Abstract: Neurogenesis is a multistep process that is involved in hippocampal-dependent cognition and behavior. The tumor suppressor gene phosphatase and tensin homolog deleted on chromosome ten *(Pten)* has previously been found to restrict the proliferation of neural stem/progenitor cells (NSPC) *in vivo*. In this study, we aimed to provide a comprehensive picture of how conditional deletion of *Pten* may regulate the genesis of NSPCs in the adult hippocampal dentate gyrus and subventricular zone lining the lateral ventricles, using gold-standard markers and quantification of the neurogenesis process. We quantified proliferating cells (Ki67+), neuroblasts/immature neurons (doublecortin [DCX+]), and apoptotic (cleaved caspase-3 [CC3+]) cells via stereology in dentate gyrus subregions (subgranular zone [SGZ], outer granule cell layer [oGCL], molecular layer, and hilus) in male and female mice at 4 weeks (N=6 each) and 10 weeks (N=5-6 each) of age. Our data demonstrate that conditional deletion of *Pten* in mice results in a transient and sequential increase in Ki67+ proliferating cells and DCX+ postmitotic neurons in the dentate gyrus, particularly in males. Specifically, we found that conditional *Pten* deletion in males initially increased Ki67+ cell number by 64% in the neurogenic SGZ at 4 weeks of age. These increases were not observed in female $Pten^{-/-}$ mice. However, by 10 weeks of age, the increase in Ki67+ cells spread to non-neurogenic dentate gyrus areas, including the hilus (988% increase), oGCL (273% increase), and molecular layer (150% increase). We also observed a transient increase (98% increase) in DCX+ neurons in male, but not female, $Pten^{-/-}$ mice at 10 weeks of age. In contrast, quantification of Ki67+ cells in the subventricular zone lining the lateral ventricles revealed a 53% decrease in $Pten^{-/-}$ mice compared to wild-type mice at 10 weeks of age. Together, our results demonstrate that loss of *Pten* results in age-, sex-, brain-region dependent increases in adult neurogenesis. Our work is consistent with the literature showing that *Pten* serves as a negative regulator of dentate gyrus neurogenesis but adds temporal and spatial components to the existing knowledge.

Title: Importance of thyroid hormones T3 for the development and activity of GnRH reproductive neurons

Authors: *C. QUIGNON[1], A. BACKER[2], H. BOW[2], S. WRAY[2];
[1]Ninds, Washington, DC; [2]NINDS, NIH, bethesda, DC

Abstract: Clinical studies have shown that thyroid disorders and alteration of thyroid hormone production by environmental endocrine disruptors (EDCs), have deleterious effects on reproduction. By acting in the brain on the hypothalamic component of the reproductive axis, abnormal levels of thyroid hormones can disturb sex hormones production, oestrus cycles or puberty onset, possibly leading to subfertility. Moreover, in animal models, endocrine disruptors and thyroid hormones have been shown to have long-lasting transgenerational effects with the maternal hormones influencing the development of foetal reproductive functions. Despite clear evidence of an interaction between the thyroid and reproductive systems, the effect of T3, the active form of thyroid hormones, on the GnRH neurons controlling reproduction, have been poorly studied. In this work we investigated how T3 functionally interacts with GnRH neurons and how abnormal concentration of T3 alters the migration of these neurons during development. Calcium imaging was used to study the direct effect of T3 on GnRH neuronal activity in an *ex vivo* nasal explants model. Acute administration of T3 was found to stimulate the activity of GnRH cells. Dual labelling of GnRH and thyroid hormone receptors (TR) showed that the GnRH neurons express both nuclear and membrane receptors. However, the use of an antagonist specifically blocking the TR nuclear receptors (1-850), didn't inhibit the T3 stimulatory effect while blockage of integrin αV/β3 membrane receptors (with cilengitide), prevented the T3-induced increase in GnRH neuronal activity. During development GnRH neurons migrate from the nasal placodes into the brain. We found that a 24hr treatment with T3 significatively increased the migration rate of the GnRH neurons in our *ex vivo* model. To assess the transgenerational effect of thyroid disruption on the development of reproductive axis, pregnant females mice have been treated with methimazole (MMI) during gestation to induce hypothyroidism. In E13 embryos, treatment with MMI didn't affect the distribution of the GnRH neurons along the migration tracks but it significantly decreased the general amount of GnRH neurons. Other stages of embryonic development will be studied to investigate this effect. Together these studies are the first to report a direct effect of thyroid hormones on GnRH neuronal activity, through the integrin αV/β3 membrane receptors and show that T3 can modulate the migration of GnRH neurons during development. These results will bring new

insights on how thyroid disruption by EDCs or thyroid diseases, especially during foetal development, can lead to long term reproductive defects.

Title: Radial glial cell basal endfeet mediate interneuron organization in the developing cortex

Authors: ***C.-F. LEE**[1], B. R. D'ARCY[2], C. M. MUSSO[2], L. J. PILAZ[2,6,7], D. L. SILVER[1,2,3,4,5]; [1]Dept. of Neurobio., [2]Dept. of Mol. Genet. and Microbiology, [3]Duke Regeneration Ctr., [4]Duke Inst. of Brain Sci., [5]Dept. of Cell Biol., Duke Univ., Durham, NC; [6]Dept. of Pediatrics, Sanford Sch. of Med., Univ. of South Dakota, Sioux Falls, SD; [7]Pediatrics and Rare Dis. Group, Sanford Res., Sioux Falls, SD

Abstract: Radial glial cells (RGCs) are neural progenitors that play an essential role in the development of the cerebral cortex. With a long basal process that extends towards the pial surface and apical and basal endfeet, RGCs' bipolar morphology serves as a scaffold to guide the radial migration of pyramidal neurons into different cortical layers. Yet, whether and how this distinct RGC morphology mediates the migration and positioning of interneurons in the developing cortex is largely unknown. Here, we focus on RGC basal endfeet, a subcellular compartment that resides in the marginal zone (MZ), one of the prominent routes taken by tangentially migrating interneurons. To uncover new roles for RGC basal endfeet in interneuron organization, we examine functions of proteins that we found are highly enriched in endfeet. We utilize siRNAs to knockdown the RhoGAP ARHGAP11A in mice and through live and fixed *ex vivo* and *in vivo* imaging, observe a significant decrease in RGC branching and basal process complexity. This disruption in morphology yields fewer interneurons touching the basement membrane within the MZ, while rescuing the morphology by localizing *Arhgap11a* to endfeet restores proper interneuron positioning. Genetic depletion of non-muscle myosin II heavy chain A (NM-IIA/MYH9) from RGCs largely phenocopies *Arhgap11a* mutants. Following dynein cytoplasmic 1 light intermediate chain 2 (*Dync1li2*) RGC knockdown, we observe an increase in RGC branching complexity and fewer interneurons within the MZ. In contrast, when endfeet are detached from the basement membrane in NM-IIB (MYH10) conditional knockout mice, we

observe a notable increase in the number of interneurons within the MZ. These findings demonstrate diverse roles for localized proteins in maintaining RGC integrity and non-cell autonomously mediating interneuron organization in the cerebral cortex. Our ongoing studies aim to interrogate the mechanism(s) underlying RGC-interneuron interactions, which can deepen our understanding of the cytoarchitecture of the cerebral cortex.

Title: Pro-neurogenic effects of Lilii Bulbus on hippocampal neurogenesis and memory

Authors: *H. PARK[1], W.-K. CHO[2], J. MA[2];
[1]KOREA INSTITUTE OF ORIENTAL MEDICINE, Daejeon, Korea, Republic of; [2]Korean Med. (KM)-Application Ctr., Korea Inst. of Oriental Med. (KIOM), Daegu, Korea, Republic of

Abstract: Lilii Bulbus, the bulb of tiger lily, has anti-oxidant and anti-tumorigenic properties. However, the effects of Lilii Bulbus on learning, memory, and hippocampal neurogenesis remain unknown. This study investigated whether water extract of Lilii Bulbus (WELB) affects memory ability and hippocampal neurogenesis. Behavioral analyses (Morris water maze and passive avoidance test), immunohistochemistry, cell proliferation assay, and immunoblot analysis were performed. WELB (50 and 100 mg/kg; for 14 days) enhanced memory retention and spatial memory in normal mice as well as in scopolamine-treated mice with memory deficits. Furthermore, the administration of WELB significantly increased the number of proliferating cells and surviving newborn cells in the dentate gyrus of the hippocampus in normal mice. We found that WELB has a pro-neurogenic effect by increasing the activation of brain-derived neurotrophic factor (BDNF)/cAMP response element-binding protein (CREB) and mitogen-activated protein kinase kinase/extracellular signal-regulated kinase (MEK/ERK) in the hippocampus. Moreover, we confirmed that WELB (100 and 200 μg/ml) significantly increased NE-4C and primary embryonic NSCs proliferation. Inhibition/knockdown of MEK/ERK blocked WELB-induced MEK/ERK phosphorylation and NSCs proliferation. Hence, MEK/ERK activation was required in WELB-induced NSCs proliferation. Our study demonstrates the first evidence for WELB promoting hippocampal neurogenesis and memory; pro-neurogenic activity may enhance brain plasticity, with implications for treating neurodegenerative diseases.

