ashyperalgesia and reduced weight gain were also observed (independent samples t-tests, $p<0.05$). Ratswere sacrificed 24h following their final saline or oxycodone treatment, and orexin expression wasassessed using immunohistochemistry. Oxycodone-treated rats (n=7) expressed greater numbers oforexin-expressing neurons compared to saline controls (n=7; independent samples t-test, $p<0.01$).Moreover, oxycodone-treated rats with more orexin neurons exhibited stronger negative affectivebehaviors during acute abstinence compared to saline-treated subjects (*Pearson's r, n=7, r=-0.90)*. Todetermine the functional significance of the orexin system in the development of negative affectivesymptoms, the inhibitory DREADD hM4Di was selectively expressed in orexin neurons of male Bac-transgenic orexin-cre rats. Oxycodone-treated rats expressing hM4Di (n=12) showed attenuated affectivesymptoms during acute abstinence compared to mCherry control rats (n=12; independent samples t-test,$p<0.05$), indicating that the orexin system must be engaged for these behaviors to develop. In sum, thedata support a novel role for the orexin system in affective behaviors associated with opioid withdrawaland further highlight this system as a potential treatment target for OUD.

Title: Role of orexin-1 receptor signaling in demand for the opioid fentanyl in adult females

Authors: *C. CORWIN[1], D. DE SA NOGUEIRA[1], V. PUNNURU[2], Y. RAKHOLIA[1], J. E. FRAGALE[1], A. S. KOHTZ[1], G. S. ASTON-JONES[1];
[1]Brain Hlth. Inst., [2]Dept. of Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: Over 10 million individuals in the United States misuse opioids, and opioids are involved in 70% of drug overdose deaths, which was exacerbated during the COVID-19 pandemic. The opioid epidemic appears to affect women differently than men, indicated by the notable increase of prescription opioid-related deaths among women over the past two decades. The orexin / hypocretin system plays a critical role in reward-processing and is a potential treatment target for drug addiction. Preclinical studies suggest that higher orexin system activity in females and female rodents exhibit higher motivation to self-administer opioids. Fluctuating hormone levels during the menstrual cycle may greatly affect drug seeking behavior, as indicated by morphine's analgesic effect being greater during the follicular phase than the luteal phase of the menstrual cycle. We previously reported that, in male rats, orexin-1 receptor (OxR1) antagonist SB-334867 (SB) decreased demand for fentanyl, a short-acting drug with 50 times the potency of heroin. A behavioral economics (BE) procedure measures drug motivation (inverse α) and drug consumption at null cost (Qo) and has been proven to be useful in the study of opioid abuse, as SB efficacy and the amount of cued reinstatement of fentanyl seeking were predicted by baseline α values in male rats. To gain insight into the role of the orexin-system in fentanyl addiction in females, we assessed the effects of OxR1 antagonism using the BE procedure in adult female Long-Evans rats while monitoring their estrous cycle. In addition, we applied different access paradigms for fentanyl self-administration (1-hr continuous access (short access [ShA]), 6-hr continuous access (long access [LgA]), or 5-min access followed by 25-min of no access for 6-hrs (intermittent access [IntA])) for 14 days, resulting in varying degrees of fentanyl demand. SB efficacy was tested using the BE procedure and its effect on cue-induced fentanyl seeking in female rats. SB significantly decreased motivation (increased α) for fentanyl at the dose of 30 mg/kg B.W. (rm-ANOVA with Dunnett's test; *$p < 0.05$; n=11) without affecting Qo (rm-ANOVA; ns). However, unlike in male rats, SB appears less effective at reducing the fentanyl seeking in highly motivated (Pearson's r; *$p < 0.05$) female rats. Lower α predicts higher cued reinstatement of fentanyl seeking (Pearson's r; $p = 0.10$; n=8) which tends to decrease with SB treatment (rm-ANOVA with Dunnett's test; $p = 0.11$; n=8). Further analysis will be performed to elucidate the role of estrous cycle in fentanyl seeking female rats. In conclusion, our study supports OxR1 antagonist as a potential pharmacotherapy for opioid addiction in women.

Title: Elevated depressive- and anxiety-like behaviors with prolonged abstinence from intermittent fentanyl self-administration

Authors: *K. A. NEWMAN[1], J. E. FRAGALE[2], G. S. ASTON-JONES[3];
[1]Rutgers Univ. Grad. Program In Neurosci., Piscataway, NJ; [3]Brain Hlth. Inst., [2]Rutgers Univ., Piscataway, NJ

Abstract: The urgency of the opioid crisis is heightened by a rise in abuse of synthetic opioids. Identifying pharmacological targets for effective opioid addiction treatments, which are scarce, requires animal models recapitulating the multifaceted addicted state. Opioid use disorder (OUD) is marked by a negative emotional state in abstinence (including depressive- and anxiety-like behaviors), the alleviation of which may motivate prolonged drug-seeking. The goal of this study was to assess depressive- and anxiety-like behaviors arising in protracted abstinence from intermittent access (IntA) fentanyl self-administration (SA), which induces strong drug motivation and relapse behaviors. We sought to correlate increased motivation for fentanyl with negative affective and relapse behaviors. Adult male Sprague Dawley rats (n=15) self-administered fentanyl (0.5g iv/infusion) in 2h sessions for 10d and until 3 consecutive sessions resulted in at least 25 infusions. Baseline fentanyl motivation was measured using a within-session behavioral economics (BE) procedure, which assesses drug consumption with increasing price, followed by 14d of fentanyl IntA SA. Post-access fentanyl demand was tested with BE. Rats were tested either in acute withdrawal or following 30d of abstinence for depressive- and anxiety-like behaviors with saccharin preference, social interaction (SI), and light-dark box (LDB) tests and the elevated plus maze (EPM). All rats were re-exposed to the SA chamber for 2h without infusions and cues to test relapse behavior. The abstinence group was tested on BE for persistent changes in fentanyl motivation. Rats showed escalated fentanyl intake during IntA and higher drug motivation with BE post-IntA compared to pre-IntA, indicating induction of a robust addiction-like state. Following 30d of abstinence, rats (n=8) showed decreased saccharin preference and SI scores and increased depressive- and anxiety-like behaviors in the LDB and EPM, respectively, compared to acute withdrawal rats (n=7; independent samples t-tests, $p<0.05$). Early data show that these behaviors are correlated to post-access fentanyl motivation, which was elevated at 30d of abstinence, and that fentanyl motivation predicts relapse behavior, such that the highest-motivated rats show greater relapse when re-exposed to the SA chamber.

These results confirm that IntA induces an expansive addiction-like state including depressive- and anxiety-like behaviors, pointing to its value as a preclinical model of OUD; that a negative emotional state arises with abstinence from opioids; and that drug motivation assessed with BE can predict this state and relapse propensity.

Title: Oxytocin attenuates progesterone-dependent perturbations in cocaine demand

Authors: *A. KOHTZ, H. DAVIES, B. LIN, J. ZHAO, M. PRESKER, G. ASTON-JONES; Brain Hlth. Inst., Rutgers Univ., Piscataway, NJ

Abstract: There are substantial sex differences in drug abuse, and a key feature of cocaine addiction is pathologically high economic demand for drug. The hypothalamic neuropeptide oxytocin (OXT) is heavily implicated in the modern treatment of substance abuse disorders. Notably, OXT neuron activity is reduced during abstinence from chronic cocaine exposure in both males and females. Female rats may be particularly sensitive to OXT dysfunction following cocaine use, as there are substantial differences in OXT mRNA, binding affinity, and OXT target neuron activity across the estrous cycle that are progesterone (P4)-dependent. Using a within-session threshold behavioral economics (BE) procedure, we quantified demand elasticity (α, inverse motivation) and free consumption (Q_0, hedonic setpoint) in female rats across the estrous cycle and in ovariectomized (OVX) and hormone-replaced female rats. Overall, female rats showed lower demand elasticity (greater motivation) for cocaine compared to males, with estrus cycle phase accounting for 70% of the variance between data points within a subject. High serum P4 (e.g., in proestrus) predicted decreased cocaine motivation, and administering P4 (4 mg/kg) to low P4 females (OVX, diestrus) decreased cocaine motivation. Notably also, long-term cocaine self-administration altered estrous cyclicity; indicating substantial endocrine disruption. By 13 weeks, proestrus epochs were no longer observed, and cocaine demand was potentiated by permanent estrus. Using naturally cycling rats, we found that OXT efficacy to decrease motivation for cocaine is greater during the high-demand phase of the estrous cycle (diestrus) as

compared to low demand phases (proestrus) or male rats that have lower demand overall. Following each individual injection, OXT at either 0.1mg/kg or 0.3mg/kg restored estrous cycling in intact females with prior cocaine experience for a period of one week and was continuously effective with up to 4 weeks of injections. Centrally, activity of OXT neurons in the paraventricular hypothalamic nucleus correlated to both decreased demand in females, and to increased circulating levels of P4. Effects of P4-replacement in OVX females were blocked by Atosiban (1 mg/kg; OXT receptor antagonist). Thus, OXT may represent a viable treatment option, not only for acute suppression of drug demand, but also for its long-term effects to reverse the endocrine disrupting effects of cocaine.

Title: A sex-specific role for PKMζ in oxycodone self-administration

Authors: *M. C. KNOUSE[1], T. M. HOUSER[1], E. A. BIRMINGHAM[1], L. A. BRIAND[2]; [2]Psychology, [1]Temple Univ., Philadelphia, PA

Abstract: The Protein Kinase C (PKC) family works to control the function of other proteins via phosphorylation. One particular member of this family, PKMζ, is constitutively active and found exclusively in the central nervous system. Previous work from our lab demonstrated that constitutive deletion of PKMζ potentiates cocaine self-administration and cue-induced reinstatement in both male and female mice. Additionally, other groups have demonstrated that disrupting PKMζ leads to increased alcohol drinking. However, it is not known whether PKMζ plays a role in opiate reward. Therefore, in the current experiments we examined the effect of constitutive PKMζ deletion on oxycodone self-administration in both sexes. In contrast to what has been seen with cocaine self-administration, we find that PKMζ knockout leads to an increase in oxycodone self-administration in female mice at multiple doses tested. However, male PKMζ knockout mice do not exhibit alterations in oxycodone self-administration compared to wildtype mice. We next went on to examine the influence of oxycodone self-administration on synaptic plasticity within the nucleus accumbens of wildtype and PKMζ knockout mice. Preliminary

electrophysiological data indicate that both wildtype and PKMζ knockout mice exhibit normal long-term depression following oxycodone self-administration. Current work is extending these findings to examine presynaptic plasticity with paired-pulse ratios and spontaneous glutatmate transmission with sEPSCs in wildtype and PKMζ knockout mice following oxycodone self-administration. These results suggest that PKMζ plays a sex-specific role in opioid drug taking.

Title: The role of PKMζ in anxiety-like behavior in male and female mice.

Authors: *A. M. MCBRIDE[1], R. DEARRING[2], R. E. PEREZ TREMBLE[2], E. A. BIRMINGHAM[2], L. A. BRIAND[2];
[1]Dept. of Psychology and Neurosci. Program, [2]Temple Univ., Philadelphia, PA

Abstract: The constitutively active, atypical protein kinase C, protein kinase M-ζ, is exclusively expressed in the brain and plays a role in drug seeking. Constitutive deletion of PKMζ leads an increase in drug seeking. However, the role of PKMζ in drug seeking is sex-specific, with accumbal PKMζ knockdown only affecting cocaine seeking in male mice, while constitutive deletion increases cocaine seeking in both sexes. Mood disorders are often comorbid with substance use disorder and play a role in both vulnerability to drug use and propensity for drug relapse. Along with its established role in drug seeking, previous research has determined that PKMζ plays a role in anxiety-like behavior as well. However, despite the fact that mood disorders are more prevalent in women, the previous work was conducted only in male rodents, therefore, it is not clear whether the role of PKMζ in anxiety-like behavior is also influenced by biological sex. The goal of the current studies was to determine the role of PKMζ on anxiety-like behavior in male and female mice. We found that constitutive PKMζ deletion led to alterations in the novelty-suppressed feeding task that were sex specific. Studies are underway to determine if these sex-specific findings extend to other tests of anxiety-like behavior. Further, as we have previously found PKMζ deletion within the accumbens plays a role in cocaine seeking in males, we are extending these findings to determine the influence of site-specific manipulations of

PKMζ expression. These findings suggest that PKMζ within the mesolimbic pathway plays a role in anxiety and drug seeking.

Title: Post-weaning social isolation alters addiction-like behaviors and synaptic plasticity in the nucleus accumbens and prefrontal cortex: Role of sex and neuroimmune signaling.

Authors: *A. G. MCGRATH, B. T. RHOADS, E. A. BIRMINGHAM, M. C. KNOUSE, L. A. BRIAND;
Psychology, Temple Univ., Philadelphia, PA

Abstract: Mitigation efforts during the coronavirus pandemic led to an increase in social isolation. This can be particularly difficult for adolescents, when social interaction with peers is particularly rewarding. Animal models have demonstrated that social isolation during adolescence can have long lasting effects. Our lab has shown that post-weaning social isolation leads to increased motivation for cocaine and greater vulnerability to cue-induced relapse in adulthood. However, little is known about how post-weaning social isolation alters the brain. Early life stress can lead to persistent restructuring of neurons. Changes in dendritic spines can be long-lasting and have been theorized to play an important role in the maintenance of cocaine craving even after long periods of abstinence. In the current study, we found that post-weaning social isolation stress led to a persistent increase in spine density in adulthood within both the core and shell regions of the nucleus accumbens in male mice, but not female mice. In contrast, post-weaning isolation increased spine density within the prelimbic cortex of both males and females. Further, in the infralimbic cortex, post-weaning social isolation led to an increase in spine density only in female mice. This study highlights the long-lasting, sex-specific effects of post-weaning isolation, however the mechanisms by which isolation alters spine density remains unknown. Microglia have been shown to assist in both the formation and elimination of dendritic spines, and are activated following exposure to stress and cocaine. Therefore, we hypothesized that microglia may be involved in the restructuring of dendritic spines during post-weaning isolation, and contribute to addiction-like behavior in adulthood. We examined whether

inhibiting microglia with minocycline during the first three weeks of post-weaning isolation would alter the impact of isolation in cocaine seeking. Isolated animals that received minocycline showed increased cocaine seeking in adulthood compared to group housed mice and isolated mice that received saline. This increased cocaine seeking was associated with increased spine density in the nucleus accumbens. The findings of these studies provide insight into the mechanisms by which social isolation during adolescence increases vulnerability to addiction later in life.

Title: Post-weaning social isolation alters sociability in male mice but not female mice.

Authors: *E. A. BIRMINGHAM[1], B. T. RHOADS[1], A. G. MCGRATH[1], N. A. MILES[1], L. A. BRIAND[2];
[2]Psychology, [1]Temple Univ., Philadelphia, PA

Abstract: Adolescence is a critical period for brain development and social adversity during adolescence can have long lasting impacts on mental health. Social reward is particularly salient during adolescence and a lack of social interaction can lead to long-lasting effects on behavior and brain development. Social isolation and loneliness may lead to more detrimental mental health outcomes in women[14] however, much of the work on the impact of social isolation has been performed exclusively in male animals. Our lab has previously shown that post-weaning social isolation increases vulnerability to reinstatement of cocaine seeking in adulthood and this impact of social isolation does not extend to reinstatement of natural rewards. However, to date, it is not known whether this social isolation paradigm influences social reward behavior. The goal of these experiments was to examine the effects of post-weaning social isolation on sociability and social reward both during adolescence and adulthood. First, we examined the impact of housing condition on a three-chamber sociability task during adolescence at PND45 (24 days after the start of social isolation). We found that adolescent male mice spend more time sniffing a novel mouse than a novel object and this preference for social interaction was not influenced by their housing condition. In contrast adolescent female mice spend equal times

interacting with the novel mouse and the novel object. Overall, female mice that were socially isolated and left unhandled in their cage exhibited lower novelty seeking than group housed females. When the mice were tested during adulthood, we found that male mice that were socially isolated at weaning maintained this preference for interacting with a novel social partner, whereas male group housed animals did not. Current work is underway to extend these findings to examine social reward and social recognition memory in male and female mice following post-weaning social isolation.

Title: Impact of access conditions on substance use disorder-like phenotypes and receptor densities in rats self-administering cocaine or 3,4-methylenedioxypyrovalerone

Authors: *M. R. DOYLE[1,3], G. G. GOULD[2], M. S. BUSHNELL[1], M. SYED[1], K. C. RICE[4], L. C. DAWS[2,1], G. T. COLLINS[1,3];

Abstract: Despite decades of research, the behavioral, pharmacological, and neurobiological determinants of one's vulnerability to develop a substance use disorder (SUD) are not well understood. When rats self-administer cocaine under short-access conditions, patterns of drug-taking tend to be well-regulated; however, manipulating drug access conditions (e.g., long-access or intermittent-access) can produce neurobiological and behavioral changes thought to be related to SUD. In contrast to cocaine, when rats self-administer the synthetic cathinone 3,4-methylenedioxypyrovalerone (MDPV) under short-access conditions, a subset of rats rapidly develop high levels of dysregulated drug-taking behavior. MDPV has not been studied under extended access conditions, and it is unknown whether this MDPV phenotype is an earlier manifestation of the SUD-like phenotype observed with extended access to cocaine, or whether the two phenotypes are qualitatively different. Additionally, changes in receptor densities (e.g.,

dopamine D_2, dopamine D_3, 5-HT_{2A} or 5-HT_{2C}) in rats with more severe SUD-like phenotypes are not well characterized. The current studies used male and female Sprague Dawley rats self-administering MDPV (0.032 mg/kg/infusion) or cocaine (0.32 mg/kg/infusion) to test the hypotheses that (1) under short-access conditions, rats self-administering MDPV exhibit higher levels of drug taking, greater levels of responding when drug is not available, and reduced sensitivity to punishment by foot shock (i.e., SUD-like behaviors); (2) that 21 days of long- and intermittent-access to MDPV or cocaine self-administration will result in greater SUD-like behaviors compared to short-access self-administration; and (3) differences in receptor densities will be related to the SUD-like phenotype score. After short-access self-administration, rats that self-administer MDPV exhibited greater SUD-related behaviors than rats self-administering cocaine. Though long- and intermittent-access altered patterns and/or levels of drug-taking behavior, manipulating access condition did not appear to systematically alter the SUD-like behaviors or receptor densities in rats self-administering either cocaine or MDPV. Early analyses suggest no difference in receptor densities among groups, however quantification is in early stages. These results suggest that the phenotype exhibited by rats self-administering MDPV is not the same phenotype as that observed for rats self-administering cocaine. Therefore, short-access MDPV self-administration may be a useful method to study individual differences in drug-taking behavior that may be related to SUD in humans.

Title: Intermittent social defeat stress decreases the neuronal response to reward-predicting cues in the prefrontal cortex during a reward-seeking task

Authors: H. M. HARRIS[1], ***A. DEL ARCO**[2];
[1]Columbia Univ., New York, NY; [2]Univ. of Mississippi, Oxford, MS

Abstract: The intermittent (episodic) exposure to social defeat stress (ISD) increases cocaine self-administration and makes animals more vulnerable to develop substance use disorders. Previous studies suggest that an increased reward-seeking behavior is associated with an impaired reward processing in the prefrontal cortex (PFC). The present study tests the hypothesis that ISD impairs reward processing in the PFC by recording cue-evoked neuronal activity in this

area of the brain. Male Long Evans rats (3-4 months old) were trained in a discriminative-stimulus (DS) reward-seeking task in which rats were required to engage in or withhold responding on trial-by-trial basis depending on a specific stimulus. Briefly, rats were trained to discriminate between a rewarded (continuous tone) and a non-rewarded (intermittent tone) stimulus that was paired to the extension of a lever (right or left, counterbalanced). Responding to the rewarded cue by pressing the lever delivered a sugar pellet. After stable performance, rats were implanted with multiunit electrode arrays in the medial PFC (prelimbic area) and divided in two groups (Control, n= 7; Stress, n= 8). Then, they were exposed to ISD (or handling, Control group) once every three days for ten days (four stress episodes in total). PFC activity was recorded during the DS task in both stressed and control animals two weeks after the last stress episode. The results show that both stressed and control animals made more responses (lever presses) to the rewarded cue compared to the non-rewarded cue across sessions ($F_{(7,13)}$= 34.37; $p< 0.001$, ANOVA). There were not group differences in the number of lever presses in response to both cues. The onset of the reward cue produced the activation and inhibition of different neuronal populations in the PFC. Critically, the number of activated neurons in response to the reward cue was significantly lower in stressed animals compared to controls ($\chi^2(2)= 10.64$, $p< 0.01$). Moreover, and in contrast to controls, stressed animals showed an inhibition of the average population activity in response to the cue. These results show that ISD alters cue-evoked prefrontal neuronal activity in the long term (weeks after stress) and suggest that a decreased sensitivity to reward-predicting cues in the PFC increases vulnerability to develop drug abuse.

Title: Activation of gaba projection neurons from the ventral tegmental area to the nucleus accumbens facilitates cocaine self-administration at low doses

Authors: *M. SUAREZ[1], C. E. BASS[2];
[1]Univ. At Buffalo, Buffalo, NY; [2]955Main St., Univ. At Buffalo SUNY, Buffalo, NY

Abstract: Several brain areas play a role in sensitivity to both cocaine and cocaine-associated cues; the Ventral Tegmental Area (VTA) is heterogeneous midbrain region with dense afferents

to the Nucleus Accumbens (NAc) that has been extensively studied for its role in natural- and cocaine-associated behaviors. Most of the neurons in the VTA are dopaminergic, however, the VTA also contains GABA interneurons, as well as GABA projection neurons (GPNs). Approximately one third of mesoaccumbal afferents are GABAergic and are critical for cue-motivated responding. Using a combinatorial viral approach to target activating designer receptors exclusively activated by designer drugs (DREADDs) to VTA glutamate decarboxylase 1-positive neurons in rats, our lab has previously demonstrated that chemogenetic global activation of all VTA GABA neurons decreases motivation for sucrose-predictive cues. Furthermore, when reward value was unexpectedly reduced by decreasing the volume of sucrose earned, clozapine N-oxide (CNO) microinfused only in the NAc reduced responding to the sucrose-predictive cue when compared to controls. Currently, the role of these GPNs in cocaine-mediated behaviors is still largely unknown. Rats were trained to self-administer cocaine (0.5 mg/kg/inf), by lever pressing, for 10 days. A dose-response curve was then generated by allowing rats to self-administer one of five doses (0.09, 0.18, 0.37, 0.75, or 1.5 mg/kg/inf) every other day (maintaining on training dose in between). We chemogenetically activated either all VTA GABA neurons by giving the CNO systemically (0.3 mg/kg i.p.), or just the VTA GABA neuron terminals in the NAc by microinfusion of CNO. We then trained a separate group of rats to train for 5 days (0.5 mg/kg/inf) to establish responding, then changed them to a progressive ratio to evaluate break-points at the same five doses for the dose response, splitting the rats into the same treatment conditions as before. Our results show that a descending dose-response curve is readily generated, with rats lever pressing the most at the lowest dose, and the least at the highest dose. Systemic CNO decreased responding on the active lever only the two lowest doses. Activating only accumbal terminals of VTA GABA projection neurons, increased responding on the two lowest doses. A similar result was seen at the lowest dose of break points on progressive ratio. CNO had no effect in virus control rats. These results clearly establish that mesoaccumbal GABA neurotransmission facilitates either a reduction in motivation to seek and take drug, after global VTA GABA activation, or an increase following local terminal activation at the level of the nucleus accumbens.

Title: Effects of chemogenetic nucleus accumbens astrocyte stimulation on the incubation of cocaine craving

Authors: *E. V. HARDER[1], A. TESTEN[2], K. J. REISSNER[1,2];
[1]Psychology and Neurosci., [2]Neurosci. Curriculum, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Astrocytes play important and complex roles in the modulation of behavior, including those involved in neuropsychiatric disease. Previous data from our lab has found that astrocytes in the nucleus accumbens (NAc) core undergo changes in surface area and synaptic colocalization following cocaine self-administration and extinction (Testen et al., 2018, Scofield et al., 2016). Further unpublished data has indicated similar, but more pronounced structural changes following incubation of cocaine craving, a clinically-relevant phenomenon characterized by an increase in behavioral measures of drug seeking across abstinence (Kim et al., SfN 2019), raising the hypothesis that normalization of astrocyte structure and activity may oppose cocaine-induced adaptations. Chemogenetic stimulation of astrocytes has been explored as a means of reducing cocaine seeking after self-administration due to its potential for stimulating transmitter release from astrocytes and its potential for increasing their complexity (Chen et al., 2016) and cell body area (Brockett et al., 2018). While chemogenetic stimulation of NAc core astrocytes was found to be successful at preventing cue-induced cocaine reinstatement (Scofield et al., 2015), the same has not been examined in the context of an incubation of craving model. To address this question, we first tested astrocyte-specific expression of two commercially available DREADDs in the rat nucleus accumbens: AAV5-GFAP-hM3Dq-mCherry (Addgene cat #50478) and AAV5-GfaABC1D-hM3Dq-mCherry (Addgene cat #92284). We observed significantly greater specificity and efficiency of transduction in astrocytes with AAV5-GfaABC1D-hM3Dq-mCherry (Addgene cat #92284, astrocyte specificity: 92.1-99.3%) relative to AAV5-GFAP-hM3Dq-mCherry (Addgene cat #50478, astrocyte specificity: 34.5-80.6%). We observed that that diluting AAV5-GFAP-hM3Dq-mCherry (Addgene cat #50478) resulted in greater specificity and efficiency of transduction in astrocytes. We next tested effects of these AAVs versus AAV5-GFAP-mCherry following 10 days of long-access (6h/day) cocaine self-administration followed by 45 days of home-cage abstinence. Prior to a cue-primed seeking extinction test, animals received either CNO or vehicle treatment. Results indicated that animals that received AAV5-GFAP-hM3Dq-mCherry (cat #50478) showed significantly reduced cocaine seeking relative to all other control groups. Ongoing experiments are evaluating the effects of AAV5-GfaABC1D-hM3Dq-mCherry.

Title: Rat infralimbic projections to the nucleus accumbens shell encode cocaine extinction contingencies during temporally specific windows

Authors: *K. E. NETT[1,2], M. S. MCGREGOR[1,2], A. R. ZIMBELMAN[1], R. T. LALUMIERE[1,2,3];
[1]Dept. of Psychological and Brain Sci., [2]Interdisciplinary Grad. Program in Neurosci., [3]Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA

Abstract: Prior evidence indicates that the medial prefrontal cortex regulates cocaine-seeking behavior in rats. In particular, studies suggest that the ventral portion of this region, known as the infralimbic cortex (IL), mediates the ongoing inhibition of cocaine seeking, specifically through its projections to the nucleus accumbens (NA) shell. Our own data indicates IL activity during the 20 s immediately following an unreinforced lever press is critical for extinction encoding. However, whether signaling from the IL to the NA shell encodes extinction learning remains unclear. Moreover, it is unknown whether the critical period for this encoding is limited to the initial 20 s period after a lever press or extends longer. To address this issue, we used an activity-controlled, “closed-loop” optogenetic approach in which IL-NAshell activity was silenced following an unreinforced lever press for the first 20 s (0-20 s) or for the second 20 s after the lever press (20-40 s) during extinction training. Male and female Sprague-Dawley rats received bilateral injections of AAV-CaMKII-eArchT3.0 into the IL and bilateral fiber optic probes above the NAshell. Rats then underwent two weeks of daily 2 h cocaine self-administration sessions, in which active lever presses produced a cocaine infusion (0.33 mg/kg/inf), light/tone cues, and retraction of the active lever for 20 s or 40 s. Following this, rats underwent 5 d of manipulated extinction training (30 min sessions), in which active lever presses yielded no cocaine or cues but led to lever retraction (20 s or 40 s) and bilateral illumination of IL terminals in the NAshell (from 0-20 s or 20-40 s). Following those 5 days with inhibition, each rat underwent 7 d of full length (2 h), unmanipulated extinction sessions in which lever presses only resulted in a lever retraction for 20 or 40 s. The results indicate that IL-NAshell inhibition from 0-20 s post lever press, and not 20-40 s post lever press, significantly impairs extinction learning during the manipulated sessions and the retention of this extinction learning, as assessed during the unmanipulated sessions. These findings point to a critical window following an unreinforced lever press during which activity from IL inputs to the NAshell encodes the new extinction contingencies between the lever press and lack of a cocaine reinforcer. Moreover, combined with previous work, the results suggest that plasticity underlying extinction encoding occurs, at least in part, beyond the IL itself and in the synaptic inputs to the NAshell.

Title: Investigating the role of the intralaminar nuclei of the thalamus in compulsive cocaine seeking in rats

Authors: *A. M. CRUZ[1], R. J. SMITH[2];
[1]Psychological and Brain Sci., [2]Psychological and Brain Sciences, Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: Compulsive drug seeking that continues despite negative consequences may result from a loss of behavioral flexibility. The intralaminar nuclei of the thalamus (ILN), which is comprised of parafascicular, centromedian, centrolateral, and paracentral nuclei, has been implicated in behavioral flexibility. Therefore, we hypothesized that ILN may play a role in maintaining flexible control over drug seeking when faced with negative consequences. To determine the role of ILN in compulsive cocaine seeking, we tested the effects of post-training lesions of ILN on sensitivity to footshock punishment. Male Sprague Dawley rats were trained to self-administer cocaine on a seeking-taking chained schedule of reinforcement during daily 2-hour sessions for ~3 weeks. The rats then received NMDA or sham lesions of bilateral ILN and resumed self-administration following recovery from surgery. To assess compulsive cocaine seeking, rats were first given 4 days of mild footshock (0.4 mA, 0.3 s, randomly 1/3 of trials) upon completion of the seeking link of the chain during self-administration. Following recovery from punishment, rats were then given a second round of ramped footshock in which there was a quarter-log increase in footshock amplitude each day (0.18 mA, 0.32 mA, 0.56 mA, 1.0 mA, 0.3 s, every trial) to determine a threshold for sensitivity. With both types of footshock punishment testing, we observed no difference in punishment sensitivity in rats that received ILN lesions, as compared to rats with sham lesions. These results indicate that, despite a role in behavioral flexibility, ILN is not involved in flexibility related to footshock-induced suppression of cocaine seeking.

Title: Drug Reinforcement Impairs Cognitive Flexibility via Inhibiting Striatal Cholinergic Neurons

Authors: *H. GANGAL, Y. CHENG, X. XIE, X. WANG, J. LU, X. ZHUANG, Y. HUANG, W. WANG, L. N. SMITH, J. WANG;
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Reinforcing behaviors are associated with deficits in cognitive flexibility, wherein a subject is required to extinguish an old behavioral strategy and explore a new one if the old strategy is no longer rewarding. The neural circuitry underlying this flexibility deficit is not known. Cholinergic interneurons (CINs) in the dorsomedial striatum (DMS) are known to play a critical role in behavioral flexibility. In this study, we used chronic cocaine and alcohol exposure as reinforcement models to investigate the role of DMS CINs in the reversal of instrumental learning. We found that chronic cocaine or alcohol exposure increased GABAergic inputs to DMS CINs and reduced their spontaneous firing activity. Morphological and physiological studies demonstrate that the major GABAergic input to the DMS CIN originates from the direct-pathway medium spiny neurons (dMSNs) and this input was potentiated by chronic cocaine or alcohol exposure. To artificially mimic the inhibition of DMS CINs, we employed chemogenetic and time-locked optogenetic approaches to downregulate DMS CIN activity, which led to deficits in behavioral flexibility. The dMSN to SNr (Substantia Nigra Reticulata) pathway is known to mediate reinforcing behaviors. Functionally, we test that dMSNs also send collateral inhibitory connections to the CINs. Therefore, we propose that, on one hand dMSN to SNr pathway causes reinforcement, at the same time dMSN to CIN pathway leads to inflexibility, thus providing the neural substrate for deficits in flexibility caused by reinforcing behaviors.

Title: The Role of the Patch Compartment of Striatum in Reward-Driven Behaviors.

Authors: *J. AHN[1], D. J. CHRISTY[2], K. HORNER[2];
[1]Master of Biomed. Sci. Program, [2]Biomed. Sci., Mercer Univ. Sch. of Med., Macon, GA

Abstract: The striatum is a neural structure that plays a critical role in cognitive functions, behavioral decision-making, and reward generation. The striatum exhibits a heterogeneous composition, containing neurons belonging to the patch compartment—which is thought to be involved in habitual reward-related behaviors—surrounded by neurons belonging to the matrix compartment—which is thought to be involved in adaptive motor control. Additionally, the striatum is further subdivided into the dorsolateral striatum (DLS) and the dorsomedial striatum (DMS), each with their own patch and matrix compartments. The DMS has been associated with goal-oriented behavior seen during the initial stages of addiction. Conversely, the DLS has been associated with habitual behaviors seen during late-stage addictive behaviors that are inflexible. It is thought that drug addiction is initially mediated by the DMS before DLS activity becomes predominant. Previously, it has been shown that the patch compartment of the DLS is necessary for development of habitual behavior, but the role of the patch compartment of the DMS is less clear. Our study intends to demonstrate that selective ablation of DMS patch compartment neurons will result in a negative impact on the initial development of reward-driven behaviors during the early stages of drug addiction. Since patch compartment neurons express a high level of mu opioid receptors compared to the surrounding matrix, we used dermorphin-saporin, a toxin that selectively destroys mu opioid receptor-containing neurons to target patch compartment neurons in the DMS and DLS for ablation. Following infusion in the DMS or DLS with dermorphin-saporin (17 ng/μl) or vehicle, rats were trained to self-administer cocaine (0.4 mg/kg/infusion) on progressive ratio schedule of reinforcement, starting with fixed ratio of 1 and ending with a fixed ratio of 5. Ablation of the patch compartment altered the level of responding for cocaine as the schedule of reinforcement became progressively labor-intensive. These data suggest that the patch compartment contributes to reward-driven behaviors.

Title: Activation of the basolateral amygdala alters rearing-induced changes in cocaine-seeking

Authors: A. BROWN[1], K. FROIDCOEUR[1], C. SANTAMARIA[2], M. WOHRLEY[1], J. GREENBERG[1], M. VOGEL[1], M. LINDEN[1], R. HEBRON[1], ***M. GILL**[1];
[1]North Central Col., Naperville, IL; [2]Mayo Clin., Rochester, MN

Abstract: Early environmental rearing impacts susceptibility to drug abuse later in life. Rearing rats in enriched (EC), impoverished (IC), or social (SC) conditions results in neurobiological, neurochemical, and behavioral changes (Bowling, Rowlett, & Bardo, 1993). In EC rats, these rearing-induced changes result in a protective effect, as EC rats self-administer less drug at low doses and reinstate drug seeking at lower rates than IC and SC rats. We hypothesize that the glutamatergic system is responsible for this protective effect based on previous work implicating accumbal GluA1 in cocaine self-administration (Pierce & Wolf, 2013) and reinstatement (Anderson et al., 2008). Previous work from our lab implicates the nucleus accumbens shell (NAshell) in reversing rearing-induced reinstatement differences, but the glutamatergic input from the infralimbic cortex (IL) only partially accounts for these differences; suggesting a secondary input is impacting the NAshell. The basolateral amygdala (BLA) receives glutamatergic input from the IL, and projects to the NAshell, and previous work shows that inactivation of the BLA attenuates cue-induced reinstatement (McLauglin & See, 2003). Additionally, environmental enrichment reverses cocaine incubation-induced molecular changes in the BLA-NA pathway when used as an intervention (Ma et al., 2016). Based on these findings, the current study focuses on the impact of the BLA on cocaine seeking in differentially reared rats. Specifically, PEPA, an AMPA positive allosteric modulator, was infused into the BLA immediately prior to reinstatement of cocaine seeking behavior. Male Sprague-Dawley rats arrived at 21 days of age, and were reared in EC, IC, or SC contexts for 30 days. Beginning at 52 days of age, were trained using a standard 2-hr cocaine self-administration model including extinction, and reinstatement. Rats were pseudo-randomly assigned to receive PBS or PEPA infusions into the BLA prior to cocaine-primed, cue-induced or yohimbine plus cue-induced reinstatement tests. Results show an attenuation of rearing-induced reinstatement differences following cue-induced and yohimbine plus cue reinstatement tests.