Title: Investigating the role of the deubiquitinase USP15 in the development of the murine cerebral cortex

Authors: *K. BURNS, P. AU, G. YANG;
Univ. of Calgary, Calgary, AB, Canada

Abstract: The cerebral cortex is involved in processing higher-order tasks such as thinking, learning, and understanding sensory input. The development of the cortex is an intricate and highly regulated process that is susceptible to changes or disruptions to protein expression levels. One class of enzymes which contributes to the proteostasis of cells are deubiquitinases (DUBs), which typically remove ubiquitin from targets and save them from degradation. DUBs have not been well studied in the context of brain development, but some studies have found they can play important roles in the brain. Our objective is to explore whether the DUB, USP15, plays a role in cortical development. Using quantitative real-time PCR and immunohistochemistry, we assessed USP15 expression levels in the developing cerebral cortex of male and female mice from embryonic day 12 (E12) to postnatal day 21 (P21) (n=3). We found that USP15 is expressed in the cortex throughout development, peaking at P3 and then reducing into adulthood. To address USP15 function, we performed in utero electroporation of embryos at E13, and five days later, neurons with ectopic expression of USP15 showed a significant alteration in their distribution across the cortex compared to control neurons ($n = 7$, $\chi^2=54.4$, $p<0.0001$), suggesting that USP15 impacts how cortical neurons migrate during cortical development. Interestingly, USP15 subcellular localization appears to be different amongst cell populations, with neural precursor cells having more cytoplasmic USP15 than migrating post-mitotic neurons. Correspondingly, changes to USP15 nucleocytoplasmic localization altered neuronal migration in the developing cortex. In conclusion, our study reveals that the nucleocytoplasmic localization of USP15 in newborn neurons is critical for their proper migration during cortical development.

Title: A BAIAP3 variant in males with pubertal failure: role of BAIAP3, a dense core vesicle protein, in the development and functioning of the hypothalamo-pituitary-gonadal axis

Authors: *M. AKRAM[1], S. WRAY[2];
[1]NINDS, NIH, Bethesda, MD; [2]NIH NINDS, NIH NINDS, Bethesda, MD

Abstract: Puberty is a crucial biological process leading to sexual maturation and reproduction. Puberty is controlled by the hypothalamo-pituitary-gonadal (HPG) axis, where secretion from gonadotropin releasing hormone (GnRH) neurons stimulates pituitary gonadotropes to release follicle stimulating hormone (FSH) and luteinizing hormone (LH), which subsequently activate the gonads. Any interruption in the development and/or regulation of the components of this axis may result in short-term or long-lasting dysfunction of reproductive axis such as delayed puberty and/or infertility. Delayed puberty in boys is defined as the deficiency of masculinization and increase in the volume of testes (testicular volume <4 mL) in combination with absent or low sperm count until 14 years of age. Notably, the genetic basis of delayed puberty in humans remains unknown in majority of the cases. Therefore, whole exome sequencing (WES) of genomic DNA was carried out on 6 male patients, over 18 years of age, exhibiting failed puberty. WES with bioinformatics analysis identified non-synonymous variants in 16 genes expressed along different pathways of the HPG axis which could cause failed male puberty. Out of 16 genes, 4 genes (*IL*17*RD*, *SPRY*4, *GNRHR*, *FLNA*) were previously reported to cause delayed puberty, 4 genes (*NPBWR*1, *SLC*17*A*6, *CACNA*1*B*, *CAPRIN*2) were expressed along the HPG axis but no mutations therein were reported to cause delayed puberty and 8 genes (*SRRM*4, *EFHC*1, *ERMARD*, *ATP*2*B*3,*BAIAP*3, *ADCY*8, *MAPK*6, *C*1*ORF*86) were novel candidate genes (Akram et al., 2022). To validate these novel genes, each one must be systematically examined along the HPG axis and subsequently perturbed in a model system. *BAIAP*3 (brain-specific angiogenesis inhibitor I-associated protein 3) was chosen due to its role in neuropeptide secretion and expression in cells in nasal areas during embryonic development, coinciding with the migratory route taken by GnRH neurons (Allen brain atlas). Microarray data showed expression of BAIAP3 increased as GnRH cells stopped migration. STRING analysis indicates connections of BAIAP3 protein with neuropeptides B (NPB) and W (NPW) and their receptor, NPBWR1. A mutation in *NPBWR*1 was also identified in this patient. Therefore, to determine the role of *BAIAP*3 gene in the HPG axis, expression of the protein will be examined in GnRH neurons as well as pituitary gonadotropes during pre- and postnatal development. Subsequently, *in vivo* and *in vitro* mouse models will be used to study the effect of WT and mutant/lack of *BAIAP*3 on the function of these important components of the HPG axis.

Title: Csde1 mediates neurogenesis via post-transcriptional regulation of cell cycle

Authors: *X. JIA, K. XIA, H. GUO;
Central South Univ., Changsha, China

Abstract: Autism spectrum disorder (ASD) represents a group of neurodevelopmental disorders with substantial genetic and clinical heterogeneity. We previously reported that disruptive variants in *CSDE1* increase ASD risk and interfere with neuronal development and synaptic transmission. However, whether and how CSDE1 regulates neurogenesis is still unknown. By analyzing a Csde1 conditional (Nestin-cre) knockout mouse model, we revealed that *Csde1* knockout results in defective neural progenitor proliferation and differentiation that manifests in number reduction of neurons in both deeper and upper layers. RNA-seq and CLIP-seq data implicated that Csde1 facilitate the transcription of multiple cell cycle genes including CDK6. RIP-qPCR further confirmed that CSDE1 regulate cell cycle genes by directly binding to the mRNA. By introducing BrdU incorporation experiment, we demonstrated that the cell cycles of neural progenitors were prolonged in *Csde1* knockout mice. Our findings demonstrated that *Csde1* mediates neurogenesis via post-transcriptional regulation of cell cycle network, which provide new insights into the neurodevelopmental roles of *Csde1*.

Title: Visualization of secretory events in GnRH neurons

Authors: *F. SHAFIGHI, S. WRAY;
Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: The hypothalamic-pituitary-gonadal (HPG) axis controls reproduction. According to the World Health Organization, fertility disorders affect millions of individuals worldwide. Potential dysfunction(s) leading to infertility can occur at one or more levels of the HPG axis. Within the hypothalamus, Gonadotropin-releasing hormone (GnRH) secreting neurons play a critical role in integrating extrinsic and intrinsic cues that regulate puberty, fertility, and sexual behavior. This population of neurons secretes GnRH in a pulsatile manner into the portal capillary system, activating gonadotropes of the pituitary gland to release luteinizing hormone

(LH) and follicle-stimulation hormone (FSH) which act on the gonads to regulate the reproductive function. Dysfunction of the GnRH neurons can cause a physiological 'domino' effect that subsequently leads to delayed onset of puberty, infertility, and other reproductive disorders. The secretory behavior of GnRH neurons is not well understood. To clarify how GnRH is released in a pulsatile fashion, we need to understand the cellular and molecular mechanisms involved. Thus, to visualize GnRH secretion, we are using an explant model that maintains many of the characteristic of GnRH cells reported in postnatal mice, including pulsatile secretion. The paradigm includes loading GnRH dense core vesicles (DCVs) with Neuropeptide Y - GFP fluorescent cargo using an AAV9 viral vector containing the GnRH-NPY-hGFP sequence. Preliminary data indicate that the NPY-GFP DCV tag was incorporated into GnRH cells. High resolution microscopy is being used to verify that expression of the tag is restricted to DCVs using DCV markers such as chromogranin A and carboxypeptidase E. Subsequently, we will visualize GnRH DCVs travelling down the axons to their terminals in situ under basal and kisspeptin (a peptide known to cause GnRH release in vivo) stimulated conditions. Delineating the mechanisms involved in GnRH neuropeptide secretion will facilitate our understanding of the physiology of these neuroendocrine cells, as well as provide candidate genes to screen in patients with reproductive dysfunctions.