Title: Investigating neural activity in the rodent lateral amygdala during and after cocaine-self administration

Authors: *J. KLEINBART[1], S. J. STRINGFIELD[2], A. K. FELDMAN[3], M. M. TORREGROSSA[2], D. J. WEBER[4];
[1]Dept. of Bioengineering, [2]Dept. of Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [4]Mechanical Engin., [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: While viable pharmacological interventions exist for certain substance use disorders (SUDs), there is currently no reliable intervention for psychostimulant use disorders. SUDs are known to affect learning and memory processes, but little is known about neural mechanisms of drug memory formation. By seeking a better understanding of the mechanisms through which neutral sensory cues become associated with psychostimulant use, we aim to identify targets for future interventions for SUDs. Rats were implanted with two-shank 32-contact depth electrodes (NeuroNexus) for recordings in the lateral amygdala (LA). Rats were then trained to self-administer cocaine where active lever presses led to a cocaine infusion and presentation of a 10 second audio-visual stimulus. Following acquisition, rats underwent a cue extinction procedure where the audio-visual cue was presented 120 times in the absence of lever in order to weaken the association between sensory cues and drug reward. Spiking and LFP activity were analyzed in order to look for changes in neural signaling in the LA that occur during memory formation (self-administration) and memory weakening (cue extinction).
Current density analysis of signals recorded on each probe shank during self-administration revealed differential activity along the depth of the probe, suggesting that LA activity is not uniform; this aligns with expectations, as the LA is not organized into layers. Spectrograms depicting RMS power of low-frequency (<300 Hz) signal components on each electrode were produced and selected channels were examined for cue-driven activity by calculating and comparing mean RMS power of early-session lever presses with late-session lever presses. Preliminary data reveal late-session driven responses that appear time-locked to audio-visual stimulus onset and offset. Cue extinction data were similarly analyzed; cue-driven responses present during self-administration appear to dissipate during cue extinction, suggesting a neural mechanism of drug memory encoding and extinction. Additional preliminary spike bandwidth analyses of self-administration trials show consistent spike firing rate increases around 5 seconds after audio-visual cue onset, while cue extinction analysis reveals early session firing rate increases at cue onset and 5 seconds after cue onset and late-session absence of time-locked responses. Taken together, these results suggest that the LA could serve as a viable target for intervention therapies due to the presence of robust but reversible changes in signaling during cue-related drug seeking.

Title: Adolescent cocaine-associated contextual relapse: pattern of neuronal activation in the prefrontal cortex

Authors: D. I. OLEKANMA, B. CHO, A. HERRERA CHARPENTIER, C. REEVES, A. A. ARGUELLO;
Psychology, Michigan State Univ., East Lansing, MI

Abstract: Relapse to drug use is a major problem associated with Substance Use Disorders (SUDs). In 2017, there were approximately 2 million adolescent users of illicit drugs (age 12-17). Initiation of drug use during adolescence can lead to a lifelong risk to develop SUDs, potentially due to strengthened drug-associated stimuli that elicit craving over the lifespan. Previous research using adult rodent models of relapse have shown that in response to drug-associated cues, drug-seeking behavior increases with abstinence time. This incubation effect has also been observed in adolescent rodents: both adolescent and adult rats show a time-dependent increase in seeking behavior. Furthermore, time-dependent, drug seeking behavior in response to drug-associated cues correlated with elevated neuronal activation (cFos) in the medial prefrontal cortex (mPFC) in both adolescent and adult rats.
However, much less is known about the brain regions that are recruited during context-induced cocaine-seeking during adolescence. To determine the pattern of neuronal activation during adolescent relapse, we used an abbreviated rodent model of cocaine self-administration, which allows us to examine relapse-like behavior during the adolescence and adulthood.
Adolescent (postnatal day 32 (P32)) male Sprague Dawley rats received jugular catheterization surgery. Following a recovery period, rats received cocaine self-administration (Coc-SA) training in one context (2h, 2x/d, minimum 10 sessions), followed by extinction (EXT) training in a second distinct context (2h, 2x/d, minimum 8 sessions). Following the last session of EXT, one group of rats received a 2h test in the EXT context. Two additional groups received 2h tests in the cocaine-paired context, 1 day (Test 1) or 15 days (Test 15) after the last EXT session. Adolescent rats displayed an increase in drug-seeking behavior upon re-exposure to the Coc-SA context compared to the EXT context. Furthermore, drug-seeking was significantly higher in rats tested in the cocaine-paired context at Test 15 compared to Test 1. Preliminary neuronal activation data showed a time-dependent increase in cFos expressing cells in the prelimbic cortex correlated with drug-seeking behavior.
Context-driven cocaine relapse occurs during adolescence and is correlated with increased

neuronal activation in the prelimbic region of the PFC. Future directions will examine whether the pattern of relapse-induced neuronal activation differs between adolescent and adult rats across other related brain regions including the orbitofrontal cortex (OFC), basolateral amygdala (BLA) and nucleus accumbens (NAc).

Title: Cocaine-induced nucleus accumbens glutamatergic plasticity in males and females

Authors: *A. M. FRANCE[1], T. L. FETTERLY[1], A. M. NIETO[1], T. E. ROBINSON[2], C. R. FERRARIO[1,2];
[1]Pharmacol., [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The development and persistence of addiction is mediated in part by drug-induced alterations in the function of the nucleus accumbens (NAc), a region that mediates drug-craving and seeking behaviors. AMPA-type glutamate receptors provide the main source of excitatory drive to the NAc, and enhancements in transmission of calcium-permeable AMPAR (CP-AMPARs) within the NAc mediate cue-triggered drug-seeking following long access self-administration. Previous work has shown that cocaine treatment regimens that result in psychomotor sensitization enhance subsequent drug-seeking and drug-taking behaviors. Furthermore, cocaine-induced locomotor sensitization followed by 14 days of withdrawal is accompanied by increases in the surface expression of GluA1 and GluA2 AMPAR subunits (consistent with increases in non-CP-AMPARs) and increases in AMPA/NMDA ratio in males. However, potential effects of cocaine-induced sensitization on glutamatergic transmission in females is poorly understood. In addition, recent studies show that intermittent access self-administration produces robust psychomotor sensitization compared to long access, but effects on NAc glutamate transmission are unknown. We examined, therefore, the effects of experimenter administered cocaine (15 mg/kg, i.p, 8 days) or intermittent vs long-access cocaine self-administration on NAc glutamate. Whole-cell patch clamp approaches were used to measure effects on spontaneous excitatory post synaptic current (sEPSC) frequency and amplitude, and sensitivity to the CP-AMPAR antagonist Naspm (200 μM). Cocaine injections induced

locomotor sensitization in males and females, but enhancements in NAc glutamate transmission were only found only in males. In addition, preliminary results suggest that intermittent access produces enhancements in NAc glutamate transmission that are distinct from those seen following long access. These results will be discussed in light of established sex differences in the induction and expression of psychomotor sensitization, and the ability of intermittent access to produce more robust addiction-like behaviors despite much less total drug consumption.

Title: Retinoic acid signaling and AMPA receptor plasticity during the incubation of cocaine craving

Authors: *E.-K. HWANG[1], A. M. WUNSCH[1], D. T. CHRISTIAN[2], M. E. WOLF[1];
[1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: Incubation of cocaine craving refers to the progressive intensification of cue-induced craving that occurs during forced abstinence from cocaine self-administration in rats, and has also been observed in abstinent cocaine users. A key adaptation mediating the expression of incubated craving is accumulation of GluA2-lacking calcium-permeable AMPARs (CP-AMPARs; homomeric GluA1) in excitatory synapses on medium spiny neurons (MSN) in the nucleus accumbens core (NAcc). CP-AMPARs are present at very low levels in NAcc MSN of drug-naïve rats. A rise in their synaptic levels is first detected after several weeks of abstinence; after this time, CP-AMPAR levels remain high for months. Once CP-AMPAR levels are elevated, blocking or removing them from NAcc synapses reduces the expression of incubated craving for cocaine. We are testing the hypothesis that CP-AMPAR upregulation represents a homeostatic response to the contrast between high activity in the reward circuitry during drug self-administration and substantially lower activity during abstinence. Specifically, we hypothesize that a form of retinoic acid (RA)-dependent homeostatic plasticity previously described in hippocampus - in which reduced cellular calcium levels lead to disinhibition of RA synthesis, which in turn disinhibits GluA1 translation and promotes synaptic insertion of

homomeric GluA1 receptors (see L. Chen et al., Neuropharmacology 2014) - is responsible for CP-AMPAR upregulation during incubation of craving. Here we tested the ability of RA to modulate CP-AMPAR levels in MSN of the NAcc. Whole-cell patch clamp recordings were performed in MSN from drug-naïve rats or rats that underwent extended-access cocaine or saline self-administration and >40 days of forced abstinence. In MSN from drug-naïve rats, preincubation of slices for 1 h coupled with bath application of RA (2 μM) resulted in synaptic incorporation of CP-AMPARs, detected as a significant increase in the rectification index (RI) and greater sensitivity to the CP-AMPAR antagonist naspm. This was also observed in response to the retinoic acid receptor α (RARα) selective agonist AM580. The paired pulse ratio was not altered. In cocaine rats, preliminary data indicate occlusion of the RA-induced increase in the RI. Furthermore, preincubation (1 h) of slices with 50 μM DEAB, an inhibitor of RA synthesis, significantly decreased the RI in cocaine rats. These results indicate regulation of synaptic CP-AMPAR levels by RA signaling. Studies are being extended to distinguish D1 and A2a/D2 receptor expressing MSN using transgenic rats expressing Cre recombinase in each MSN population bred to reporter lines.

Title: The role of protein translation in D1 and D2-receptor containing neurons of the nucleus accumbens in the expression of incubation of cocaine craving

Authors: *A. B. KAWA[1], E.-K. HWANG[1], A. R. NECTOW[2], H. ZHOU[3], M. COSTA-MATTIOLI[3], M. E. WOLF[1];
[1]Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [2]Dept. of Med., Columbia Univ., New York, NY; [3]Baylor Col. of Med., Houston, TX

Abstract: In the ‘incubation of cocaine craving’ model of relapse, rats self-administer cocaine using an extended access procedure, and then experience a prolonged abstinence period. During abstinence, rats exhibit a progressive intensification (incubation) of cue-induced craving. We have shown that Ca^{2+}-permeable AMPA receptors (CP-AMPAR), comprised exclusively of the

GluA1 subunit, accumulate in the nucleus accumbens (NAc) during abstinence and are required for the expression of incubated craving. Further, these CP-AMPARs can be removed from the synapse via mGlu1 positive allosteric modulation, and this treatment reduces incubated seeking. Work in other brain regions has shown that CP-AMPARs can be regulated by the Integrated Stress Response (ISR) pathway. Cellular consequences of activating the ISR pathway include increased phosphorylation of eukaryotic initiation factor 2α (eIF2α). Increased levels of p-eIF2α decrease general mRNA translation but increase translation of a subset of mRNA with 5' upstream open reading frames, such as Oligophrenin-1 (OPHN1). Thus, OPHN1 translation is positively regulated by p-eIF2α. In the hippocampus, OPHN1 is necessary for eIF2α-mediated mGluR-LTD and the removal of synaptic AMPARs. In the VTA, this pathway plays a role in bidirectional CP-AMPAR plasticity in cocaine-exposed animals. Thus, in our NAc studies, mGlu1 stimulation may increase p-eIF2α, leading to increased translation of OPHN1 and the removal of synaptic CP-AMPARs. We are testing this hypothesis by bidirectionally manipulating OPHN1 using acute pharmacological manipulations and chronic viral manipulations. Studies to date show that knocking down OPHN1 or blocking p-eIF2α mediated translation with ISRIB prevents mGlu1-mediated removal of CP-AMPARs from NAc synapses and mGlu1-mediated reduction of craving. A related study is examining protein translation in the NAc of 'incubated' rats more broadly. In this study we are using rats that express Cre recombinase in either D1R or A2a/D2R medium spiny neurons to express GFP-tagged ribosomes in a cell specific manner, enabling us to isolate actively translating mRNAs from both neuronal subtypes for subsequent analysis by RNA-Seq. In support of this sequencing study, we have characterized these novel transgenic rats to ensure a high-fidelity of Cre expression in the NAc, using RNAscope and qRT-PCR.

Title: Activity of D1 medium spiny neurons in the nucleus accumbens core is necessary for incubation of cocaine craving

Authors: *A. M. WUNSCH, J. R. FUNKE, M. E. WOLF;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: One contributing factor to relapse in individuals with substance use disorder is exposure to cues associated with drug use, which leads to intense craving and subsequent relapse. In the incubation of cocaine craving rodent model of relapse, cue-induced cocaine seeking progressively intensifies, or incubates, over the first 1-2 months of abstinence and remains elevated for at least 6 months following the last cocaine exposure. The nucleus accumbens core (NAcCo) is a critical node in the brain circuits associated with incubation. Medium spiny neurons (MSN) are the predominant neurons in the NAcCo, and can be subdivided into two populations. Neuronal activity in MSN expressing the dopamine D1 receptor (D1 MSN) drives responses to cues paired with non-contingent cocaine exposure, whereas MSN expressing the dopamine D2 receptor (D2 MSN) are not involved. To date, no studies have been performed to parse the role of these two neuron types in NAcCo in incubation. Rats expressing cre-recombinase in D1 MSN or adenosine receptor 2a (A2a) MSN (A2a is expressed exclusively in D2 MSN) received bilateral infusions of an AAV expressing cre-dependent inhibitory DREADD with a fluorescent mCherry tag (hM_4Di) or mCherry (control) in NAcCo. Two weeks later, rats underwent extended access cocaine self-administration (6h/d for 10d). Cocaine seeking tests were administered during withdrawal, during which rats nose poke for exposure to the cocaine paired cue but receive no drug. Thirty minutes prior to seeking tests on withdrawal day (WD) 50 and WD55 (when rats express maximally incubated cocaine seeking), each rat received an i.p. injection of either clozapine-N-oxide (CNO) to activate hM_4Di and reduce activity of MSN or vehicle (counterbalanced within subject design). Reducing activity of D1 MSN on WD55 attenuated drug seeking compared to vehicle injection on WD50, whereas there was no effect of the same manipulation in A2a (D2) MSN and mCherry controls. Surprisingly, activation of hM_4Di in D1 MSN with CNO injections on WD50 followed by vehicle on WD55 lead to a continued reduction in drug seeking on WD55, indicating a possible long term suppression of cocaine craving. Future studies will test how long this suppression of seeking behavior lasts following the hM4Di manipulation in D1 MSN. Furthermore, fiber photometry studies are in progress to directly assess alterations in intracellular calcium of these two neuron populations during incubated cocaine craving. Overall these results indicate that activity in D1 MSN in NAcCo is necessary for incubated cocaine seeking, and may be a therapeutic target for prevention of relapse.

Title: Role of nucleus accumbens dopamine in the incubation of cocaine craving

Authors: *S. J. WEBER[1], A. B. KAWA[2], A. M. WUNSCH[2], M. E. WOLF[2];
[2]Behavioral Neurosci., [1]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Relapse represents a consistent clinical problem when treating individuals with Substance Use Disorder. We and others have studied this in rodents using the incubation of cocaine craving model. In this model rats undergo extended access drug self-administration where they learn to nose poke in the active port for a single infusion of cocaine paired with a 20s light cue. Next, they undergo a period of prolonged abstinence during which drug-craving increases (incubates) over time as measured by cue-induced drug seeking tests. Previous work in the Wolf lab has established glutamate plasticity, specifically the synaptic insertion of calcium permeable AMPA receptors, within the nucleus accumbens core (NAcc) as critical to the expression of incubation of cocaine craving. However, it remains unknown whether or not dopamine plays a role in incubation of cocaine craving. Dopamine is well-known for its role in motivation and salience, and would therefore be expected to contribute to a behavior reliant on increased salience of cues. In order to investigate this, we expressed dLight1.3b and implanted a fiber optic cannula in the NAcc of male and female Long Evans rats prior to cocaine self-administration (6 h/d for 10 d; 0.5 mg/kg/infusion; FR1). The dLight signal was recorded via fiber photometry during a 15-30 min cue-induced seeking test on the day immediately after self-administration ends, withdrawal day (WD) 1, and a second test late into abstinence, WD40-45. Results from an initial experiment (10 rats) show an increased dLight response following pokes into the active port compared to the inactive port. Furthermore, we observed a small trend toward an increased dLight response following active port responses in late abstinence compared to early abstinence. However, these data are preliminary and require the addition of more rats as well as saline controls. With further validation and replication this work could enhance our understanding of factors influencing relapse to cocaine.

Title: Inhibition of PSD95-nNOS protein-protein interactions decreases morphine reward and relapse vulnerability in rats

Authors: *I. OLIVA[1], S. A. SABERI[1], C. RANGEL BARAJAS[2], V. IYER[1], K. D. BUNNER[1], Y. Y. LAI[1], P. M. KULKARNI[3], S. GARAI[3], G. A. THAKUR[3], J. D. CRYSTAL[1], G. V. REBEC[1], A. G. HOHMANN[1];
[1]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [2]Dept. of Psychology, Indiana Univ., Indianapolis, IN; [3]Dept. of Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: Glutamate-dopamine interactions through the *N*-methyl-D-aspartate receptor (NMDAR) play an unquestionable role in opioid addiction. Nevertheless, NMDAR glutamate receptor antagonists limited medical use due to their adverse side-effects. Here, we explored an alternative approach to target NMDAR signaling to reduce opiate reward and relapse through disruption of protein-protein interactions. Glutamate signaling through the NMDAR activates the enzyme neuronal nitric oxide synthase (nNOS) to produce the signaling molecule nitric oxide (NO). nNOS is tethered to NMDARs via the scaffolding protein postsynaptic density 95 kDa (PSD95). We hypothesized that the disruption of the protein-protein interaction between PSD95 and nNOS would block NMDAR-dependent NO signaling and represent a viable therapeutic route to decrease opioid reward and relapse without the unwanted side-effects of NMDAR antagonists. We used a conditioned place preference approach to evaluate the impact of two small-molecule PSD95-nNOS inhibitors – IC87201 and ZL006 – on the rewarding effects of morphine. Both IC87201 and ZL006 blocked conditioned place preference to morphine at doses that lacked intrinsic rewarding or aversive properties. Moreover, we employed intravenous morphine self-administration to examine the influence of ZL006 on the reinforcing effects of morphine. Interestingly, ZL006 did not affect morphine infusion intake, but markedly reduced lever pressing during morphine relapse after forced abstinence. Furthermore, *in vivo* fast-scan cyclic voltammetry was used to ascertain the impact of ZL006 on morphine-induced increases in dopamine efflux in the nucleus accumbens core (NAc-core) that was evoked by electrical stimulation of the medial forebrain bundle. ZL006 attenuated morphine-induced increases in dopamine efflux in the NAc-core at a dose that did not have intrinsic effects on dopamine release. Our results provide behavioral and neurochemical support for the hypothesis that inhibition of PSD95-nNOS protein-protein interactions decreases morphine reward and relapse without producing abuse liability on its own. Our studies highlight a previously unrecognized role for the use of PSD95-nNOS disruptors as a novel non-narcotic therapeutic strategy that shows promise for treating opioid addiction.

Title: Individual differences in frustrative nonreward behavior for sucrose in rats predict motivation for fentanyl under progressive ratio

Authors: *T. E. S. VASQUEZ, P. SHAH, J. DI RE, F. LAEZZA, T. A. GREEN;
Univ. of Texas Med. Br. At Galveston, Galveston, TX

Abstract: Abstract Frustrative nonreward is a construct in the Negative Valence Systems domain of the Research Domain Criteria (RDoC) from the US National Institute of Mental Health. An organism's response to frustrating situations (e.g. inability to obtain an expected reward) has broad implications for a variety of neuropsychiatric conditions, including substance use disorders. However, there are limited studies that investigate the role of frustration in substance use disorders. The few human studies that do investigate the role of frustration in substance use disorders highlighted that persons with substance use disorder rate higher in tests of frustration (i.e. lower frustration tolerance) and that sensitivity to frustration correlates with number of relapses. The current project developed a first of its kind rat operant behavioral model of frustrative nonreward using bar press durations as a measure of frustration-like behavior. Furthermore, the frustrative nonreward behavioral task was designed to be based loosely on the human Point Subtraction Aggression Paradigm. The present study shows that individual differences in frustrative nonreward for sucrose pellets are consistent across sessions at baseline and that the task is sensitive to reward size. More importantly, high frustrative nonreward behavior for sucrose predicts early "breaking" for intravenous fentanyl self-administration under a progressive ratio schedule demonstrating that the frustrative nonreward tasks can be used as a tool to identify rat's individual differences in frustration-like behavior during self-administration of sucrose pellets to predict a rat's drug seeking and taking prior to exposure to drug. Additionally, the "breakpoint" of an animal's behavior is also used as a measure of the relative effectiveness of the motivational properties of substance. Thus, these results support frustration/frustrative nonreward as an important aspect of motivation in substance use disorders. Furthermore, the frustrative nonreward task may be applied in future animal studies of mental health disorders as frustration is a significant component of many other neuropsychiatric conditions.

Title: Therapeutic Index Assessment of the M_5 Negative Allosteric Modulator VU6008667 for Attenuation of Opioid Seeking Behaviors in Rodents

Authors: L. TEAL[1], R. GOULD[2], M. BUBSER[1], M. RAGLAND[1], E. DUNCAN[1], C. W. LINDSLEY[1], *C. JONES[1];
[1]Vanderbilt Univ., NASHVILLE, TN; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Accumulating data indicate that the selective inhibition of the M_5 muscarinic acetylcholine receptor subtype (mAChR) may provide an alternative therapeutic mechanism for the treatment of opioid use disorder (OUD). Previous studies by our group and others have identified the expression of M_5 mAChRs within the mesocorticolimbic dopaminergic reward circuitry and demonstrated that M_5 negative allosteric modulators (NAM) can attenuate the reinforcing effects of various substances of abuse, including cocaine, opioids and ethanol, in rats. In the present studies, we evaluated the potential dose-related effects of the highly selective M_5 NAM VU6008667 on attenuation of opioid seeking behaviors relative to the effects observed across other preclinical measures of general motor output, motivation, and autonomic and somatic motor nervous system functions in male Sprague-Dawley rats. Acute administration of VU6008667 produced dose-dependent reductions in responding for oxycodone under both fixed- and progressive-ratio schedules of reinforcement. VU6008667 also attenuated responding on the drug-associated lever in a model of opioid seeking, i.e., cue-induced responding after response extinction. Moreover, daily pretreatment of VU6008667 delayed acquisition of oxycodone self-administration in opioid naïve rats over a 21 day period. In contrast, VU6008667 had no significant effects on self-administration of sucrose pellets or rotarod performance over the dose range tested. Using the modified Irwin neurological test battery, we demonstrated that VU6008667 had no off-target effects on any autonomic or somatic motor nervous system functions at the top dose tested. Taken together, these findings suggest that negative modulation of the M_5 receptor may provide an innovative therapeutic approach with a broad therapeutic index for the treatment of OUD or prevention of misuse of prescription opioids.

Abstract: Kratom is being developed as a pharmacotherapy to mitigate withdrawal symptoms from opioids; however, the presence of active metabolites of the primary kratom alkaloid mitragynine (MG) at mu-opioid receptors [(MORs), 7-hydoxymitragynine (7-OH-MG) and mitragynine pseudoindoxyl (MG-P)] may limit effectiveness due to their abuse potential. On the other hand, the adrenergic α_2 receptor ($A\alpha_2R$) agonist lofexidine has recently been approved as a medication to treat opioid withdrawal and several $A\alpha_2R$ antagonists have been reported to antagonize the *in vivo* effects of MG. Using an intravenous drug self-administration assay, the present study compared abuse potential of MG and its metabolites, and medications for opioid withdrawal (methadone, buprenorphine, and lofexidine), and assessed specificity of MG to antagonize the reinforcing effects of the MOR agonist remifentanil in rats. In rats self-administering remifentanil (0.1-3.2 µg/kg/injection), reference MOR agonists (methadone and buprenorphine) and the dopamine uptake inhibitor cocaine maintained self-administration responding above extinction (no injection) levels whereas lofexidine and antagonists at MOR and $A\alpha_2R$ (naltrexone and yohimbine, respectively) did not. Self-administration responding above extinction was maintained by 7-OH-MG (1.0-10 µg/kg/injection) and MGP (0.32 µg/kg/injection), but not MG (up to 3.2 mg/kg/injection) when substituted for remifentanil. Self administration of remifentanil, 7-OH-MG, and MGP was antagonized by naltrexone (3.2 mg/kg, i.p.). Self administration of remifentanil was also antagonized by methadone, buprenorphine, and lofexidine as well as MG (32 mg/kg, i.p.). The antagonizing effects of MG on remifentanil self administration were specific for remifentanil because MG (32 mg/kg, i.p.) failed to affect the dose-effect function of cocaine self-administration (0.032-1.0 mg/kg/injection). It appears that the antagonizing effects of MG on remifentanil self administration were due to the low MOR efficacy of MG relative to efficacy of remifentanil because yohimbine (3.2 mg/kg, i.p.) fully reversed the antagonizing effects of lofexidine but not of MG on remifentanil self administration. Despite the abuse potential of active metabolites of MG, these results suggest that low if any abuse potential of MG. The lack of obvious reinforcing effects of MG suggests if any low contribution of 7-OH-MG and MGP to the *in vivo* MOR activity of MG. These results also support the further development of MG as a medication with low abuse potential for opioid use disorder.

Title: Deep brain stimulation shortens extinction of persistent morphine-seeking.

Authors: *M. E. LLORET-TORRES[1], J. L. BARRETO-ESTRADA[2];
[2]Anat. and Neurobio., [1]Univ. of Puerto Rico Med. Sci. Campus, San Juan, PR

Abstract: Opiate addiction is a chronic relapsing disorder characterized by compulsive drug use and drug seeking, regardless of negative consequences. In the United States, opiate related deaths continue to increase in what is being classified as a public health crisis. Currently, opiate addiction is treated with a combination of behavioral therapies and replacement medication. However, for a significant part of opiate addicts, these treatments remain ineffective. Deep brain stimulation (DBS) is a relatively new and novel treatment for addiction, including refractory patients under opiate abuse. Because DBS is both reversible and adjustable, it is more clinically viable than other surgical interventions. Clinical studies on DBS for addiction have shown positive results, but they tend to be limited due to the low number of participants, and some adverse effects. Therefore, pre-clinical studies to obtain more consistent and reliable results are needed. For this reason, we have previously shown that applying LF-DBS (130-Hz) to the Ventral striatum/Nucleus accumbens (VS/NAc) in male rats during sessions of morphine extinction, strengthens extinction memory. Although this result was achieved by using a partial extinction protocol, the effect of LF-DBS during full extinction remains unknown. Here, we study the effects of LF-DBS on the full extinction of morphine (5mg/kg) place preference. In addition, drug reinstatement was evaluated 24 h and 7 days after the final day of extinction. Our results show that DBS-treated animals decrease the number of extinction sessions to acquire full morphine extinction ($P < 0.001$), as compared to sham-DBS animals. Reinstatement at 7 days after the final day of extinction showed a significant reduction in drug-seeking, in animals who received LF-DBS (29%; $p < 0.005$), as compared to 57% of animals in the sham-DBS group. Our data suggest a potential therapeutic effect of LF-DBS in refractory patients of addiction by reducing both the amount of time required to fully extinguish drug-seeking, and relapse.

Title: Glucagon-like peptide-1 receptor agonism in the interpeduncular nucleus decreases opioid reinstatement

Authors: *R. J. HERMAN, S. ZEB, K. RAGNINI, H. D. SCHMIDT;
Dept Psychiatry, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Fatal opioid overdose is a leading cause of preventable death in the United States. Oxycodone is one of the most commonly abused opioid analgesics, and over one half of all opioid overdose deaths are associated with synthetic opioids including fentanyl and its analogs. Uncovering the neural mechanisms of opioid seeking will facilitate the development of novel treatments for opioid use disorder that may help to decrease or prevent opioid overdose deaths. Recent evidence indicates that glucagon-like peptide-1 receptors (GLP-1Rs) play an important role in the reinforcing and rewarding effects of drugs of abuse including opioids. Our previous studies showed that systemic administration of the GLP-1R agonist Exendin-4 (Ex-4) decreased intravenous opioid self-administration and the reinstatement of opioid-seeking behavior, an animal model of relapse, in rats. Given that GLP-1Rs are expressed throughout the brain, it is crucial to identify the GLP-1R-expressing circuits that mediate the efficacy of GLP-1R agonists in attenuating opioid seeking. GLP-1Rs are expressed at high levels in the interpeduncular nucleus (IPN), a brain region known to regulate the mesolimbic dopamine system. Based on our pilot studies with systemic Ex-4, we hypothesized that activation of GLP-1Rs in the IPN would attenuate opioid reinstatement. We trained rats to self-administer intravenous oxycodone (0.06 mg/kg/infusion) or fentanyl (1.25 μg/kg/infusion) for 21 days on a fixed-ratio 5 schedule of reinforcement. Drug taking was then extinguished by replacing the opioid solution with saline and turning off the contingent light cue. After extinction, reinstatement of opioid seeking was assessed after an acute opioid priming injection and re-exposure to conditioned light cues. Prior to each reinstatement test, rats were pre-treated with intra-IPN infusions of vehicle or Ex-4 (0.01 or 0.1 μg). We showed that intra-IPN infusions of Ex-4 dose-dependently decreased drug + cue-induced reinstatement of fentanyl- and oxycodone-seeking behaviors. Importantly, our preliminary data indicate that IPN Ex-4 inhibits opioid seeking at doses that do not affect 24 hr body weight and water intake. Additionally, we found that GLP-1Rs are expressed on GABAergic neurons on the IPN, providing a potential mechanism for Ex-4's effect on opioid seeking. Overall, these results support a functional role of IPN GLP-1R activation in Ex-4's effect on opioid seeking and support the use of GLP-1R agonists as a potential treatment for opioid use disorders.

Title: Effects of sucrose exposure during the adolescent period on oxycodone self-administration

Authors: J. WATSON[1], M. CRAWFORD[2], M. HOCHSTETLER[1], C. ALONSO[1], L. EVANS[1], *A. GANCARZ-KAUSCH[1];
[1]California State University, Bakersfield, Bakersfield, CA; [2]Florida State Univ., Tallahasse, FL

Abstract: Sugar is a ubiquitous naturally occurring substance that holds strong hedonic value, and many adolescents exceed the U.S. Dietary Guidelines for sugar consumption (Ervin, R.B. et al., 2012). The adolescent period is a critical time of development and is also a time where adolescents face an increased risk for substance abuse (Winstanley & Stover, 2019). Furthermore, ample evidence suggests that drug use during the adolescent period increases future vulnerability to drug abuse, including opioids (Windisch & Kreek, 2020). However, the impact that natural rewards, like sugar, have on adult behavior is less understood. Previous work from our lab indicates that exposure to sucrose in adolescence increases vulnerability to cocaine and alcohol self-administration in adult male and female rats. The purpose of this study was to investigate if the effects of adolescence sucrose exposure generalize to self-administration of oxycodone in adulthood. To test this, adolescent male rats (PND 28-42) were given noncontingent access to either 10% sucrose solution or water. Exposure sessions were 30 min in duration and 100 microliters of solution (sucrose or water) was presented according to a variable time 1 min schedule of reinforcement for 15 days. After this phase, rats were placed back in the colony room with food and water available ad libitum until adulthood. Once the rats reached adulthood (PND 60), they were tested for oxycodone self-administration for 3-hour sessions across 7 days. Active responses resulted in the delivery of 0.15 mg/kg/infusion oxycodone according to a FR1 schedule of reinforcement. Rats exposed to sucrose during the adolescent period earned significantly more infusions of oxycodone compared to water-exposed controls during self-administration testing. Furthermore, rats exposed to sucrose during the adolescent period show significantly greater preference for oxycodone, as measured by the relative frequency of active responses, compared to water controls. Taken together, these findings have important implications to the human condition, suggesting exposure to sucrose during the adolescent period may increase susceptibility to non-natural rewards in adulthood.

Title: Intravenous self-administration of heroin in an animal model of internalizing vs externalizing temperament

Authors: *M. A. EMERY[1], A. PARSEGIAN[1], P. M. MARAS[1], E. K. HEBDA-BAUER[1], S. B. FLAGEL[1,2], S. J. WATSON, Jr.[1,2], H. AKIL[1,2];
[1]Michigan Neurosci. Inst., [2]Dept. of Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: In humans, only a small portion of those who experiment with recreational drug use transition to a substance use disorder (SUD). Multiple factors are thought to underlie this susceptibility, including differences in temperament. Those with externalizing temperaments are hypothesized to approach drugs of abuse from a sensation-seeking pathway, while those with internalizing temperaments appear less likely to approach drugs of abuse for purely recreational reasons but rather in response to other triggers such as psychosocial stress. Our lab has used a selective breeding strategy based on degree of exploratory locomotion in a novel environment to derive two lines of rats with distinct behavioral and neurobiological phenotypes, termed selectively-bred high-responders (bHRs) and low-responders (bLRs). We have previously shown that temperamental differences between these rats determines their propensity to seek and take psychostimulant drugs. Specifically, bHRs, who display a sensation-seeking phenotype, demonstrate a higher basal propensity to take drugs; whereas bLRs appear less susceptible at baseline but will seek and take drugs in response to psychosocial stress. While we have shown that bHRs and bLRs have biological differences in endogenous opioid system, such as differential expression levels of mu opioid receptor, we had not examined bHR/bLR differences in intravenous self-administration of opioids. Here, we used a free access self-administration paradigm of diacetylmorphine (heroin) to determine whether these individual differences impact self-administration of opioids. We observed the expected phenotype differences at baseline where bLRs seek and take less drug, replicating the pattern seen with psychostimulants. Interestingly, a small but potentially important sex x genotype interaction has emerged where female bHRs sought and took more heroin than males, a pattern not observed for bLRs. Future experiments will elaborate on this sex difference, as well as exploring the impact of stress on heroin self-administration. These findings contribute to our understanding of the impact of individual differences as well as a potential interaction between biological sex and temperament upon the trajectory of opioid addiction development.

Title: Stressor Controllability Provides Resilience Against Oxycodone Seeking in a Forced Abstinence Incubation of Drug Craving Model

Authors: *K. T. BROWN[1], K. A. SILETTI[2], M. C. HILLMAN[2], E. C. WARNOCK[2], M. V. BARATTA[2], M. P. SADDORIS[2];
[1]Psychology & Neurosci., Univ. of Colorado, Boulder, CO; [2]Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: Psychological stress is a critical barrier to the maintenance of abstinence among individuals with opioid use disorder. A substantial pre-clinical literature has modeled the effects of stress on drug-seeking and has identified neural circuit and neurochemical consequences of stress-induced drug seeking. The perception of control over a stressor (i.e., stressor controllability) is an important mitigating factor that determines the behavioral and neurobiological consequences of stress. Despite its known importance, stressor controllability has not been modeled in pre-clinical models of opioid drug-seeking. The present study uses a well-characterized model of stressor controllability to examine its behavioral consequences in a forced abstinence model of incubation of craving. Sprague-Dawley rats self-administered intravenous oxycodone hydrochloride (Oxy) (100 µg/kg/infusion) on a fixed-ratio 1 schedule of reinforcement during 14 daily 6-hour sessions. During these sessions, presses on an active lever delivered i.v. Oxy along with illumination of a cue light for 5 sec over the lever; presses on the inactive lever illuminated the above cue light, but did not deliver any drug. Rats then underwent a 30-minute drug-associated cue-reinforced drug seeking session on day 1 of forced abstinence from Oxy and a 1-hour drug-seeking session on day 15 of forced abstinence. 48 hours before the day 15 session, rats were randomly assigned to a home-cage control (HC) group, escapable stress (ES) session, or inescapable stress (IS) session. Rats in the escapable stress group underwent a 120-minute session during which 100 1 mA tail-shocks were administered. Rats in the ES condition controlled the duration of the tail-shock by turning a wheel on a FR4 schedule. Rats in the IS group were yoked to the ES group and experienced identical duration and intensity of tail-shock as the yoked subjects in the ES group. Importantly, the IS group was not able to control the stressor via wheel turns. Rats in the ES, but not IS, group pressed significantly less on the

cue-reinforced, previously drug-associated lever than the HC group during the day 15 drug-seeking session. Future studies will assess the effects of manipulating the medial prefrontal cortex, a brain region previously found to underlie protective effects of stressor controllability, during stress to better understand neural circuitry involved in ES mediated reductions in Oxy seeking. These data suggest that the experience of stressor controllability reduces drug-seeking and may provide a pre-clinical model to investigate neurobiological mechanisms contributing to the protective effects of stressor controllability.

Title: Cognitive-motivational traits indexed by sign- vs. goal-tracking extend to cortico-striatal glutamatergic signaling and complex movement control

Authors: *C. AVILA[1], M. SARTER[2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Psychol, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI

Abstract: Complex movements involve the utilization of task cues to guide movement selection and sequencing. We previously demonstrated that such detection of cues necessitates cortical cholinergic signaling, and that rats mimicking the cortical cholinergic and striatal dopaminergic losses that characterizes Parkinsonian fallers likewise are prone to falls. Indeed, rats with only cortical cholinergic signaling deficiencies exhibit complex movement control deficits. We also reported that sign-tracking rats (STs), that is, rats which are prone to readily approach and utilize drug cues, are characterized by poor attentional performance, relative to their counterparts, the goal-trackers (GTs), and that this is mediated by attenuated cortical cholinergic activity. Predictably, STs are less efficient in traversing dynamic surfaces than GTs. Here, we measured real-time dorsomedial striatal glutamate (GLU) signaling, using amperometry and biosensors, to test the hypotheses that; a) cues guiding movement shifts are encoded by cortico-striatal GLU and; b) that GLU activity is attenuated in STs when compared with GTs. STs and GTs were trained to perform a cue-triggered turning task (CTTT), requiring rats walking on a treadmill to utilize turn and stop cues. GLU bursts were selectively evoked by the turn cue in all rats.