Title: Anoctamin 1, a Ca^{2+}-activated Cl^- channel, regulates the proliferation of radial glia in the medial ganglionic eminence

Authors: *K. KIM[1], B. KANG[1], P. LEE[1], H.-Y. KIM[1], M.-S. KIM[1], U. OH[2], G.-S. HONG[1]; [1]Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Korea Inst. of Sci. and Technol. (KIST), Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of

Abstract: Development of the central nervous system (CNS) requires the fine regulation of neurogenesis and gliogenesis by ventral radial glia (vRG). In a previous study, we exploited high resolution RNAscope experiment to investigate the spatio-temporal expression patterns of *Ano1* during the neurogenic period in embryonic brain. The majority of *Ano1* transcripts was were highly expressed in *Fabp7*+ and *Sox2*+ vRGs of the medial ganglionic eminence (MGE) from E11.5 to E14.5. In the present study, we checked examined whether ANO1 controls vRG fate in

MGE during early- to mid-neurogenic period. A decreased ratio of EdU-positive cells was observed in *Ano1*-ablated MGE at E14.5. Furthermore, the immunostaining experiments revealed a the decreased population of GABAergic neurons in the cortex of *Ano1* KO mice at E18.55 as a consequence. However, the ratio of intermediate progenitors (IP) was shown to be increased whereas the ratio of RG did not changed in MGE of *AnoNO1* KO mice. We therefore suggestpropose that *Ano1* promotes vRG proliferation. and may switch drive vRG fate to a basal rather than apical progenitors during GABAergic neurogenesis.

Library, Taipei City, Taiwan; [6]Team Genet. and Develop. of the Cerebral Cortex, Imagine Inst., Paris, France

Abstract: The piriform cortex (PC) is a major cortical processing center for the sense of smell that receives direct inputs from the olfactory bulb. In mice, the PC consists of three neuronal layers, which are populated by cells with distinct developmental origins. One origin of PC neurons is the pool of Dbx1-expressing neural progenitors located in the ventral pallium at the pallial-subpallial boundary. Since the precise mechanisms of PC neuron development are largely unknown, we sought to define the distribution, timing of neurogenesis, morphology and projection patterns of PC neurons from the Dbx1 lineage. We found that Dbx1-lineage neurons are preferentially distributed in layer 2 and enriched in the ventral portion of the PC. Further, Dbx1 neurons are early-born neurons and contribute to most neuronal subtypes in the PC. Our data also revealed an enrichment of Dbx1-lineage neurons in the ventral anterior PC that project to the orbitofrontal cortex. These findings suggest a specific association between the developmental origin of PC neurons and their neuronal properties.

Title: Mct8 and dio2 regulate the transcriptional and cellular landscape of the adult mouse subventricular zone

Authors: *S. REMAUD[1], V. VALCÁRCEL-HERNÁNDEZ[2], P. VANCAMP[1], A. GUADAÑO[2];
[1]CNRS MNHN 7221, PARIS, France; [2]Inst. de Investigaciones Biomédicas Alberto Sols, Madrid, Spain

Abstract: Activated neural stem cells (NSCs) in the adult rodent subventricular zone (SVZ) generate new neuroblasts and oligodendrocyte precursor cells (OPCs). Increased intracellular levels of T_3 - the transcriptional active form of thyroid hormones (THs) - maintain NSC and progenitor renewal and promote NSC/progenitor commitment preferentially toward a neuronal fate. However, how regulators of the TH pathway regulate T_3 availability in SVZ cells and how this regulation affects neurogliogenic processes, is less understood. Here, we used adult *Mct8/Dio2* double knockout (*Mct8/Dio2* KO) mice to assess the role of the TH transporter monocarboxylate transporter 8 (MCT8) and deiodinase type 2 (DIO2). First, we characterized which cell types expressed *Mct8* and *Dio2* in the adult SVZ. Our single-cell RNAseq on dissected SVZs revealed that absence of both MCT8 and DIO2 dysregulated the SVZ cells' transcriptome and increased the proportion of neuroblasts. Immunohistochemistry confirmed increased neuron/oligodendroglial ratios in the adult SVZ. In addition, OPC differentiation into mature myelinating oligodendrocytes was impaired in the corpus callosum. *Ex vivo neurosphere assay* showed increased progenitor proliferation and hampered neuronal migration. Accordingly, migration of SVZ-generated neuroblasts is impaired along the rostro- medial stream in *Mct8/Dio2* KO, thus modifying the cellular architecture of the olfactory bulbs. The observed lowered neuronal integration in the olfactory networks was associated with compromising short-term olfactory memory and discrimination in *Mct8/Dio2* KO mice, showing that absence of both TH regulators functionally impaired SVZ-neurogenesis. In conclusion, MCT8 and DIO2 are pivotal in adult murine SVZ homeostasis and function. Further elucidating their precise function offers new targets to manipulate neurogliogenesis in several white matter diseases including multiple sclerosis and MCT8-deficiency.

Title: Neural stem cell division and ciliation in the embryonic cerebral cortex are disrupted by loss of abscission protein Cep55

Authors: *K. LETTIERI, K. MCNEELY, J. LITTLE, N. DWYER;
Cell Biol., Univ. of Virginia, Charlottesville, VA

Abstract: Proper proliferation of neural stem cells (NSCs) during development is essential for building an appropriately sized cerebral cortex. Defects to these processes can lead to lethal brain malformations such as microcephaly. Primary cilia play an important role regulating the cell cycle of these NSCs. Cilia are microtubule-based structures that protrude from the apical membrane of NSCs into the ventricle. They sense the extracellular environment and regulate signaling pathways. Moreover, primary cilia assembly and disassembly is coupled to the cell cycle. Before a cell can re-enter mitosis, the primary cilium needs to be disassembled to release the centrioles to form the mitotic spindle poles. After mitosis is complete, and during late cytokinesis (abscission), the primary cilia are reassembled. Cep55 is a scaffolding protein with an important role in cytokinetic abscission, required for efficient severing of the midbody in the intercellular bridge. It was also reported to localized to centrosomes. In humans, Cep55 mutations were shown to cause multiple brain malformations. Our previous analyses of *Cep55* knockout (KO) mouse brains showed that Cep55 localizes to the center of NSC midbodies, and promotes ESCRT-III recruitment and the timely disassembly of midbody microtubules. KO brains display many binucleate cells, but most NSCs can still complete abscission. In the brain, but not other tissues, cells that fail abscission activate p53-dependent apoptosis. This results in severe microcephaly, but preservation of normal body size (J. Nsci. 41(15):3344). To better understand how loss of Cep55 affects NSC proliferation, we asked whether primary cilia of NSCs were also affected. To address this, we assessed the primary cilia of embryonic cerebral cortex NSCs. Interestingly, cilia length and the number of biciliated NSCs were affected. In addition, we noticed enlarged apical endfeet (AE) of *Cep55* KO NSCs. To determine whether these enlarged AE were due to high levels of apoptosis, we blocked apoptosis by breeding *Cep55;p53* double KOs (dKO). However, blocking apoptosis did not rescue the large AE phenotype, but exacerbated it. Furthermore, the nuclei and cilia of these extra-large AE appear abnormal. Our data are consistent with Cep55 having an indirect effect on cilia due to its role in

abscission. Through this ongoing experimentation, we hope to gain further insight into how Cep55 function regulates proper NSC proliferation and brain growth.

Title: Expression patterns of Piezo1 in the developing mouse forebrain.

Authors: *H. KIM, P.-R. LEE, G.-S. HONG;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Malformation in cortical development disrupts excitatory/inhibitory neural circuits associated with psychiatric and developmental disorders. One of the key factors of cortical neural networks is fine regulation of neurogenesis. A variety of researches on embryonic development have documented important transcription factors and neurotrophic factors. However, there are still unanswered questions for the role of ion channels in embrogenesis and neurodevelopment. The recent emerging field of mechanobiology reveals that mechanical cues, such as cytoskeletal movements, shear stress and the forces exerted by neighboring cells, are regarded as important regulators for embryonic development. Piezo1, a mechanically-activated ion channel, is involved in NSC fate control and cell migration. However, its functional expression and the role during embryonic development *in vivo* remain unexplored. Therefore, to address this question, we conducted an RNAscope experiment to visualize the location of *Piezo1* with several embryonic neuronal/glial lineage cell markers. Furthermore, embryonic brain slice calcium imaging was performed to measure the functional expression of Piezo1. Our data demonstrates that Piezo1 mRNA is expressed in migrating interneurons and oligodendrocyte progenitor cells during the embryonic forebrain development.