However, in trials in which the cue was not utilized ("missed turns"), glutamate bursts were attenuated GTs but not STs. These findings indicate that only cues triggering a shift in movement programming - turns - evoke striatal GLU, and that GLU bursts predict trial outcome in GTs but not in STs. Performance did not differ between STs and GTs, consistent with prior evidence indicating that instructional cues are learned similarly by both phenotypes and that differences emerge specifically on tests that probe motivational value. Such an "insulation" of the striatum from cortical influence may essentially contribute to the vulnerability of STs for addiction-like behavior. Ongoing experiments are designed to demonstrate that cue-locked glutamatergic signaling originates specifically from cortico-striatal projections and that the indiscriminate striatal glutamate signaling seen in STs can be reproduced in GTs by cortical cholinergic deafferentation.

Title: Vulnerable for addiction-like behavior: disrupted cholinergic signaling and exaggerated neuroimmune response in sign-tracking rats

Authors: *H. CARMON[1], V. PARIKH[2], E. HALEY[2], N. TRONSON[1], M. SARTER[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Temple Univ., Philadelphia, PA

Abstract: Some rats (sign-trackers; STs) are prone to attribute incentive salience to reward cues, which can manifest as a propensity to approach and contact Pavlovian cues, and for addiction-like behavior. STs also exhibit poor attentional performance, relative to their counterparts, the goal-trackers (GTs), mediated by attenuated cholinergic activity. Poor cholinergic-attentional control contributes to the propensity of STs to approach and utilize Pavlovian drug cues. In STs, increases in neuronal activity fail to translocate choline transporters (CHTs) into synaptosomal plasma membrane, thereby limiting the capacity of cholinergic terminals to sustain cholinergic activity. Here we investigated post-translational modifications responsible for disrupted CHT trafficking in STs, and the hypothesis that attenuated cholinergic activity in STs causes exaggerated (neuro)immune responses. We determined levels of ubiquitinylated CHTs because ubiquitin-mediated processes can account for attenuated externalization of intracellular CHTs, ranging from proteolysis to enhanced internalization or alternative compartmentalization. The proportion of ubiquitinylated CHTs, extracted from cortex, was robustly higher in STs than in

GTs, with no overlap in the data from the two phenotypes. Moreover, modified CHTs located in intracellular domains, but not in synaptosomal plasma membrane, completely accounted for the phenotype-specific ubiquitylation levels. Ongoing experiments suggest elevated spleen levels of pro-inflammatory cytokines in unchallenged STs. Following a systemic lipopolysaccharide (LPS) immune challenge, brain levels of certain cytokines were elevated as a complex function of LPS dose, phenotype, and sex. Moreover, following LPS challenge, ubiquitinylation levels of CHTs from the cortex were drastically increased in GTs, but not STs, suggesting that in unchallenged STs, ubiquitinylated CHTs already are at maximum levels and unresponsive to an additional immune challenge. Together, this evidence supports potentially escalating, bidirectional interactions between disrupted cholinergic signaling and elevated (neuro)immune responses as an integral component of the cognitive-motivational trait indexed by sign-tracking.

Title: The acetylcholinesterase inhibitor Donepezil and the M_1 positive allosteric modulator VU0453595 produce distinct dose dependent pro-cognitive profiles in monkeys

Authors: *S.-A. HASSANI[1], J. RUSSELL[2], S. LENDOR[3], A. NEUMANN[2], K. SINHA ROY[3], K. BANAIE BOROUJENI[1], J. PAWLISZYN[3], K. L. HOFFMAN[1], C. K. JONES[2], T. WOMELSDORF[1];
[1]Dept. of Psychology, [2]Vanderbilt Univ., Nashville, TN; [3]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: The cholinergic system consists of nicotinic and muscarinic receptors and is impaired in numerous neuropsychiatric and neurodegenerative disorders such as Alzheimer's disease (AD). Donepezil, an acetylcholinesterase inhibitor, is one of the few FDA approved pro-cognitive drugs for the treatment of dementia in AD. Previous animal studies have demonstrated that donepezil can enhance multiple cognitive domains, including learning, working memory, and attention functions. However, the therapeutic potential of Donepezil is limited by peripheral cholinergically mediated dose-limiting adverse effects and by differences in the maximally effective dose for different cognitive domains. Here, we addressed these limitations by first determining the optimal dose range of Donepezil for enhancing multiple cognitive domains with a novel cognitive assessment protocol for rhesus monkeys, and secondly by evaluating the selective M_1 muscarinic receptor positive allosteric modulator (PAM) VU0453595 under the

same protocol to determine whether this mechanism would provide a broader therapeutic index for cognitive enhancement. We evaluated the potential dose-related effects of Donepezil and VU0453595 in four male adult (6-9 years old) rhesus macaques (*Macaca mulatta*) performing a visual search task for assessing interference control (attention), arousal, and impulsivity, and a feature learning task for assessing cognitive flexibility, reward sensitivity and perseveration tendencies. We found that Donepezil enhanced cognitive flexibility and interference control, contingent on task difficulty. The dose at which Donepezil exerted its maximal pro-cognitive effects differed based on task specifics. These enhancements were accompanied by slower reaction times and peripheral cholinergic side effects at the maximally cognitively-effective doses. We also utilized solid phase micro-extraction (SPME) microprobes to validate that Donepezil was available in the prefrontal cortex and striatum, highly relevant brain regions for the performed tasks. In contrast to Donepezil, VU0453595 improved both reaction times and accuracy at doses with no adverse effects, producing a distinct profile of pro-cognitive effects.In summary, Donepezil and the M_1 PAM VU0453595 produced distinct dose-dependent pro-cognitive effects across two cognitive domains. Current findings indicate that our novel multi-task cognitive assessment protocol provides a versatile framework for evaluating pharmacological influences on multiple cognitive domains in the rhesus monkey.

Title: Recovery of sustained attention following general anesthesia in rats

Authors: *K. VINCENT, E. ZHANG, R. KATO, A. CHO, O. MOODY, K. SOLT; Anesthesia, Critical Care, and Pain Med., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Despite the ubiquity of general anesthesia in medical practice, our understanding of how cognition is restored following anesthetic-induced breaks in consciousness is surprisingly limited. Of particular importance is the recovery of attentional processes. Attentional deficits are a hallmark of postoperative delirium, a serious and common postoperative complication in elderly patients. Establishing valid and relevant models to investigate these impairments preclinically will be critical for understanding their underlying neural mechanisms. Here we implement the 5-choice serial reaction time task (5-CSRTT), an analog to human continuous performance tasks, to assess the real-time recovery of sustained attention in rats following general anesthesia. In the task, rats attend a 5-windowed screen for the brief presentation of a white square. Selecting the correct window within 5 seconds is rewarded with a food pellet while incorrect selections or missed responses are punished with a time-out. During each session we tracked both the proportion of correct responses (accuracy) and proportion of missed responses (omissions) over time. We assessed attention recovery trajectories from isoflurane (2%, one hour), sevoflurane (3%, 20 minutes), propofol (10 mg/kg I.V. bolus), ketamine (50 mg/kg over 10 minutes I.V.), and dexmedetomidine (20 and 35 μg/kg over 10 minutes I.V.) for up to three hours following the return of the righting reflex (RORR), a measure of consciousness. We classified rats as having recovered accuracy performance when four of their last five responses were correct, and as having recovered low omission performance when they missed one or fewer of their last five trials. Following isoflurane, sevoflurane, and propofol anesthesia the majority (63-88%) of rats recover both accuracy and low omission performance within an hour of RORR. Following ketamine, accuracy performance in most (63%) rats recovers by two hours, but low omission performance recovers in only a minority (32%) of rats within three hours. Finally, following either high or low doses of dexmedetomidine, few rats (25-32%) recover accuracy performance within three hours, and even fewer (0-13%) recover low omission performance within three hours. Regardless of the anesthetic, RORR latency is not correlated with 5-CSRTT performance, which suggests that recovery of neurocognitive function cannot be inferred from changes in levels of consciousness. Overall, we demonstrate that the 5-CSRTT can be exploited to track real-time recovery of sustained attention in trained rats following anesthetic emergence to capture clinically relevant features of neurocognitive function.

Title: Role of the caudal patch of the secondary motor cortex (cM2) in visual decision-making in mice

Authors: *W.-K. YOU, S. P. MYSORE;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: The caudal patch of the secondary motor cortex (cM2) sits at a unique position in the motor network of the mouse brain. Unlike the rest of the motor cortices, which connect profoundly to somatosensory cortices and are involved in the control of body movements, the cM2 connects mainly to visual cortices and has been documented to be responsive to visual stimuli. Electrically stimulating this area causes saccade-like eye movements, while optogenetically inactivating this area prohibits contraversive eye movements in mice. These results suggest that cM2 may be a key area in the mouse oculomotor network. Nonetheless, the visual response properties of cM2 neurons remain largely uncharacterized, and the necessity of cM2 in visual decision-making has not yet been examined. Here, with *in vivo* calcium imaging using the Quartet microendoscope (Neurescence Inc.), we characterize the properties of cM2 neurons in response to visual stimuli. We also examine the necessity of cM2 in visual decision-making by chemogenetically inactivating it in freely behaving mice engaged in an orientation discrimination task. Our results can reveal novel properties and function of this visuomotor nexus within mouse M2.

Title: Coherent beta (15-30 Hz) activity inhibits exogenous selection in prefrontal cortex (PFC)

Authors: *A. DUBEY[1], D. A. MARKOWITZ[1], B. PESARAN[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: Visual selection is an attentional mechanism with which we decide what to see and act upon. In primates, at least two distinct attentional processes, sensory-driven exogenous (“bottom-

up") and goal-driven endogenous ("top-down") attention, drive visual selection for eye movement decisions. Behavioral evidence indicates that exogenous processing is faster and deployed earlier in time, endogenous processing is slower and occurs later in time and exogenous and endogenous attention linearly combine in time to guide visual selection. While the neural mechanisms of attentional selection remain unclear, they must support the dynamic interplay between endogenous and exogenous attentional processing. We investigated the neural mechanisms of attentional selection in the lateral prefrontal cortex (PFC) which is known to receive inputs from both visual-driven exogenous and reward-driven endogenous processes. We simultaneously recorded spiking and field potential activity from a semi-chronic 32-channel drive in two monkeys, during a two-target, eye-movement task. The task dissociated exogenous and endogenous processes by simultaneously manipulating relative luminance and reward differences. We found that the firing rate of individual visual-movement (VM) neurons (and not visual and movement neurons) encodes both exogenous and endogenous selection. Consistent with behavioral performance, selection times estimated from neural firing were faster for exogenous than endogenous selection (mean ST:88 vs 163ms). Further, neural activity during the pre-target baseline period reflected the action of a coherent beta (15-30 Hz) network. Spike-field coherence was significantly stronger during high-amplitude beta events than low-amplitude beta events. Importantly, increased pre-target beta power showed a decrease in post-target firing activity for exogenous selection but not endogenous selection. These results provide neural evidence of distinct exogenous and endogenous attentional mechanisms and suggest that inhibitory mechanisms due to coherent beta activity specifically modulate exogenous attentional selection.

Title: Mouse hippocampus neural ensembles are tuned near criticality during a cognition task

Authors: F. HABIBOLLAHI[1], J. WINNE[2], R. N. LEAO[3], A. N. BURKITT[4], *C. FRENCH[1]; [1]Univ. of Melbourne, Melbourne, Australia; [2]Developmental Genet. Unit, Federal Univ. of the Rio Grande do Norte, Brazil, Rio Grande de Norte, Brazil; [3]Brain Inst., UFRN, Natal, Brazil; [4]Dept. of Biomed. Engin., The Univ. of Melbourne, Melbourne, Australia

Abstract: Background Dynamical systems exhibit transitions between ordered and disordered states and “criticality” occurs when the system lies at the borderline between these states at which the input is neither strongly damped nor excessively amplified. In this study we report strong evidence of criticality properties in freely behaving animals using widefield neural calcium imaging.
Methods 15-minute episodes of widefield calcium imaging from several hundred hippocampal CA1 neurons using “Miniscopes” in 6 freely behaving mice were used to study criticality measures during the cognitive task of novel object recognition (NOR). Neural avalanches were identified using another thresholding step on the ensemble activity and four independent criticality measures were measured: power-law distribution, deviation from criticality (DCC), shape collapse, and branching ratio (BR).
Results The 4 criticality parameters were measured in 7 recording sessions of approximately 300 detected units, each of 15 mins, from 6 freely behaving mice. These consist of 3 inactive sessions and 4 sessions during NOR. We find that while the hippocampus neural network exhibits characteristics of a near-critical system at rest (power law expands less than 2 orders of magnitude, DCC = 0.770±0.416, shape collapse error = 0.260±0.018, BR = 0.958±0.004 in mean±SE), the network activity shifts closer to a critical state when the mice engaged in cognitive tasks (power law expanded at least 2 orders of magnitude, DCC = 0.291±0.095, shape collapse error = 0.090±0.033, BR = 0.979±0.018 in mean±SE).
Conclusions Our results utilizing a novel calcium imaging technique and analysing 4 independent measures of criticality in the hippocampus neural during a cognitive task, for the first time , suggest that switching from inactivity to a cognitively active state modulates the network’s distance from criticality; meaning it decreases DCC and shape collapse error while increasing BR. Our findings imply that being tuned near criticality is potentially the optimal state for the brain network while engaged in a cognitive task given at criticality, the dynamical range and the information content and transmission are maximized.

Title: Maternal sleep disordered breathing during pregnancy is a previously unrecognized facilitator of autism-relevant neuronal and behavioral aberrations in the offspring.

Authors: *A. VANDERPLOW[1], B. A. KERMATH[1], C. R. BERNHARDT[1], K. T. GUMS[1], A. S. ROOPRA[2], T. L. BAKER[1], J. J. WATTERS[1], M. E. CAHILL[1];
[1]Comparative Biosci., [2]Neurosci., The Univ. of Wisconsin-Madison, Madison, WI

Abstract: Sleep disordered breathing (SDB) is characterized by recurring breathing cessations during sleep, causing intermittent hypoxia (oxygen deprivation) often several hundred times per night. Obstructive sleep apnea is the most common form of SDB in pregnancy, and confers risk for detrimental maternal-fetal outcomes. Although many of the maternal risk factors for the onset SDB during pregnancy and the development of autism spectrum disorders (ASD) in her offspring are highly overlapping (e.g., maternal obesity, advanced maternal age), no studies to date have empirically investigated the potential link between these conditions. We subjected pregnant rat dams to intermittent hypoxia or normoxia (GIH and GNX, respectively) from gestation day 10-21 to investigate the consequences of maternal SDB on offspring neural function. We found that male GIH offspring exhibited deficits in several behaviors which were accompanied by increased pyramidal neuron dendritic spine density in the medial prefrontal cortex (PFC). These effects appear to arise from a disruption of normal developmental synaptic pruning late in childhood and persisting into early adolescence. The mTOR kinase signal transduction pathway has emerged as a critical regulator of dendritic spine formation, and dysregulation of key components of this pathway are implicated in the etiology of the increased cortical dendritic spine density of ASD. Our data in prefrontal cortical neuronal synaptic fractions from male GIH offspring indicate that mTOR activity exhibits a biphasic pattern: mTOR signaling is increased in juvenile offspring, yet decreased in adult offspring, relative to male GNX offspring. RNA-sequencing data from adult male GIH microglia isolated from the PFC also identified increased mTOR-dependent gene expression, suggestive of mTOR pathway dysregulation in both neurons and microglia. Together, these data indicate that excessive neuronal mTOR signaling could contribute to the lack of spine pruning in juvenile male GIH offspring, while the subsequent decrease in neuronal mTOR signaling at later stages of development could serve a compensatory role to mitigate further surges in spine numbers. Enhanced microglial TOR signaling may also contribute to increased spine numbers by reducing the natural ability of microglia to prune synapses. Ongoing studies are aimed at determining whether reducing mTOR activity in juvenile GIH offspring ameliorates the behavioral, neuronal, and microglial abnormalities in adolescent GIH offspring.

Title: Estimating subjective value and decoding choice intent from neural populations in primate orbitofrontal cortex

Authors: *V. B. MCGINTY, S. M. LUPKIN;
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: In neuroeconomics, one of the key ways of identifying decision mechanisms is to show a trial-to-trial relationship between neural variability and decision variability. In a classic example, Britten et al. (1996) showed that the activity of motion-sensitive neurons could explain variability in motion judgements, even over trials in which the same noisy motion stimulus was repeated many times. Finding this fine-grained neural-behavioral link is important because it provides insight into how neural activity is read out by downstream circuits, and (along with other findings) evinces the causal role of neural activity for behavior. For value-based decisions, neurons in the primate orbitofrontal cortex (OFC) are thought to have such a causal role. Specifically, they are thought to shape decision outcomes by encoding economic value; however, a robust link between variability in OFC value coding and variability in value-based decisions has yet to be found. In this study, we report such a link for the first time. Macaque monkeys performed a decision task in which they selected between two visual targets on the basis of reward value (number of drops of juice). Critically, many trials offered choices between targets of similar or equal value, producing substantial inter-trial variability in decision outcomes. Neural recordings were obtained from populations of OFC neurons (~45 cells per session) using acutely placed linear arrays. To link decision variability to neural variability, we used a regularized linear encoder/decoder that took advantage of the simultaneous nature of the neural recordings. First, a set of training trials was used to assign to each cell a weight which indicated that cell's unique contribution to representing the target values (encoding); then, over a set of held out test trials, we found the weighted sum of spiking across all cells, which we took as an estimate of the subjective values of the targets on each trial (decoding). Finally, the subjective value estimates were used to classify decision outcomes (i.e. to infer decision intent) in the test trials. With this population-level decoder, it was possible to predict decision outcomes with far higher accuracy than with a decoder that used single cells individually. Examination of the encoding/decoding weight vectors indicated that OFC value representations were nearly orthogonal at the population level, and were therefore linearly separable by downstream circuits. Thus, these findings provide an essential piece of evidence to support the role of OFC in value-based choice, as well as specific insights into the mechanisms by which OFC value representations inform economic decisions.

Title: Lateral orbitofrontal cortex is required for inferring hidden task states

Authors: *S. SCHIERECK, A. MAH, C. CONSTANTINOPLE;
New York Univ., New York, NY

Abstract: A principle of modern decision theories is reference dependence, in which the subjective value of a reward is computed relative to an internal reference point that is thought to reflect outcome expectations. Previous work has often assumed that reference points are retrospective, deriving directly from past experiences. Here, we show that rats can use inference to compute and switch between multiple reference points, and that the lateral orbitofrontal cortex (lOFC) is required for this capacity. We have designed a behavioral paradigm with partially-observable states (blocks of trials offering small or large rewards). Rats must determine how long to wait for uncertain rewards, providing an explicit behavioral readout of a rat's subjective value for rewards. Rats' wait times are sensitive to the reward volumes and also the block structure: rats tend to wait longer for the same volume of water reward in blocks of trials with a low average expected reward compared to blocks of trials with a high average expected reward. Behavioral analysis suggests that they are using inference, as opposed to retrospection, to adjust their reference points based on the inferred block. To assess the role of lOFC in this task, we performed whole-session inactivation of lOFC using bilateral muscimol infusions (n=8 rats). We found that modulation of wait-time by reward volume is not impaired by lOFC inactivation, suggesting that this region is not required for computing the subjective value for different reward volumes, per se, or for time estimation. However, modulation of wait-time by reward block was dramatically reduced, suggesting that lOFC was required for rats to infer the hidden block. We present results from behavioral modeling, comparing models that instantiate retrospective or inferential strategies, to characterize the precise nature of the behavioral deficit in greater detail. Additionally, we are performing chronic freely-behaving neuropixels recordings to understand

when and how task-relevant variables including the current reward block, offered reward volume, and delay to reward are encoded in lOFC in this task.

Title: Basal forebrain cholinergic projections to reciprocally connected orbitofrontal and secondary visual cortex.

Authors: *C. CHAVEZ, L. ZABORSZKY;
Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: The basal forebrain (BF) cholinergic system provides acetylcholine (ACh) throughout the cerebral cortex and has been implicated in cortical activation, attention, sensory processing, learning, and memory. Despite innervating the entire neocortex, studies have found selective ACh release in distinct cortical areas, likely supported by the neuroanatomical findings that cholinergic cells within the BF project to specific cortical targets. Together, this suggests that the BF may be involved in modulating cortical function in particular cortical regions rather than in a global manner. Recently, using electrophysiology we showed that neurons in sub-regions of the BF are dynamically recruited during various behavioral epochs of a visual discrimination task (Gombkoto et al., 2021). Additionally, we found that specific BF cholinergic cells may be involved in modulating gamma coherence between reciprocally connected cortical regions. We hypothesize that interconnected cortical regions may share overlapping cholinergic projection neurons within specific sub-regions of the BF that underlie the increased corticocortical coherence observed during behavior. Using dual retrograde tracer injections, we targeted both the secondary visual (V2) and orbitofrontal cortex (OFC) which our study found is co-modulated by BF cholinergic activity and is known to be reciprocally connected. Adult Chat/Cre negative rats were injected with Fluoro-Gold (Fluorochrome) and Fast Blue (Polysciences, Inc.) retrograde tracers into V2 and OFC respectively. After a 1-week survival period, the brain tissue was collected and processed for observation using a fluorescence microscope (Axioskop, Zeiss). Tissue sections were evaluated every 200µM for fluorescent labeling using Neurolucida software (MBF Bioscience). Preliminary data suggests that a subpopulation of OFC projecting and V2 projecting BF neurons overlap in their localization within the BF. Further, preliminary data utilizing viral tracing methods in Chat/Cre positive rats identified several cholinergic cells

double labeled for both the OFC and V2 projections, suggesting that single cells within the BF may collateralize to project to the interconnected cortical targets. This preliminary data along with our previous electrophysiological data supports the hypothesis that interconnected cortical regions share overlapping subpopulations of BF projection cells and they may underlie the co-modulation observed in these cortical targets during behavior.

Title: Aspiration lesions of OFC disrupt cholinergic innervation of the prefrontal cortex in the rhesus macaque

Authors: *B. E. HINES, M. A. ELDRIDGE, E. A. MURRAY;
Lab. of Neuropsychology, NIMH, NIH, Bethesda, MD

Abstract: Previous studies have shown that monkeys with bilateral aspiration lesions of orbitofrontal cortex (OFC) are impaired in serial object reversal learning, whereas monkeys with excitotoxic lesions of the same region are not (PH Rudebeck et al., *Nat. Neurosci*., 2013). This discrepancy indicates that aspiration lesions of OFC affect the brain differently than excitotoxic lesions of OFC, presumably by disrupting fibers of passage, i.e., axons passing nearby or through the OFC en route to other regions of the brain. Here, we sought to determine how aspiration lesions of OFC impact the distribution of cholinergic fibers in other regions of prefrontal cortex. Three rhesus monkeys received unilateral aspiration lesions of OFC. Monkeys were sacrificed 5, 6 and 56 weeks after surgery, their brains were fixed, slices were cut at 40 microns, and Acetylcholine-esterase (AChE) immunohistochemistry was performed. AChE distribution was measured as a proxy for cholinergic fiber distribution, quantified, and comparisons between the OFC-lesioned and intact hemispheres were performed. Densitometry analysis was used to quantify the strength of cholinergic fibers in five sections of each hemisphere per monkey. We examined anterior cingulate cortex because it receives inputs from many temporal lobe structures via projections that run through or nearby the OFC, in addition to receiving inputs from cholinergic neurons in the basal forebrain. As a negative control, we examined the striatum. Aspiration removals of OFC significantly reduced the density of acetylcholine fibers in the anterior cingulate cortex, but not our control site in the striatum. The significant reduction in the density of stained fibers in the ACC of hemispheres with aspiration lesions of OFC indicates that cholinergic projections travel through the OFC en route to the ACC, consistent with earlier

reports (Kitt et al., *Brain Res*. 1987). These results suggest a possible explanation for the differential effects on behavior of aspiration versus excitotoxic lesions of OFC.

Title: Medial orbitofrontal cortex outputs facilitate risk assessment and govern reward-related circuits in an age-dependent manner

Authors: *M. K. LOH, N. C. FERRARA, J. M. TORRES, J. A. ROSENKRANZ;
Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. & Sci., North Chicago, IL

Abstract: Risk assessment precedes appropriate decision-making, which is crucial for survival but riskier during adolescence. The developing circuits that underlie risk assessment are not well understood but can further our understanding of high-risk behaviors. The nucleus accumbens (NAc) integrates excitatory inputs from both cortical and limbic structures, which are communicated to downstream motor regions. As inputs from cortical and limbic structures carry goal- and reward-related information, the summation of these signals at the level of the NAc likely combines information about rewards and risks to direct decision-making. Previous work suggests the medial orbitofrontal cortex (MO) incorporates risk information to bias behavior towards more conservative options. This effect is perhaps due to the inhibition of reward-related circuits such as basolateral amygdala (BLA)-NAc pathways. Using pharmacological inactivation of MO and NAc, we found that MO-NAc interactions permit specific risk assessment behaviors in adult rats. Using in vivo electrophysiology, we also found that MO stimulation modulated the timing and probability of BLA-evoked NAc spiking in a time- and frequency-dependent manner. Single-pulse MO stimulation reduced BLA-evoked NAc spike latency, whereas MO train stimulation produced a frequency-dependent effect on BLA-evoked NAc spike probability. MO train stimulation delivered at 10 Hz facilitated BLA-evoked NAc spike probability but diminished the interactions at 40 and 60 Hz. These opposing effects by MO train stimulation may reflect biases in optimal decision-making, where a subject is inclined towards large-reward/high risk or small-reward/low-risk choices based on previous outcomes and overall long-term benefit. Further, we found that adolescents exhibit fewer risk assessment behaviors than adults during elevated plus-maze exploration. In parallel electrophysiology recordings we found

that MO inputs to NAc exert a unique effect in adolescents. Unlike adults, the adolescent MO failed to produce the bimodal effects on BLA-NAc interactions; MO train stimulation diminished BLA-NAc spiking at all tested frequencies. These effects may reflect suboptimal adolescent decision-making. While the matured MO can regulate the strength of reward-related circuits, the immature MO cannot produce the same bimodal effect to guide decision-making appropriately. Collectively, these results indicate that the development of the MO and its afferents may underlie the age-dependent differences seen in decision-making.

Title: Neuronal origins of choice biases under sequential offers

Authors: *W. SHI[1], S. N. BALLESTA[2], C. PADOA-SCHIOPPA[1];
[1]Washington Univ. in St Louis, Saint Louis, MO; [2]Neurosci., Univ. of Strasbourg, Strasbourg, France

Abstract: Shedding light on choice biases observed behaviorally is a long-term goal of neuroeconomics (Glimcher and Rustichini, 2004), but progress on this front has been arguably modest. Here we examined the neural origins of choice biases measured when goods available for choice are offered sequentially. In the experiments, monkeys chose between two juices offered in variable amounts. In each session, two choice tasks were randomly interleaved. In Task 1, offers were presented simultaneously; in Task 2, offers were presented in sequence. Comparing choices across tasks revealed three phenomena: (I) Monkeys were substantially less accurate in Task 2 compared to Task 1. (II) Choices in Task 2 were biased in favor of the second offer (order bias). (III) Choices in Task 2 were biased in favor of the preferred juice (preference bias).
Choosing between goods entails a series of operations. In broad strokes, sensory information and the internal state are integrated to compute the subjective value of individual offers. Offer values are then compared in a decision process. Finally, the decision outcome, possibly held in working memory, guides the construction of some action plan. Critically, choice biases may emerge

during any of these computations. Previous work identified in the orbitofrontal cortex (OFC) different groups of neurons encoding individual offer values, the binary choice outcome and the chosen value. These variables capture both the input and output of the decision process, suggesting that decisions might be formed within OFC (Padoa-Schioppa and Conen, 2017). Recent work showed that choices under sequential offers engage the same cell groups (Shi et al., 2021). If so, suitable analyses of their activity may shed light on the origins of choice biases. Building on this ideas, we examined the activity of 1,204 cells from the OFC of two monkeys. Our analyses revealed that different biases emerged at different computational stages. Specifically, the lower choice accuracy observed in Task 2 offers emerged, at least partly, at the valuation stage (weaker offer value signals). The order bias found in Task 2 did not have neural correlates during valuation, and emerged during the decision. Finally, the preference bias found in Task 2 emerged late in the trial, possibly due to failures in working memory.
In conclusion, offer values integrate multiple dimensions on which goods may vary. Naturally, all of these dimensions influence choices. Adding to this account, our results provide a more articulated picture, in which choices are also affected by biases emerging during the decision or in subsequent computational stages.

Title: The medial orbitofrontal cortex controls value-based action through neurotrophin systems and interactions with the ventral hippocampus

Authors: *E. P. WOON[1], A. ELBASHEIR[1], S. L. GOURLEY[2];
[2]Pediatrics, Neurosci. Program, [1]Emory Univ., Atlanta, GA

Abstract: Value-based decision making, referring to selecting actions based on the value of prospective outcomes, relies on the medial orbitofrontal cortex (MO), yet molecular mechanisms are unclear. One candidate is the Brain-derived Neurotrophic Factor receptor, tyrosine/tropomyosin receptor kinase B (TrkB). Here, we trained mice to respond for 2 distinct food outcomes. We next reduced the value of one outcome using conditioned taste aversion (CTA), then characterized decision-making strategies. We administered a TrkB antagonist during

outcome value updating (during the CTA procedure) or during a period of value memory retrieval (the choice test). Inhibiting TrkB during the updating, but not retrieval, of memories regarding food value impaired the ability of mice to preferentially respond for high-value foods. Both overexpression of an inactive isoform of TrkB, *Trkb*.t1, and knockdown of the active receptor, TrkB.FL, selectively in the MO had the same consequences, particularly when outcomes were unobservable and had to be envisioned. What inputs to the MO might be needed to update the value of outcomes? We determined that vHC-to-MO projections are essential for updating the value of outcomes to guide future action selection. In particular, preliminary evidence suggest that vHC-to-MO projections facilitate the processing of aversive homeostatic state information to influence later decisions. Preliminary evidence also indicates that vHC-to-MO connections require TrkB activity on MO neurons to update outcome value for future action selection. In summary, these patterns suggest neurotrophin activity in the MO is necessary for value-based action, as are inputs from the vHC to the MO. Future experiments will determine whether value updating influences dendritic spines on excitatory neurons in the MO that specifically receive input from the vHC.

Title: Mice prone to habits exhibit compulsive-like behavior: Possible involvement of orbitofrontal melanocortin 4 receptor

Authors: *S. T. YOUNT[1], A. G. ALLEN[2], S. L. GOURLEY[2];
[1]Grad. Program in Mol. & Systems Pharmacol., [2]Pediatrics, Neurosci. Program, Emory Univ., Atlanta, GA

Abstract: Adjusting familiar actions based on changes in the surrounding environment is part of everyday life. Goal-directed behavior (i.e., making a choice based on changes in outcome expectation) is antithetical to habitual behavior, which is instead triggered by cues and not outcome predictability. Habitual behavior is adaptive under many circumstances, but it could be

antecedent to compulsions - intrusive thoughts that drive persistent and potentially maladaptive behavior. Hyperactivity of the orbitofrontal cortex (OFC) is a hallmark characteristic of patients with obsessive compulsive disorder, and melanocortin 4 receptor (MC4R) signaling may be involved. We hypothesized that mice with a natural propensity for habitual behavior would exhibit compulsive-like behavior. We selectively bred mice that fail to update instrumental behaviors when expected rewards are not delivered and instead defer to familiar behavioral sequences. Their offspring developed the same response biases and compulsive-like and risk-taking behavior. Compulsive-like behavior was corrected by fluoxetine and correlated with instrumental response strategies. We next hypothesized that compulsive-like behavior may be attributable MC4R systems in the OFC. Repeated, but not acute, chemogenetic stimulation of MC4R+ glutamatergic OFC neurons triggered compulsive-like grooming. A prominent theory of addiction and compulsive disorders is that they involve a loss of control over habits. Understanding whether action strategies correlate with compulsions, and whether melanocortin signaling alters cortico-striatal connectivity, will advance future efforts to mitigate harmful habitual behavior.

Title: To share or not to share? iEEG evidence for state-dependent inequity encoding in the OFC

Authors: *D. MARCIANO[1], B. R. STAVELAND[1], J. LIN[2], I. SAEZ[3], M. HSU[1], R. T. KNIGHT[1];

Abstract: A wealth of functional neuroimaging and lesion evidence has pointed to the involvement of the human orbitofrontal cortex (OFC) in social valuation and decision-making. However, due to inherent limitations of spatiotemporal resolution of these methods, mechanistic understanding of OFC's role in underlying processes have remained elusive. Here we sought to shed light on these questions by conducting intracranial recordings in neurosurgical patients

while they performed a social decision-making task. Nine intracranial patients (808 electrodes, 101 OFC electrodes) played a repeated Dictator Game, a task in which participants unilaterally decide on the allocation of a money between themselves and an anonymous other. On each trial, patients chose between two options: an equitable, constant option ($10 for themselves, and $10 for the other), and a second inequitable option which varied from trial to trial. The Inequity of the varying option came in one of two types: (i) advantageous inequity (AI) where the dictator received more (e.g., $15 and $8 respectively), and (ii) disadvantageous inequity (DI) where the dictator received less (e.g., $12 and $22). Consistent with suggestions from neuroimaging studies, we found extensive reward-related representations (e.g., own payoff, maximal payoff) in High Frequency Activity (HFA; 70-150 Hz) in the OFC, as well as whether the varying option contained advantageous or disadvantageous inequity with a significant effect in 43% of OFC electrodes (permutation test: $p < 0.05$). In addition, owing to improvements of temporal resolution and signal to noise (SNR), we found strong evidence for state-dependent encoding of these reward-related representations. Specifically, encoding depended on the nature of inequity of the varying option—i.e., whether the inequity of the varying option was advantageous or disadvantageous. For example, 34% of OFC electrodes encoded maximal value only in DI trials, but not in AI trials, and 43% of electrodes encoded the other's payoff only in advantageous trials, but not in disadvantageous trials. Together, these results support the idea that OFC high-frequency activity encodes relevant social decision-making computations in a context-sensitive way. Our findings are consistent with notions that OFC encodes the current abstract space of a task (a global "task space"), which in turns modulates the neural representation of valuation computations (Niv et al., 2014; Zhou et al., 2019; Shuck et al., 2016); and extend the previous literature to social contexts.

Title: Mu-opioid receptors in the medial orbital cortex contribute to cross-hemispheric regulation of reward-guided behavior

Authors: *S. R. WHITE, C. B. DARDEN, K. CHAVEZ LOPEZ, M. LAUBACH; American Univ., Washington, DC

Abstract: The medial orbital cortex (mOFC) is a key frontal region for processing of reward information that is enriched with mu-opioid receptors. Reversible inactivation of mOFC reduces incentive contrast effects and palatability measures (Parent et al., 2015). Neuronal activity in mOFC is modulated when rats initiate consummatory licking (Horst and Laubach, 2013) and encodes the value of liquid sucrose rewards (Amarante et al., 2017). Few studies have examined the roles of mOFC mu-opioid receptors in reward-guided behavior. We tested rats in an incentive contrast licking task and a value-guided decision making task (Swanson et al., 2021) following infusion of muscimol and the selective mu-opioid receptor agonist DAMGO. In the licking task, rats were trained to lick on a contact-sensitive spout to receive access to liquid sucrose, which alternated between high (16%) and low (4%) values over 30sec periods. With training, rats learned to persistently lick for the higher value fluid and suppress licking for the lower value fluid. Bilateral infusion of DAMGO (1μg/μL), targeting mOFC, slowed licking rates and increased the number of licking bouts and reduced their duration, without increasing overall consumption or altering relative reward value. By comparison, infusion into the lateral ventricle, targeting the entire forebrain, increased consumption and had mixed effects on microstructural measures of licking. In the decision making task, rats nosepoked to produce visual stimuli, with the brightness of the stimuli associated with their reward value. Bilateral infusions of both muscimol (0.1 ug/ul) and DAMGO (1 ug/ul) led to dramatic disruptions of performance, suggestive of impaired procedural memory. We further examined neural correlates of these effects in the licking task by implanting a drug cannula in one hemisphere and a microwire array in the other. Unilateral DAMGO infusions increased delta (<4 Hz) power, disrupted phase locking at the lick frequency, and enhanced phase locking at higher frequencies. Together these data suggest that mu-opioid stimulation in the mOFC disregulates cross-hemispheric rhythmicity which may lead to the changes in reward-guided behaviors.