Title: A tissue-engineered rostral migratory stream as an in vitro platform to investigate subventricular zone-derived neuroblast migration

Authors: *E. KRIZMAN[1,2], E. M. PURVIS[1,2,3], A. D. GARCIA-EPELBOIM[1,2], J. C. O'DONNELL[1,2], D. CULLEN[1,2,4];

Abstract: Brain injury can result in progressive neuronal loss that is exacerbated by the limited regenerative capacity of the central nervous system. The rostral migratory stream (RMS) facilitates neuroblast migration from the subventricular zone to the olfactory bulb throughout adulthood. Brain lesions attract neuroblast migration out of the RMS, but resultant regeneration is insufficient without intervention. Our lab has biofabricated a “living scaffold” that is implanted to enhance endogenous neuroblast migration from the subventricular zone to neuron-deficient brain regions. This approach utilizes the first biomimetic tissue-engineered RMS (TE-RMS), designed to leverage the brain’s natural mechanism for sustained neuronal replacement by replicating the native RMS to direct neuroblasts to distal sites of injury. Our previous work has characterized the structure of the TE-RMS fabricated from both rat and human astrocyte cell sources. In addition to a promising new strategy for endogenous neuronal replacement, the TE-RMS is a powerful tool to unlock previously unanswered questions about adult neurogenesis. Here, we focus on the *in vitro* applications of the TE-RMS. We report an improved method of TE-RMS fabrication that has augmented construct survival and stability compared to previous methods. Specifically, we fabricated TE-RMSs using 4 different custom-designed micro-channel architectures featuring concave, convex, and orthogonal wall geometries (n=27 per group). Excitingly, TE-RMSs successfully self-assembled in all 4 channel geometries, demonstrating that the TE-RMS can form in the presence of various topographical conditions. Fabrication in a rectangular channel geometry had the highest success rate and therefore this channel shape was selected for subsequent *in vitro* studies. We also demonstrate that we can harvest neural precursor cells (NPCs) from the SVZ of adult male and female rats and culture them as neurospheres that reliably express stem cell markers. Following loading of SVZ-derived neurospheres into the end of TE-RMSs, individual neuroblasts migrated out of the neurospheres

and throughout TE-RMSs toward “destination” co-cultures consisting of rat cortical neurons and astrocytes. Our tissue engineered system allows for the examination of maturation and integration patterns of SVZ-derived neuroblasts following migration through the TE-RMS and into destination co-cultures *in vitro*. Overall, the TE-RMS provides a unique *in vitro* platform to examine SVZ neuroblast migration and maturation, providing an avenue to investigate key chemical and molecular cues in these complex processes.

Abstract: Cerebral cortex folding represents an important evolutionary mechanism that is incompletely understood. Present evidence suggests that cortex folding is caused by two cellular mechanisms: (1) expansion of progenitor cells and (2) divergent radial migration of neurons. We have previously generated a mouse model (*Flrt1/Flrt3* DKO; del Toro et al., 2017) with sulci-like folding induced by divergent radial neuronal migration without expansion of progenitor cells. We have used this ‘cell migration’ model to ask if the two folding mechanisms synergize

and whether the expansion of certain types of progenitors leads to qualitatively different cortical folds. We report that increasing the length of the early cortical stem cell expansion phase by deletion of fibroblast growth factor 10 (FGF10) in the 'cell migration' model (*Fgf10/Flrt1/Flrt3*^{TKO}, we now call *Fgf10*^{TKO}) leads to cortical folding with increased penetrance and, importantly, with gyrus-like protrusions. Conversely, overproduction of intermediate progenitors by deletion of centrosomal protein 83 (Cep83) in the 'cell migration' model (*Cep83/Flrt1/Flrt3*^{TKO}, we now call *Cep83*^{TKO}) leads to cortical folding with increased penetrance and sulci-like appearance. These results indicate that expansion of progenitor cells and divergent radial migration of neurons synergize in vivo to induce cortical folding. They further show that expanding different types of progenitors can lead to qualitatively different folding, suggesting that the formation of gyri and sulci requires the timely expansion of distinct progenitors.

Abstract: Cellular-level histological data still remains the gold standard for studying the organization of developing human brains. Obtaining histological data from the whole fetal brain is currently sparse, primarily due to the challenges including the retrieval and acquisition of high-quality postmortem specimens and the difficulties in the subsequent processing of these brains due to its high-water content. Employing a technology-enabled high-resolution multimodal imaging pipeline consisting of postmortem MRI, blockface imaging, and high-

resolution histology, we characterize the developmental patterns of the fetal brain from 13 to 21 Gestational Weeks (GW) (n=5). The whole brain specimens were sectioned in the sagittal plane at 20µm thickness and stained for three series Nissl, Hematoxylin and Eosin and Immunohistochemistry (IHC). Our histological data, 13-15 GW, shows the appearance of early-stage sulcal roots, particularly on the mesial surface. We report the well-organized laminar organization of the sulcal roots, showing the transient developing layers from the ventricular zone to the marginal zone. We also describe the developing pattern of the radial glial processes with Glial Fibrillary Acidic Protein (GFAP) IHC, which shows a similar pattern of labeling, to other regions in the cerebral cortex, that do not have these sulcal roots. We show the progression of these early sulcal roots into the cingulate sulcus from 13-21GW, mainly due to the changing size of the lateral ventricles, and the increase in neuropil. Our results show a systematic progression of the developing brain and the primary sulci from 13-21 GW. The cellular-level dataset provides valuable comparative data for studying developmental delays and malformation in the developing human brain.

Title: Analysis of the role of YIPF5 in ER-export and Microcephaly

Authors: ***F. BRUNO**[1], M. ANITEI[1], D. DI FRAIA[1], M. SANNAI[1], I. MESTRES[2], T. DAU[1], A. ORI[1], F. CALEGARI[2], C. KAETHER[1];

Abstract: YIPF5 and SURF4 proteins are crucial for transporting the endoplasmic reticulum and the Golgi. YIPF5 mutations have been associated with primary microcephaly and neonatal diabetes. This study investigates the impact of YIPF5 depletion or mutation on cellular migration in vitro and in vivo. We utilized the IncuCyte system and a wound healing assay to observe wound density changes over a 15-hour live imaging acquisition period (n=3). We found that YIPF5 absence or mutation significantly affected cellular migration. Additionally, we conducted a proteomic analysis of Immunoprecipitated-YIPF5 to identify its interaction partners, and discovered that SURF4 strongly interacts with YIPF5, the finding was validated via WB and Immunofluorescence (IF).To investigate the influence of YIPF5 on neuronal migration, GFP-

tagged shLuciferase and shYIPF5 constructs were electroporated into E13 mouse embryos. EdU was injected at E14.5 to label dividing cells, and GFP-expressing neurons were visualized by immunostaining at E15.5. Cortical sections were treated with the EdU staining kit, and the distribution of GFP-positive neurons was examined via IF in the cortical plate (CP), three sections of the intermediate zone, and the Ventricular zone-Subventricular Zone. (n=6). Quantification of the percentage distribution of GFP-positive-shYIPF5 neurons in each cortical layer was compared to the shLuciferase control group. Intriguingly, the analysis revealed a significant increase in the number of YIPF5-knockdown neurons in the cortical plate (CP). This observation suggests an over-migration phenotype, indicating that YIPF5 depletion leads to abnormal migration of neurons into the CP. Secretome and cell-surface proteomics analyses reveal that YIPF5 regulates the ER exit of specific proteins essential for neurodevelopment, cell migration, and cell adhesion. The insufficient presence of these proteins at the plasma membrane due to YIPF5 depletion or mutation may contribute to dysregulated neuronal migration and associated phenotypes, such as microcephaly. The proteomic findings, combined with the in-utero electroporation experiments, highlight the crucial role of YIPF5 in regulating proper neuronal migration during cortical development. Our results provide compelling evidence of the YIPF5-SURF4 interaction and YIPF5´s involvement in neuronal migration. This study contributes to the understanding of the molecular mechanisms underlying proper cortical layer formation and emphasizes the potential implications of disrupted YIPF5-SURF4 interactions in neurodevelopmental disorders associated with aberrant neuronal migration, such as microcephaly.