Title: Adolescent female valproic acid rats are impaired on the extra-dimensional shift of attention

Authors: C. KING, T. DAVISON, Z. E. MCKINNELL, B. CHALLANS, *B. PLAKKE; Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: The valproic acid (VPA) model of Autism Spectrum Disorder (ASD) is a widely accepted model of early environmental exposure to sodium valproate to induce ASD-like symptoms in offspring. It has both face and construct validity. Previous research has found that VPA rats are impaired at attentional set-shifting in adulthood (McKinnell et al., 2021). The current research examined if the same cognitive deficits can be observed earlier in development during adolescence. Pregnant dams were injected on gestational day 12 with VPA (600mg/kg) or saline. It was hypothesized that VPA rats would perform worse on the extradimensional shift (ED) phase of the attentional set-shifting task. The study used N=32 Long-Evans rats (9 male controls, 7 VPA males, 9 control females, 7 VPA females). All of the rats were trained to complete the set-shifting task on postnatal day 35-38. Male and female data were analyzed separately based on the lab's previous findings that VPA females and males perform differently on the set-shifting task (McKinnell, et al., 2021). Researchers running behavioral tests were blind to treatment conditions. Preliminary data analysis demonstrates that female VPA rats performed significantly worse on the ED phase of the task compared to controls ($p<0.01$). These results support the hypothesis that executive function deficits in females are occurring within ASD at an earlier age compared to males. Ongoing research is measuring the volumes of the medial prefrontal cortices (mPFC) of these rats, which is the critical structure for ED performance. These data support the hypothesis that the VPA model is capturing some of the same cognitive deficits present in humans with ASD, which allows for a greater understanding of the underlying neurobiology of the disorder.

Title: The role of D_4 receptors in cognitive flexibility and ADHD

Authors: *Z. MCKINNELL[1], T. MAZE[1], C. KING[1], T. DAVIDSON[1], B. PLAKKE[2]; [1]Psychological Sci., [2]Psychological Sciences, Behavioral Neurosci., Kansas State Univ., Manhattan, KS

Abstract: Impairments in cognitive flexibility are found in a wide range of psychiatric disorders, such as schizophrenia, Parkinson's disease, and attention-deficit hyperactivity disorder (ADHD). These disorders are all linked to altered dopamine (DA) network processing (Klanker et al., 2013), therefore; understanding the role of DA in models of cognitive flexibility and attention is crucial for determining disease progression and designing effective treatments at each disease stage. Although, medications are available for treating ADHD it is still important to find the most effective and efficient treatment options for individuals diagnosed with ADHD or other similar disorders. Using a D_4 antagonist, SHR and Long-Evans were treated with the drug over a 14-day period to simulate real-life treatment and was run through the marble-burying task, open-field Test, and the attentional set-shifting task, which is the rodent equivalent of the Wisconsin Card Sorting Task (Birrell et al., 2000). The marble task and the open-field test were used to test multiple side effects of the drug and will be used to determine whether the SHRs exhibit the appropriate symptomology for ADHD. Previous studies have identified that the variability in ADHD symptoms in SHRs is extremely high, which could lead to effects being masked and unimpaired rats being assumed to be impaired (Ha et al., 2020). Behavioral profiling is currently underway, but preliminary analyses have indicated that control SHRs were impaired across multiple phases of the attentional set-shifting task, while SHRs in the treatment group performed marginally better across the task. Long-Evans in the treatment group performed worse than control Long-Evans, which could be due to the drug treatment having a negative effect on our control strain due to their lack of need. This is not surprising given that individuals who take unprescribed ADHD medication perform worse on cognitive tasks. These results will add to the literature about whether more specific DA drugs will work more efficiently than non-selective treatments, which have many unwanted side effects for treated individuals.

Title: Phasic Dopamine Release Measurements in Two Different Rat Models of Attention-Deficit/Hyperactivity Disorder: Spontaneously Hypertensive Versus Lphn3 Knockout Rats

Authors: *P. NALAN[1], R. L. PACE[1], C. B. HICKS[1], S. L. REGAN[2,3], M. T. WILLIAMS[2], C. V. VORHEES[3], H. J. SABLE[1], D. B. LESTER[1];

Abstract: Attention-Deficit/Hyperactivity Disorder (ADHD) is associated with a dysfunction in dopamine transmission and is often treated with drugs that increase extracellular dopamine levels. The present study examined dopamine release in the nucleus accumbens core (NAc) of two rat models of ADHD. Spontaneously Hypertensive Rats (SHRs) are an accepted phenotypic ADHD model that exhibit impulsivity/hyperactivity and inattention. *Lphn3*$^{-/-}$ (knockout, KO) rats are a genetic model that also exhibit impulsivity/hyperactivity, but to a lesser degree than the SHRs. The *Lphn3*KO rats were created based on data from a genome-wide, multigenerational study that linked variants in the *Lphn3*(*Adgrl3*) gene [OMIM 616417] to ADHD. Using *in vivo* fixed potential amperometry, we quantified stimulation-evoked phasic dopamine release in the NAc of the *Lphn3* KO and *Lphn3*$^{+/+}$ (wildtype, WT) rats as well as SHRs and their control strain, Wistar-Kyoto (WKY) rats, before and after administration of nomifensine (10 mg/kg, ip), a dopamine transporter (DAT) blocker. Both SHRs and *Lphn3* KO rats displayed decreased baseline dopamine release compared to their respective controls, with no difference between sexes. However, the dopaminergic response to DAT inhibition differed. Sex effects were observed in SHR rats, with male SHR rats displaying a decreased dopaminergic response to nomifensine compared to WKY males and female SHR rats responding similarly to WKY females. No differences were observed between male and female *Lphn3* KO rats; both sexes displayed an increased dopaminergic response to nomifensine relative to WTs. These findings indicate differences in DAT functioning between SHR and *Lphn3* KO rats and suggest that DAT inhibitors, such as those used to treat ADHD, may produce different therapeutic outcomes.

Title: Ventral hippocampal input to the infralimbic cortex is necessary for the effects of extinction on set shifting after chronic stress

Authors: *D. PAREDES[1], S. WAY[1], D. A. MORILAK[2];
[1]Univ. of Texas Hlth. Sci. Ctr. San Anto, San Antonio, TX; [2]Pharmacol. and Ctr. for Biomed. Neurosci., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Psychiatric disorders such as post traumatic stress disorder and major depressive disorder are characterized by deficits in cognitive flexibility. We have established extinction learning in rats as a behavioral intervention that models the effects of exposure therapy on cognition. Extinction reverses chronic stress-induced deficits in cognitive flexibility on the attentional set-shifting test (AST), a medial prefrontal cortically-mediated executive process. Extinction requires the activity of pyramidal neurons in the infralimbic cortex. The ventral hippocampus plays a key role in regulating infralimbic activity during extinction learning, and plasticity in the ventral hippocampus is necessary for extinction memory consolidation. Thus, in these experiments we set out to investigate the role of ventral hippocampal input to the infralimbic cortex (IL) for the therapeutic effects of extinction after chronic stress. Further, we investigated whether chronic stress induces deficits in the novel object recognition test (NOR), and whether the effects of stress were reversed by extinction learning. Male and female rats received viral injections of inhibitory or control designer receptor exclusively activated by designer drugs (DREADDs) into the ventral hippocampus. Subsequently, rats were fear conditioned or received tone control treatment and underwent chronic unpredictable stress (CUS). Prior to extinction treatment, rats received a bilateral microinjection of CNO (200umol) into the IL. 24 hours after, rats were tested on the NOR test and AST. Our results show that inhibiting ventral hippocampal input to the IL during extinction blocks the therapeutic effects of extinction (n=4-6/group, p=0.0045, males and females). Preliminary data show that stress may induce a deficit on NOR, ongoing experiments will determine whether extinction reverses impairments on NOR (n=4-6/group, p=0.4). Supported by research grants from the NIMH (MH72672), the William and Ella Owens Foundation, and the Veterans Administration (BX003512).

Title: Ketamine increases activity of a fronto-striatal projection that regulates compulsive behavior in SAPAP3 knockout mice

Authors: *G. L. DAVIS[1], A. R. MINERVA[2], A. LARIO[1], L. D. SIMMLER[3], C. RODRIGUEZ[4], L. A. GUNAYDIN[1];
[1]UCSF, San Francisco, CA; [2]Princeton Univ., Princeton, NJ; [3]Neurosciences Fondamentales, Univ. of Geneva, Geneve 14, Switzerland; [4]Stanford Univ., Palo Alto, CA

Abstract: Obsessive-Compulsive Disorder (OCD), characterized by intrusive thoughts (obsessions) and repetitive behaviors (compulsions), is associated with dysfunction in fronto-striatal circuits. There are currently no fast-acting pharmacological treatments for OCD. However, recent clinical studies demonstrated that an intravenous infusion of ketamine rapidly reduces OCD symptoms. To probe mechanisms underlying ketamine's therapeutic effect on OCD-like behaviors, we used the SAPAP3 knockout (KO) mouse model of compulsive grooming. Here we recapitulate the fast-acting therapeutic effect of ketamine on compulsive behavior, and show that ketamine increases activity of dorsomedial prefrontal neurons projecting to the dorsomedial striatum in KO mice. Optogenetically mimicking this increase in fronto-striatal activity reduced compulsive grooming behavior in KO mice. Conversely, inhibiting this circuit in wild-type mice increased grooming. Finally, we demonstrate that ketamine blocks the exacerbation of grooming in KO mice caused by optogenetically inhibiting fronto-striatal activity. These studies demonstrate that ketamine increases activity in a fronto-striatal circuit that causally controls compulsive grooming behavior, suggesting this circuit may be important for ketamine's therapeutic effects in OCD.

Title: Impulsive action and working memory impairments in two different rat models of Attention-Deficit/Hyperactivity Disorder: Spontaneously Hypertensive versus Lphn3 knockout rats

Authors: *H. J. K. SABLE[1], D. B. LESTER[1], J. L. POTTER[1], H. G. NOLEN[1], D. M. CRUTHIRD[1], L. M. ESTES[1], A. D. JOHNSON[1], S. L. REGAN[2,3], M. T. WILLIAMS[2,3], C. V. VORHEES[2,3];

Abstract: Attention-Deficit/Hyperactivity Disorder (ADHD) is characterized by two primary presentations - hyperactivity/impulsivity and inattention - which can occur individually or together, thereby resulting in three unique ADHD sub-types: hyperactive/impulsive, inattentive, or combined. Recent data from a genome-wide, multigenerational sample linked variants in the *Lphn3* (*Adgrl3*) gene [OMIM 616417] to ADHD. While, previous research has demonstrated *Lphn3*$^{-/-}$ (i.e., knockout, KO) rats are hyperactive compared with *Lphn3*$^{+/+}$ (i.e., wildtype, WT) rats, this project was done to examine the impact of *Lphn3* deletion in rats on operant measures of impulsive action and working memory. Impulsive action was measured via a differential reinforcement of low rates of responding (DRL) task in which rats were required to wait 15 s (i.e., DRL 15) between lever presses to earn a food reinforcer. Working memory was assessed using a delayed spatial alternation (DSA) task that required rats to alternate lever presses from one trial to the next to earn the food reinforcer. Random delays of 0, 5, 10, or 20 s were imposed between trials during DSA. “Positive control” measures on the same tasks were collected in Spontaneously Hypertensive Rats (SHRs), which are an accepted animal model of ADHD. Compared with WT controls, the *Lphn3* KO rats exhibited deficits on both the DRL and DSA tasks, indicative of deficits in impulsive action and working memory, respectively. These deficits were less severe than those observed in SHRs, who were *profoundly* impaired on both tasks compared with their control strain, Wistar-Kyoto rats (WKY). When combined with previous research, both the L*phn3* KO rats and the SHRs encompass the impulsive/hyperactive presentation of ADHD. While previous research has also shown the SHR rat to have attentional impairments (thus representing the combined ADHD subtype), additional research is necessary to assess whether the L*phn3* KO rats are also inattentive, or whether they represent only the hyperactive/impulsive sub-type.

Title: Unveiling the abstract format of mnemonic representations

Authors: *Y. KWAK, C. CURTIS;
New York Univ., New York, NY

Abstract: The precise contents of working memory (WM) can be decoded from the patterns of neural activity in human visual cortex (Harrison and Tong, 2009; Serences et al., 2009), leading to the idea that the same encoding mechanisms are used for perception and WM maintenance (Serences, 2016). However, results are inconsistent as to whether sensory representations are good predictors of memory representations (Albers et al. 2013; Rademaker et al., 2019), and distracting sensory inputs sometimes have negligible effects on WM (Bettencourt and Xu, 2016; Hallenbeck et al., under revision; Lorenc et al., 2018). One reasonable hypothesis of WM representation that accounts for these inconsistencies is that mnemonic codes are perhaps abstractions of low level stimulus features. Yet the format of these putative abstract representations has thus far remained impenetrable. Here, we demonstrate that different types of visual stimuli can be flexibly re-coded into the same WM format when that representation is useful for memory-guided behavior. Specifically, we found that the pattern of activity in visual and parietal cortex during WM for dot motion and for gratings, two very different retinal inputs, are interchangeable when participants were later tested on the global direction of the motion or the orientation of the grating. To reveal the representational format of WM, we then used simulations and models that reconstructed WM representations within topographic populations. We found evidence that the behaviorally relevant feature of each type of stimulus (motion direction and orientation) was extracted and re-coded into a shared mnemonic representation that takes the form of an abstract line-like pattern within spatial topographic maps. These findings suggest that mnemonic representations can take on formats that are efficient summaries of perceptual representations with more proximal links to the behavioral affordances contingent on the memory.

Title: Bifurcation in hierarchy space as a mechanism for distributed working memory in a large-scale model of the macaque neocortex

Authors: J. JIANG[1], U. PEREIRA OBILINOVIC[2], X.-J. WANG[3];
[1]New York Univ. Ctr. For Neural Sci., New York, NY; [2]Ctr. for Neural Sci., [3]New York Univ., New York, NY

Abstract: Numerous electrophysiological and imaging studies in non-human primates and humans demonstrate the distributed nature of working memory. Working memory-related sustained activity is rarely observed in the sensory areas but robustly displayed in the prefrontal, parietal, and inferotemporal association cortices. What are the organizing principles that determine the pattern of distributed working memory activity across the cortex? To address this question, we use a modeling framework that integrates a generative model for the mesoscopic connectivity of the macaque neocortex (Song et al, 2014) with biophysically realistic neuronal dynamics. First, we use the diffusion map method on the generated connectivity data to estimate the hierarchical position of each cortical region. Using this hierarchy, we define a macroscopic gradient for the strength of excitation across the cortical mantle, consistent with experimental observations. Then, we use the resulting connectivity and gradient of excitation to construct a large-scale dynamical model of the macaque neocortex. Our model naturally displays multiple distributed working memory-related persistent activity patterns, consistent with experimental observations. Strikingly, only higher hierarchical regions display persistent activity while lower areas present background activity. There is a sudden transition in firing rate activity along the hierarchy, determining which brain region will present working memory-related persistent activity. This phenomenon corresponds to a bifurcation in the hierarchy space. The critical hierarchical position when this transition occurs corresponds to the bifurcation point. We find that areas around the bifurcation point present slow fluctuations or switching between background and persistent activity. Thus, the time scale of cortical areas around the bifurcation point increases dramatically to seconds. As reported in association areas, the time scale for cortical areas after the bifurcation could also reach seconds, while areas lower in the hierarchy have much shorter intrinsic time scales. Together, our work suggests that working memory states are organized around a bifurcation in cortical hierarchy. Signatures of this bifurcation are predicted to be present in cortical time scales.

Title: Transient inactivation of the nucleus reuniens, but not dorsal hippocampus, impairs performance on a delayed nonmatch to position task

Authors: S. D. DUNN[1], E. J. CIACCIARELLI[1], T. GOHAR[1,2], P. C. KUMPF[1], P. D. KUMPF[1], T. J. SLOAND[1,3], M. NIEDRINGHAUS[1], ***E. A. WEST**[1,3];

Abstract: Working memory is the ability to hold information online to guide behavior and is critical for navigating the environment. The rat medial prefrontal cortex (mPFC), the dorsal hippocampus (dHPC) and their functional connection, are required for working memory using a delayed nonmatch to sample task in a radial arm maze. Since there is no direct projection between the mPFC and dHPC, the thalamic nucleus reuniens (RE) is a likely intermediary between these structures due to its anatomical connections and role in spatial working memory. Here, we aimed to determine if RE and dHPC are required for performance on a delayed nonmatch to position (DNMTP) task. This task consists of a 1) sample phase (one lever extended, e.g., right) 2) time delay (2-32s) and 3) a choice phase, initiated by nosepoke, where the opposite lever (i.e., nonmatch) from the sample phase must be pressed (e.g., left) in order to receive a reward. Failure to press the sample lever, nosepoke, or press the choice lever, resulted in a trial omission. Fischer F344 rats (males and females) were trained on the DNMTP task. Once criterion (80% correct, 50 trials, 2s delay) was met, rats underwent stereotaxic surgery for bilateral implantation of infusion guide cannulae into RE (n=6) or dHPC (n=7). Rats were then trained in the task with 4 distinct delays (last session: 4, 8, 16, 32 s). Rats then received bilateral intracerebral infusions of the GABAA agonist muscimol (0.5 mM) or equal volume saline infusion into the RE (0.1 ul) or dHPC (0.3 ul) with the order of drug treatment counterbalanced across rats. We found that pharmacological inactivation of the RE led to overall decreased performance on the DNMTP task as indicated by a decrease in percent correct across all delays. Specifically, we found a significant main effect of drug treatment (muscimol vs saline) across delays ($F(1,5) = 14.84$, $p = 0.01$) but no effect of delay ($F(1.631, 8.155) = 1.51$, $p=0.27$). Pharmacological inactivation of the dHPC, however, did not lead to overall decreased performance on the DNMTP. We found no significant effect of drug treatment ($F(1.276, 25.52) = 0.293$, $p=0.65$) but an effect of delay ($F(3,20) = 14.33$, $p=0.0001$). In addition, even when we increased the muscimol concentration (1mM and 5mM) we found no effect of dHPC inactivation on DNMTP performance. Thus, transient inactivation of the RE, but not dHPC, impaired overall performance DNMTP in a delay independent manner. Ongoing studies are examining how

transient inactivation of the mPFC affects performance on the DNMTP. Finally, we will use inhibitory chemogenetic manipulation to determine if the mPFC-RE and the RE-mPFC circuits are required for behavioral performance.

Title: Simultaneous visual and motor selection in working memory

Authors: *R. WEESE[1], E. F. ESTER[2];
[1]Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Psychology, Univ. of Nevada, Reno, NV

Abstract: Working memory enables adaptive behavior by forming a temporal bridge between prior sensations and anticipated future actions, and a large body of research suggests that working memory storage and action planning are tightly coupled. Under some circumstances, the selection of information stored in working memory and the selection of linked motor plans occurs in parallel, enabling both fast and accurate behavior. This arrangement is advantageous in controlled settings where mappings between the contents of memory and specific actions remain constant, but potentially disadvantageous in more complex settings where memory representations and motor plans must be constantly updated to match changing environmental circumstances. Thus, in this study we ask whether memory representations and associated motor plans are invariably accessed simultaneously, even when there is no incentive to do so. We recorded EEG while human volunteers remembered the orientation of two Gabor-like stimuli over a short delay, then adjusted a probe stimulus to match one of the remembered items. At the end of each trial, participants adjusted a probe Gabor to match one of the remembered stimuli. A valid retrospective cue presented one second prior to the onset of the response period informed volunteers which Gabor stimulus would be probed. Following earlier work (van Ede et al., Nature Neuroscience, 2019) we linked different stimuli to specific affordances (left vs. right hand button presses) and independently manipulated the location, color, and orientation of the to-be-remembered stimuli. This allowed us to independently assess the time-course of visual and action selection through an analysis of lateralized occipitoparietal alpha-band (8-13 Hz) and frontocentral beta-power (15-35 Hz), respectively. We observed simultaneous changes in these signals beginning approximately 300 ms after the onset of the retrospective cue, consistent with a

parallel selection of visual and motor information. This occurred even though a one-second gap separated cue and probe onset, minimizing the necessity of parallel selection. These findings suggest that mechanisms responsible for visual and motor selection are tightly coupled, even when task circumstances do not demand it.

Title: Frequency tradeoff in neural variability predicts working memory success

Authors: *F. R. BAUMGARDT, V. VISWANATHAN, O. F. TWEEN, R. M. REINHART; Dept. of Psychological & Brain Sci., Boston Univ., Boston, MA

Abstract: Recurring fluctuations in neural activity have been proposed as a mechanistic foundation for behavior. Modulation in neural variability across trials is a general cortical event, appearing in numerous brain regions and elicited by different stimuli and tasks in animals and humans. Here, we examine the effects of working memory load on ongoing neural variability in humans. While signal enhancement has been thoroughly investigated in human and animal models, changes in neural variability as a result of working memory load has received substantially less attention. Further, human working memory neuroscience has largely focused on averaged delay-period activity rather than the neural dynamics within the delay. Using human electroencephalography and a delayed-match-to-sample task, we show that as more complex real-world objects are loaded into memory, an opposing pattern of behaviorally relevant cross-trial neural variability is observed between low- and high-frequency oscillations. Variability in delta (2-4 Hz) and theta (4-8 Hz) bands was positively correlated with upcoming memory accuracy within the delay period and across set sizes. However, as set size increased, the spatial distribution of memory-related theta variability shifted across the head from posterior to anterior, and generally decreased over time within the delay, with the largest set size inducing more temporally sustained variability predictive of later behavior. In contrast, cross-trial variability of high-frequency oscillations in beta (13-30 Hz) and gamma (30-60 Hz) bands were negatively correlated with memory accuracy. High-frequency memory variability was absent early within the delay and for low set sizes but steadily increased with time and memory load, particularly over central-parietal regions. Further, correlations between neural variability and total power

were scarce, and total power did not predict memory performance for any frequency band, set size, or time-point within the delay, suggesting that memory-related neural variability was not merely a correlate of signal power. The findings suggest that working memory behavioral success is mediated by a tradeoff between early low-frequency oscillatory enhancement and later high-frequency oscillatory diminution in trial-by-trial neural variability, underscoring the importance of spontaneous neural variability for improved working memory.

Title: The P300 event related potential as a predictor of phonological working memory skills in school-aged children

Authors: *V. HARWOOD, A. BARON;
Univ. of Rhode Island Interdisciplinary Neurosci. Program, Kingston, RI

Abstract: Phonological processing skills play a significant role in the development of word reading ability (Nelson et al., 2012), yet the neural substrates of phonological processing in children remains unknown. One main component of phonological processing is phonological working memory (PWM) (Wagner et al., 1993). Nonword repetition tasks are the gold-standard clinical tool used in measuring PWM. Further, the P300 Event Related Potential (ERP) has been cited as an index of PWM (Bonala & Jensen, 2012). The current study investigates the prognostic power of the P300 component in predicting behavioral measures of PWM skills in a cohort of monolingual English and bilingual Spanish-English early school-aged children. Forty-two typically-developing 1st and 2nd grade children between the ages of 6.1 and 9.1 years of age (M: 7.3 years, 15 Female, 27 Male) participated in a battery of standardized language and literacy assessments as well as an electrophysiological task. Thirty-three students were monolingual and 9 students were identified as bilingual through behavioral assessments and parent interviews. The ERP task consisted of a classic auditory oddball paradigm task in which one block contained English contrasts (/ta/ standard, /pa/ deviant) and another block contained Spanish contrasts (/t̪a/ standard, /d̪a/ deviant). The deviant trials occurred 20% of the time. Children were instructed to listen to the sounds and press a button when they heard the deviant

tone. The P300 component was identified in a cluster of 10 parietal electrodes. Latency and amplitude data between 250-500 ms post stimulus onset were extracted for both the averaged standard and deviant trials. Difference waves (deviant - standard) were created for all participants. The latency difference within the P300 ERP component recorded in response to auditory English speech contrasts significantly predicted English nonword repetition scores on the Comprehensive Test of Phonological Processing, 2nd Edition (CTOPP-2) for both monolingual and Spanish-English bilingual children (R^2 = .18), F(1, 37) = 7.81, p = .01. The P300 ERP component recorded in response to auditory Spanish speech contrasts did not significantly predict English nonword repetition scores for either group of children (R^2 = .01), F(1, 37) = .51, p =.48. The P300 component recorded in response to English phonemes is a strong predictor of behavioral English PWM skills as measured by a nonword repetition task in young school-aged monolingual and bilingual children. The P300 component as a measure of PWM has potential diagnostic and therapeutic relevance to clinicians working with school-aged children.

Title: Frontotemporal dynamics of verbal working memory revealed by iEEG

Authors: *A. LLORENS[1], L. BELLIER[1], E. L. JOHNSON[1], J. IVANOVIC[3], P. G. LARSSON[3], T. ENDESTAD[4], A.-K. SOLBAKK[4], R. T. KNIGHT[2];
[1]Helen Wills Neurosci. Inst., [2]Univ. of California, Berkeley, Berkeley, CA; [3]Dept. of Neurosurg., Oslo Univ. Hosp., Oslo, Norway; [4]Univ. of Oslo, Oslo, Norway

Abstract: Keeping in mind the items chosen from a menu while waiting to order requires verbal Working Memory (vWM). Cognitively, vWM consists of three sequential phases: encoding (storing information in memory), maintenance (keeping information in memory), and probe (recalling information from memory). vWM studies typically focus on one of these three phases, involvement of one brain region, or modulation of one specific neural frequency band. Detailed

analysis of the entire vWM process is typically lacking. We recorded intracranial electroencephalography (iEEG) from fronto-temporal regions of eleven patients with intractable epilepsy. We analyzed the time course of four frequency bands: theta, alpha, beta, and high frequency activity (HFA; [70-150Hz]), as vWM unfolded. The task consisted of a list of 5 letters presented in succession (displayed for 500-ms with a 500-ms interstimulus interval), followed by a 4-s maintenance phase, and then a 2-s probe asking participants to answer whether a given letter was on the list. Participants performed the task with an average of 81% correct answers. The percentage of correct negative answers was significantly higher than the positive ones (87% vs. 75%, $p<.05$), consistent with previous literature suggesting that it is easier to correctly reject a lure not presented in the trial than to confirm the presence of an item. Electrophysiological analyses showed significant frequency band effects throughout vWM phases ($p<.001$), which were distinct across four clusters of electrodes defined along two anatomical axes: left vs. right hemisphere and frontal vs. temporal lobes. Cluster-based permutation analysis revealed significant power increases in the low frequencies (theta and alpha) in temporal regions bilaterally during the encoding and the maintenance phases ($p<.05$). In addition, a power correlation analysis identified a left alpha-beta frontotemporal network which tracked memory load with the presentation of each letter during encoding. Presentation of the probe elicited HFA in frontal regions bilaterally, but no correlation was found between hemispheres. Collectively, these results suggest an electrophysiological signature of the language network due to the verbal aspect of the task, followed by a dissociable signature of activity in the frontal lobes when decision making is required. These findings provide evidence of complex coordination of multiple frequency bands in bilateral frontotemporal regions in support of vWM.

Title: Eeg signals represent updated memory representations in visual working memory

Authors: *Y. SHIN[1], S. L. SHEREMATA[2];
[1]Ctr. for Complex Systems and Brain Sci., [2]Psychology, Florida Atlantic Univ., Boca Raton, FL

Abstract: Visual short-term memory (VSTM) creates stable internal representations over time. Working memory, in addition, allows us to manipulate or update these representations. Visual representations stored in VSTM have been successfully reconstructed from measurements of neural activity. However, it is unclear whether the updated state of a remembered item is

reflected in these neural representations. The present study addressed whether representations reflect updated representations using electroencephalography (EEG) by asking participants to update the orientation of a remembered Gabor. In the task, participants were instructed to mentally rotate a grating based on a color cue that indicated whether participants should rotate the remembered item 1) clockwise, 2) counter-clockwise, or 3) not at all. Then the orientation of the remembered item was decoded from alpha-band oscillations (8-12Hz), associated with visual attention, and sustained EEG potentials (<6Hz), associated with visual short-term memory. We found that reconstructions from sustained EEG (< 6 Hz) reflected updated representations as well as initial sensory representations with higher reconstruction probability at the target orientation while alpha-band frequency (8-12Hz) computed broad scope of reconstructions of target orientations. These results suggest that the neural signal carries not only the sensory information but also manipulated memory representations. Moreover, precision of mnemonic representations was higher in sustained EEG potentials compared to alpha-band oscillations. These results demonstrate that visual short-term memory representations can be updated to reflect behaviorally-relevant information in the absence of perceptual input.

Title: Spatial recoding of oriented gratings maintained in visual working memory revealed by predictive modeling of fMRI activation patterns

Authors: *K. VU-CHEUNG, T. C. SPRAGUE;
UC Santa Barbara, Santa Barbara, CA

Abstract: When participants are remembering the precise orientation of a grating, activation patterns measured from primary visual cortex can be used to decode which orientation value is held in working memory (WM; Serences et al, 2009; Harrison & Tong, 2009), and the quality of decoding is related to behavioral performance (Ester et al, 2013; Albers et al, 2013). Results from these studies support the sensory recruitment model of WM by which neurons responsible for representing perceived visual features additionally are recruited for representing those features during WM (Serences, 2016). However, for a feature like orientation, it may equivalently be the case that participants strategically recode the remembered grating orientation

using a spatial code (e.g., attending to a location on the screen and/or imagining a line). In such a coding scheme, the pattern of activation would still depend on the remembered feature, so linear classifiers or inverted encoding models trained on grating orientations would still perform accurately. Here, we tested whether participants use a spatial code during an orientation WM task by building a forward model of orientation WM based on spatial voxel receptive field (vRF) models (e.g., Mackey et al, 2017). If it is the case that visual information in working memory is being converted into spatial information, we would expect to see voxels with vRF positions aligned parallel with the remembered orientation to exhibit higher activation than voxels aligned to the orthogonal orientation. Here, participants performed a visual WM task where they maintained the precise orientation of a grating, then reported that orientation after a 12 second delay. Additionally, we identified each voxel's spatial selectivity during a vRF mapping session. On each trial, we sorted voxels based on their vRF preference into 'parallel' and 'orthogonal' groups based on their spatial position relative to the remembered orientation and compared their mean activation levels during the delay. This analysis, which involves no free parameters, tests the explicit forward model that an oriented grating is recoded into a specific spatial format. In primary visual cortex, the parallel voxels exhibited greater delay-period activation than orthogonal voxels, consistent with the spatial recoding hypothesis. These results are consistent with previous reports that participants store information in the code most meaningful for upcoming behavior (Lee et al, 2013; Henderson et al, pp2021). Additionally, this approach whereby we generate model-based predictions of activation patterns during a WM task can be used to further probe neural coding schemes during cognitive behaviors.

Title: Nabilone Impairs Spatial and Verbal Working Memory in Healthy Subjects

Authors: *F. KASSIM[1], S. TOD[1], M. ALBRECHT[2], S. HOOD[1], J. W. LEE[1], J. RODGER[1], M. MARTIN-IVERSON[1];
[1]Univ. of Western Australia, Western Australia, Australia; [2]Curtin Univ., Perth, Australia

Abstract: Several studies have reported that memory-related impairments and psychotic-like experiences are adverse effects of cannabis uses. However, data on the acute and chronic cognitive impacts of cannabis use are not consistent. The present study aimed to investigate the

effect of acute cannabinoid receptor activation on verbal (VWM) and spatial (SWM) working memory by administering oral doses of synthetic cannabinoid agonist, nabilone (1-2 mg, PO). The study also aimed to investigate the effect of nabilone on schizotypy (psychosis-proneness) scores and resultant associations with WM, VWM and SWM.
Methods: Healthy participants completed spatial span and digit span across different delay conditions for WM (n = 28) and psychological testing for schizotypy measures (n = 25) in each of two days after receiving nabilone (1-2 mg, PO) or placebo in a randomized, double-blind, counterbalanced, crossover manner.
Results: SWM performance exhibited significant decreases with delay ($p = 0.0005$), but VWM performance increased with delay indicating likely rehearsal or attentional processes inconsistent with a good measure of WM. Nabilone impaired SWM ($p = 0.00016$) in a delay-dependent manner and VWM ($p = 0.03$) independent of delay, indicating that it was influencing VWM performance via non-memory processes, likely attention. Nabilone did not significantly change schizotypy scores. Schizotypy scores were negatively correlated with WM ($\rho = -0.43$, $p = 0.028$) and VWM ($\rho = -0.35$, $p = 0.07$) but not with SWM ($\rho = -0.24$, $p = 0.23$) across averaged delay condition.
Conclusion: low doses of synthetic cannabinoid (nabilone) impaired SWM and VWM performance indicating that exogenous activation of the cannabinoid system impaired cognitive performance. Furthermore, the relationship between WM impairment and schizotypy in healthy individuals suggests that whatever produces this delay-independent effect (likely attention) on WM performance deficit may be a cognitive dysfunction in people with a schizophrenia spectrum disorder.

Title: Multi-regional dynamics of short-term memory explored with brain-wide Neuropixels recordings and multiple statistical models

Authors: *Y. LIU[1], S. CHEN[2], L. D. LIU[3,2], B. KANG[1], H. HOU[3,2], N. LI[3,2], K. SVOBODA[2], S. DRUCKMANN[1];
[1]Stanford Univ., Stanford, CA; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA; [3]Baylor Col. of Med., Houston, TX

Abstract: Persistent neural activity encoding short-term memory (STM) is observed in many brain regions, but how brain regions interact to maintain STM is unclear.
We used up to five Neuropixels probes to simultaneously record the activity of hundreds of neurons across more than a dozen brain regions during a memory-guided delayed response task in the mouse. Anterior lateral motor cortex (ALM; part of M2) is an essential hub for the planning and execution of memory-guided directional licking. We targeted regions that form multi-regional networks with ALM, including nuclei in thalamus, basal ganglia, midbrain, pons, medulla, cerebellum and others (see Susu Chen et al SFN 2021). Here, we compare neural coding across brain areas and employ statistical models to understand brain region interactions under STM.
We decoded stimulus and choice information in individual brain regions. Although coding was distributed across brain regions, individual areas exhibited distinct dynamics. Stimulus information emerged first in midbrain, followed by thalamus and ALM. ALM exhibited a distinct ramp-up of choice information during the memory epoch.
We assessed coordination of choice-related information by projecting population activity into a subspace related to choice (coding dimension, CD). Simultaneously recorded brain areas were highly correlated on a single-trial level.
We compared three statistical methods to infer communication strength between brain regions [1]. Communication subspace analysis and canonical correlation analysis perform dimensionality reduction on the full population activity to maximize variance explained or correlation across populations respectively. The influence model examines the influence of one brain region on another along specific dimensions (e.g. CD) [1]. All models found stronger communication between ALM and connected compared to unconnected brain regions. Inferred communication strengths predicted the impact of optogenetic perturbations on downstream brain regions. However, only the influence model predicted changes in selectivity induced by perturbations. Communication strengths were dynamically regulated across behavioral epochs. These results reveal spatial and temporal interactions between brain regions and their relations to neural coding of task information.

Title: Organization of memory ensembles across brain regions

Authors: *A. LAVI, M. SEHGAL, F. SISAN, A. OKABE, D. TER-MKRYCHYAN, A. J. SILVA;
Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA

Abstract: Although memory formation, consolidation and retrieval engage neuronal ensembles in multiple brain regions, little is known concerning the principles and mechanisms that coordinate the dynamic interactions between these ensembles. For example, in Conditioned Taste Aversion (CTA), studies have shown that silencing memory-encoding neurons in either the basolateral Amygdala (BLA) or insular cortex (IC), impairs memory storage and retrieval. Since these regions are inter-connected, we hypothesized that IC and BLA coordinate CTA memory ensembles through direct networks that connect neurons in these two regions. To test this hypothesis, we used CREB expression (diverts memory allocation to targeted neurons) and Rabies monosynaptic retrograde tracing to detect whether neurons in memory ensembles in one region project to other memory ensembles in the connected regions. Using c-fos immunostaining as a marker for neuronal activation, we find that connected memory networks in the BLA and the IC are 2.5 times more likely to take part in CTA memory, compared to a) chance levels, b) to local memory neurons, and c) to control groups. We also find that these interregional memory networks are specific to task-relevant brain regions, and they are not present in regions unrelated to the learning task used (e.g., CTA versus auditory conditioning). By expressing CREB in both the BLA and the IC, we drove an increase in both connectivity between CREB expressing cells and, importantly, memory performance: CREB-expressing neurons in the IC were 2 times more likely to connect to CREB-expressing neurons in the BLA, compared to the control group. Dual CREB activation (in the BLA and IC) also resulted in an increase in performance in the CTA task. Modeling studies of our results revealed the surprising finding that a retrograde mechanism coordinates memory ensembles in BLA and IC, suggesting that beyond anterograde mechanisms that establish memory ensembles across brain regions, retrograde mechanisms have a role in fine tuning this complex and dynamic process.

Title: Learning-to-learn emerges from learning to efficiently reuse neural representations

Authors: *V. GOUDAR[1], B. PEYSAKHOVICH[2], E. A. BUFFALO[4], D. J. FREEDMAN[3], X.-J. WANG[1];
[1]New York Univ., New York, NY; [3]Neurobio. and Computat. Neurosci., [2]Univ. of Chicago, Chicago, IL; [4]Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: It is far easier to learn new information when its content is familiar. Our brain engages internal representations of relevant prior knowledge, known as *schemas*, to improve how we interpret and learn new information. In tandem, schema-based learning prospectively refines the schema's effectiveness in promoting future learning. *Learning-to-learn* is a result of this reciprocity, whereby learning a series of problems with shared task structure is accompanied by a progressive speedup in learning. We trained a Recurrent Neural Network (RNN) model on a series of visuomotor mapping problems to identify the neural correlates of a schema, and study the circuit-level mechanisms of this reciprocal improvement. In each problem, the RNN learns to map two high-dimensional inputs (images) onto two outputs (saccades). The trial structure and outputs are shared by problems, but the inputs change across them.
We found that RNNs robustly learn-to-learn: the number of trials to learn a problem decreases exponentially with the number of previously learned problems, consistent with the exponential speedup in association task learning that we observed in macaque monkeys. A subspace decomposition of the RNN's neural activity patterns revealed that the shared task variables, i.e. the trial structure, decisions and choices, are represented consistently across problems by shared low-dimensional neural manifolds. These manifolds are generalized from prior learning, reused to solve new problems, and to control the model's output responses. Importantly, their reuse improves the RNN's learning efficiency. Thus, the shared manifolds form a neural substrate of a visuomotor mapping schema.
While large neural activity changes are evident during learning, analysis showed that they mostly stem from reusing neural representations. This curtails the formation of new representations, which limits the requisite connection weight changes (CWCs) and accelerates learning. We introduce a measure of the role of CWCs in learning — the *weight-driven vector field change* — which showed that CWCs are mainly recruited to preserve the representational structure during learning. Finally, we identified a novel mechanism for learning-to-learn: The CWCs in early

problems prospectively improve the RNN's ability to preserve its representational structure while learning later problems. This further limits the requisite CWCs in later problems and accelerates learning. The accumulation of these prospective CWCs over previously learned problems elicits learning-to-learn. These findings link changes in neural activity and network structure to offer a mechanistic explanation for learning-to-learn.

Title: Anterior cingulate neurons signal valueless associative information during sensory preconditioning

Authors: *E. HART[1], M. P. H. GARDNER[1], G. SCHOENBAUM[2];
[1]NIH, NIDA IRP, Baltimore, MD; [2]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: Studies of anterior cingulate cortex (ACC) function have primarily employed tasks where subjects learned about or used information that involved items of clear biological significance, or where subjects were required to respond. What these had in common was the same general structure in which one event followed another. It is therefore possible that ACC neurons could simply encode associations between events, irrespective of value. Sensory preconditioning provides an opportunity to test this. Rats (n = 8) were implanted with microelectrodes for recording single units (n = 1,307 total) in ACC and trained in a sensory preconditioning task. During the first phase, preconditioning, rats were presented with two separate pairs of neutral auditory cues. To reveal latent learning of the cue-cue pairings, rats then received reward conditioning during which one of the previously neutral cues was paired with food. Following this, rats were given a probe test during which they were presented with never-reward-paired cues. Rats showed higher responding to the cue that predicted the food-paired cue in this probe test, indicating that the neutral cue pair information was learned during preconditioning. During preconditioning, single ACC neurons fired differently to different sensory cues, and population-level analyses revealed that the neurons developed firing patterns that classified cues into pairs. Further, the development of this encoding of the cue pairs by ACC

neurons during preconditioning predicted appropriate behavioral responding to the preconditioned cues during the probe test. These findings demonstrate that ACC serves a broader role in learning than previously thought, contributing to the formation of valueless associative structure when items of biological significance are not involved.

Title: Task structure governs activity in the monkey hippocampus

Authors: *J. W. RUECKEMANN[1,3], Y. BROWNING[2,1], A. MALLORY[1], B. KIM[1], C. I. O'LEARY[1], A. L. FAIRHALL[1], E. A. BUFFALO[1,3];

Abstract: Hippocampal neurons have been most often studied in rodents running mazes, resulting in a rich history characterizing their activity as spatial correlates. However, these neurons have been recently shown to respond in a variety of tasks without an explicit spatial component, suggesting that hippocampal activity patterns more generally reflect the progression of experience through salient task events.
To examine hippocampal activity in primates, we analyzed data from three rhesus macaques performing a delayed alternation task in a virtual maze - a task chosen to facilitate comparison to the rat literature. Neurons were recorded from the hippocampus in three monkeys using chronically-implanted hyperdrives housing 124 independently movable electrodes. We characterized spatial specificity using two reference frames: avatar position in the maze and location of the monkey's gaze in the virtual world. Approximately 30% of neurons exhibit reliable activity relative to avatar position in the maze as determined through a GLM framework and an information theoretic approach. A majority of these neurons also demonstrate reliable activity with respect to the animal's gaze location. Direct comparison of these variables demonstrates that avatar location better predicts spiking; however, high correlation of these variables prevents a strong interpretation of these results. Notably, many neurons exhibit fields that cover wide expanses of a maze arm, standing in contrast to the punctate place fields

observed in rats and raising the possibility that precise location is not the best predictor of the neuronal activity. In addition, ostensibly spatial activity is not evenly distributed through the maze; key event locations, including the start, choice, and goal locations, are overrepresented in the neural population, suggesting that the wide spatial fields might instead reflect parcellation of the maze into distinct task phases. This interpretation is further evidenced by distinct neural populations that are selectively active during the reward and delay periods. We also examined neural activity in distinct environments by changing the visual appearance of the maze. While some neurons "remap" their responses, the majority of neurons maintain their task phase-specific responses irrespective of the visual cues defining the environment. The stability of activity across distinct contexts suggests that the hippocampus is operating on a schematized representation of this well-learned task. In combination with the parcellation of the representation by salient events, these data indicate that representing task structure is foundational to activity in the hippocampus.

Title: A role for the Locus Coeruleus dorsal CA1 dopaminergic projection in the modulation of contextual memory ensembles and contextual memory linking

Authors: A. CHOWDHURY[1], ***A. LUCHETTI**[1], G. FERNANDES[1], D. ALMEIDA FILHO[1], A. TZILIVAKI[2], G. KASTELLAKIS[2], E. RAMIREZ[1], M. TRAN[1], P. POIRAZI[2], A. J. SILVA[3]; [1]UCLA, Los Angeles, CA; [2]IMBB-FORTH, Heraklion, Crete, Greece; [3]Dept Neurobiol, UCLA Med. Ctr., Los Angeles, CA

Abstract: Our brain not only encodes memories of individual events, it can also link memories encoded close in time, such that the recall of one memory triggers the recall of the other. For example, our lab showed that when two contextual memories are encoded close in time (e.g., 5 hours apart) the recall of one triggers the recall of the other (i.e., the two memories are linked). Importantly, our lab also showed that the overlap between the two contextual memory ensembles

in dorsal CA1 (dCA1) is key for contextual memory linking. A number of factors such as salience, reward and novelty are known to affect memory encoding, but it is unclear whether and how these factors affect memory linking. Neuromodulatory projections are thought to have a role in sending information about novelty to dCA1, including dopaminergic/noradrenergic projections from Locus Coeruleus (LC) and serotonergic projections from the Raphe Nucleus (RN). Although both the LC and RN are activated by contextual exploration, only inhibition of LC to CA1-projecting neurons disrupted contextual memory linking. Importantly, this same manipulation did not disrupt contextual learning and memory. Furthermore, pharmacological manipulations demonstrated that this effect was mediated by dopamine and not by noradrenaline. Studies with head mounted fluorescent microscopes (UCLA miniscopes) in dCA1 showed that the manipulations that disrupted contextual memory linking also impaired the overlap between dCA1 contextual memory ensembles observed during contextual memory linking. Additionally, we found that the inhibition of LC to CA1-projecting neurons also affected the synchrony of firing between subpopulations of dCA1 neurons activated by both contextual memories, as well as their activity patterns within cell assemblies. These results report the first modulatory pathway specific to memory linking, they support a key role for the overlap between dCA1 memory ensembles in contextual memory linking, and they reveal novel circuit properties that may underlie memory linking.

Title: Role of type I interferon signaling and microglia in the abnormal L-LTP and object place recognition deficits of male mice with a mutation of the Tuberous Sclerosis 2 gene

Authors: *M. F. LOPEZ-ARANDA[1], G. M. BOXX[2], M. PHAN[1], I. HERRERA[1], S. TALOMA[1], R. MANDANAS[1], K. BACH[1], C. THADANI[1], E. LUGO[1], O. LU[1], K. DINGLE[1], R. BUI[1], S. LIU[3], N. LI[3], Y. ZHOU[3], G. CHENG[2], A. J. SILVA[1];

Abstract: Tuberous Sclerosis Complex (TSC) is a genetic disorder associated with high rates of intellectual disability and autism. A mouse model of TSC, with a heterozygous null mutation of the Tsc2 gene ($Tsc2^{+/-}$), is associated with deficits in hippocampal dependent tasks as well as abnormal late long term potentiation (L-LTP) in the hippocampal CA1 region. Previous studies in our laboratory that we reproduced here, indicate that these deficits can be reversed in adults by rapamycin, an inhibitor of mammalian Target of Rapamycin (mTOR) function. Here, we show that microglia and type I interferon signaling (IFN1) have a key role in the object place recognition (OPR; a hippocampal dependent task) deficits and abnormal L-LTP of $Tsc2^{+/-}$ male mice. Unexpectedly, we demonstrate that male, but not female, $Tsc2^{+/-}$ mice showed OPR deficits. Importantly, these deficits can be rescued by depletion of microglia as well as by a manipulation of a signaling pathway known to modulate microglia function (interferon-alpha/beta receptor alpha chain KO). In addition to rescuing the OPR deficits, depletion of microglia also rescued the abnormal L-LTP of the $Tsc2^{+/-}$ mice. Altogether, our results suggest that abnormal IFN1 signaling in microglia cause the abnormal L-LTP and OPR deficits of male $Tsc2^{+/-}$ mice.

Title: Impaired stability of hippocampal dorsal CA1 neuronal activity in mouse models of Noonan Syndrome is related to Memory Linking deficits

Authors: *D. ALMEIDA-FILHO, Y. CAI, A. MACALINO, A. J. SILVA;
Neurobio., UCLA, Los Angeles, CA

Abstract: Interactions between Individual memories are key for adaptive behavior. For example, contextual memories encoded close in time (e.g., 5 hours apart) are linked, such that the recall of one memory increases the likelihood of retrieving the other, a phenomenon referred to as memory linking. The 'Allocate-to-Link' hypothesis of memory linking states that learning triggers a transient increase in intrinsic excitability within the ensemble encoding the first memory such that these cells are more likely to encode a new event experienced hours later. When one of the two memories is recalled this overlap between the memory ensembles drives the recall of the other linked memory. In support of this hypothesis, we have shown that the activity-dependent expression of the cAMP response element-binding protein (CREB) modulates the excitability and the co-allocation of neuronal ensembles for the encoding of distinct memories, thus driving the overlap between these ensembles at the heart of memory linking. Here, we report the results of studies of memory linking in mouse models of Noonan Syndrome (NS), an autosomal dominant disorder that results in the basal overexpression of the phosphorylated extracellular signal-related kinase (pERK), an upstream regulator of the transcription factor CREB. For these experiments, we used NS mice models with a knock-in mutation in *Ptpn11* (*Ptpn11*$^{D61G/+}$) as well as mice with viral overexpression of a NS-associated allele (*PTPN11*^{D61G}) in adult mouse dorsal hippocampus. Although individual contextual memories were normally encoded under the conditions tested, contextual memory linking studied with a 5-hour interval was impaired in these mouse models of NS. Studies with head-mounted miniature microscopes in freely behaving mice showed that, unlike their wild type littermates or animals infused with a control virus, NS mice showed impairments in the stability of individual neuronal activity and of coactivity patterns of dCA1 neurons measured when the mice visited two contexts 5-hours apart. These findings suggest that the stability of neuronal activity dynamics during contextual memory encoding is important for linking distinct contextual memories experienced close in time, and that these dynamic processes are impaired in mouse models of Noonan syndrome.

Title: Noradrenergic and glutamatergic transmission during exploratory behavior within the hippocampus and amygdala of a juvenile model of diet induced cognitive impairment.

Authors: *P. SALCEDO-TELLO[1], A. HERNANDEZ-MATIAS[2], D. OSORIO-GÓMEZ[2], F. BERMUDEZ-RATTONI[2], G. PACHECO-LOPEZ[1], G. FERREIRA[3], K. R. GUZMAN-RAMOS[1];

Abstract: According to the World Health Organization obesity has tripled since 1975. Not only adults have been affected with this obesity epidemic; in 2019, 38 million children and adolescents were overweight or obese. In addition to its association with chronic diseases like hypertension and diabetes, obesity affects neurocognitive features including learning and memory. To assess the effects of juvenile obesity on hippocampal function, we used a model of diet-induced obesity in male Wistar rats. Rats were exposed after weaning to a regular diet (control group, 2.9Kcal/g) or a high-fat diet (HFD group, 4.7Kcal/g) for 3 months thus covering adolescence. HFD induced increased basal glucose blood levels, diminished glucose tolerance and insulin insensitivity. Once completed the diet exposure time, rats were implanted with microdialysis guide cannulae in the ventral hippocampus (VH) and basolateral amygdala (BLA). While rats from both groups were submitted to an exploration task, 4 minutes samples were collected to assess glutamate, noradrenaline and dopamine release from both structures. We found that in the control group, hippocampal norepinephrine release increased during exploration compared to HFD group. Conversely, glutamate release increased within the hippocampus of HFD group compared to control group. Regarding amygdalar activity, we found that during exploration, control animals increased glutamate release, but HFD group levels remain unchanged. During exploration noradrenergic neurotransmission augmented in HFD rats but not in control rats. Dopamine did not show a difference between groups in hippocampus or amygdala. Our results suggest that consumption of HFD during adolescence interfere with normal neurotransmission, besides altering metabolic parameters. This deregulation seems to be differential between structures as seen in hippocampus and amygdala indicating a modulatory role regarding the specific functions on memory trace formation.

Title: Impact of High-Fat Diet on aversive conditioning and its relation to amygdalar and hippocampal neurotransmission in a juvenile obesity model

Authors: A. HERNANDEZ-MATIAS[1], P. SALCEDO-TELLO[2], F. BERMUDEZ-RATTONI[1], G. PACHECO-LOPEZ[2], G. FERREIRA[3], K. R. GUZMAN-RAMOS[2], ***D. OSORIO-GÓMEZ**[1];

Abstract: Obesity has become a major health issue around the world; according to the World Health Organization, the prevalence of obesity has alarmingly increased. Excess in energy intake and the subsequent increased adiposity during childhood and adolescence have been observed independently of age, sex, ethnicity or socioeconomic status. Overweight and obesity are related to chronic diseases such as cardiovascular diseases, diabetes, kidney failure and cancer. However, obesity also promotes cognitive deficits including learning and memory. We assessed the impact of high-fat diet intake during adolescence on the formation of an aversive memory and its relation to amygdalar and hippocampal neurotransmission. We used a juvenile obesity model in Male Wistar rats, which were exposed to a regular diet (Chow, 2.9 kcal/g) or a High-Fat diet (HFD, 4.7 kcal/g) for 12 weeks after weaning. According to metabolic parameters, HFD induced an augmentation in weight, adiposity, and basal glucose blood levels. In addition, HFD diminished glucose tolerance and insulin sensitivity. At the final stage of diet, rats were implanted with microdialysis guides aiming at the basolateral amygdala (BLA) and ventral hippocampus (VH). We monitored glutamate, noradrenaline and dopamine within BLA and HV during the acquisition of a Conditioned Odor Aversion (COA) task. Results indicated that HFD animals showed an enhancement of the aversive response in comparison to animals exposed to Chow. This behavioral response is associated to an increase in glutamate and norepinephrine release within the BLA and VH after the administration of a gastric-malaise inductor agent (LiCl). Therefore, HFD exposure during adolescence alters metabolic parameters and enhances emotional-associated memories through the increased neurochemical transmission within the BLA and VH. Thus, adolescence is a vulnerable period where diet-induced obesity impacts on cognition via neurochemical alterations.

Title: Establishing an ex vivo model for aversive associative learning in fruit flies

Authors: *M. ADEL, L. GRIFFITH;
Brandeis Univ. Grad. Neurosci. Program, Waltham, MA

Abstract: The general rules that govern the *Drosophila melanogaster* associative memory circuit have been characterized by a multitude of *in vivo* studies in the past decade. However, certain challenges associated with experimenting on behaving flies have left outstanding questions regarding the mechanisms that govern the specificity of dopamine release on particular synapses and the precise role of dopamine in encoding associative memory. In mammals, the development of the *ex vivo* LTP model in hippocampal slices revolutionized our understanding of memory formation. Establishing an *ex vivo* model for the fruit fly associative memory circuit would similarly allow for in-depth investigation of the innerworkings of this circuit, while overcoming the limitations of *in vivo* techniques. To accomplish this goal, we developed an *ex vivo* model for aversive associative learning in which pairing activation of the odor pathway with activation of ascending cervical inputs in the dissected fly central nervous system mimics aversive training (pairing an odor with punishment). We show that our model recapitulates the main features of aversive learning: 1) Aversive *ex vivo p*lasticity is specific to the trained odor; 2) This plasticity potentiates the trained odor responses in specific axons of the mushroom body intrinsic neurons and suppresses the trained odor responses in their postsynaptic partners, mushroom body output neurons (enhancement and suppression memory traces). We also demonstrate that pharmacological application of dopamine, or activation of a specific cluster of dopaminergic neurons (PPL1), can replace activation of the punishment pathway, but not the odor pathway, resolving a point of conflict in the literature with a previous *ex vivo* model. We use our preparation to show that one night of sleep deprivation impairs associative memory formation, indicated by failure to form pairing-induced memory traces. This failure was reversed by allowing flies a sleep rebound of 2 hours in early morning. In sum, we established a model that can be reliably utilized to further detail the mechanisms of *Drosophila* associative memory and lays the groundwork for future experiments investigating the dynamics of neural plasticity in this circuit.

Title: A study by diffusion tensor imaging and connectometry analysis, in patients with specific language impairments and patients with autism spectrum disorder

Authors: *F. VILLANUEVA[1], P. DIES-SUAREZ[2], E. BARRAGÁN[3], D. ALVAREZ[3], S. HIDALGO-TOBON[4];
[1]UAM-Iztapalapa, Mexico City, Mexico; [2]Imagenology, Hosp. Infantil de México "Federico Gómez", Mexico City, Mexico; [3]Neurol., Hosp. Infantil de México "Federico Gómez", Mexico, Mexico; [4]UAM-Hospital Infantil de México "Federico Gómez", Mexico City, Mexico

Abstract: The prevalence of Specific Languages Impairments (SLI) is 9.92%, while for Autism Spectrum Disorders (ASD) it's just over 1%, both disorders may present overlaps in symptoms, which it can complicate its correct diagnosis.Using diffusion weighted images obtained in a 3T scanner, through the diffusion tensor and connectometry [1], 41 patients with a mean age of 7.33 years were studied divided into three groups: controls, TDL and TEA. Through the tensor, 12 Regions of Interest (ROI's) were analyzed: arcuate fasciculus, superior longitudinal, medium longitudinal, inferior longitudinal, inferior fronto occipital and uncinate in both hemispheres, quantifying their parameters of fractional anisotropy (FA), mean diffusivity (MD), axial (AD) and radial (RD), in order to find significant differences in any parameter of any region. Connectometry was used to contrast the results of the diffusion tensor and search new regions where some parameter was correlated with the "diagnosis", which was used as an ordinal variable. The DSI software was used in the ROI study and for the connectometrys.The left arcuate fascicle showed a significant difference between the control and TDL patients, in the MD and AD with p-values of 0.054 and 0.013, while the right superior longitudinal fasciculus the significance appeared in the MD and RD, with p-values of 0.037 and 0.034.The connectometrys yielded various correlations, the most important ones appeared in the quantitative anisotropy (QA), RD and AD in fibers of the corpus callosum, left and right cerebellum and middle cerebellar pedunculum. Connectometry works with many null hypotheses hence the FDR was 0.0616, 0.0004, 0.003 and 0.0092. All these latest regions are not considered in the language organization models, however various studies have correlated them with the lateralization of language (corpus callosum)[2], semantic and phonetic processing, contralateral to the dominant hemisphere of language (cerebellar hemispheres) [3].Although the sample is small and has an impact on the results of descriptive statistics, connectometry, by using robust methods such as permutation and bootstrapping tests, generates more reliable and novel results. This work sought to generate information on SLI and ASD in Spanish-speaking patients, of which not enough information has been generated in the specialized literature.

Title: Left temporal lobe is a convergence region for retrieval of knowledge of unique entities: A neuropsychological study

Authors: *J. KAMINSKI[1], M. BOWREN, Jr[2], K. MANZEL[3], D. TRANEL[4];
[1]Div. of Psychological and Brain Sci., [2]Div. of Neuropsychology and Cognitive Neurosci., [3]Dept. of Neurol., Univ. of Iowa, Iowa City, IA; [4]Dept. of Neurol., Univ. Iowa, Iowa City, IA

Abstract: Following damage to the anterior temporal lobes (ATL), it is not uncommon for patients to experience a new and sometimes profound impairment in the retrieval of proper names. Proper naming is a critical complex function used to identify "semantically-unique" entities; that is, proper nouns are used to denote unique, "one of a kind" entities, such as specific persons or places. Previous research has linked proper naming to the left ATL, whereas retrieval of conceptual knowledge for unique entities ("recognition") has been linked to the right ATL. Here, we studied a sample of 242 (124 female) neurological patients with focal brain lesions to explore the prevalence and neuroanatomical correlates of recognition and naming impairments for two categories of unique entities: famous persons and famous landmarks. Patients were assessed in the chronic epoch ($\geq$3 months post-onset) using the Iowa Famous Faces Test and the Iowa Famous Landmarks Test. Patients were presented with pictures of 145 famous people and 65 famous landmarks and directed to identify the entity by providing the associated proper name. If unable, the patient was subsequently asked to provide sufficient identifying details of the person or landmark to demonstrate recognition. We found that recognition of famous faces and famous landmarks were positively correlated (Pearson's $r(208) = 0.51$, $p < 0.001$). Naming of faces and landmarks were also strongly positively correlated (Pearson's $r(210) = 0.65$, $p < 0.001$). Among
demographic variables, only education had a statistically significant association with the percent recognized and percent named scores for both faces ($F(1, 236) = 23.78$, $p < 0.001$; $F(1, 236) = 14.34$, $p < 0.001$) and landmarks ($F(1, 209) = 57.24$, $p < 0.001$; $F(1, 209) = 17.27$, $p < 0.001$), respectively. Impairments in both recognition and naming for both categories were linked to left-sided ATL lesions. Our results further establish the left ATL as a critical hub in the process of

retrieving a unique lexical entry (proper name) associated with a semantically-unique entity (person, place). The results may reflect recruitment of naming regions during recognition, as many patients provided alternative names (e.g., movie titles, character names, countries, etc.) to demonstrate recognition. Overall, these results are consistent with the existing literature that identifies the temporal lobes as crucial regions for naming and recognition of unique entities.

Title: Functional brain differences due to familial history of dyslexia: a meta-analysis

Authors: J. MORREL[1], *A. J. KRAFNICK[3], T. M. EVANS[2];
[1]Psychology, [2]Sch. of Educ. and Human Develop., Univ. of Virginia, Charlottesville, VA;
[3]Psychology, Dominican Univ., River Forest, IL

Abstract: Introduction: Structural and functional neuroimaging studies have established a network of brain regions associated with developmental dyslexia. While consensus suggests a left lateralized language-oriented network, there are open questions about the heterogeneity of results (Krafnick & Evans, 2019; Ramus et al., 2018). One open area of interest is whether these observed abnormalities are a consequence of reading difficulties or are present even before formal reading instruction has begun (Krafnick et al., 2014; Vandermosten et al., 2016). This study provides an updated synthesis of current functional neuroimaging studies focused on pre- and emerging readers with a family history of dyslexia through meta-analysis. Methods: PubMed and Google Scholar were used to identify neuroimaging studies of pre- and emerging readers with and without a familial risk of dyslexia. Search terms included (dyslexia AND neuroimaging), (pre-readers AND familial risk), (pre-readers AND dyslexia). From these results, studies not using neuroimaging methods, only including literate subjects, and not including a whole brain direct comparison of familial history groups were removed. The remaining fMRI studies were included for meta-analysis using GingerALE 3.0 (Eickhoff et al. 2009, 2012; Turkeltaub et al., 2012). Individual analyses for each direction of family history of dyslexia (FHD+) vs no family history of dyslexia (FHD-) were conducted. Results: Eleven individual fMRI studies were included (n = 499; total foci FHD- > FHD+ contrast = 60; total foci FHD+ >

FHD- contrast = 21). No results were found at an FWE cluster corrected 0.05 threshold. At an uncorrected threshold of p<.001 (min. cluster of 100mm^3), the FHD- > FHD+ contrast showed 6 significant clusters (see Figure). For the FHD+ > FHD- contrast, there was one significant cluster in the right middle frontal gyrus. Discussion: Overall there is some consistency across studies, but only at uncorrected thresholds. This is likely due in part to the diversity in functional tasks and some differences in subject inclusion across studies.

Title: Quantifying the causal impact of different sub-regions of tumor lesion on semantic naming ability

Authors: *E. AHN[1], S. DARK[1], O. WIESE[1], C. FINE[1], S. KAKAIZADA[2], J. KAUR[2], S. HERVEY-JUMPER[2], D. BRANG[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Univ. of California San Francisco, San Francisco, CA

Abstract: The ability to accurately name an object and access semantic information is an important component of an individual's social health and vocational outlook. Neuroimaging research has shown involvement of temporal and frontal regions in semantic naming tasks, such as when naming a presented item. However, most methods are unable to show that a brain region is causally involved in a particular behavior, limiting our understanding of the process and lowering the prediction of associated deficits following neurosurgical resection. Voxel-lesion symptom mapping (VLSM) has been widely used to study the causal relationship between brain regions and behavioral impairments at the level of individual voxels by analyzing the continuous behavioral score at each voxel. Applied to patients with a lesion caused by a stroke, VLSM studies have reported a causal relationship between anterior and mid-temporal regions and semantic language functions. However, these studies are biased to identify critical areas around major neuro-vasculature and observed in a restricted clinical population, limiting the generalizability. In contrast, damage by tumors is more evenly distributed throughout the brain and occurs in a broader cross-section of age groups. While tumor-models may provide validation and extension of stroke VLSM findings, few studies have applied VLSM to tumor data, resulting in gaps in what features of a tumor account for variance in VLSM models. Thus, we sought to: (1) Replicate findings from stroke VLSM research to identify regions associated with semantic naming deficits in non-vascular lesions, and (2) Investigate how dimensions that are unique to tumor lesions can further account for variance in VLSM models. Our preliminary findings in *n*=133 individuals validate stroke VLSM research by showing a relationship between semantic naming and damage to the left temporal lobe (maximal at middle and inferior temporal regions). Next, we examined how each histological sub-region of the tumor (i.e., peritumoral edema or core) differentially contribute to semantic naming impairment. While the presence of either edema or core in temporal regions was associated with poor semantic naming, deficits were larger for voxels in the tumor core. Finally, consistent with stroke VLSM research, larger core volume was associated with greater semantic naming impairment regardless of its location, highlighting the importance of covarying this dimension. Our findings suggest that different sub-regions of the tumor differentially impair semantic naming function and that the unequal distribution of tumor cells within the lesion are causally linked to varying levels of language deficit.

Title: Language Performance in Children with Early Brain Injuries: Does Location of the Lesion Play a Role as Children Reach School-age?

Authors: *P. T. LAI;
Communication Disorders, Univ. of Nebraska At Kearney, Kearney, NE

Abstract: Children with Perinatal Strokes provide a unique opportunity to study the neural basis of communication. These children suffered a brain injury around the perinatal period (i.e. between the last trimester of gestation up to the first month after birth). Lacking the ability to process and effectively convey social information can lead to deficits in maintaining relationships and can lead to academic failure in school. Few studies have investigated the social phenotypes of these children during school-age as the majority of studies occur before the age of 6. The purpose of this study is to explore if children with left (LHI) or right hemisphere injury (RHI) are similar in how they behave/communicate at school age or are they more similar to their typically developing (TD) peers. Our questions: (1) Is the child's injury related to their language performance (Broca's area or Wernicke's area)? (2) Are facial expressions related to injuries especially within the right hemisphere? The children in this project were between the ages of 7-14 and the dataset includes a 7 to 10-minute interview from 8 LHI children, 8 RHI children and 8 TD children. The procedure was to code social interactions using Eudico Linguistic Annotator software to observe various communicative behaviors. From our behavioral dataset, we determined which children are continuing to show the impacts of their injuries and from our imaging dataset, we documented where in the brain the damage occurred. Results showed that LHI children do not talk as much as the other two groups, a result similar to adults who have Broca's aphasia. A second result found that subcortical damage, rather than Broca's area or Wernicke's area resulted in more language deficits in LHI. Lastly, the TD children performed well in producing facial expressions, whereas children with brain injuries had delays/deficits. The two children who struggled the most were in the LHI group. Both had subcortical damage without any damage to Broca's area or Wernicke's area. This result is in line with a prior study where they found similar results regarding subcortical damage leading to language deficits. In that study, it was found that subcortical involvement to either hemisphere may be the most important determiner of failure on certain language task (i.e., syntax). Insights from this study adds unique knowledge to our understanding of communication as well as contribute to better-informed treatment methods in the future.

Title: Development of touchscreen-based mnemonic similarity task to assess cognitive abilities in rodent models

Authors: *A. ROSS[1], S. N. BURKE[2], C. N. LOGAN[3], S. A. JOHNSON[4], J. L. BIZON[5], C. WATSON[1], T. GATTON[1];

[5]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: Age-related cognitive decline and Alzheimer's disease (AD) lead to loss of independence and burden caregivers. To better understand the neurobiological basis of age-related cognitive decline, we need animal models that accurately reflect the deficits observed in humans. Previous work in our lab has demonstrated that aged rats, like older adults, are impaired in their ability to distinguish similar stimuli, referred to as mnemonic discrimination. However, this test was run on a maze and not comparable to how humans are assessed in clinical setting. In moving toward integration of tools for manipulating and recording neural activity with behavioral assessment with higher translational potential, we have utilized a mnemonic similarity task (MST) developed by Lee et al (2015) that can be administered in automated operant touchscreen chambers. In the current study, we trained and tested rats in a single-stimulus presentation version of the touchscreen-based MST. Young (4 months) and adult (21 months) 344 Hybrid x Brown Norway rats of both sexes were first shaped to respond to a visual stimulus presented on the touchscreens by providing liquid reward. Rats were then trained to distinguish pairs of image stimuli (i.e. A vs. B) by associating each stimulus with touching different side of the screen (i.e. A-tap Left, B-tap Right). Rats were then tested by presenting morphed image stimuli that shared 5%, 25%, or 45% overlapping visible features with the previously learned target image stimuli (i.e. A and B). Results show that rats' mnemonic discrimination performance declines on trials when morphed images with greater percent overlapping features are presented. We predict that this task will be particularly sensitive to age-related deficits so that its implementation will be useful in future assessments of cognitive aging and neurodegenerative diseases such as AD.

Title: Hippocampal contributions to theta in the primary visual cortex

Authors: *J. KENNEDY[1], Y. ZHOU[2], Y. QIN[3], S. D. LOVETT[1], A. SHEREMET[2], S. N. BURKE[1], A. P. MAURER[4];
[1]Neurosci., [2]Engin. Sch. for Sustainable Infrastructure and Envrn. (ESSIE), [3]Civil & Coastal Eng., [4]Evelyn F. McKnight Brain Inst., Univ. of Florida, Gainesville, FL

Abstract: Large amplitude-low frequency oscillations, such as 4-12Hz hippocampal theta, have been consistently shown to entrain faster, lower amplitude oscillations such as gamma. As the local field potentials are primarily shaped by synaptic transmembrane potentials, high-amplitude, low-frequency interactions are thought to serve as a mechanism by which the brain facilitates coordination across regions. As theta has been reported in various cortical and subcortical brain regions, it has been suggested to support a global read-out of synaptic coordination. However, the origin of cortical theta remains the subject of debate. As the hippocampus is one of the largest generators of theta, it has been proposed that cortical theta results from volume conduction from the hippocampus (Winson, 1974; Bland and Whishaw, 1976; Gerbrandt et al., 1978; Sirota et al., 2008; Senzai et al., 2019). Alternatively, others have proposed the hypothesis that cortical theta is locally generated (Zold and Shuler, 2015) or exists as some combination of local generation and volume conduction (Holsheimer et al., 1979; Leung and Borst, 1987). To further explore this hippocampal-cortical interaction, four F344xBN hybrid rats were implanted with a single-shank 64 channel silicon probe in the dorsal hippocampus and primary visual cortex. Visual cortex theta was lower in amplitude than hippocampal theta and exhibited a decrease in coherence further from the hippocampus. Linear cross-region analysis revealed power-power and phase-phase coupling between hippocampal and cortical theta and gamma (50-120 Hz). Bicoherence and cross-region bicoherence were utilized to estimate the magnitude of the nonlinear cross-frequency coupling within the visual cortex and between the visual cortex and hippocampus. Initial results indicate a strong nonlinear phase coupling between theta and its harmonics in the visual cortex and hippocampus. However, no cross-frequency coupling was observed between theta and gamma in the visual cortex. Notably, theta-gamma cross-frequency coupling was observed in mouse visual cortex data generously provided by the Buzsaki laboratory (Senzai et al., 2019). While preliminary results suggest that cortical neurons can

generate theta locally, these data support the hypothesis that cortical theta is, at least in part, the result of volume conduction from the hippocampus.

Title: Aging and its Effects on Theta Modulation Across Hippocampal Layers

Authors: *N. M. DICOLA[1,2,3], A. L. LACY[4], K. M. KIMSEY[4], J. L. WHITNEY[4], S. D. LOVETT[4], P. TOH[4,5], A. SHEREMET[6], S. N. BURKE[1,2], A. P. MAURER[1,6,2];

Abstract: The theta oscillation (6-12 Hz) is a ubiquitous rhythm found throughout the brain and is related to coordinated synaptic activity across large numbers of neurons. These oscillations are prominent during REM sleep (Graystan and Karmos, 1961) and intentional activity (Vanderwolf, 1969), where they are highly modulated by animal movement speed (Sheremet et al., 2016). Theta in the hippocampus is prominent in the CA1 lacunosum moleculare (LM) and outer molecular layer of the dentate gyrus (OM). Both of these regions have axonal termination sites of the perforant pathway originating from lateral entorhinal cortical layers 3 and 2, respectively. This pathway is degraded in aged rats (Barnes, 1979), non-human primates (Tigges et al., 1995), and humans (Yassa et al., 2010), but the effects of this degradation on animal speed modulation of theta have been under studied. While prior investigations into aging and theta have reported little to no age-related differences (Barnes 1979; Shen et al. 1996; Shen et al. 1997; Abe and Toyosawa, 1999; Orr et al. 2001), these studies were performed using either single wires or tetrodes which do not allow for analyses such as Current Source Density which can be used to localize recording sites based on electrophysiology markers. We therefore implanted male young (4-6 month old) and aged (23-26 month old) Fisher Brown-Norway hybrid rats with linear, 64 channel, 50 µm spaced, silicon probes that spanned 3.15 mm from the pyramidal oriens to the bottom blade of the dentate gyrus. These rats then ran a battery of tasks relating to spatial and

object memory. The aging LM and OM showed significantly increased theta power, even though CA1 pyramidal layer showed no difference. Additionally, theta power in the LM was more heavily modulated by slower velocities in aged rats compared to young. These findings suggest that perforant path degradation has likely caused a compensatory, but more limited, synaptic response in both the LM and OM implying that smaller synaptic drive is required to initiate hippocampal theta in aged rats. This observation may be consistent with the finding that the evoked excitatory post-synaptic population response in the dentate to a given pre-synaptic fiber potential is greater in aged compared to young rats (Foster et al., 1991).

Title: Methamphetamine increases cross-frequency interactions in rodent hippocampal LFP and cortical EEG

Authors: *S. D. LOVETT[1], J. P. KENNEDY[1], N. M. DICOLA[1], K. L. ROBERTSON[1], H. KHOSHBOUEI[1], S. N. BURKE[1,2], A. P. MAURER[1,3,4];
[1]McKnight Brain Inst., [2]Inst. on Aging, [3]Biomed. Engin., [4]Engin. Sch. of Sustainable Infrastructure and Envrn., Univ. of Florida, Gainesville, FL

Abstract: A common practice in neurophysiology is to measure the local field potential (LFP) using invasive intercortical electrodes in animal models. The information gained from these methods is often used to advance our understanding of humans, where conclusions are drawn from non-invasive electroencephalogram (EEG) measures. While EEG recordings can also be obtained from rodents, there is a dearth of data relating scalp recordings to the LFP. To imbricate these approaches, we demonstrated how surface EEG can be recorded through skull screws and related to the hippocampal LFP via intracranial silicon probes. Rats were trained to run on a circular track for a food reward. Following baseline recordings under saline administration, rats received I.P. administration of 2.0 mg/kg methamphetamine. Methamphetamine administration resulted in perseverative behavior in which rats traversed the circular track while bypassing the food reward. Furthermore, both the hippocampal and cortical oscillations exhibited a dramatic

increase in power relative to saline conditions. The power of hippocampal theta increased following methamphetamine administration, suggesting that this is a consequence of direct dopamine influence on the hippocampus. However, a more pragmatic explanation is that the effects of methamphetamine are global to the point of increasing total synaptic activity and increasing the mass of synaptic volleys across the brain.