Abstract: Autism spectrum disorder (ASD) is a highly heritable, heterogeneous neurodevelopmental disorder affecting 1 in 36 children in the US, with a male-to-female prevalence ratio of 4:1. The cerebral cortex, particularly the prefrontal cortex, which mediates social cognition and language, is abnormally enlarged in up to 20% of young patients with ASD who have the most severe symptoms, but normalizes by early adulthood. However, it is unclear to what extent macrocephaly or megalencephaly itself contributes to ASD. Recently, we have developed a unique mouse model of ASD with macrocephaly and social deficits by knocking in an ASD-associated point mutation in the abnormal spindle-like microcephaly-associated (ASPM) gene, a major determinant of brain size, particularly in the prefrontal cortex. Aspm knock-in (KI) mice show excessive embryonic neurogenesis with increased progenitor proliferation and cortical thickness resulting in macrocephaly between embryonic day 14.5 (E14.5) and postnatal day 10 (P10). Interestingly, macrocephaly normalizes around P50, similar to the time course of macrocephaly in human patients with ASD. Aspm KI mice also exhibit reduced density of inhibitory synapses at P10, which normalizes at P50. Importantly, male KI mice show deficits in the social novelty test, whereas female KI mice do not, suggesting sex-specific effects. We are currently investigating transcriptional abnormalities at the single cell level and behavioral abnormalities (e.g. ultrasonic vocalizations, cognitive flexibility) in KI mice. In summary, we are rigorously testing the hypothesis that excessive embryonic neurogenesis is sufficient to induce at least some ASD-like behaviors in male mice by disrupting transcription, cell composition, and synaptic connectivity.

Title: Tracking the zebrafish optic nerve regeneration using the optokinetic response

Authors: S. YOUNG, M. HORUTZ, A. TIEMAN, A. HERMANS, S. TAJNAI, ***S. J. HENLE**; Neurosci., Carthage Col., Kenosha, WI

Abstract: Zebrafish have eyes similar to humans making them a useful model organism for studying vision. However, zebrafish are different in that they are able to regenerate their optic nerve after injury. Measuring vision in people who have communicative ability is achieved using eye charts. Fish cannot use an eye chart, so we utilize the optokinetic response (OKR) that is present in virtually all vertebrates to determine if a zebrafish has eyesight. The OKR is observed by monitoring eye movement in response to moving visual stimuli. By injuring the optic nerve

on a zebrafish we can track its regeneration by measuring the return of its OKR. Recorded videos of the OKR are then analyzed manually or by using DeepLabCut. Using the optokinetic response provides insight into the functional process of regeneration, whereas previous work has focused on the anatomical process. Additionally, it allows us to access regeneration in individual animals over time, unlike histological methods that require sacrificing the animal for a single timepoint. Moreover, we have designed an entire setup to measure the OKR in adult and larval zebrafish that is 3D printed and relies on open-source software. This will allow us to scale up more easily and potentially use this in classroom labs as well. Understanding the functional regeneration in zebrafish will aid in developing treatment for humans with optic nerve injuries.

Sci., Rutgers University-Newark, Newark, NJ

Abstract: Axonal mRNAs are translated into new proteins after neurotrauma and these new proteins are needed for regeneration. We previously showed that the stress granule protein G3BP1 serves as a mRNA storage depot in axons and slows axon growth after injury. Exogenously expressing the acidic domain of G3BP1 disassembles axonal G3BP1 granules and accelerates PNS axon growth. A cell-permeable peptide (CPP) consisting of G3BP1 amino acids 190-208 triggers rapid disassembly of axonal G3BP1 granules and promotes axon growth in culture. Here, we show that the 190-208 CPP increases axon regeneration and acutely improves NMJ reinnervation when applied 2 d after nerve crush. G3BP1 granules are also seen in CNS axons, including in the spinal cord. Following spinal cord transection, injured reticulospinal

axons will grow into the permissive environment of a peripheral nerve graft (PNG) but halt growth upon reaching the distal cord. AAV transduction of reticulospinal neurons with the G3BP1 acidic domain accelerates growth within the PNG. Similarly, AAV transduction of retinal ganglion cells with G3BP1 acidic domain increased axon regeneration following optic nerve crush, indicating that G3BP1 granules attenuate CNS axon regeneration. Surprisingly, injecting the 190-208 CPP into the proximal transected spinal cord triggered sprouting-type growth within a PNG. In contrast, injecting 190-208 CPP directly into the graft promoted axon growth across the distal interface back into the spinal cord. Finally, returning to the PNS, treatment with the 190-208 CPP did not increase regeneration in chronically injured sciatic nerve axons. Together with the sprouting response in reticulospinal neurons, this raises the interesting possibility that response to the 190-208 CPP, which triggers G3BP1 granule disassembly in acutely injured axons, is context-dependent and possibly influenced by the environment of the injured axon.

Title: Re-expression of developmental transcription factors induces generation of retinal-ganglion-cell-like neurons

Authors: *M. WOODWORTH[1], L. C. GREIG[2], B. K. YOUNG[3], E. L. HUIE[3], M. NAHMOU[3], J. L. GOLDBERG[3];

[1]Program in Neurosci., Bates Col., Lewiston, ME; [2]Ophthalmology, USC, Los Angeles, CA; [3]Ophthalmology and Spencer Ctr. for Vision Res., Stanford Univ., Palo Alto, CA

Abstract: Retinal ganglion cells (RGCs) are a critically important retinal neuron type connecting the retina with the brain, and because the adult mammalian retina has minimal to no regenerative capability, irreversible visual impairment results from RGC injury or death. In this study, we aimed to identify a method to induce RGC development from endogenous retinal progenitor cells. *In vivo* postnatal electroporation of a set of candidate developmentally-expressed transcription factors induces development of RGC-like cells outside the window of endogenous RGC development. These induced RGCs represent a population distinct from endogenous RGCs. When forced to express this set of developmental transcription factors, retinal progenitors to first produce induced RGCs, then sequentially produce later retinal neuron types, uncoupling real time from developmental time. Induced RGCs express programs of genes characteristic of RGCs, and not of late-born retinal neurons or progenitors. Axons of induced RGCs progressively extend from the optic nerve, reaching visual targets in the thalamus and midbrain, but these projections are not maintained. Overall, we aim to understand the generation and development of new RGCs from existing cells intrinsic to the retina, which could enable restoration of vision in blind patients.

Title: Bdnf promotes expression of lotus, an endogenous nogo receptor antagonist

Authors: *J. MATSUBAYASHI, Y. KAWAGUCHI, Y. KAWAKAMI, K. TAKEI; Neural Regenerative Med. Laboratory, Dept. of Regenerative Med., Yokohama City Univ. Sch. of Med., Yokohama, Japan

Abstract: Trauma and neurological disorders strongly limit neuronal regenerative capacity and give rise to irreversible loss of function in the adult mammalian CNS. The molecular interaction between axonal growth inhibitors (AGIs) derived from myelin debris and glial cells such as Nogo protein and its receptor, Nogo receptor-1 (NgR1) is major obstacle preventing neuronal repair in injured CNS. Therefore, blockade of the molecular interaction between AGIs and NgR1 is beneficial therapeutic target for CNS regeneration. Lateral olfactory tract usher substance (LOTUS) contributes to axonal tract formation in the developing brain and axon regrowth in the

injured adult brain as an endogenous NgR1 antagonist. Additionally, LOTUS enhances synapse formation and memory. Thus, LOTUS functions as a potent neuronal agent by inhibiting NgR1 functions. However, the expression level of LOTUS is drastically decreased after CNS injury and declines along with aging. Therefore, suppression of down-regulating LOTUS expression and supplementation of LOTUS can be effective to maintain “healthy” CNS environment, but how LOTUS expression is regulated remains elucidated. Herein, we examined molecular mechanism of regulation in LOTUS expression and found that brain-derived neurotrophic factor (BDNF) increases the expression level of LOTUS in cultured hippocampal neurons. Exogenous application of recombinant BDNF increased LOTUS expression approximately 50% at both mRNA and protein levels in cultured hippocampal neurons on days in vitro 7 (DIV 7). Pharmacological inhibition with K252a, a tropomyosin-related kinase B (TrkB) inhibitor, blockade of TrkB with decoy protein and gene knockdown of TrkB siRNA suppressed BDNF-induced increase in LOTUS expression. Further pharmacological analysis of the TrkB signaling pathways revealed that BDNF increases in LOTUS expression through mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-kinase (PI3K) cascades. Furthermore, treatment with c-AMP response element binding protein (CREB) inhibitor partially suppressed BDNF-induced LOTUS expression. Finally, neurite outgrowth assay in cultured hippocampal neurons from wild-type mice and *lotus*-deficient mice revealed that BDNF-induced up-regulation of LOTUS promotes neurite outgrowth by antagonism for NgR1. Our findings suggest that BDNF may act as a positive regulator of LOTUS through TrkB receptor. We propose that increase of LOTUS expression by BDNF may be a beneficial therapeutic strategy for CNS injury as it is expected to be synergistic with axon growth-promoting effects of BDNF.