Title: Expression of the Immediate-early Genes Arc and Narp during Cognitive Multitasking is Attenuated in Aged Rats

Authors: *C. N. LOGAN, K. N. LUBKE, *S. N. BURKE;
Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Aged humans (Clapp et al., 2011), monkeys (Gray et al., 2017), and rats are impaired at cognitive multitasking (Hernandez et al., 2015; Hernandez et al., 2019). The working memory/biconditional association task (WM/BAT), which requires the perirhinal cortex (Hernandez et al., 2017), has been used in rats to examine the neurobiological basis of these deficits. For this task, an animal must simultaneously perform a spatial alternation task simultaneously with an object discrimination task in which the correct choice updates based on the animal's position in the maze. Poor performance on this task is related to altered expression of the immediate-early gene Arc in the perirhinal cortex (PER). The expression patterns of other immediate-early genes (IEGs) that may be critical for updating PER cortical circuits in response to behavior, however, have not been examined. The IEG Narp/Nptx2 is a candidate gene that could be disrupted in old age, as this gene is upregulated in response to behavior and its protein is secreted from axon terminals to cluster AMPA receptors on parvalbumin-positive interneurons (Chang et al., 2010; O'Brien et al., 1999). Interestingly, aged rats have reduced monosynaptic coupling between excitatory principal cells and interneurons in the PER (Maurer, Burke, et al., 2017), which could potentially manifest from altered Narp. The current work quantified the co-expression of Arc and Narp in young and aged rats that performed the WM/BAT and a control alternation task. The proportion of cells that were positive for Narp mRNA and co-expression of

Arc and Narp were decreased in aged compared to young rats. These data provide additional evidence that a dysregulation of the balance between inhibition and excitation within the PER contributes to the interruption in feedforward inhibition necessary for cognitive multitasking. Future studies will continue to examine the relationship between the hyperactivation and hypoactivation in cognitive deficits in aging.

Abstract: In the United States alone, it is estimated that 1.1 million individuals are treated for Traumatic Brain Injury (TBI) annually. Additionally, 52% of TBI survivors report moderate to severe disabilities 1-year post injury. Animal models of TBI continue to be critical for assessing both the neuropsychological and molecular features of TBI and advancing therapeutic interventions following injury. TBI is characterized by two injury phases. The initial, or acute phase of the injury, leads to tissue loss. The secondary phase of injury is associated with inflammation and molecular cascades that impact neuronal function and can lead to long-term cognitive changes. Currently, preclinical TBI studies rarely characterize injury severity with

clinically relevant cognitive tasks. This study aimed to bridge this gap by using a clinically relevant measure of visuospatial learning and memory on a rodent model of TBI. The task is adapted from the Cambridge Neuropsychological Test Automated Battery (CANTAB), which is used in human clinical settings to assess working memory, learning, and executive function in TBI and dementia. Within CANTAB, we used the paired associates learning (PAL) task, where subjects must associate images with their matched locations on a screen. The development of a touchscreen version of the PAL task for rodents has allowed for increased efficiency and standardization with less input from the researcher. We used a rodent model of controlled cortical impact (CCI) to assess cognitive dysfunction following unilateral parietal (males=4, females= 3) cortical injury or parietal (males=3, females=2) sham craniotomies. Unilateral TBI in the parietal cortex impaired performance on the PAL task relative to sham control animals. Specifically, rats with parietal injury show significantly decreased accuracy on the PAL task and required an increased number of days to reach criterion compared to sham rats. After cognitive testing was completed over several months, quantitative immunohistochemistry was used to evaluate the extent of neuroinflammation as characterized by Iba1 and GFAP immunostaining in affected brain regions. These data indicate that the PAL task could be used to assess cognitive deficits following brain injury. By incorporating the PAL task in models of TBI, we can gain a more complete picture of cognitive outcomes for developing and testing future therapeutic targets.

Title: The Role of the Dorsal Striatum in Paired-Associates Learning

Authors: *S. M. SMITH[1], E. GARCIA[1], S. LOVETT[1], S. N. BURKE[2];
[2]Neurosci., [1]Univ. of Florida, Gainesville, FL

Abstract: Despite memory being one of the most frequently studied and well-characterized cognitive domains to date, how different memory systems interact, cooperate, and compete with one another across the lifespan is incompletely understood. This poses a distinct challenge in the

field of cognitive aging, where some systems might be more “vulnerable” or “resistant” than others. It has been hypothesized that there are multiple dissociable systems working in conjunction to support the multifaceted domain of memory. Two of these systems support distinct types of spatial memory. One is supported by the hippocampus and mediates allocentric spatial behaviors. The other is linked to the dorsal striatum and related to response-driven spatial behavior. While both the hippocampus and striatum can support memory-guided behaviors, they are hypothesized to interact antagonistically. Furthermore, aged rats are more likely than young to use striatal-based strategies to solve spatial tasks, and this is related to elevated activity in the dorsal striatum of old animals. Recently is has also been shown that while young rodents perform better on a hippocampal-dependent task than their aged counterparts, aged rodents perform better on a dorsal striatal-dependent task. Interestingly, aged rats that perform comparable to young on a spatial memory task are better able to flexibly switch between tasks that depend on hippocampus or striatum compared to both young rats and aged rats with spatial memory impairment. Together these data suggest that dorsal striatal-dependent memory may either be resilient or compensatory in comparison to hippocampus-dependent memory in advanced age. The role of striatal versus hippocampus-dependent memory systems has not been examined outside of spatial navigation behaviors, however, and it is unclear if the dissociation of age-related vulnerability of different memory systems applies to associative learning. To further investigate the role of dorsal striatum in the context of different memory systems, the current study used an automated, touchscreen-based platform to assess hippocampus-dependent paired associative learning (PAL) after bilateral cannulation and inactivation of the dorsal striatum in rats. Our lab has recently shown that this task is sensitive to age-related cognitive decline. A total of 14 rats were trained to criterion on the PAL task before undergoing cannulation surgery. After surgery, rodents were tested on both PAL and a control T-maze task with infusions of the GABA agonist muscimol. Preliminary data suggests a minimal role for dorsal striatal activity in the retention of acquired visuospatial associations in young rodents.

Title: Effects of long-term ketosis and time restricted feeding on cognitive performance in aged rats

Authors: *C. WATSON[1], A. R. HERNANDEZ[3], R. FLETCHER[1], A. BROTGANDEL[1], A. ROSS[1], T. COOPER[1], J. THOMPSON[1], Q. FEDERICO[1], S. N. BURKE[2];
[2]Neurosci., [1]Univ. of Florida, Gainesville, FL; [3]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Declining cognitive function is a hallmark of advanced age, reducing quality of life. While caloric restriction can increase lifespan in several species, the data have been equivocal as to whether or not this intervention modifies the cognitive health span. Other interventions such as a ketogenic diet or intermittent fasting have also been shown to increase the lifespan and may be more feasible interventions for enhancing cognitive functioning in old age. We have previously demonstrated that 3+ months of nutritional ketosis improves cognitive function. Furthermore, aged rats fed a ketogenic diet had significantly peripheral metabolic health. Little is known, however, regarding the long-term effects of ketosis during adulthood through advanced age. To investigate this, 8-month old male Fischer 344 x Brown Norway rats were placed on a time-restricted feeding schedule of either a high-fat, low-carbohydrate ketogenic diet (76% fat, 4% carbohydrates, 20% protein) or a calorie equivalent control diet (16% fat, 65% carbohydrates, 19% protein), for 12 months. An additional group was allowed to eat standard rat chow *ad libitum* during this same time frame. After 1 year on the diets, rats were trained on an object-place paired association (OPPA) task and a simple object recognition control task until they reached a criterion performance of 80% correct on two consecutive days. Rats fed ab libitum required significantly more incorrect trials before meeting criterion relative to rats fed via time restricted feeding, regardless of macronutrient composition. Statistically equivalent performance on the control object discrimination task indicated that enhanced cognition on the OPPA task could not be accounted for by differences in motivation, procedural or sensorimotor impairments. Interestingly, there was no significant difference in performance between the ketogenic or control diets, indicating that 12 months of intermittent fasting, with or without carbohydrate restriction, preserves cognitive function later in life. Together these data suggest that mid-life dietary interventions capable of preventing metabolic impairments may also serve to prevent age-related cognitive decline.

Title: Cell type specific differences in prefrontal cortex of young and aging tame and aggressive foxes

Authors: *A. KUKEKOVA[1], J. L. JOHNSON[1], E. E. HECHT[2], D. SHEPELEVA[3], A. V. VLADIMIROVA[3], S. G. SHISHKEVICH[3], R. G. GULEVICH[3], A. V. KHARLAMOVA[3], Y. E. HERBECK[3], L. N. TRUT[3];
[1]Animal Sci., Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Dept. of Human Evolutionary Biol., Harvard Univ., Cambridge, MA; [3]Inst. of Cytology and Genet. of the Russian Acad. of Sci., Novosibirsk, Russian Federation

Abstract: Late onset Alzheimer's disease (LOAD) is the leading cause of dementia with over 40 loci having been identified as risk factors. A LOAD-associated gene, *SorCS1*, regulates trafficking of AMPA glutamate receptors and neurorexins and may play a role in APP trafficking and beta-amyloid production. Genetic analysis of tame and aggressive fox populations (*Vulpes vulpes*) developed by 60 years of selection for behavior identified *SorCS1* as one of the main loci implicated in behavioral differences between tame and aggressive foxes. To identify brain transcriptomic differences associated with aging in these populations we performed single nuclei RNA-seq analysis of the prefrontal cortex of six young (7 months of age) and six old (7-9 years of age) female foxes with an equal number of tame and aggressive individuals per group. Sequencing of single nuclei RNA-seq libraries prepared with the Chromium Next GEM Single Cell 3' Library kit (10x Genomics) generated ~498 million reads per sample. The filtered reads were mapped against the dog genome using Cell Ranger 3.0.2 and processed using Seurat. After filtering we identified on average 7,137 cells per sample, 70,396 reads per cell, and 3,878 genes per cell. The clustering analysis identified clusters of excitatory neurons, interneurons, astrocytes, oligodendrocytes, oligodendrocyte precursor cells, microglia, and endothelial cells, annotated using known cell type markers. Further clustering revealed multiple subtypes, with the largest subclusters of Layer 2/3 neurons being overrepresented in young foxes and another subcluster of Layer 2/3 neurons and a subcluster of PV interneurons being overrepresented in old foxes. The analysis of differentially expressed genes and Gene Ontology terms in each subcluster revealed larger differences between age groups than between populations. The population specific age-related differences were also identified but the small number of animals in the specific subgroups limited the power to discover and verify these differences rigorously. The analysis of LOAD genes in neuronal subclusters identified 25 genes, including *SorCS1*, significantly upregulated in tame foxes and 35 genes significantly upregulated in aggressive foxes. Two genes (*SorCS3*, *CNTNAP2*) were found to be upregulated in sublusters of Layers 2/3/4 of tame foxes and in a subcluster of Layers 5/6 of aggressive foxes. The well-established fox populations with genetically determined differences in aggressive, affiliative, and anxiety-related behaviors and the life span exciding ten years can provide a new animal model for studying age associated changes in brain functioning and behavior.

Title: Post-operative morphine decreases hippocampal synaptic proteins of aged animals during memory consolidation.

Authors: *N. P. DEEMS[1], M. J. BUTLER[1], E. A. SCARIA[1], S. M. MUSCAT[1], K. C. RICE[2], S. F. MAIER[3], G. P. CORTESE[4], R. M. BARRIENTOS[1];

Abstract: Older adults are more susceptible to cognitive impairments following surgery, and postoperative opioids, such as morphine, can significantly prolong these impairments. Importantly, persistent postoperative cognitive deficits (POCD) are associated with higher risk for dementia, but the mechanisms driving this association are not well understood. In our recently developed rodent model of persistent POCD, we have shown that aged rats that undergo an exploratory abdominal surgery (i.e., laparotomy) followed by one-week of morphine injections (2mg/kg/i.p.) exhibit robust hippocampal-dependent memory impairments lasting at least eight-weeks after surgery. This impairment is associated with many changes in gene expression in whole hippocampus, including increased mRNA expression of synaptophysin and PSD95—two genes which code for proteins highly localized to the pre-and-post synaptic compartments, respectively. To further investigate how synaptic proteins might be impacted in our model, we generated hippocampal synaptoneurosomes from aged, vehicle or morphine-treated animals two-weeks after surgery and performed Western blots to assess relative protein abundance in the synaptic fraction. At baseline there were no significant differences in protein expression of PSD95, synaptophysin, and subunits of the AMPA and NMDA receptors. However, 2 hours post-learning (context preexposure), marked differences between groups were observed. Vehicle-treated animals demonstrated robust increases in levels of synaptic proteins while morphine-treated animals exhibited profound decreases compared to those at baseline. These data suggest that the combination of aging, surgery, and morphine disrupts the proper

abundance and coordination of synaptic proteins necessary for the formation of memory in the hippocampus.

Title: Anti-diabetic effects of chaya Cnidoscolus chayamanasa in type 2 diabetes mouse model TallyHO

Authors: *B. RAMASUBRAMANIAN[1], M. HANSON[3], C. GRIFFITH[3], P. H. REDDY[2]; [1]Intrnl. Med., [2]Dept. of Intrnl. Med., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX; [3]Texas Tech. Univ., Lubbock, TX

Abstract: The purpose of our study is to understand the protective effects of Chaya (*Cnidoscolus chayamansa*) leaf extract against type 2 diabetes (T2D). Type 2 diabetes accounts for 90 to 95% of all diabetic patients. Diabetes is highly prevalent in elderly populations and is a major health concern. Increasing evidence suggests that T2D is a major factor for developing late-onset Alzheimer's disease (AD), although a direct link between T2D and AD has not been understood well. Chaya is an edible, spinach-like medicinal plant native to Central America that has been believed to have anti-diabetic properties. Chaya is believed to cure diabetes and other cardiovascular diseases. To date, very few laboratory experiments on Chaya have been conducted, yet all of them have shown Chaya to have some degree of antihyperglycemic effects. **Methods:** In the current study, we have used a polygenic mouse model for T2D, the TallyHo (TH) mice to elucidate the anti-diabetic effects of Chaya. Only male TH mice develop hyperglycemia, hyperinsulinemia, hyperlipidemia, moderate obesity, and enlargement of the islets of Langerhans at the age of 16 weeks of age. Female mice display moderate hyperinsulinemia, hyperlipidemia, and obesity but do not manifest overt diabetes. We used Chaya leaf extract, mixed with regular chow as a diet supplement. Our preliminary study indicates that glucose levels were maintained in Chaya-fed fully diabetic 12 month-old TH mice compared to control TH mice fed with regular chow. In addition, Chaya Chow fed TH male mice showed significantly reduced body weight compared to regular Chow Fed TH male mice. **Results:** Our results also indicate that the expression for mitochondrial dynamics proteins, Drp1 and Fis1 show a significant increase in the diabetic mice (TH) compared to the non-diabetic control mice. However, the protein expression is comparable to the non-diabetic control mice in the Chaya treated TH mice. Our results also show a significant decrease in the fission proteins,

autophagy, mitophagy proteins, biogenesis and synaptic proteins in the TH mice compared to the non-diabetic control mice. The expression of proteins in the Chaya treated TH mice are equivalent to the non-diabetic control mice. **Conclusions:** Findings from our study suggests that *Chaya* protects against hyperglycemic effects and improves mitochondrial biogenesis, autophagy and mitophagy in TH mice.

Title: Chronic high sucrose diet in early stages induced impairment cognition in spatial memory in young Wistar rats

Authors: *A. LLANES-DURAN[1], G. E. ARANDA-ABREU[2], M. E. HERNÁNDEZ-AGUILAR[2], J. MANZO-DENES[2], D. HERRERA-COVARRUBIAS[2], C. A. PÉREZ-ESTUDILLO[2], F. ROJAS-DURAN[2];

Abstract: The consumption of sugar-sweetened beverages (SSBs) has increased over the past 30 years; in adolescent and young adult this SSBs apport 15% of the calories of their diet and are strongly associated not only with the development of obesity and metabolic diseases but also with cognitive impairment. In particular negative effects have been reported in hippocampal dependent task such as spatial memory when chronic but restricted SSBs are given in adult animal models. The effects of acute stimuli in critical stages as puberty in addition to chronical and continous SSBs should be discussed.The aim of study is to analyse if spatial memory impairment is observed in the BM after the continuous consumption of SSBs from postnatal day 21 (p21) to young adulthood, and if this impairment persists until 3 months of age with long-lasting SSBs consumption; furthermore we observe if an acute LPS administration during prepuberal phase (p37) could enhance the effects of the SSBs consumption in the acquisition and retention of the task. We used 18 male Wistar rats postweaded (p21) fed with standard chow, SSBs (sucrose 35%) ad libitum for the High Sucrose Diet group (HSD). For the High Sucrose Diet with LPS group (HSD-LPS) standard chow and SSBs ad libitum and a unique dose of Lipopolisacharid (LPS) 1.5mg/kg intraperitoneal (i.p) at p37 was given, and finally, the control group (CTRL) took standard chow and water ad libitum. Each group was assessed at p54, p81, p101 with a BM and latency escape was measured. At the acquisition training (At) 7 trails were

taken and 24hrs after the adqusition probe (Ap) and recovery probe (Rp) phase was taken. During the experiment both diets showed significant lower weights compared to the CTRL group, glucose levels increased significantly at the second week of the DHS group, but DHS-LPS increased their glucose levels until the sixth week. In BM task. DHS-LPS group took more time in the latency escape at the first sessions when the At was evaluated. For the Ap the latency seems significantly higher for both groups during the first 2 sessions and finally the latency escape during the Rp was higher during the first session for both groups. We conclude for instance that both treatments affect the spatial memory since they took more time on trails for the acquisition of the task comparing to the CTRL group. Also, the maintenance of the task in the memory (24h) was affected in both groups, eventhough it seems more severe for the DHS-LPS group than for the DHS group. This could be related with the anxiolytic effect that beverages rich in sugar could cause when acute stressors are presented, but no when the diet is the stressor itself.

Title: Genetic ablation of dentate hilar somatostatin-positive GABAergic interneurons is sufficient to induce cognitive impairment

Authors: *R. NAGARAJAN[1], J. LYU[1,2], M. KAMBALI[1], M. WANG[1,2], C. D. COURTNEY[3,2], C. A. CHRISTIAN-HINMAN[3], U. RUDOLPH[1];
[1]Dept. of Comparative Biosci., [2]Neurosci. Program, [3]Dept. of Mol. and Integrative Physiology, Col. of Liberal Arts and Sci., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Aging is often associated with a decline in cognitive function. The molecular and cellular mechanisms underlying these cognitive impairments remain poorly defined, but mounting evidence points to changes in GABAergic function as a major causal factor. Interestingly, a reduction in the number of somatostatin-positive (Sst+) interneurons in the DG has been described in aged cognitively impaired but not in unimpaired rodents. However, it

remains unclear whether the reduction in Sst+ interneurons in the DG hilus is directly related to or even causal for age-related cognitive dysfunction. We hypothesized that hilar Sst+ interneurons play an essential role in maintaining cognitive function and that a reduction in the number of hilar Sst+ interneurons might be sufficient to induce cognitive dysfunction. Hilar Sst+ interneurons were ablated by expressing a diptheria toxin transgene specifically in these interneurons. An AAV-mCherry-flex-dtA construct with the EF1α promoter was stereotaxically injected (bilaterally) into the DG hilus of young adult Sst-Cre mice (2-3 months). The control group was injected with an AAV-mCherry virus. After 21 days, the mice were employed for the novel object recognition test (CA1-dependent), the Morris water maze with reversal learning (learning: CA1- and CA3-dependent; reversal learning: DG-dependent), and a Y-maze test (HP, PFC). Brain tissue was collected for immunohistochemistry (c-Fos, GAD-67, Sst). We found that partial genetic ablation of Sst+ hilar interneurons impaired learning and memory functions as determined in the behavioral test battery. It also significantly increased the number of c-Fos-positive neurons in the DG and CA3 regions. Moreover, the number of Sst+ interneurons in the DG was decreased by 49 %, and the number of GAD-67+ neurons 33%. Our results show that the partial ablation of hilar Sst+ interneurons is sufficient to induce changes similar to those observed in aged rodents, such as reduction of Sst in the DG hilus, hyperactivity in DG and CA3 of the hippocampus, and cognitive impairments. This suggests that the changes elicited by partial ablation of hilar Sst+ interneurons may contribute to the development of cognitive dysfunction in aging animals. Furthermore, mice with a partial ablation of hilar Sst+ interneurons may represent a model for studying mechanisms underlying cognitive decline in aging.

Title: Late deficits in PV+ interneurons, E/I balance, and mechanism of synaptic plasticity in dorsal hippocampus linked to neurobehavioral abnormalities after neonatal hypoxic-ischemic brain injury

Authors: P. PARMAR[1], N. RASTOGI[1], S. MILLER[1], C. LECHNER[1], M. ST. PIERRE[1], H. SPAHIC[1], A. KIRKWOOD[2], *R. CHAVEZ-VALDEZ[1];
[2]Mind Brain Inst., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Infants suffering of hypoxic-ischemic (HI) brain injury have a higher risk for neurobehavioral deficits despite therapeutic hypothermia (TH). Neonatal HI decreases the number of hippocampal parvalbumin $(PV)^+$ interneurons (INs) in the mouse. Whether deficits persist to adulthood leading to excitatory/inhibitory (E/I) and behavioral disturbances is still unknown. We hypothesized that neonatal HI results in deficits in hippocampal PV^+INs, E/I balance, and mechanisms of synaptic plasticity, which correlate with behavioral deficits. We induced brain HI in P10 C57BL6 mice with R carotid ligation + 45m of hypoxia (8%), and then randomized to normothermia (36ºC, NT) or TH (30ºC) for 4h with anesthesia-shams as controls. Number and morphology of PV^+ INs in the dorsal hippocampus were assessed using IHC. E/I disturbance was assessed using puntae quantification for VGlut2 to SYT2. Images were processed using Zenlite, ImageJ/FIJI, and IMARIS software. Extracellular field potentials (EFP) were performed to assess LTD and LTP in Shaffer collateral synapses at P18 and P40. Behavioral testing, which included open field (OF), object location test (OLT), and Y-maze testing was processed using AnyMaze software. At P40, the number of PV^+ interneurons was decreased by 47% and 42% ($p<0.05$) in the dorsal hippocampus of injured mice treated with NT or TH, respectively. These deficits were similar in both sexes. GFAP score correlated well with residual hippocampal volume at P40 ($p<0.001$). Dendritic simplification of PV^+ interneurons 30 days after HI was documented by the decreased number of branches (44%), segments (48%), braching points (45%) , and sholl intersections (30%). Ratios of Vglut2/SYT2 punctae count, volume and intensity, were increased by 4-fold, 5-fold, and 5.5-fold, respectively, at P40. TH did not prevented any of these disturbances. At both P18 and P40, LTD and LTP were impaired using EFP in dorsal Schaffer collateral synapse ($p<0.001$). The decreased time spent in the center of the arena (OF), in novel arm (Y-maze), and exploring the novel object (OLT) suggested impaired memory and increased anxiety after neonatal HI, which correlated with decreased number of PV^+ INs in the dorsal hippocampus. Neonatal HI produces a long-lasting deficit in PV^+ interneurons in the dorsal hippocampus, which is independent to severity of injury, and is not attenuated by TH. This deficit results in disturbed E/I balance towards excitation, impaired mechanisms of synaptic plasticity and correlates with memory deficits and anxiety-like behavior. Persistent GABAergic deficits may explain neurobehavioral anomalies described in patients surviving neonatal HI encephalopathy.

Title: Inbred WMI rat strain as a genetic model for mild cognitive impairment

Authors: *C. KIM[1], K. J. PRZYBYL[2], E. E. REDEI[3];
[1]Northwestern Univ., Chicago, IL; [2]Northwestern Univ., Evanston, IL; [3]Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: The link between Alzheimer's Disease-related dementia and mild cognitive impairment (MCI) is an area of interest with growing possibilities. MCI can progress to Alzheimer's Disease (AD) and this path is vulnerable to specific risk factors. Stress and stress-related disorders, like major depressive disorder (MDD), have been associated with accelerated cognitive aging. Despite the significance of this issue, naturally occurring MCI models are very scarce. Thus, an animal model that shows premature memory loss, and is genetically characterized, could be a very useful tool for drug discovery. Our genetic model was developed from the Wistar Kyoto (WKY) rat strain, with depression and anxiety-like behaviors. Two fully inbred strains were generated with opposite behavior in the FST: the WKY More Immobile (WMI), and the WKY Less Immobile (WLI) strains. Middle-aged (12 months old) WMI females showed a 75% reduction of fear memory from the young adult (6 months old) WMI females' freeze duration in the contextual fear conditioning (CFC) (age, $F[1,30]=25.17$, $p<0.01$; age x strain, $F[1,30]=16.25$, $p<0.01$); no age effect was seen in the males (age, $F[1,75]=0.53$, NS). However, in the hippocampus-dependent spatial memory task, the Morris Water Maze (MWM), both middle-aged WMI males and females showed significantly lower levels of memory as measured by latency to reach the platform compared to WLIs (females: strain, $F[1,10]=9.07$, $p=0.01$; males: strain, $F[1,10]=30.50$, $p<0.01$; strain x day, $F[3,30]=7.67$, $p<0.01$). Middle-aged WMI females showed consistently lower levels of learning (Day 1) and memory (Day 4) compared to WLIs, while WMI males consistently missed the platform, being unable to remember the orientating signs on Days 3 and 4. The CFC and the MWM assess hippocampus-dependent fear and spatial working/reference memory, respectively, which are highly sensitive to aging. There were no differences in these measures between young WLI and WMI animals. Interestingly, CFC is thought to be not as sensitive to aging as other hippocampus-dependent tasks. Perhaps this explains why spatial memory decline can be detected in both middle-aged WMI males and females in the MWM but only in females in the CFC. Alternatively, strain and sex-specific expression differences found in the hippocampus of middle-aged animals in sex hormone receptors can contribute to the sex-differences in CFC and in the pattern of MWM at middle age.

Title: Generation and characterization of mice harboring Jordan's Syndrome alleles causing intellectual disability with autism

Authors: *R. MERRILL[1], C. JONG[2], C. CHEN[2], P. SANDAL[2], G. HEALEY[2], Y. KONG[2], S. STRACK[3];
[2]Neurosci. and Pharmacol., [1]Univ. of Iowa, Iowa City, IA; [3]Univ. Iowa Col. Med., Iowa City, IA

Abstract: BACKGROUND: Protein phosphatase 2A (PP2A) is an abundant and essential serine/threonine phosphatase in eukaryotic cells. Much of PP2A's specificity is directed through the different regulatory subunits, and many of these regulatory subunits have recently described mutations associated with a wide variety of human diseases ranging from cancer to intellectual disability. To date, there are more than two hundred individuals identified with Jordan's Syndrome, a disease characterized by the presence of *de novo* mutations in the *PPP2R5D* gene, which encodes the PP2A regulatory protein B'delta. The affected individuals' symptoms vary depending on the specific allele but can include intellectual disability, language delay, autism spectrum disorder, and seizures.
METHODS: The frequency and severity of the disease-causing mutations varies in humans but most are negative to positive charge-reversal mutations. To investigate phenotypes and develop animal models of the Jordan's Syndrome, we generated three mouse lines harboring mutations in *Ppp2r5d* using CRISPR-Cas9 gene editing at the University of Iowa Genome Editing Core Facility. Two mutations, E198K and E200K, are in contained in a highly conserved loop but have differing symptoms in humans, with the E198K being more severe. The third mutation, E420K, is further away on the primary protein sequence, but patients with this allele also display severe symptoms.
RESULTS: Mice heterozygous for any of these mutations are viable, but pups with E198K or E420K are born below the expected frequency. Additionally, the E198K and E420K mice often die as juveniles and show craniofacial abnormalities including cranial bossing as determined by CT scans. We have performed a battery of behavioral tests, and the mice show hyperactivity and learning memory deficits that vary with the specific mutation but correlates well the severity observed in humans. Lastly, all three mouse lines demonstrate spontaneous and handling induced seizures.

CONCLUSION: Mice heterozygous for the *Ppp2r5d* mutations (reflecting the condition of the patients) have phenotypes that correspond with the severity observed in Jordan's Syndrome patients. These generated mouse lines represent faithful models for studying the human disease.

Title: Tcf4 reinstatement in glutamatergic neurons rescues cognitive deficits in a mouse model for Pitt-Hopkins Syndrome

Authors: S. M. STRUGAR, M. M. BISHOP, M. M. CARON, A. HOWARD, X. ZHANG, B. MALACHOWSKY, *A. J. KENNEDY;
Bates Col., Lewiston, ME

Abstract: *Tcf4* is a transcription factor that is expressed in high levels in neural tissue and its haploinsufficiency is the cause of an autism-spectrum known as Pitt-Hopkins Syndrome. The deletion of one *Tcf4* gene copy in mice causes severe cognitive deficits. Here we utilize a lox-stop-lox *Tcf4* mouse model that allows for Cre-dependent reinstatement of gene function. After assessing different cell populations, it was found that the reinstatement of *Tcf4* in glutamatergic neurons post-developmentally rescued learning and memory phenotypes measured by object location memory and the Morris water maze. These data suggest that a gene therapy targeting glutamatergic *Tcf4* reinstatement post-developmentally may be efficacious to treat the cognitive deficits found in Pitt-Hopkins Syndrome.

Title: Dendritic spine abnormalities and behavioral deficits in forebrain specific Par1c/MARK1 knockout mice

Authors: *E. C. KELLY-CASTRO[1], M. SUN[1], H. ZHANG[2];
[1]Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; [2]Neurosci. and Cell Biol., Rutgers Univ., Piscataway, NJ

Abstract: Dendritic spines are dynamic postsynaptic structures that play an important role in cognitive functions, such as learning and memory. The dysregulation of spine size, shape and density may lead to learning and memory deficiencies, as well as neurological disorders such as autism spectrum disorders (ASD). Previous studies from our laboratory have demonstrated that partitioning defective 1 c (Par1c), also known as microtubule affinity regulating kinase 1 (MARK1), regulates dendritic spine morphogenesis and plasticity in cultured hippocampal neurons. Interestingly, studies have found multiple single nucleotide polymorphisms of MARK1 associated with ASD and bipolar disorder. However, the role of Par1c/MARK1 in synaptic plasticity and cognitive functions *in vivo* is still unknown. Therefore, we developed a conditional knockout (cKO) MARK1 mouse model to examine the effects of MARK1 depletion on spine morphogenesis and cognitive functions such as learning and memory. In this mouse model, MARK1 is depleted postnatally from pyramidal neurons of the forebrain including the hippocampus and the cerebral cortex. The MARK1 conditional KO mice show a significant decrease in dendritic spine density, width, and length in the hippocampal CA1 region compared to wild-type controls. In addition, there is an increase in stubby spines and a reduction in mushroom-shaped spines. We also studied different synaptic proteins levels and found increased synaptic levels of GluR2 in the MARK1 cKO mice. Furthermore, MARK1 cKO mice show a defect in spatial learning in the Morris water maze test and significantly reduced anxiety in the elevated plus-maze. Proteomic analyses show MARK1 targets synaptic proteins as well as proteins regulating cytoskeletal dynamics and vesicle trafficking. Specifically, there is a significant decrease in the phosphorylation at residue S797 of RalGAPα1, which is a GTPase-activating protein (GAP) for Ral GTPases. Since Ral GTPases regulate membrane trafficking, current studies are aimed at examining whether MARK1 regulates receptor trafficking through RalGAPα1. Together, our studies point to an important role for Par1c/MARK1 in regulating dendritic spine morphogenesis, spatial learning and anxiety-related behavior *in vivo*.

Title: Effect of different organic fluorophores on signal quality and multiplexing ability of fluorescence in situ hybridization chain reaction method

Authors: *V. KUMAR, D. M. KROLEWSKI, A. PARSEGIAN, M. FOLTZ, B. MARTIN, H. AKIL, S. J. WATSON, Jr.;
Michigan Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI

Abstract: Fluorescence in situ hybridization chain reaction (HCR FISH) offers one of the most efficient and simple methods of signal amplification for transcript probing in varied technological settings including thin section as well as large intact tissues (Choi et. al., 2014, 2018, Sylwestrak et. al., 2016, Kumar et. al., 2021). Applying multiple custom designed split-pair probes, and fluorophore-labeled DNA hairpins to tissue concurrently allows for multiplexing of up to five targets with high specificity. Consistent fluorescence signal with optimum signal to noise (S/N) ratio is a determining factor for both qualitative and quantitative analysis, especially dependent upon the colocalization. Through our repeated studies using thin sections (10-30 µm) as well as iDISCO$^+$ processed large rodent brain tissues (few mm thick slices to intact hemispheres), we discovered that effectiveness of the HCR FISH technique was critically dependent on the choice of organic dyes used as fluorophores. For example, we consistently found that hairpins conjugated with AlexaFluor-647 (AF-647) produced the most reliable fluorescence signal with highest S/N ratio and proved to be the most resilient to buffers and mounting mediums as well as photobleaching under extended imaging sessions using both confocal and light sheet microscopes. In contrast, hairpins tagged with AF-405/-488/-594 often failed to produce as consistent and comparable S/N ratios across the experiments, however it was dependent upon the target gene and tissue processing method. The fluorophore-based differences were most evident when HCR FISH was performed on low copy number genes using perfused and or iDISCO$^+$ cleared brain samples. Next, we tested DNA hairpins conjugated with non-AF fluorophores, FITC, Cy3, JaneliaFluor-525 and BODIPY-590, but these dyes too failed to produce a comparable signal to that of AF-647. Here, we report and discuss above-mentioned findings and their potential mechanisms. Then, we explore the future directions to establish the exact cause of such fluorophore-based differences in signal output and alternate solutions to achieve adequate and consistent fluorescence for multiplexed labeling and benefit both qualitative as well as quantitative studies.

Title: Generation of recombinant monoclonal antibodies and scFvs against brain targets using sequences derived from high-throughput hybridoma sequencing

Authors: *J. S. TRIMMER, J. BERNAL, H. N. FRIZZO, C. GAVIRA-O'NEILL, B. GONG, K. D. MURRAY, K. M. TEMPELTON, D. VAN DER LIST;
Physiol. and Membrane Biol., Univ. of California, Davis Sch. of Med., Davis, CA

Abstract: We previously developed a widely-used collection of monoclonal antibodies (mAbs) targeting brain proteins. These mAbs have been extensively validated in essential neuroscience applications including immunoblots and immunohistochemistry on mammalian brain samples (neuromab.ucdavis.edu). We are now converting this hybridoma-based mAb collection into recombinant form (i.e., into recombinant mAbs or R-mAbs) to create molecularly-defined research reagents. Conversion into recombinant form will also allow for enhanced archiving and dissemination as plasmids and/or DNA sequences, more reliable expression, and will allow for diverse forms of antibody engineering. Our initial efforts (Andrews et al., 2019, eLife 8: e43322) employed cloning of RT-PCR amplified heavy and light chain variable (V_H and V_L) domain sequences into a mammalian expression plasmid, followed by sequencing of V_H and V_L domains. We have more recently employed a high-throughput Illumina-based sequencing platform to sequence the V_H and V_L domain sequences directly from hybridomas, and are posting these sequences on the NeuroMabSeq website (neuromabseq.ucdavis.edu). We have now used these V_H and V_L domain sequences to develop R-mAb expression plasmids. We synthesize gene fragments corresponding to V_H and V_L domain sequences, and use Gibson Assembly to insert them into a mammalian expression plasmid containing all other elements needed for expression of R-mAbs, while engineering an IgG subclass switch to facilitate multiplex labeling. We transfect these plasmids into mammalian cells to generate R-mAb samples for validation relative to the hybridoma-derived mAbs. We use an analogous approach to engineer mammalian expression plasmids for miniaturized single chain variable fragments (scFvs). We synthesize V_H -linker- V_L domain gene fragments and use these in Gibson Assembly reactions to generate scFv expression plasmids. Due to their smaller size, these scFvs have enhanced tissue penetration and yield higher resolution imaging than conventional antibodies. We have partnered with Addgene to make these R-mAb and scFv plasmids and sequences publicly available

(https://www.addgene.org/James_Trimmer/). Together, these efforts will provide the community with open source, renewable, recombinant research reagents to support neuroscience research.