Title: Mechanical environment afforded by hydrogel determines the engraftment of the neural stem cells via regulation of cellular adhesion and survival in the injured spinal cord

Authors: *B. KIM[1], H. PARK[2];
[1]Ajou sch of medicine, Suwon, Korea, Republic of; [2]Dep. of Brain Sci., Ajou Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: The therapeutic potential of cell transplantation for spinal cord injury (SCI) is frequently compromised by poor survival of grafted cells. Biomaterial-based scaffolds may

support cellular engraftment in the inhospitable microenvironment of the injured spinal cord. We have previously demonstrated that injection of a thermosensitive injectable hydrogel can bridge cystic cavities accompanied by the formation of extracellular matrix (ECM) in the lesion epicenter that would otherwise become tissue defects following SCI. We initially expected that hydrogel-induced bridging effects would be highly conducive to graft survival. However, E14 spinal cord-derived neural stem cells (NSCs) delivered as a complex with the hydrogel barely survived the transplantation with frequent graft failures. We hypothesized that the mechanical properties of the hydrogel may be crucial to regulate the survival of NSCs transplanted within the hydrogel complex. Transplantation of NSCs with a varying percentage of hydrogel in the injured spinal cord showed a concentration-dependent increase in the areas of NSC grafts and engraftment rate *in vivo*, demonstrating that modulation of hydrogel mechanical stiffness can improve the survival of transplanted NSCs. To elucidate the molecular mechanisms underlying stiffness-dependent increase in graft survival, we established an *in vitro* culture system where NSCs were grown on hydrogel substrates with different stiffness ranging from 0.2 to 25 kPa. NSCs cultured on a rigid substrate showed an increase in the spreading area and cellular perimeter in a stiffness-dependent manner, indicating an improvement in cellular adhesion. This was accompanied by a significant increase and decrease in the percentage of living and dying cells, respectively. Moreover, NSCs cultured in a softer environment exhibited a compromise in cellular membrane elasticity and intracellular calcium oscillation, all of which were dependent on actin polymerization. We almost demonstrated that mechanical forces derived from substrate rigidity may be converted into biochemical events via mechanosensitive channels in the plasma membrane. Future studies will be carried out to determine whether mechanosensitive channels in NSCs with stiffer hydrogel are necessary for successful engraftment in the injured spinal cord.

Title: Generation and characterization of exogenic microglia-like cells using blastocyst complementation

Authors: *P. STRELL[1], S. JOHNSON[2], A. SHETTY[3], W. C. LOW[4];
[1]Vet. and Biomed. Sci., Univ. of Minnesota, Saint Paul, MN; [2]Stem Cell Inst., [3]Molecular, Cellular, Developmental Biology, and Genet., [4]Neurosurg., Univ. of Minnesota, Minneapolis, MN

Abstract: Alzheimer’s disease (AD) is a degenerative brain disease that leads dementia diagnoses and impacts 6.2 million Americans 65 and older. Current treatments are limited, and neither stop the pathology of progressive beta-amyloid and tau accumulation, nor the neuronal

damage and loss. Microglia dysfunction has been implicated as a major contributing factor of AD, worsening neuronal loss and tau pathology. Yet healthy microglia show neuroprotective functions like regeneration, inflammatory response suppression, and reversal of behavioral deficits. Our aim is to develop a novel approach for a renewable source of young microglia. We hypothesize that targeting microglial genes for deletion in the embryo will create a niche to generate exogenic microglia-like cells, and these cells, in turn, recapitulate primary healthy microglia. Blastocyst complementation (BC) with pluripotent stem cells (PSCs) and targeted gene-edited embryos will be used to generate exogenic microglia-like cells.
Because the HHEX gene is involved in liver, forebrain, and hematopoietic system development, it is an early microglia development target gene, as microglia are derived from an early wave of hematopoiesis. *PU.1* is important in hematopoietic and myeloid cell development. *PU.1* deficient mice lack circulating monocytes, tissue macrophages, and parenchymal microglia in the brain. We engineered the loss of *HHEX* and *PU.1* gene expression in early mouse embryos and performed intraspecies BC of *HHEX* and *PU.1* KO embryos with eGFP-labeled PSCs to rescue microglia development.
In blastocysts, loss of *HHEX* gene results in a homozygous KO and heterozygous rate of 25.6% and 26.8%, respectively. Intraspecies BC of *HHEX* KO embryos led to the formation of microglia-like cells derived from both the eGFP-labeled donor-derived cells and host. We also observed a proportion of perivascular macrophages generated from the eGFP-labeled donor-derived cells. Loss of *PU.1* gene resulted in a homozygous and heterozygous KO rate of 28.6% in *PU.1*, and a homozygous KO rate of 66.7% and heterozygous KO rate of 16.7%, using two different constructs respectively. These results demonstrate that young microglia-like cells and perivascular macrophages can be generated via BC methods. However, the generation of the perivascular macrophages shows that *HHEX* may not be specific enough to only produce microglia, therefore *PU.1* may be a more specific gene target.

Title: Glial fibrillary acidic protein (GFAP) isoforms expression in bone marrow mesenchymal stem cells differentiated towards Schwann-like phenotype

Authors: *G. REYES-GUTIERREZ, N. CARRILLO-GONZÁLEZ, T. CAMPOS-ORDOÑEZ, G. ESCOBAR-CAMBEROS, Y. GASCA-MARTÍNEZ, G. GUDIÑO-CABRERA; Deparment of Mol. and Cell Biology-CUCBA, Univ. de Guadalajara, Zapopan, Mexico

Abstract: Central nervous system (CNS) has a limited capacity to repair and restore itself from the damage, however, CNS can contain it through reactive gliosis. Several strategies have been proposed to promote regeneration using cell therapy. Olfactory ensheathing cells (OECs) or Schwann-like cells can promote CNS reparation, but it is difficult their obtention and purification for cell therapy. Thus, we use a model based on bone marrow-mesenchymal stem cells (BM-MSC) differentiated into a phenotype Schwann-like cells (BM-MSCdif). Schwann cells express the glial fibrillary acidic protein mRNA isoforms β (GFAPβ), and GFAPδ isoform is characteristic of precursor cells. Therefore, we characterized the mRNA isoforms of GFAPβ and GFAPδ between three conditions: 1) primary cultures of OEC and 2) BM-MSC of adult Wistar rats; and 3) MSC cells exposed to olfactory ensheathing cells-conditioned medium (BM-MSCdif) to determine their possible use as a cell therapy. In our results, as we expected OEC with spindle-like morphology expressed CD73, p75 and GFAP; BM-MSC with fibroblast-like morphology showed CD90, CD73, p75, and GFAP; and BM-MSCdif showed spindle-like morphology and expressed CD73, p75 and GFAP by immunocytochemistry. In addition, all three cell types expressed GFAPβ and GFAPδ isoforms by end point PCR and RT-qPCR. Finally, we observed the diffuse granulated distribution of GFAP in the three cell types studied by immunocytochemistry. These data suggest that exist a possible morphological and molecular relationship in BM-MSCdif with OECs. Findings about GFAP and its isoforms are expressed in BM-MSC reveal the possibility to study the role of this cytoskeletal protein in neural regeneration processes.

Title: A recombinant protein derived from a component of the extra-axonal environment promotes retinal ganglion cell survival and axon regeneration after injury in vivo

Authors: *M. P. FROST, A. LUKOMSKA, B. A. RHEAUME, W. C. THEUNE, J. XING, E. F. TRAKHTENBERG;
Neurosci., UConn Hlth., Farmington, CT

Abstract: Central nervous system (CNS) projection neurons in mammals fail to regenerate damaged axons and restore connections with appropriate targets following injury. Consequently, disruption of these axons by either stroke or traumatic injury results in irreversible loss of function and subsequent neuronal cell death. For example, retinal ganglion cells (RGCs) are the

major CNS projection neurons of the eye and are responsible for the relay of visual information to the brain through the optic nerve. Stroke or traumatic injury of RGC axons in the optic nerve results in blindness and progressive RGC cell death. Modest regeneration of CNS axons has been achieved by manipulation of neuronal intrinsic and extrinsic factors. However, currently there are no therapeutics available that can repair the CNS circuits damaged by such injuries. The failure of CNS neurons to regenerate their long-distance axons remains an important unmet clinical problem. Here, using bioinformatic analysis of single cell RNA-seq-profiled RGCs, we predicted extra-axonal environment molecules that could interact with the axons and regulate their growth. We then tested the effects of these molecules on adult RGCs, which otherwise survive poorly and do not grow long axons in culture. We found that one of these molecules (identity masked due to proprietary information) enabled a subset of axotomized adult RGCs to survive for a long period and stimulated long-distance axon growth in a permissive culture environment. Next, we synthesized a recombinant variant of this molecule, and found that its targeted delivery promoted axon regeneration after optic nerve crush injury *in vivo*. Thus, this recombinant molecule presents a novel potential therapeutic for neuroprotection and axon regeneration treatments.

Title: Micrornas associated with maturation of retinal ganglion cells regulate survival and long-distance axon regeneration after optic nerve injury

Authors: *A. LUKOMSKA, W. THEUNE, J. XING, M. FROST, M. GUPTA, E. F. TRAKHTENBERG;
UCONN Sch. of Med., Farmington, CT

Abstract: Retinal ganglion cells (RGCs) are central nervous system (CNS) projection neurons, which do not regenerate axons severed in optic neuropathies, such as those resulting from optic nerve trauma, ischemia, and glaucoma. Several factors that are developmentally regulated in RGCs were discovered to contribute to their failure to regenerate the injured axons. No clinical treatments exist to date that could help patients with such axonal injuries. Thus, the failure of RGC and other CNS long-distance axons to regenerate after injury remains a major unmet problem. Here, we bioinformatically analyzed small-RNA-seq datasets, which we generated using RGCs purified from different stages of development, in order to identify developmentally-

regulated microRNAs (miRNAs). Then, we investigated the roles of the identified miRNAs in RGC survival and axon regeneration after optic nerve injury, using a well-established mouse *in vivo* model of optic nerve crush (ONC). The RGCs were pre-treated with intravitreally injected AAV2 vectors, which either upregulate or knockdown the candidate miRNAs. Two weeks later, ONC was performed and RGC survival and axon regeneration were evaluated two weeks after injury. We found several novel miRNA targets, which either promoted or inhibited RGC survival and axon regeneration. We then proceeded to test the identified novel miRNA-regulators of RGC survival and axon regeneration in a long-term assay, in which the extent of neuroprotection and axon regeneration was evaluated at 6 weeks after ONC injury. By this time-point after ONC, most RGCs usually die. However, for a few of the tested miRNA targets we found many-fold increase in RGC survival, and also detected axons that regenerated through the optic nerve, optic chiasm, and entered the optic tract. Thus, the identified novel miRNA-regulators of RGC survival and axon regeneration present potential therapeutic targets for treating optic neuropathies and glaucoma, as well as axonal injuries in other white matter tracts of the CNS.

Title: Reconstructing visual circuits to investigate synapse re-connection in hiPSC-retinal ganglion cells

Authors: *K.-C. HUANG[1], A. HO[2], C. GOMES[4], J. MEYER[4], M. A. SAMUEL[3]; [1]Huffington Ctr. on Aging, Baylor Col. of Med., Houston, TX; [2]Dept. of Neuroscience, Huffington Ctr. on Aging, Baylor Col. of Med., HOUSTON, TX; [3]Dept. of Neuroscience, Huffington Ctr. on Aging, Baylor Col. of Med., Houston, TX; [4]Indiana Univ. Sch. of Med., INDIANAPOLIS, IN

Abstract: Transplantation of donor neurons has emerged as an advantageous approach to repopulate neuron circuitry in the context of neuronal disorders. Yet, how to guide neurons to re-innervate appropriate brain targets is not clear. This is particularly challenging in the context of neurodegenerative diseases in the visual system because of the long-distance that axons from

retinal ganglion cells (RGCs) must traverse to reinnervate retinorecipient areas in the brain. To provide insight into cues that may guide RGC axon re-innervation, we aim to elucidate axonal pathfinding and synaptic connectivity pathways by reconstructing visual circuits in human induced-pluripotent stem cells (hiPSCs)-derived RGCs (hiPSC-RGCs). We first asked whether cultured hiPSC-RGCs can segregate their dendritic and axonal compartment in a partitioned microfluidic device connected by microgrooves. We found hiPSC-RGCs neurites successfully segregated into dendrites and axons, with marginal overlap between the dendritic and axonal markers MAP2 and SMI-312. Over the course of maturation, hiPSC-RGCs axons grew and crossed into the axonal chamber and exclusively expressed SMI-312. These data suggest that hiPSC-RGCs are able to polarize their dendrite and axon compartments properly. To study postsynaptic neuronal connectivity in the brain, we then co-cultured hiPSC-RGCs with mouse primary lateral geniculate nucleus (LGN) and suprachiasmatic nucleus (SCN) neurons, two major retinorecipient regions. We are currently examining whether co-culture improves neurite maturation by quantifying synapse density in hiPSC-RGCs neurites. Finally, we are extending our study to reconstruct visual circuits in a multi chamber microfluidic device to determine whether RGC axons connect specificity with LGN or SCN neurons. Together, our data suggest that an in vitro model of primary visual system connectivity can be used to inform synaptic specificity pathways. Such results will facilitate the future development of strategies that may improve neuronal transplantation therapies.

Title: Gene expressions regulated by pharmacological inhibition of histone deacetylase in rat Schwann cell

Authors: *H. MAEJIMA[1], T. NISHIO[2], Y. DING[2], K. TSUTSUMI[3], Y. TAKAMATSU[1], T. MASAKI[4];

Abstract: Transplantation therapy using Schwann cell has been focused on specifically in central nervous system (CNS) disorders such as spinal cord injury. Oligodendrocytes comprise myelin sheath in the CNS, whereas Schwann cells comprise it in the peripheral nerve system.

However, Oligodendrocytes express Myelin-associated inhibitor such as NOGO, MAG and OMgp against axonal regeneration. Thus, instead of oligodendrocytes, transplantation of Schwann cells to the injured CNS has been expected to contribute to myelination, axonal regeneration and remodeling of the CNS, accompanied by the expression of neurotrophic genes without expression of inhibitory molecules mentioned above. Histone acetylation is a potent epigenetic modification that is related to transcriptional regulation. Histone acetylation typically promotes gene expression. Thus, inhibition of histone deacetylases (HDACs) enhances histone acetylation globally, promoting gene expression. Pharmacological treatment using HDAC inhibitors (HADCis), which can enhance acetylation levels and increase anti-inflammatory and neurotrophic gene expression in the CNS, is expected to be a potential CNS conditioning method for neurorehabilitation. Therefore, targeting combined therapy of Schwann cell transplantation with pharmacological treatment using HDACi, we examined the effects of sodium butyrate (NaB), an HDACi on the gene expressions related to myelination, neuroprotection, neurotrophic function in addition to apoptosis in Schwann cell. Rat Schwann cells were cultured in the medium with NaB at different concentrations of 0, 0.1, 1.0, 5.0, 10.0 and 50mM for 24h, followed by the evaluation of cell viability. Subsequently, total RNA were collected from treated cells and cDNA was reverse-transcribed from isolated mRNA. Gene expression of neurotrophic factors (BDNF, GDNF and IGF-1), myelin-associated proteins (MBP and MPZ), and apoptosis marker (caspase-3) were assayed using real time PCR. Treatment with high concentration of 50mM NaB increased expression of caspase-3 and BDNF, and decreased cell viability. Meanwhile, treatment with lower concentration of 5.0mM NaB could increase IGF-1 expression, whereas 1.0mM NaB could increase the expressions of GDNF, MBP and MPZ, indicating that treatment with lower concentration of NaB could enhance myelin-associated protein and neurotrophic factors without apoptotic signaling. Altogether, this study suggests that it is important for transplantation therapy using Schwann cells to find a minimal and appropriate dose of HDACi enhancing beneficial gene expression related to myelination and neurotrophic function.