Title: Resolving Spatial Gene and Protein Expression in the FFPE Mammalian Central Nervous System

Authors: A. D. HARTNETT, P. MIELINIS, ***C. R. UYTINGCO**, J. CHEW, F. MESCHI, R. CHAN, C. GALONSKA, A. JUREK, L. KATIREAEE, T. CHEN, D. MORALES, M. TURKKUL, T. DRENNON, S. R. WILLIAMS, P. ROELLI, N. WEISENFELD, F. BAUMGARTNER, J. STERN, K. R. MILLER, D. WALKER, Y. YIN, M. STOECKIUS, C. GALLANT, J. CHELL;
10X Genomics, Pleasanton, CA

Abstract: Understanding the detailed cellular composition and gene expression of the mammalian central nervous system (CNS) is critical for gaining insights into normal, developing, and diseased states. In addition, correlating transcriptional changes with translational profiles provides a more holistic view of the underlying CNS biology. Despite the sensitivity of gene expression measurements from RNA-seq, the loss of tissue structure with the inability to examine protein expression limit the technology. The recently introduced 10x Genomics Visium Spatial Gene Expression Solution enables the use of histological techniques together with the highly multiplexed identification of RNA molecules to spatially map the gene expression patterns in FFPE samples. Visium for FFPE incorporates ~5,000 gene expression spots per sample area on a slide, wherein each spot has spatially barcoded primers over which tissue is placed. The tissue sections are subsequently H&E stained or immunostained, imaged, and then permeabilized, allowing for the detection of native RNA. In the present experiment, whole mouse and human transcriptome probe panels were used to capture the transcriptional profiles of the respective CNS tissues. Libraries were generated and sequenced and the resulting RNA-seq data were mapped back to image coordinates, placing gene expression into context within the H&E or immunostained tissue image. The data were integrated into the 10x Genomics Space Ranger analysis pipeline in which a single section whole transcriptome readout and the reference image were correlated and subsequently visualized using the 10x Genomics Loupe Browser desktop software. By aggregating proteomic and transcriptomic data from immunostained

sections, the resolution of cell-type identification was improved. Results from these efforts suggest that this multiomics approach can provide a powerful complement to traditional histopathology, enabling a greater understanding of cellular heterogeneity and organization within the mammalian CNS. Furthermore, this more detailed view of the mammalian CNS anatomy can provide essential insight into the cell type-specific nature of neurobiology and neurodegenerative diseases.

Title: Progress toward megaplexed cellular barcoding of the mouse brain

Authors: T. LEBAR[1,2], I. HAN[1], N. ARKAN[1], G. M. CHURCH[1,2], ***R. E. KOHMAN**[1,2,3]; [1]The Wyss Inst. at Harvard, Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]The Wyss Ctr. for Bio and Neuroengineering, Geneva, Switzerland

Abstract: A basic understanding of how individual cells within the brain operate and organize to give rise to sensations, behavior, and thoughts is lacking. This knowledge gap is the result of the staggering complexity of the central nervous system. Each neuron sends and receives local and

long range connections through cellular projections which can often travel along complex paths. Mapping these connections with single-cell resolution would be an immense step forward for neuroscience, however no technology exists that can achieve both the necessary scale and resolution, as a tradeoff generally exists between these two. Fluorescence microscopy is potentially best suited to map neural circuitry in mammalian brains because it can image thick tissues at resolutions necessary to distinguish fine cellular processes such as dendritic spines. Its resolution limit becomes problematic however when imaging densely labelled tissue because overlapping features of cells cannot be distinguished. The use of multiple fluorescent colors or color combinations improves this situation, but not enough to map dense circuits over long ranges. Here we will discuss advances in the writing and reading of cellular barcodes in mammalian brain tissue. This approach involves virally labelling cells with nucleic acids or peptide identifiers in the mouse brain. Because of the high sequence diversity of these molecules, millions of "virtual colors" are useable for labelling cells rather than a small color palette of fluorophores. This megaplexed labelling strategy can potentially scale to label all cells within mammalian brains and lead to high throughput circuit mapping over large distances.

Title: Microcomputed tomography and computer vision based morphometric analysis pipeline for characterizing anatomical variations in skull morphologies in wildtype and transgenic mice strains

Authors: *B. R. GULNER, Z. S. NAVABI, B. VANHEEL, S. B. KODANDARAMAIAH; Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: The anatomy of the skull and the brain of commonly used laboratory mice strains, such as the C57/BL6 strain have been exhaustively characterized, and precise anatomical atlases of brain have been constructed. While these results indicate a well conserved brain anatomy within standard strains, much less is known of any variations in size and shape of brain and skull of genetically engineered transgenic mice derived from the C57/BL6. A precise characterization of variations in skull morphologies, and in turn brain morphology, may enable more accurate targeting of deep brain targets during stereotactic surgery, and a comprehensive mapping of skull thickness variations may improve guiding of automated cranial microsurgeries. We have developed a high throughput computer-vision based analysis pipeline for analyzing microcomputed tomography (µCT) scans of skulls of mice to evaluate geometric morphometrics and skull thickness. We performed µCT scans on 5 male and 5 female C57/BL6 mice at 15 weeks age procured from a commercial vendor (Jackson Laboratories) and on 4 female in-house bred Thy1-GCaMP6f mice at 16 weeks age. A custom MATLAB program was used to measure the thickness of the dorsal skull in the resulting µCT image stack. Eleven landmarks were used to automatically register each skull to an average reference skull using piecewise linear transformations. The landmark locations were similar across sex and strain, indicating that the gross morphology of the skull was conserved. Thickness of the dorsal skull in three regions of interest (ROIs) comprising the parietal, frontal, and interparietal bones lateral to the midline were measured. We found that the male C57BL/6J mice had significantly thicker skulls than the female C57BL/6J mice in the parietal and frontal ROIs ($p=0.002$ for both regions, t-test). The mean thickness of the interparietal ROI did not vary significantly between the male and female C57BL/6J mice ($p=0.6$). The female C57BL/6J mice had thicker skulls than the 16-week female Thy1-GCaMP6f mice in all three ROIs ($p=0.01$ parietal; $p=0.03$, frontal; and $p=1e-4$, interparietal ROI). We are currently performing similar analysis on other in-house strains and sexes of mice using this pipeline and extending our analysis to geometric morphometrics. Our results indicate strain- and sex-specific differences which need to be considered when planning stereotactic cranial microsurgery. In the future, detailed maps of skull anatomy and thickness may assist automated cranial microsurgeries. The method used for automatically extracting bone thickness from µCT scans also may be widely useful for efficiently measuring dimensions of radiopaque features in µCT scans.

Abstract: Comprehensive cytoarchitectonic atlases that visualize areal, laminar and cellular diversity in human brains are invaluable to the study of human brain disease, since they provide anatomical descriptions of brain areas under normal conditions that serve as a reference for pathological changes in disease states. However, most current atlases are limited in scale and resolution; volumetric atlases from resonance imaging data span whole brains but cannot visualize laminar or cellular diversity, while histological atlases from light microscopy data reveal fine structure but are typically limited to serial sections <100um. Recent advances in hydrogel-based tissue clearing methods and light sheet microscopy enable the generation of high resolution cytoarchitectonic data in large volumes of cleared tissue.
Human brain tissue is difficult to clear, fluorescently label, and image in large volumes (>300 um) due to the density of the white matter and the typically high levels of fixation for archived human specimens. These issues have posed barriers for the development of high-resolution cellular and pathological maps of human brains. Advances in tissue clearing methods have helped mitigate these problems, but to our knowledge have not been used so far to create large-scale volumetric atlases, which would exceed 1 petavoxel for a human brain imaged at 1 micrometer resolution.
We have employed the ELAST protocol (Ku et al, Chung 2020 Nature Methods) because it adds structural stability to brain tissue while enabling faster clearing and increased label penetration throughout thick volumes. We subjected cleared tissue-hydrogel matrices to cytoarchitecture-specific stains to fluorescently label nuclei, cell bodies, and vasculature. We then used light-sheet fluorescence microscopy to image these tissue volumes at high speed but modest (~1 micrometer) resolution. We have thus built a pipeline for efficiently creating high-resolution cytoarchitecture maps. By applying specific pathological stains, such as for AD beta amyloid plaques and neurofibrillary degeneration, this pipeline will be useful in the development of neuropathologic atlases as well.

Title: Morphological patterns of the superior parietal sulcus in the human brain

Authors: *K. DRUDIK[1,2], V. ZLATKINA[1], M. PETRIDES[1,2];
[1]Dept. of Neurol. and Neurosurg., Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Dept. of Psychology, McGill Univ., Montreal, QC, Canada

Abstract: The superior parietal sulcus (*sps*) is the main sulcus of the superior parietal lobule. The sulcal maps of the 20th century show the sps as a single and continuous sulcus that separates the anterior from the posterior portion of the superior parietal lobule (Economo, Koskinas 1925, *J. Springer*). The present study examined the morphology of this sulcus to provide criteria for its identification and its variants, and thus facilitate anatomo-functional correlations in functional neuroimaging studies. MRI scans were randomly selected from the International Consortium for Brain Mapping (Mazziotta et al. 2001, *Phil. Trans. R. Soc.*). These subjects had no history of neurological and/or psychiatric illness, and gave informed consent. Identification of the sps was based on criteria established in recent atlases of the sulcal morphology of the human cerebral cortex in MNI stereotaxic space (Petrides 2018, *Elsevier Academic*). Voxels of the sps were manually identified on individual *in-vivo* MRI brain volumes using an interactive imaging software package called Display (MacDonald 1996, *McConnell BIC*). The sps was examined in the coronal, horizontal, and sagittal sections at 1mm intervals to determine its direction, extent, and pattern with respect to neighboring sulci. The sps was identified in all hemispheres and the morphological patterns of the sulcus were classified into three groups. 1) In the majority of cases, the sps was a distinct sulcus that did not merge with other sulci, i.e. it was clearly separate from surrounding parietal sulci visible on the surface of the brain or by way of a submerged gyral bridge. 2) The sps merged with another parietal sulcus, such as the anterior ramus of the horizontal part of the intraparietal sulcus (*IPSa*), the superior postcentral sulcus (*spcs*), and less frequently the posterior ramus of the horizontal part of the intraparietal sulcus (*IPSp*). Finally, 3) the sps was observed in two or more branches that were distinct and running in proximity, or connected to form an sps complex. Less frequently, the sps complex was found as a group of dimples, rather than well-defined sulci. The present study examined the morphology of the

superior parietal sulcus and established consistent morphological patterns in a common anatomical space to facilitate structural and functional analyses of the superior parietal lobule.

Title: Caress the Detail: A Human Brain in vivo MRI Reference Dataset.

Authors: *M. M. SCHIRA[1,3], G. PAXINOS[3], Z. J. ISHERWOOD[4,2], S. KASSEM[3], M. BARTH[5], T. B. SHAW[5], M. ROBERTS[6,1];

Abstract: Virtually all major discoveries in neuroscience for the last 100 years have been underpinned by an increasingly detailed understanding of the architecture and connectivity. Brain atlases assist students, scientists and clinicians to navigate the brain and understand its function. Histological atlases, provide exquisite detail, accuracy and a long history of refinements and cross species references, but rely on invasive post mortem procedures and often distorted 2D slices. MRI atlases are 3D, rely on and inform in vivo applications, but are of significantly lower detail and annotations.
Introducing “Caress the Detail” an initiative aiming to provide a new generation of high-resolution, open-access brain atlases combining histology-derived annotation detail of human brain anatomy with cutting edge 3D in vivo MRI imaging. We present the first step of this initiative: a comprehensive dataset of two healthy male volunteers reconstructed at 0.25 mm isotropic spatial resolution for T1w, T2w and DWI contrasts. Multiple acquisitions for each contrast and each participant (20 T1w, 12 T2w, 10 DWI) and were averaged within subject using symmetric group-wise normalisation (Advanced Normalisation Tools). T1w and T2w data were acquired using a 7T human research scanner (Siemens MAGNETOM) at the Centre for Advanced Imaging, University of Queensland. T1w scans were recorded using a MP2RAGE sequence (WIP944) at 0.4mm3 isotropic resolution using: TR=4300ms, TE=1.8ms, TI1=830ms, TI2380ms, GRAPPA=2. T2w scans were recorded using a TSE sequence (WIP692) at 0.4 mm3 isotropic resolution using TR=1330ms, TE=118ms, GRAPPA 3. DWI scans were recorded with

a 3T MRI (Philips Achieva CX) (NeuRA Imaging Centre) using an inverse blip corrected SPIR sequence at 1.25 mm3 isotropic resolution, with 32 directions, 5 b-factor averages, B-val=1000, TE=60ms, TR=26.5s, SENSE=3. The high-resolution datasets, the analysis protocols and the annotations will be made available via the platform hba.neura.edu.au, inviting the community to enjoy the detail and contribute annotations and analysis.

Title: Longitudinal changes in gray to white matter T1-weighted contrast and T2* relaxation times in an ex vivo-in situ human brain fixed by perfusion

Authors: E.-M. FRIGON[1], I. R. LEPPERT[2], C. L. TARDIF[3], M. DADAR[4], ***J. MARANZANO**[5];
[1]Univ. Du Quebec A Trois-Rivieres, Trois-Rivieres, QC, Canada; [2]McGill Univ., Montreal;, QC, Canada; [3]McGill Univ., Montreal, QC, Canada; [4]Laval Univ., Quebec, QC, Canada; [5]Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: Understanding MRI changes of post-mortem human brain during fixation is key to the comprehension of ex vivo MRI-histology studies. Changes in MRI contrast and relaxation times reflect changes in tissue properties. Those changes are progressive since the fixation period may extend for several weeks or months. Changes in relaxation times have been previously described in brains fixed by immersion, showing progressive shortening, reaching a plateau at 6 months (Dawe RJ et al. Magn Reson Med. 2009). Differences in T2 relaxation times between the superficial and deep brain tissue have also been noted in immersed-fixed brains (Raman MR et al. Magn Reson Med. 2017).To our knowledge, changes in T2* relaxation times and gray matter (GM) to white matter (WM) T1-weighted (T1w) contrast in in situ, perfused-fixed brains have not been reported during the length of the fixation period. We used a human brain fixed in situ by whole body perfusion of a 10% formalin solution through the carotid artery (anatomists' technique). We subsequently severed the head and proceeded to acquire monthly scans for six months. We collected T1w (MPRAGE), T2weighted (T2w), and multi-echo gradient (GRE) sequences. We used T1w and T2w contrasts to generate GM and WM, masks. We segmented areas showing high T1w GM-WM contrast, and areas with low T1w GM-WM contrast. qMRlab (MATLAB based open-source software for quantitative MRI analysis) was used to map the T2* relaxation times curves from the multi-echo GRE images.The volume of brain tissue showing a high T1w GM-WM contrast progressively decreased over time, while the volume showing low T1w GM-WM contrast progressively and reciprocally increased over time. We also detected progressive shortening of T2* values with time. Interestingly, the tissue experiencing loss of GM-WM contrast at each visit showed different levels of T2* shortening, with tissues losing GM-WM contrast at first visit showing the shortest T2* times (GM 45.9 ms ±1.2; WM 33.4 ms ±0.9), tissue losing GM-WM contrast later (3rdvisit) showing the longest T2* times (GM 50.1 ±0.9; WM 37.6 ms ±1.2), and tissue losing contrast even later (5th visit) showing times that shorten again (GM 48.6 ±0.5; WM 35.0 ms ±0.7).These results show that the time elapsed from the loss of GM-WM contrast on T1w is related to the magnitude of the shortening in T2* relaxation times, potentially reflecting different degrees of fixation in these areas and/or some degree of pre-fixation changes (decomposition) before fixation takes place.

Title: Leveraging neuroimaging tools to assess precision and accuracy in an alzheimer's disease neuropathological sampling protocol

Authors: *J. WEBSTER[1], T. MADHYASTHA[1], L. GIBBONS[2], C. D. KEENE[3], T. J. GRABOWSKI, Jr[4], C. S. LATIMER[3];
[1]Radiology, [2]Med., [3]Labratory Med. and Pathology, Univ. of Washington, Seattle, WA;
[4]Radiology, Univ. of Washington Dept. of Radiology, Seattle, WA

Abstract: INTRODUCTION: The study of Alzheimer's disease (AD) investigates topographic patterns of degeneration in the context of connected networks of functionally distinct domains using increasingly sophisticated molecular techniques. Therefore, obtaining high precision and accuracy of neuropathologic tissue sampling will enhance the reliability of molecular studies and contribute the understanding of Alzheimer's pathology. Neuroimaging tools can help assess these aspects of current sampling protocols as well as contribute directly to their improvement. **METHODS:** Using a virtual sampling method on magnetic resonance images from 35 participants (ages 59-91; 21 women), we compared the precision and accuracy of traditional neuropathological vs. neuroimaging-guided sampling. The impact of the resulting differences was assessed by evaluating the functional connectivity pattern of regions selected by each approach. **RESULTS:** Virtual sampling using the traditional neuropathologic approach had low neuroanatomical accuracy and precision for all cortical regions tested. Neuroimaging-guided strategies narrowed these gaps. Discrepancies in the location of traditional and neuroimaging-guided samples corresponded to differences in functional connectivity.**DISCUSSION:** Integrating neuroimaging tools with the neuropathologic assessment will improve neuropathologic-neuroimaging correlations, which is particularly important for linking antemortem clinical assessments and neuroimaging data to postmortem cellular and biomolecular findings. Our neuroimaging-based simulation of current sampling practices provides a benchmark of accuracy and precision against which to measure improvements with novel tissue sampling approaches. Our results suggest that relying on gross landmarks alone to select samples at autopsy leads to significant variability, even when sampled by the same neuropathologist. Further, this exercise highlights how sampling precision could be enhanced if neuroimaging were integrated with the standard neuropathologic assessment. More accurate targeting and improved biological homogeneity of sampled brain tissue will facilitate the interpretation of neuropathological analyses in AD and the downstream research applications of neural tissue from biorepositories.

Title: Simultaneous Functional and Thermal Imaging of Mouse Cortex

Authors: *S. CHEN[1], H. BANKS[2], J. BUMSTEAD[1], L. BRIER[2], A. BICE[2], S. GAINES[2], J. CULVER[2];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Wide-field two photon microscopy is able to map mouse brain functions with large field of view (FOV) at cellular resolution. However, due to the decrease of pixel dwell time, obtaining sufficient signal to noise ratio (SNR) at high frame rate remains a challenge. Although increasing laser power can potentially improve SNR, a technique for monitoring the mouse brain temperature under high laser power is needed to ensure the mouse will be imaged safely. In this study, we proposed an imaging setup for simultaneous functional and thermal imaging for monitoring and studying the thermal effect of laser light on mouse cortex during the scan. This was achieved by using an air-coupled, long working distance objective with an Indium-tin-oxide slide placed on top of the mouse cranial window. The infrared light was reflected by the slide and redirected to the thermal camera. We found that the Indium-tin-oxide slide has around 85% transmission of 900nm light, and the image quality did not degrade significantly. Using this setup, we monitored the brain as a function of scan area and laser power. As anticipated, for a fixed laser power, the max temperature of the brain decreases as the area of the laser scanning increases, demonstrating the possibility of using higher laser power when scanning larger areas. With a large 5 x 5 mm FOV, we found that the mouse brain peak temperature at the surface was 39°C during a scan with 400mW laser power, whereas for a smaller 1 x 1 mm FOV the peak temperature was 39°C for only 200 mW of laser power. We confirmed that two photon signal scales as the power squared, so that the large 5 x 5 mm FOV had 4x more signal with 400 mW than it did with 200 mW. On the other hand, the large FOV also had shorter dwell times. Keeping the same frame rate and number of lines, the dwell time per equivalent pixel size is 5 times smaller for 5 x 5 mm FOV vs 1 x 1 mm FOV. This is approximately balanced out by the gains in signal increase from the higher power. We will present the full parameter space results of FOV and power, and also the results of feasibility studies evaluating brain activities both under hind paw stimulation and at rest. Together, these results demonstrated that high laser power for wide-field two-photon imaging can potentially be used for obtaining sufficient SNR functional data with little damage to the mouse cortex.

Title: Axially independent optical control and readout of neuronal circuit activity using the olfactory bulb as a model.

Authors: D. F. ALBEANU[1], M. S. KOH[1], F. ANSELMI[1], S. SADHU[1], P. GUPTA[1], H. CHAE[1], D. HERNANDEZ-TREJO[1], P. S. VILLAR[2], *A. BANERJEE[1];

Abstract: All-optical methods for manipulating and measuring neuronal activity in vivo is a promising strategy to map the functional connectivity of layer-organized neural circuits at cellular resolution. We manipulated neural activity via one-photon patterned illumination with optogenetic stimulation and coupled this with quasi-simultaneous optical readout of neuronal activity using multiphoton microscopy. We used a digital micro-mirror device (DMD) to create patterned illumination profiles. Axial separation of stimulation and readout planes (up to 500 µm axial shift), was implemented by conjugating a motorized translatable holographic diffuser with the desired photo-stimulation plane, thus achieving widefield axial optical sectioning (15 µm x-y, 30 µm z-resolution, across 1.5 x 1.5 mm). To demonstrate the utility of stimulating and monitoring neural activity at two independent optical planes, we specifically controlled the activity of single glomeruli (stimulation of OSN terminals in OMP-Cre x ReaChR mice) on the surface of the olfactory bulb, while monitoring responses (GCaMP6f/s/7b) of the output neurons (mitral and tufted cells). We sampled mitral and tufted cell responses either within the photo-stimulation plane (glomerular dendritic tufts) or at 150-250 µm (cell bodies) below the photo-stimulation plane across a range of photo-stimulation intensities. Glomerular stimulation of OSN terminals selectively evoked responses in the targeted glomerulus and in the cell bodies of sister mitral and tufted cells receiving input from the photo-stimulated glomerulus and, further, revealed lateral inhibitory interactions between glomeruli. In ongoing experiments, we analyze the odor response properties of the identified sister cells as a function of brain state and experience. This technique can be readily applied to other brain regions that have layer-specific organization such as the neocortex.

Title: Further development of the GRINtrode, a head-mounted miniature microscope with simultaneous extracellular electrophysiology, and analysis of optical vs. electrical data

Authors: *C. MCCULLOUGH, T. CORRIGAN, D. RAMIREZ-GORDILLO, G. FUTIA, M. YOUNG, E. GIBSON, D. RESTREPO;
Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: *In-vivo* imaging of neural activity has become a powerful tool for researching neural networks in action. The most popular optical reporter, GCaMP, is a calcium-based fluorescent reporter that provides excellent signal-to-noise ratio, is available in transgenic mouse lines, and is compatible with a wide variety of imaging methods. However, GCaMP is inherently limited in temporal resolution due to its dependence on calcium dynamics. This limitation makes it difficult to identify individual action potentials in optical data collected using GCaMP. *In-vivo* extracellular electrophysiology is a direct measure of neural activity that allows researchers to identify single action potentials as well as record the local field potential. To allow researchers the benefits of both recording modalities, we have developed a GRIN lens-based head-mounted miniature microscope, the GRINtrode, that provides simultaneous extracellular electrophysiology with 4 tetrodes on the periphery of the GRIN lens. Here we present our progress with development of the GRINtrode, including demonstration of fiber-coupling capability, and analysis of the relationship between GCaMP and tetrode data.

Abstract: Two-photon voltage imaging with genetically encoded indicators is a non-invasive, reliable method to record membrane electrical transients from deeper brain structures with cellular resolution. However, the lack of high-performing 2P-sensitive indicators and rapid imaging systems significantly limits the application of this approach. The best opsin-based GEVIs are sensitive and fast enough to report individual action potentials in collections of superficial neurons under single-photon excitation. However, this class of GEVIs is voltage insensitive under multi-photon excitation. High-speed, multi-photon voltage imaging has been demonstrated using ASAP3, the VSD-based GEVI. However, optical properties of ASAP3 (i.e., brightness and bleach rate) will need to be optimized to facilitate long-lasting in vivo imaging sessions in the mouse brain. Additionally, brighter and more photo-stable VSD-based variants (e.g., ArcLight-family) have slower kinetics that reduces spike detection fidelity. To develop GEVI variants optimized for multi-photon imaging, we have developed a semi-automated, multidimensional 2P-based screening platform. This unique system supports fast (~2hours/96-well plate) multidimensional screening of relevant GEVI features (brightness, photo-stability, and voltage sensitivity) in hundreds of cells simultaneously. The structure-guided protein evolution supported by this high throughput screening system resulted in several ultra-fast, sensitive, and photo-stable GEVIs optimized for prolonged multi-photon imaging.

Title: Dual polarity voltage imaging reveals state-dependent spiking and subthreshold dynamics in multiple cell types

Authors: *G. VASAN[1], M. KANNAN[2], S. HAZIZA[4], C. HUANG[5], J. LUO[6], M. J. SCHNITZER[7], V. A. PIERIBONE[3];

Abstract: Genetically encoded voltage indicators have the potential to uncover millisecond-scale interactions between multiple identified cell types in live animals. However, current indicators have reduced voltage sensitivities and are incompatible for simultaneous multipopulation imaging. Here, we report next-generation FRET-opsin indicators Ace-mNeon2 and VARNAM2 with improved sensitivities and their respective reverse response-polarity variants pAce and pAceR. Combining the dual-color and dual-polarity indicators, we capture the simultaneous spiking and subthreshold dynamics of large ensembles belonging to up to three identified excitatory and inhibitory subpopulations in awake mice and flies. We further unravel inter-population voltage cross-correlations during behavioral state transitions. By overcoming the limitation of spectral bandwidth, and with enhanced signal-to-noise ratios, our dual-polarity indicators provide the most comprehensive insight to-date into cellular resolution voltage dynamics across identified subpopulations.

Title: Label-free optical microscopy of millisecond-scale neural activity using phase-sensitive and polarization-sensitive full-field interferometry in optically sensitive neurons

Authors: *R. R. IYER[1,2], Y.-Z. LIU[1], C. A. RENTERIA[1,3], B. E. TIBBLE[1], H. CHOI[1], M. ŽURAUSKAS[1], S. A. BOPPART[1,2,3,4,5];
[1]Beckman Inst. of Advanced Sci. and Technol., [2]Dept. of Electrical and Computer Engin., [3]Dept. of Bioengineering, [4]Carle Illinois Col. of Med., [5]Cancer Ctr. at Illinois, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: We present a new versatile all-optical technique for neurophysiology that utilizes a novel label-free optical microscopy system called Superfast Polarization-sensitive Off-axis Full-field Optical Coherence Microscopy (SPoOF OCM). SPoOF OCM captures the changes to both the optical path length and birefringence induced by the millisecond-scale electrical activity of neurons. This multimodal response is imaged in a widefield configuration at 4000 frames per second, with a field-of-view of 200×200 μm^2, 1 μm transverse resolution, and 4.5 μm axial resolution. With an ability to capture responses spanning three orders of magnitude in both space and time, SPoOF OCM meets the exacting needs of a comprehensive neurophysiology tool. Hence, SPoOF OCM overcomes the existing limitations of traditional electrophysiology and fluorescence microscopy. SPoOF OCM is validated in mammalian neurons by comparing the nanometer-scale optical path differences and qualitative birefringence of the scattered fields to field-potential electrophysiology measurements. The off-axis configuration, dual reference arms, and no moving parts ensure phase stability as low as 0.3 nm. The millisecond-scale responses for both spontaneous and electrically stimulated activity of mammalian neurons from every pixel in the field of view are used to estimate instantaneous connectivity patterns and videos of dynamic neural activity within neural circuits. We demonstrate an all-optical configuration of this system for excitation and stimulation of mammalian neurons. Differentiated mouse neuroectodermal stem cells (NE-4C) are transfected with channelrhodopsin-2 and its variant CHETA. The cells are excited, both locally and widefield, with different pulse duration and reputation rates. The responses to optical stimulation were imaged using SPoOF OCM to study the dynamics of the neural network and the interplay between the optically sensitive and wildtype cells in the co-culture. We highlight the noninvasiveness and versatility of an all-optical system and the higher data throughput of SPoOF OCM that overcomes the limitations of electrophysiology. Our label-free imaging setup is particularly relevant for research involving the retina and vision. Since SPoOF OCM can track the millisecond-scale activity of neurons across an entire field of view, it provides a framework to progress from low-throughput electrophysiology to highly parallelized, non-invasive, and label-free optophysiology.

Abstract: Understanding the complexity of neural networks *in vivo* requires simultaneous recordings of neuronal populations with action potential resolution. Genetically-encoded voltage indicators (GEVIs) provide direct and reliable optical readouts of neural activity with high temporal resolution. The fast dynamic of spike-evoked GEVI responses necessitates the development of kilohertz-rate two-photon (2P) imaging systems. Existing high-speed 2P microscopes scan restricted field of views (FOVs), limiting the number of simultaneously imaged neurons. We developed an Ultra-Fast 2-Photon (UF2P) microscope which is capable of full-frame high-speed imaging of a 400x400μm^2 FOV of up to ~300 microns deep in mouse cortex at a kilohertz scan rate. We used a combination of spatial and temporal beam multiplexing to achieve parallel resonance frame scanning of 8 beams at up to 1 kHz framerate. Spatially multiplexed beams were spaced 200μm apart to avoid crosstalk from light scatter in deeper tissue depths and emitted photons were resolved using a multi-anode photomultiplier tube. For temporal demultiplexing, a fixed 920nm-wavelength, low repetition rate laser was used to deliver interleaved laser pulses and emitted photons were digitized and temporally de-multiplexed with custom electronic components. We compared the photobleaching performance and neural activity readouts of two-photon compatible GEVIs in the primary somatosensory cortex of awake mice. Using a self-supervised deep-learning-based denoising algorithm, sensory-evoked action potentials could be identified from neurons imaged at resolutions near 1μm^2/pixel. An automated in vivo patch clamp system was integrated into the microscope to enable simultaneous electrophysiology recordings to potentially characterize GEVIs using the system. This microscope system demonstrates the capacity to perform two-photon voltage imaging across larger neuronal populations.

Title: Ultra-lightweight and large field-of-view head-mounted microscopes for in vivo neural recording

Authors: *J. SCHERRER, G. F. LYNCH, J. ZHANG, M. S. FEE;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Miniature head-mounted microscopes have enabled in vivo optical measurements of neural activity in freely moving animals. Recent improvements to these techniques have both decreased device weight and increased field-of-view (FOV). Light-weight devices enable neural recordings in freely behaving small animals, while increased FOV enhances the number of neurons that can be simultaneously observed. However, existing microscope designs suffer from a fundamental tradeoff between weight, FOV, and resolution. Microscopes optimized for low weight suffer from low resolution and FOV, while conversely designs optimized for a large FOV (greater than 1 mm^2) are too heavy to be used in small animals such as songbirds.
Here, we present two different head-mounted microscopes that overcome these limitations by using a novel compact optical design. Specifically, we eliminate the need for a dichroic filter by instead introducing excitation light at the back aperture of the objective lens with an optical fiber coupled to a small prism. The first design (Featherscope) weighs just 1.0 g while maintaining cellular resolution across 1.0 x 1.0 mm FOV, enabling neural recordings in animals that are too small for existing head-mounted microscopes, such as juvenile songbirds. The second design (wide FOV scope) provides cellular resolution imaging across 4.8 x 3.6 mm FOV in a device weighing only 1.4 g, opening the door to wide-field neural recordings in freely behaving mice and songbirds. We have used these microscopes to collect the first calcium recordings of LMAN in juvenile zebra finches during subsong. We have also obtained simultaneous recordings from several hundred neurons in multiple cortical of a freely-behaving mouse.

Title: A coded exposure camera to enhance the speed and SNR of GEVI imaging

Authors: *J. ZHANG[1], J. P. NEWMAN[1], G. BROWN[4], C. LINGHU[2], P. CHIN[4], E. S. BOYDEN[2], M. A. WILSON[3];
[1]Dept. of Brain and Cognitive Sci., [2]Media Lab., [3]Picower Inst. Learn/Memory, MIT, Cambridge, MA; [4]Computer Sci., Boston Univ., Boston, MA

Abstract: Genetically encoded voltage indicators (GEVIs) permit cell-type-specific measurements of spiking activity and subthreshold voltages. However, the speed requirement for wide-field, spike-resolution GEVI imaging presents significant challenges for conventional image sensors: fast frame rates (>1 kHz) lead to short photon integration times (<1 ms) of already weak fluorescent signals. On the other hand, GEVI videos have significant spatiotemporal correlations that can be exploited to improve SNR while maintaining temporal resolution using non-traditional sampling architectures. To this end, we designed a digital camera that allows independent exposure control over every pixel. We show that by temporally staggering pixel exposures (“coded staggered exposure”; CSE), we can accurately capture GEVI signals free of aliasing even with sub-Nyquist, per-pixel sampling rates. Using the CSE image sensor, we imaged and resolved 1KHz-equivalent membrane voltage activity using a sampling rate < 200 Hz and pixel integration time > 5 ms. Further, we show that CSE outperforms global pixel exposure used in conventional CMOS cameras, especially at higher noise levels typically seen in miniature, head-mounted microscopes that are not actively cooled. Our CSE image sensor is implemented using a 180nm CMOS image sensor process and contains 240 x 352 pixels with a 7um pixel pitch occupying an area of 5 x 4 mm. The CSE image sensor is fully integrated and achieves pixel exposure staggering without, for instance, external optical modulation. Thus it can be used directly in place of a standard image sensor in both head-fixed and freely moving animal experiments.

Title: Www.3photon.org provides information about 3-photon excitation.

Authors: *J. WATERS;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Much like 2-photon microscopy, 3-photon microscopy uses IR pulsed laser light to drive multiphoton excitation. 3-photon excitation extends the maximum imaging depth towards 2 mm, considerably deeper than is possible with 2-photon excitation. We explored the depth limit of 2-photon microscopy, building a microscope that performed near-simultaneous 2- and 3-photon excitation and thereby enabling a direct comparison of 2- and 3-photon images. Two-photon and three-photon results from superficial locations were almost identical, with the tuning properties from neurons in V1 being indistinguishable. Two-photon results were inaccurate beyond ~450 um in mice with dense GCaMP expression, shallower than predicted by calculations. Information on our microscope design, and much more information about 3-photon microscopy, is available at www.3photon.org. One of the main purposes of www.3photon.org is the provision of information on the key differences between 2- and 3-photon excitation, to facilitate adoption of 3-photon excitation. 3photon.org pulls together information from the literature about - the properties and limits of 3-photon excitation - fluorophore cross-sections - microscope components - pulse shape, dispersion and dispersion compensation - data sets and software tools - publications - the latest advances Our results and the information available at www.3photon.org compare the performance of 2- and 3-photon excitation *in vivo* and provide information to facilitate the adoption of 3-photon excitation.

Genomics/Computational Biology, Thomas Jefferson Univ., Philadelphia, PA; [4]Neurol., Kings County Hosp., Brooklyn, NY

Abstract: Neurons in the right atrial ganglionic plexus (RAGP), a component of the intrinsic cardiac nervous system, mediate vagal modulation of the SA node. RAGP neuron anatomical, electrophysiologic, and molecular properties have been studied in vitro in rat and mini pig. We used transcriptomic data to inform single-compartment computational models of RAGP neurons. We created neuronal models of phenotypically distinct neurons from genes coding for ion channels in the RAGP as identified in a transcriptomic map generated from qPCR and RNAseq for 405 single RAGP principal neurons in mini pig. We mined the transcriptomic data to identify ion channels encoded by expressed genes and evaluated kinetic models using Hodgkin-Huxley formalisms available on Ion Channel Genealogy, Channelpedia, and ModelDB. From the transcriptomics, we identified 115 unique cell types defined by different combinations of 12 ion channels including Naf (*Scn1a*), KDR (*Kcnc1*, *Kcna1b1*), P-, L-, N-, and T-type Ca^{2+} (*Cacna1a*, *b*, *c*, *g*, *i*), and *HCN1*, *HCN2*, *HCN3*, and *HCN4*. Conductance values in the RAGP neuronal models were optimized to generate realistic firing responses to a current clamp. Across 3 parameter sets and a range of current input values, 5 cell responses were observed: subthreshold, single-spike phasic, tonic, and tonic (i) during stimulus and (ii) continuing post-stimulus, consistent with published experimental data on RAGP neurons in rat. Pooling responses across parameter sets, at 0.5 nA 47.0% (162/345) were single-spike phasic, 27.5% (95/345) tonic with 0.6% (2/345) brief and 2.3% (8/345) sustained post-stimulus; at 0.8 nA 47.0% were phasic, 28.1% tonic with 0% brief and 2.3% sustained post-stimulus; and at 1.0 nA 47.0% again were phasic, 23.0% tonic with 3.5% brief, 3.5% sustained. Overall, we found that multiple transcriptomically distinct neuronal models generated a limited repertoire of cell responses. We next aim to simulate networks of these neuronal models, incorporating anatomic and neuromodulatory data collected earlier to help elucidate the role of RAGP in the pacemaker function of the heart.

Abstract: Bladder dysfunction stemming from aging, trauma, surgery, or disorders of the nervous system impairs the quality-of-life and productivity of millions of individuals. Lifestyle changes and pharmaceuticals are often insufficient to resolve bladder dysfunction; therefore, neurostimulation-based approaches are of particular interest. The pudendal nerve, which forms from the S2-S4 spinal nerve roots and innervates the genitals, perineum, urethra, and anal sphincter, is the target of one such emerging neuromodulation technique that may ameliorate bladder dysfunction. Pudendal nerve stimulation has been examined extensively in preclinical studies. However, there have been few studies of direct nerve stimulation in patients and little is understood about variations in effectiveness and outcomes across patients. The present work aims to investigate pathway activation during pudendal nerve stimulation through the use of patient-specific computational models of human participants receiving pudendal nerve stimulators. Specifically, we developed volume conductor models of participants' pelvic anatomy by segmenting magnetic resonance and computed tomography images. We assigned physiologically appropriate electric conductivities to the various tissue domains of the volume conductor models and used the finite element method to predict the potential fields generated by the stimulation. To estimate the neural response to stimulation, we applied the potential fields to multi-compartment cable models of axons spatially arranged so as to approximate the nerve's course, branching, and fascicular topology. Our results characterized relative recruitment of the genital, perineal, and rectal fascicles of the pudendal nerve in the participant population during pudendal nerve stimulation. Furthermore, our models demonstrated recruitment differences for different stimulation configurations and pulse widths. In future work, we will utilize these models to establish theoretically optimal stimulation parameters that maximize excitation of targeted fascicles and minimize excitation of off-target fascicles. We believe that this patient-specific modeling approach will help increase the clinical efficacy of pudendal nerve stimulation for treating bladder dysfunction.

Title: Sparc- analysis of individual-specific computational models of vagus nerve stimulation (vns) in humans, pigs, and rats

Authors: E. D. MUSSELMAN, N. A. PELOT, W. M. GRILL;
Duke Univ., Durham, NC

Abstract: Preclinical studies show promise to expand use of VNS to treat a range of diseases and disorders beyond epilepsy and depression, but translation of therapies across species and to the clinic remains a challenge. Computational modeling of nerve responses to VNS is a valuable tool to facilitate translation of stimulation parameters by accounting for differences in nerve and electrode geometries. We used our ASCENT (Automated Simulations to Characterize Electrical Nerve Thresholds) pipeline to model stimulation of human (n=9), pig (n=12), and rat (n=9) cervical vagus nerves. ASCENT created a finite element model of each nerve, cuff electrode, and surrounding tissue in COMSOL to calculate the extracellular potentials. ASCENT simulated the responses of mammalian myelinated fibers (10 μm MRG) to electrical stimulation (100 μs/phase biphasic pulse) in NEURON by applying the time-varying extracellular potentials. We used linear regression and principal component analysis to determine how thresholds of activation related to features of nerve geometry across our population of VNS models.
Thresholds to activate model myelinated axons were ~4x higher in humans than in pigs, and humans had ~20% higher coefficient of variation (CV) than pigs. Thresholds in rats were ~23x and ~7x lower than in humans and pigs, respectively, and rats had ~5x lower CV than pigs. Fascicle size and distance from outer epineurium surface were positively correlated with threshold (R = 0.7 and 0.36, respectively), and fascicle number negatively correlated with threshold (R = -0.65). The first principal component accounted for ~36% of the variability in threshold and included large weights for terms corresponding to fascicle characteristics (i.e., number and size of fascicles, proportion of cross section occupied by perineurium), the second accounted for ~24% of the variability and included large weights for terms corresponding to proportion of nerve occupied by endoneurium and epineurium, and the third accounted for ~18% of the variability and included large weights for terms corresponding to nerve size and fascicle distance to the outer epineurium surface.
Our models highlight the utility of ASCENT to create models of VNS for individual-specific nerves in response to stimulation. We demonstrate an approach to model-based analysis that revealed how nerve characteristics affect fiber response to stimulation. Mean activation thresholds and their CV increase from rats to pigs to humans. A fundamental understanding of how individual-specific nerves respond to a set of stimulation parameters will enable innovations to target selectively fiber responses.

Title: Sparc: closed-loop optimization of vagus nerve stimulation for the cardiovascular system using long short-term memory neural network

Authors: A. BRANEN[1], Y. YAO[2], M. V. KOTHARE[2], B. MAHMOUDI[3], *G. KUMAR[4]; [1]Chem. and Biol. Engin., Univ. of Idaho, Moscow, ID; [2]Chem. and Biomolecular Engin., Lehigh Univ., Bethlehem, PA; [3]Emory Univ., Atlanta, GA; [4]Chem. and Materials Engin., San Jose State Univ., San Jose, CA

Abstract: Introduction: Cardiovascular diseases are the leading cause of mortality in the United States and remain a major health risk worldwide despite several pharmaceutical treatments, thus motivating a search for alternative therapies. Recently, vagus nerve stimulation (VNS) has been identified as a potential therapy for the treatment of cardiovascular diseases. A particular challenge preventing the application of VNS as treatment involves selecting the optimal stimulation parameters for a desired physiological response. A potential solution involves using physiological measurements as feedback to guide the VNS parameter selection in a closed-loop formulation.
Methods: In this computational work, we have developed an optimal closed-loop model-based control approach using a machine learning model that could be used to optimize the VNS parameter selection in a closed-loop sense. Specifically, we used a recently published biophysical computational model of a rat cardiac system to generate a synthetic input-output time-series dataset consisting of the VNS frequency and pulse width as the inputs and the heart rate and the mean arterial blood pressure as the outputs. Next, we trained a long short-term memory (LSTM) neural network using the synthetic data and used the trained model in a closed-loop model predictive control (MPC) framework to optimize the VNS parameters. The LSTM-based controller was used to control the heart rate and the mean arterial blood pressure of the full physiological system model. To provide additional context, we investigated the choice of the cost function, the controller design parameters, and the effect of model-mismatch on the overall closed-loop performance.
Results: Our simulation results show that the designed controller can drive the heart rate and the mean arterial blood pressure to the desired physiological set-points under various conditions. Additionally, our simulation results illustrate how various choices of the cost function in the closed-loop control formulation impact the selection and design of VNS parameters for the same

set-points.
Conclusions: We have developed a model-based closed-loop control approach using a data-driven machine learning model (LSTM) to optimize the VNS parameters for controlling cardiovascular physiology, thereby making the technique potentially suitable for use with real data.

The intrinsic cardiac nervous system (ICNs)is a local, integrative neural circuitry system which mediates the vagal control of the heart. Accurate characterization of these neurons requires a

comprehensive quantification of their physical spatial distribution on the heart as well as their molecular and cellular properties (e.g., neuromodulator and neurotransmitter expression). We have developed an aspatial framework which allows for integrating various data on individual ICNwithinacommon3Dcoordinate system known as a scaffold. The scaffold is generated from a semantic description of connected, simple-shaped elements to follow the features of the heart tissue from different subjects. The general shape of the scaffold is algorithmically generated as an *in vivo* representation of the organ which can be mathematically morphed into subject-specific configurations. Data for this study include high-resolution image stacks from isolated rat and porcine right atria allowing comprehensive annotation and 3Dmapping of corresponding subsystems of ICN. Our scaffolds are able to accurately capture the spatial distribution of these data and provide a framework to compare and analyze the variability between subjects and species. Our framework canbe generalized for application to human heart and ICN, for accelerating development of neuromodulatory therapies totreat heartdisease.

Title: Sparc: control-core: a platform for closed-loop peripheral neuromodulation control systems

Authors: P. KATHIRAVELU[1], M. ARNOLD[2], P. SARIKHANI[1], S. AWASTHI[3], S. MURPHY[2], J. FLEISCHER[2], Y. YAO[2], M. KOTHARE[2], ***B. MAHMOUDI**[1];

Abstract: CONTROL-CORE is a multi-university project to develop a platform for designing closed-loop neurostimulation control systems to treat conditions affecting internal organs. It facilitates modular simulation and deployment of closed-loop peripheral neuromodulation control systems and is part of the larger SPARC project (DAT-, MAP-, and SIM-CORE). SIM-CORE has simulations on O2S2PARC of Physiological Models (PMs), which are abstractions of the behavior of organs under electrostimulation. CONTROL-CORE represents a fourth leg to the SPARC portfolio (closed-loop control algorithms for peripheral stimulation therapies) by

allowing the interaction between a controller and the PM, previously not feasible in SIM-CORE.The CONTROL-CORE protocol, known as concore, allows modular simulation of controller and PM nodes to run on different platforms, including O2S2PARC, local (Windows, macOS, or Ubuntu), Docker, and distributed implementations. Concore works with several languages (such as Python, Matlab, C++, and Verilog) so that the developers code in their preferred language(s). The local implementations allow developers to use concore to create simulations from source code with appropriate tools installed locally (e.g. Matlab license). The Docker implementation allows nodes to be containerized so that others may reuse them without manual installation, configuration, source code, or a Matlab license. The distributed implementation communicates via the internet through "wrappers" so that a controller can be local while the PM can be remote (e.g. running on O2S2PARC). Eventually, the controller will run on an embedded processor or custom circuit implanted in an animal experiment or a patient. Since the PM may be computationally intensive and/or may only be available on specific platforms (such as O2S2PARC), it would be desirable to test such a controller on a limited-resource machine while running the more computationally intensive PM on a different machine via an internet connection.We tested concore with cardiac PMs, including pulsatile and nonpulsatile rat models, and Model Predictive Control (MPC), Reinforcement Learning (RL), and Long-Short-Term Memory (LSTM) based controllers. The time to simulate one cardiac cycle in a local implementation is about 0.1 seconds, and in a distributed implementation, a couple of seconds (faster than O2S2PARC).

Title: Sparc: a closed-loop control approach to vagal nerve stimulation (vns) of the cardiac system.

Authors: *O. ADEODU[1], Y. YAO[2], M. KOTHARE[2];
[2]Chem. & Biol. Engin., [1]Lehigh Univ., Bethlehem, PA

Abstract: The lack of clarity in effective combinations of electrical stimulation parameters and inherent variability across patients have been put forward to explain the mixed outcomes from

clinical studies that explored vagal nerve stimulation (VNS) as an alternative treatment for a variety of cardiovascular diseases. Conceptually, a closed-loop formulation of VNS can resolve these issues. In this work, we report a computational study of the application of control theory to the design of optimal, closed-loop VNS regulation systems that automatically adjusts the amplitude and frequency of electrical stimulation, based on feedback measurements. We utilize a detailed model of the human cardiac system (Park et al. 2020)) that features pulsatile blood flow through the cardiovascular system and a multi-input, multi-output baroreflex system for the autonomous regulation of sympathetic and parasympathetic activity. To close the VNS control loop, we rely on the results of computational experiments that model the interaction of physiologically and externally induced action potentials within the vagal nerve. In addition, the distinct sensitivities of the afferent and efferent fibers within the vagal bundle to stimulation amplitude are also exploited in the design of the control algorithm. With suitable approximations to reduce computational complexity, nonlinear model predictive control (NMPC) is demonstrated through simulation as a potentially viable, closed-loop VNS control strategy for the short-term mitigation of the effects of cardiac pathology. Hence, this study represents a first step towards the design of a computational tool for the development of closed-loop personalized neuromodulation therapies.

Abstract: Modulation of peripheral nerve activity is a promising tool for the treatment of multiple cardiovascular disorders such as arrhythmias, heart failure and hypertension. Multi-scale modeling of such neuromodulation allows to predict optimal disease treatment options and is an integral part of our collaborative multi-lab initiative funded by the NIH Common Fund program "Stimulating Peripheral Activity to Relieve Conditions" (SPARC). The goal of our project is to develop a predictive multi-scale neurocardiac simulator in order to understand autonomic control of the heart and reveal its fundamental mechanisms from atomic to organ system scale. At the molecular level, such neuromodulation by sympathetic and parasympathetic nervous systems is established at the neuromuscular junction by stimulating myocyte G protein-coupled receptor (GPCR) mediated signal transduction pathways with neurotransmitters like norepinephrine or acetylcholine. In this study we used atomistic structural modeling and molecular dynamics (MD) simulations to identify energetics and kinetics of neurotransmitter, G protein and β-arrestin interactions with key GPCRs at the neuroeffector junction, beta-1 and beta-2 adrenergic receptors (β_1AR and β_2AR) and type-2 muscarinic acetylcholine receptor (M_2R). We developed atomistic models of these proteins and their complexes in different conformational states using available structures and Rosetta structural modeling. These models were validated via molecular docking of βAR agonists norepinephrine and isoproterenol and MR agonists acetylcholine and carbachol followed by multi-microsecond-long all-atom MD simulations. State-dependent protein - ligand and protein - protein binding affinities and association / dissociation rates for those systems were estimated using enhanced sampling MD as well as implicit-solvent MM/PBSA and Brownian dynamics techniques. These quantities were used as parameters for our functional kinetic model of subcellular signaling in ventricular myocytes, which was able to predict rate of cyclic adenosine monophosphate (cAMP) production in good agreement with standard models and experiments. Furthermore, those models were integrated and used in cardiac tissue simulations, predicting effect of sympathetic and parasympathetic stimulation on heart rhythm in health and disease.

Title: Sparc: adaptive closed-loop control of vagal nerve stimulation for regulating cardiovascular function using deep reinforcement learning: a computational study

Authors: *P. SARIKHANI[1], H.-L. HSU[2], M. ZEYDABADINEZHAD[1], Y. YAO[3], M. KOTHARE[3], B. MAHMOUDI[1];
[1]Emory Univ., Atlanta, GA; [2]Georgia Inst. of Technol., Atlanta, GA; [3]Lehigh Univ., Bethlehem, PA

Abstract: Introduction: Vagal nerve stimulation (VNS) is actively being investigated for improving outcomes of multiple cardiovascular diseases by compensating for the dysfunction of the autonomic nervous system. Standard clinical approaches use exhaustive open-loop parameter search to determine proper stimulation parameters. However, open-loop testing is not efficient and there is a need for designing automated closed-loop control systems that continuously learn and adapt the VNS parameters to the underlying dynamics of the cardiovascular system, based on the physiological measures. We propose to leverage Reinforcement Learning (RL) techniques for designing adaptive VNS control systems that can learn from the interaction with the physiological systems. **Methods:** We used a pulsatile model of the integrated cardiovascular system and baroreflex regulation that predicted the nonlinear effects of VNS stimulation parameters (pulse width and frequency) in three locations on heart rate (HR) and mean arterial pressure (MAP) to design an RL-based VNS control system. Since the pulsatile model was computationally expensive, we used the pulsatile model to generate trajectories of HR and MAP values for 420000 randomly generated stimulation parameters and trained a temporal convolutional neural network (TCN) model as a reduced-order surrogate of the pulsatile model for computational efficiency. The mean squared error (MSE) of the TCN model on an unseen test set in single-step predictions was 0.000132 and the computations were 5.5 times faster than the pulsatile model. We designed a RL agent using the proximal policy optimization (PPO) algorithm to learn a generalized VNS control policy for regulating HR and MAP states based on closed-loop interaction with the TCN model in python. **Results:** The RL agent observed the current (HR-MAP) state at time t and took an action, i.e. delivering VNS with the parameters defined by the control policy. The TCN model returned the next state and a measure of reward at time step t+1 in response to the RL action. We used the squared exponential reward function for training the policy to simultaneously regulate HR and MAP to a desired set-point. The RL agent converged in 2000 episodes, where each episode included 500 cardiac cycles. We tested the performance of the RL agent in a set-point tracking task for three different set-points for HR and MAP for the duration of 100 cardiac cycles for each set-point. The RL agent achieved an average reward of 0.9521 and MSE of 0.0011 in this set-point tracking task. **Conclusion:** Our results show the feasibility of designing adaptive learning VNS control systems for regulating cardiovascular function using RL techniques.

Title: Customized SPARC transmission electron microscopy (TEM) tools for mapping of the autonomic nervous system and to guide new neuromodulation strategies

Authors: *N. P. BISCOLA[1], P. M. BARTMEYER[1], N. ZHANG[3], L. A. HAVTON[2,4]; [1]Neurol., [2]Neurol. and Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]David Geffen Sch. of Med. at UCLA, Los Angeles, CA; [4]James J. Peters Veterans Affairs Med. Ctr., Bronx, NY

Abstract: Detailed ultrastructural analysis and mapping of fibers and circuitry in the autonomic nervous system is important to identify new therapeutics for neuromodulation. We have developed customized transmission electron microscopy (TEM) analytical tools, including a correction factor approach to determine fiber size in oblique planes (Bartmeyer et al., Scientific Reports, 2021) , spatial distribution of fibers, and neuronal tracers and neurotransmitters by immunogold TEM. Nerve cross-sections do not provide images of perfectly rounded shapes of myelinated and unmyelinated axons. To better approximate and be closer to the real size of structures, we developed a mathematical approach based on the area and perimeter of an ellipse to determine morphometric parameters such as fiber diameter, axon diameter, myelin thickness, and g-ratio. The spatial distribution analysis provides additional descriptions of the nerve composition by considering the 2D position of each axon. Our statistical approach calculates the distance between the axon centroids and the center of the nerve and the distance between the axon centroids and the closest nerve epineurium. By crossing information from the initial dataset (area, diameter, myelin thickness, g-ratio of each axon) and the distance measurements, statistical tests verify if the axon population is evenly distributed or clustered within the nerve. Pre- and post-embedding immunogold detection techniques allows for the identification and characterization of neuronal tracers and neurotransmitters in the nervous system. Collectively, our integrated approach for TEM studies, with the introduction of our new analysis tools, allows for the identification of subsets of autonomic fibers with information relevant for the development of selective stimulation strategies. Furthermore, the implementation of standardized sampling techniques, for TEM data collection across multiple animal models and humans, and consideration of sexual dimorphism will promote increased rigor and reproducibility to guide new strategies for neuromodulation.

Title: Untangling the Graph Structure of Drosophila Brain Datasets with Open Source FlyBrainLab Utility Libraries

Authors: A. A. LAZAR, M. K. TURKCAN, ***Y. ZHOU**;
Columbia Univ., New York, NY

Abstract: We present a set of open source utility libraries written in Python to facilitate the exploration of the graph structure of fruit fly brain circuits from raw, large-scale connectomics and synaptomics datasets. The utility libraries are native in the interactive FlyBrainLab computing platform [1]. The main goal of these libraries is to extract the hidden circuits embedded in the connectome/synaptome, and to facilitate visualization of discovered circuit patterns. The utility libraries provide a large variety of tools, including algorithms for the discovery of connectivity clusters and patterns, acquiring morphometric measurements of neurons, 2D visualization of pathways as circuit diagrams or as 3D morphological views. These are described in more detail below.
The NeuroGraph library offers a set of tools to discover and analyze connectivity patterns between neuron groups of a given circuit. NeuroGraph provides an interface to connectomics datasets for the analysis of connectivity dendrograms, community detection algorithms, algorithms for investigating network controllability and comparison algorithms against random connectivity; in addition, it provides approaches to automatically generating 2D circuit diagrams. The NeuroEmbed library provides a group of algorithms for the discovery of graph embeddings into low-dimensional spaces. These feature representations provide a means for connectivity-driven cell type classification with and without morphometric features, a means to search for neurons similar to a given group of neurons with morphologically distinct but similar connectivity features. To standardize these capabilities, the library includes automated user-verifiable benchmarks for comparison of embedding algorithms on clustering and classification tasks.In addition, we provide three more libraries: (i) NeuroMetry that allows users to generate morphological measurements for neurons, (ii) NeuroSynapsis that facilitates retrieval and specification of circuits as well as statistical analysis of synaptomics data, and (iii) NeuroWatch

that provides additional utilities for 3D visualization of neurons and synapses in the FlybrainLab environment.
With examples focusing on multiple Drosophila neuropils including the antennal lobe, central complex and lateral horn, we reveal how our libraries can be used to uncover the functional logic of brain circuits. All libraries are available open source and can be found at https://github.com/FlyBrainLab/FBLClient.

Abstract: Mesoscopic analysis of single neuron reconstruction from fluorescence micro-optical sectioning tomography (fMOST) is at the frontier of cell census studies of the mouse brain. fMOST imaging allows for sub-micron, 3D localization of individual neurons, enabling the study of cell morphology and connectivity in the whole brain. The Allen Common Coordinate Framework (CCF) [https://atlas.brain-map.org/] is a standard atlas space intended to allow mouse data from different specimens and modalities to be normalized, and then studied in tandem with over 400 manually annotated brain structures. However, accurate alignment of fMOST data to the CCF for group-level analysis remains an open challenge mainly due to modality differences and morphological changes during specimen preparation, which result in significant difficulties when establishing correspondences to analogous structures in the CCF. We introduce an approach for aligning individual fMOST images into the CCF using an intermediate, symmetric 25um isotropic fMOST atlas space constructed by applying the unbiased population-specific template algorithm (Joshi et al., 2004; Avants et al., 2004) to 60 fMOST images from 30 unique specimens. A detailed canonical coordinate transform is

established between this fMOST atlas and the CCF using 14 expert-generated annotations with matching correspondences in both atlases. Individual fMOST volumes are registered to the CCF in two phases: first the fMOST image is aligned to the fMOST atlas space using a standard deformable registration model, with minimal manual intervention. The resulting transformation is composed with the transformation between the fMOST and CCF atlases to establish the direct transformation between each fMOST image and the CCF. Preliminary analysis of our alignment shows that the large morphological expansions in the ventricles and between the cortex and the midbrain, characteristic of fMOST images, can be successfully collapsed into the corresponding structures in the CCF. Dice's coefficient was used to evaluate the overlap of the expert annotations after alignment. We found a high overlap of 0.98 for overall brain and ventricular morphology, and modest overlap for key structures, including the fimbria (0.62) and optic chiasm (0.77). Accurate alignment of individual fMOST data into the CCF establishes transformations that can be used to map single neuron reconstructions from different mice into the CCF for group level-spatial analysis. Our framework frontloads the manual intervention required for this alignment into a one-time atlas-to-atlas alignment while reducing individual fMOST alignments into simpler, mono-modality tasks.

Title: Manifold learning to capture brain-state trajectories in fMRI

Authors: *E. L. BUSCH[1], J. HUANG[2], A. BENZ[3], T. WALLENSTEIN[2], G. LAJOIE[7,8], G. WOLF[7,8], S. KRISHNASWAMY[4,2,5], N. B. TURK-BROWNE[1,6];

Abstract: Brain activity as measured with fMRI gives the illusion of intractably high dimensionality: densely-sampled data, rife with biological and collection noise. However, the intrinsic dimensionality of brain activity is far lower than its measurement dimensionality due to informational redundancy of individual voxels within and across regions and networks.

Accordingly, dimensionality reduction has yielded key insights into the neural dynamics of individuals and groups. Common approaches rely upon rudimentary linear algorithms, which neglect nonlinear interactions among the neural signals underlying fMRI activity. Here we use manifold learning to project fMRI data into a lower-dimensional space, where the dimensions of the space represent dominant functional activation patterns within a region of interest. We compare manifolds learned with PHATE, a cutting-edge diffusion-based algorithm designed to preserve both local and global signal structures, to conventional dimensionality reduction methods. In two fMRI datasets collected during naturalistic viewing, PHATE models reveal trajectories through brain states that reflect dynamic representations of complex stimuli. These trajectories correspond with aspects of the task that vary over the course of the experiment better than fMRI activity modeled in linear dimensions, indicating that dominant signals measured with fMRI encoding dynamic information arise from nonlinear interactions among neural populations. We probe this hypothesis further by adding a second affinity measure to PHATE to explicitly model the transitional probability between pairs of brain states, which we term *transitional PHATE* or T-PHATE. We evaluate the quality of manifold representations by quantifying the correspondence between each subject's fMRI timeseries within the manifold and aspects of the task they performed, including narrative trajectories, event segments, and visual stimuli. Manifolds learned by T-PHATE reveal trajectories through brain states which, when projected into as few as 3 dimensions, robustly represent local stimulus content and global narrative arcs. Across datasets and classification metrics, T-PHATE improves stimulus decoding accuracy relative to other dimensionality reduction methods and voxel-resolution data. These findings indicate that nonlinear manifolds can better model fMRI data than linear manifolds or voxel-resolution data, and by utilizing nonlinear manifolds, we can overcome much of the informational redundancy and noise associated with fMRI. The characteristics of these manifolds could in turn inform theories about the nature and dynamics of human brain function.

Title: Large scale modeling and data processing and software dissemination using the Neuroscience Gateway

Authors: *A. MAJUMDAR[1], S. SIVAGNANAM[2], K. YOSHIMOTO[3], N. T. CARNEVALE[4], M. KANDES[3], S. YEU[3];
[1]Univ. of California San Diego, La Jolla, CA; [2]San Diego Supercomputer Ctr., UCSD, La Jolla, CA; [3]San Diego Supercomputer Center, UCSD, La Jolla, CA; [4]Neurosci., Yale Univ. Sch. Med., New Haven, CT

Abstract: The Neuroscience Gateway (NSG) enables neuroscientists to run large scale models and process experimental data using high performance computing (HPC) and high throughput computing (HTC) computing resources. Computational modeling of cells and networks has become an essential part of neuroscience research, and investigators are using models on HPC resources to address problems of ever increasing complexity, e.g. large scale network models and optimization or exploration of high dimensional parameter spaces. Similarly processing of experimental data (EEG, MRI, fMRI etc.) increasingly require compute power of HTC. NSG democratizes computational and data processing neuroscience research by providing open and free access to HPC and HTC resources located at academic supercomputer centers in the US. NSG lowers or eliminates the administrative and technical barriers that make it difficult for investigators to use HPC and HTC resources. NSG has been in operation since early 2013. It provides around 15 neuroscience modeling and data processing software on HPC and HTC resources. It currently has about 1300 registered users. NSG has recently been integrated with the Open Science Grid (OSG) suitable for distributed HTC. We have also demonstrated a preliminary capability of NSG job submission to AWS cloud resources where the NSG jobs use the "cloudbursting" features of supercomputers to send jobs to AWS resources. Recently added new features to NSG include (i) transfer of large data directly to NSG's backend storage (in addition to be able to upload small input files via the web interface), (ii) sharing of data with other NSG users and their collaborators, (iii) processing publicly shared data by multiple users etc. Another new NSG feature is addition of a software development platform where neuroscience software developers get direct access and which provides a neuroscience software stack. Neuroscientists can use this platform to develop, benchmark, and scale their software. Robust software can be made available in containerized or cloud image form for dissemination either via NSG or otherwise for the neuroscience community. We have added a software repository and a web front end which provides detail information about the software such that users can use the software on NSG or their computing resources of choice such as commercial cloud. NSG is increasingly used in workshops, training classes and classroom teaching. Since its inception, NSG has enabled over 250 publications, presentations and thesis work.

Title: Accessible and explainable machine learning for behavioral neuroscientists

Authors: *J. CHOONG, S. NILSSON, N. GOODWIN, V. TSAI, S. GOLDEN;
Univ. of Washington, Seattle, WA

Abstract: Background. Computational neuroethology has become an important component of modern behavioral neuroscience that is still challenging to implement for many research labs. We recently released an open-source package called Simple Behavioral Analysis (SimBA), which provides behavioral classification and analysis based on pose-estimation tracking for the greater behavioral neuroscience community. The goal of SimBA is to decrease the threshold to adopt machine learning-based methods while increasing the transparency and explainability of machine-learning derived results. **Method.** With the most recent release (github.com/sgoldenlab/simba), SimBA supports the following main applications in an inclusive and intuitive graphic interface: (*i*) generation of standard descriptive statistics and region-of-interest analysis for many open-source post-estimation architectures, (*ii*) generation and use of supervised behavioral classifiers, (*iii*) streamlined unsupervised analysis of supervised behavioral epochs, (*iv*) enhanced explainability of both supervised and unsupervised models using SHapley Additive exPlanations (SHAP), and *(v)* real-time behavioral classification for closed-loop applications. SimBA is based on a modular design philosophy so that other open-source applications can easily be integrated for either SimBA data import or compatible data export. Extensive documentation is provided at simba-docs.readthedocs.io. **Results.** SimBA enables accessible discovery of multi-relational and sequential behavioral patterns in single or multi-animal environments through decision ensembles and popular dimensionality reduction and clustering techniques. SimBA includes a range of visualization tools and dashboards for explainable classifications and real-time interactive data plotting and analysis. **Conclusion.** Although nascent, computational neuroethological approaches are now more accessible for behavioral neuroscientists. An inclusive open-source community is currently growing to support these approaches and SimBA provides a dynamic development platform within these efforts.

Title: Toward Quantitative Modeling of Variations in Autism Spectrum Disorder from Movement Data

Authors: *A. ASSADI[1], B. G. TRAVERS[2], **A. ARDALAN**[3];
[2]Waisman Center, Occup. Therapy Program in Kinesiology, [1]Univ. of Wisconsin - Madison, Madison, WI; [3]Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

Abstract: Motivation - Prior work, including ours, has shown remarkable variation in the kinematics and balance outcomes for children with autism spectrum disorder (ASD), as well as significant variation in severity of ASD as measured by standardized test scores. Also, brain imaging indicates notable inter-individual variations. However, there is a paucity of quantifiable theoretical frameworks that account for the variations in brain and behavioral data, or explain the correspondence of the variations in these domains.
Thus, we develop a data-driven theoretical framework to organize variational parameters and ASD features. Researchers could use such a framework for articulating experimentally verifiable hypotheses, e.g. regarding the neural underpinnings of the behavioral features and their variations. We discuss the consequences of such a theoretical framework for organization of information from brain to behavior and their associations at multiple scales and resolutions.
Objectives - (1) Introduce a space-like quantifiable structure Q that captures variation in motor skills, social skills and cognitive flexibility from existing data, and allows incorporating future data in Q; (2) mathematically analyze Q and design algorithms for given data to be represented in Q.
Methods - (1) study movement data obtained from children with ASD while performing static Yoga and Tai Chi poses. We introduce a template T whose spatio-temporal changes captures the dynamics of human body movement, according to Gestalt principles and psychophysics. The dynamics of T corresponds to a physics-based simplification of the body movement dynamics. The variation in T yields a (moduli) space M which is the first approximation to Q. (2) utilize algebraic and differential geometry to construct auxiliary mathematical structures to enrich M as needed for inference about ASD variations from points, paths or other substructures afforded by M.
Results - Our framework provides a means for organizing historical experimental data (e.g. neuronal recording and imaging data) and localizing new experiments in M. This is possible by the existence of the push-forward metrics and moduli structures from Q to M. The correspondence between variation in motor performance and variation in neuronal dynamics makes it possible to unambiguously construct, among other artifacts, regression and classification models.

Title: Uncued Speech Decoding with MEG

Authors: *D. DASH[1], P. FERRARI[2], J. WANG[1];
[1]Univ. of Texas at Austin, Austin, TX; [2]Helen DeVos Children's Hosp., Grand Rapids, MI

Abstract: Uncued Speech Decoding with MEG
Debadatta Dash[1], Paul Ferrari[1,2], Jun Wang[11] University of Texas at Austin, Austin TX, USA[2] Helen DeVos Children's Hospital, Grand Rapids, MI, USA
Neural speech decoding paradigms aim to decoding speech directly from the brain at natural communication rates that can assist patients with locked-in syndrome (e.g. due to amyotrophic lateral sclerosis, ALS). This contrasts with current commercial brain-computer interface spellers that can be slow (10 words/minute). However, most speech decoding studies are based on time-locked cued speech stimuli that may be decoding task effects rather than the speech-motor activation. For example, yes/no stimuli are very common in speech decoding studies but whether what's being decoded is the speech activity or the positive/negative brain state information associated with the task context, is not well known. To address this challenge, we collected magnetoencephalography (MEG) data in 7 subjects as they randomly spoke yes or no (~80 trials per word) at a self-paced rate in the absence of any cue, and present our analysis strategy for decoding speech information directly from the MEG signals. MEG has proven effective in tracking and decoding speech information in real-time due to its excellent temporal resolution. We extracted root mean square features form the MEG trials and trained a linear discriminant analysis (LDA) classifier with 4-fold cross-validation on train data to predict the labels (yes/no) from test data for each subject. Experimental results indicated that it is possible to decode uncued speech (yes/no) from the MEG signals with 79.02% ± 3.75% accuracy significantly higher than the chance level (1-tail t-test, $p<0.05$). The training cross validation accuracy was 83.09% ± 4.52%. This study demonstrates the efficacy of using MEG for uncued speech decoding and provides evidence for decoding speech activity rather contextual information.

Title: Synthesis of High-Resolution Research-Quality MRI Data from Low-Resolution Clinical MRI Data in Patients with COVID-19

Authors: *R. CALI[1], H. J. FREEMAN[1], B. BILLOT[4], D. B. FISCHER[5], W. SANDERS[1], M. BARRA[1], S. Y. HUANG[2], J. CONKLIN[3], B. FISCHL[3], J. IGLESIAS GONZALEZ[3], B. L. EDLOW[1];
[1]Neurol., [2]Neuroradiology, [3]Radiology, Massachusetts Gen. Hosp., Boston, MA; [4]Imperial Col. London, London, United Kingdom; [5]Harvard Med. Sch., Boston, MA

Abstract: Background/motivation: Neurological disorders are common in patients with coronavirus disease 2019 (COVID-19), but their underlying mechanisms are poorly understood. While hospitals worldwide are acquiring clinical MRI data in patients with COVID-19, these data lack sufficient resolution to perform cortical volumetric analyses that could provide critical insights into pathophysiologic mechanisms. Here, we apply a method for synthesis of high-resolution research-quality data from low-resolution clinical MRI data acquired in patients with COVID-19. We aimed to determine if synthesized images can be reliably used for cortical and subcortical volumetric analyses in these patients. Methods: We developed a joint super-resolution and synthesis method for generating 1 mm isotropic T1-weighted MPRAGE data from clinical MRI data of different orientation, resolution, and contrast. This method involves training a convolutional neural network (CNN) with highly diverse synthetic images generated from segmentations, which makes this technique (termed SynthSR) robust to changes in MR contrast, resolution and orientation of the clinical scans. We applied SynthSR to a dataset of nine critically

ill patients with severe COVID-19 scanned at our institution with both low-resolution clinical sequences, and a high-resolution, 1 mm isotropic T1-weighted MPRAGE sequence. We then synthesized images from the low-resolution data, and performed FreeSurfer-based cortical and subcortical volumetric analyses on both the synthesized and acquired MPRAGE. To measure the reliability of the synthesized data, we analyzed correlations between the volumetric measurements derived from each dataset.
Results: SynthSR successfully generated synthesized MPRAGE data for all nine patients. Correlations computed on cortical and subcortical volumetric measures were highest for global measures, including the cerebral cortex volume (r = 0.97), cerebral white matter volume (r = 0.92), and subcortical gray matter volume (r = 0.98), and lowest for the cerebellar white matter (r = 0.05 to 0.19). Conclusions: Synthesis of high-resolution images from low-resolution clinical MRI data creates an opportunity to examine thousands of clinical MRI scans acquired in patients with COVID-19 worldwide - scans that otherwise would not have sufficient resolution for such analysis. The SynthSR tool, which we distribute to the academic community at github.com/BBillot/SynthSR, can be used to support international collaboration in the study of COVID-19-related neurological disorders.

Title: Function and structure in cortical networks: using null models to interpret large-scale neural recordings

Authors: *A. SEDERBERG;
Univ. of Minnesota, Minneapolis, MN

Abstract: Modern recording technology enables the collection of vast quantities of neuronal data, permitting an unprecedented window on brain activity and the structural underpinnings of the circuits that generate this activity. Despite this volume of data, the number of parameters that would have to be specified to account for detailed structure-function relationships in cortical microcircuitry may be forever out of reach - and likely uninterpretable either way - necessitating alternative approaches to generate testable predictions for large-scale recordings across various

circuit structures, brain areas, individuals, and species. Moreover, determining which features of neural population activity dynamics (e.g., the structure of correlations in ensembles of cells; fluctuations in spiking rates; local field potential features) are generic features of a wide variety of network structures, and which are specifically tuned to particular systems, is a non-trivial task. Drawing on a series of recent papers [1 - 3], I suggest a roadmap for untangling the thorny relationship between structure and function across diverse neural recordings from a variety of species. Building a framework for extracting salient features of ensemble population dynamics that can be flexibly applied, I show how complex, multi-time scale dynamics can be identified across systems, and I connect these specific features in neuronal data to simple generative models. Thus, the interpretation of large-scale neural recordings requires the development of rigorous null models, with a natural starting point from (relatively) simple random-network models, with the aim of improving our ability to predict neural dynamics from structural information and vice versa. Title: A personalized cortical atlas, generated from individual subject voxelwise connectivity

Authors: *M. MOLLOY, D. E. OSHER;
The Ohio State Univ., Columbus, OH

Abstract: Functional connectivity, or the coactivations of resting state fMRI signal, varies by individual and has proven useful in describing brain organization. This macroscale organization has been described by a myriad of parcellation approaches based on various algorithms, modalities, and either group or individual approaches. However, the ‘best’ approach is unclear—the resolution and need for individualized methods likely vary depending on the research question. Here, we describe a parcellation method that integrates group and individual data and considers a range of resolutions using a large cohort from the Human Connectome Project (N = 1,018). We also describe solutions that approximate previous parcellations and identify resting state parcels that correspond with individual activity during tasks. First, we used the average high-resolution connectome from a subset of 500 individuals to find group-level parcellations using k-means clustering along a sequence of networks from 2 to 200. We found that the group-level solutions closely resembled major networks from previous group-level solutions reported in

Yeo et al., 2011. Second, we describe an unsupervised learning approach to calculate individualized parcellations based on a single subject's high-resolution connectome (from the remaining 518 individuals). Crucially, these individualized solutions are constrained by the group-level solutions and can thus be compared on a group-level while accounting for individual differences. Third, we identified group-level resting state parcels that closely matched individual task-based fMRI activity in motor, working memory, language, and high-level vision localizers. Individual task activity was defined using group-constraint subject-specific fROIs (Fedorenko et al., 2010), and we calculated the overlap between individual task activity and all previously identified individual resting state clusters. The motor-matched resting state parcels overall had the highest overlap with individual activity across subjects. These parcels were identified using the group of 500 individuals and replicated using the group of 518 individuals. Overall, we found that this parcellation methodology replicates previous group-level results, captures individual differences in functional connectivity at rest, and resembles an individual's task-based activity, particularly with motor localizers. Future work is necessary to decrease the computational load of these analyses, and to test the generalizability of these parcellations to other data and different cognitive tasks.