Title: Experimental upregulation of a novel developmentally downregulated micro RNA in retinal ganglion cells restores embryonic levels of mitochondria associated gene expression and promotes axon regeneration after injury in vivo

Authors: *W. C. THEUNE, A. LUKOMSKA, J. XING, M. P. FROST, E. F. TRAKHTENBERG;
Neurosci., Univ. of Connecticut, Farmington, Farmington, CT

Abstract: Central nervous system (CNS) projection neurons such as retinal ganglion cells (RGCs) do not spontaneously regenerate axons disrupted by injury or disease. RGC axons can be irreversibly damaged in optic neuropathies, which could be caused by optic nerve trauma, stroke, or glaucoma, and lead to loss of vision. Neuronal developmental capacity to grow long axons declines sharply after birth, and several factors that are themselves developmentally-regulated in RGCs were found to underlie the regenerative failure. No clinical treatments exist to date that could help patients with axonal injuries in the CNS to regenerate damaged circuits. Here, we identified a micro-RNA (miRNA; identity masked due to proprietary information) using small-RNA-seq of embryonic and mature purified RGCs, and investigated its role in RGC survival and axon regeneration after optic nerve injury, using a well-established murine *in vivo* model of optic nerve crush (ONC). We confirmed small-RNA-seq prediction of developmental-downregulation of the candidate miRNA by quantitative-PCR (qPCR), and also found that it is further downregulated in RGCs after ONC. Then, we pre-treated the RGCs with intraocularly injected AAV2 vector, which expressed either the candidate miRNA-mimic or a scramble shRNA (control), and performed ONC. At 2 weeks after injury, we evaluated the effects of the treatment on RGC survival and axon regeneration. We found that experimentally upregulating this miRNA promoted both RGC survival and axon regeneration. In order to characterize the mechanisms through which this miRNA elicited neuroprotection and promoted axon regeneration, we analyzed by bulk-mRNA-seq adult RGCs treated with AAV2 expressing miRNA-mimic or a scramble shRNA (control), and compared to bulk-mRNA-seq-analyzed transcriptome of purified embryonic and postnatal RGCs. These analyses led to the identification of a subset of genes, which were downregulated after treatment and whose levels were also upregulated during RGC maturation, consistent with developmental downregulation of the miRNA. Using miRNA target-prediction bioinformatic tools, several of these developmentally-upregulated genes were also predicted to be direct targets of the miRNA. Along with the genes downregulated by the treatment, we also found upregulated genes, which were presumed to be downstream of the mRNAs downregulated by the miRNA-mimic treatment, and were enriched for mitochondria-associated biological processes. Thus, a novel miRNA-regulator of RGC development and mitochondria-associated biological processes is a promising candidate for therapeutic neuroprotection and axon regeneration.

Title: Delivery of axon guidance gene-targeted siRNA nanoparticles via dual-degradable hydrogels improve cell proliferation of transplanted neural stem cells after spinal cord injury

Authors: *S. KIM[1], G. HAN[2], S. SOHN[3];
[1]CHA University, CHA Bundang Med. Ctr., Gyenggi-do, Korea, Republic of; [2]CHA University, CHA Bundang Med. Ctr., Gyunggi-do, Korea, Republic of; [3]neurosurgery, CHA University, CHA Bundang Med. Ctr., Gyeonggi-do, Korea, Republic of

Abstract: Neural stem cells (NSCs) derived from embryonic spinal cord are excellent candidates for cellular regeneration of lost neural cells after spinal cord injury (SCI). Semaphorin 3A (Sema3A) is well known that it is implicated in the major axon guidance of growth cone as a repulsive function during the central nervous system development, yet its function in the NSC transplantation therapy for SCI has not been investigated. Here, we first report that embryonic spinal cord-derived NSCs significantly expressed Sema3A in the SCI environment, which can inhibit cell proliferation after transplantation. Knockdown of Sema3A by delivering siRNA nanoparticles via dual-degradable hydrogels significantly induce to increase cell survival and neuronal differentiation of the transplanted NSCs after SCI. Of note, knockdown of Sema3A increase synaptic connectivity of transplanted NSC in the injured spinal cord. Moreover, extracellular matrix molecule and functional recovery were significantly improved in the Sema3A-inhibited rats compared to those in the NSCs transplanted-only rats. These findings show the important role of Sema3A in NSC transplantation therapy, which may be considered in future cell transplantation therapy for SCI.

Boston Children's Hosp., Boston, MA; [4]Broad Inst. of Harvard and Massachusetts Inst. of Technol., Cambridge, MA; [5]Boston Children's Hosp. Pathology Dept., Harvard Med. Sch., Boston, MA

Abstract: Maternal immune activation (MIA) by viral, bacterial, or parasitic infection that results in hospitalization enhances the risk in offspring for neurodevelopmental disorders including autism spectrum disorders (ASD). During cerebral cortical development, neural progenitors first proliferate along cerebrospinal fluid (CSF)-filled ventricles and then differentiate into neurons and glia cells that form the cerebral cortex. The choroid plexus (ChP), an epithelial structure located in each brain ventricle, regulates CSF production and composition including by secreting instructive cues and nutrients for proper brain development and provides a critical brain barrier that help protect that brain from peripheral insults. Previously, our lab found that MIA in mice leads to a pro-inflammatory cytokine state in the embryonic CSF and accumulation of macrophages at the embryonic ChP. This led us to speculate that ChP-mediated nutrient secretion into the CSF is also perturbed in MIA and we tested this by thorough characterization of the changes in mouse embryonic CSF metabolome following MIA. Leveraging the quantitative power of liquid chromatography-mass spectrometry, we performed untargeted metabolomics and profiled MIA-induced changes in the embryonic CSF. This revealed elevation of glucocorticoids and kynurenine pathway related metabolites in embryonic CSF, validated by subsequent targeted metabolomics analyses. The kynurenine pathway is known to be associated with several neuropathologies, and its elevation following inflammation is in accordance with previous findings in adult CSF. Glucocorticoids, among the most prescribed drugs for the treatment of immune and inflammatory disorders, are known for their anti-inflammatory and immunosuppressive effects, and commonly repress the expression of cytokines in macrophages. Currently, we are interrogating the functional roles of glucocorticoids and kynurenine pathway metabolites on embryonic brain development. Our in-depth characterization of the mouse embryonic CSF should reveal mechanistic insights regarding causative abnormalities in CSF composition and inform future interventions / therapeutic strategies during MIA.

Title: Strategies for the rescue of cellular and behavioral deficits in a NEXMIF-dependent mouse model of Autism spectrum disorder

Authors: *K. E. ODAMAH[1], H. MAN[1,2];
[1]Biol., Boston Univ., Boston, MA; [2]Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA

Abstract: We previously confirmed that loss of the X-linked gene NEXMIF results in Autism spectrum disorder (ASD) and intellectual disability. To study the neurobiological function of NEXMIF and its implication in ASD, we generated NEXMIF knockout (KO) male mice which display significant neuronal deficits and autism-like behaviors. As a proof-of-concept study, we utilized postnatal reintroduction of NEXMIF and its downstream genes as a strategy for rescuing the impaired cellular and behavioral phenotypes in KO mice. We find that injection of a NEXMIF lentivirus into KO mouse brains at postnatal day 1 (P1) rescues NEXMIF and synaptic protein expression, reduces anxiety, and improves preference for social novelty and novel object recognition memory by P30. Additionally, reintroduction of Filip1, a top gene transcriptionally regulated by NEXMIF, rescues impaired dendritic outgrowth in NEXMIF knockdown cortical neurons, indicating that gene reintroduction may serve as a rescue strategy in loss of NEXMIF conditions. Comparable to the majority of human female cases, our NEXMIF heterozygous (HET) female mouse model also shows autism-like behavioral impairments and defects in neuron morphology. During X chromosome inactivation (XCI) in early development, Xist RNA accumulates on the future inactive X chromosome (Xi), leading to its silencing. Because NEXMIF is an X-linked gene, random XCI results in mosaic NEXMIF expression in the HET brain: some neurons express wild-type (WT) NEXMIF, while other neurons completely lack NEXMIF (KO) and retain a silenced copy of WT NEXMIF on the Xi. Therefore, the silenced NEXMIF copy in the KO neurons of HET mice could potentially be expressed via X-chromosome reactivation. Indeed, we demonstrate that potent DNA methylation inhibitors can successfully reactivate NEXMIF from the Xi in cultured WT and HET female mouse cortical neurons. Moreover, injection of the inhibitors into WT and HET female mouse brains at P1 is sufficient to increase cortical NEXMIF expression by P15, which is still evident at P30. Overall, these findings lay the groundwork for further research aimed toward investigating the therapeutic potential of gene reintroduction and reactivation techniques in NEXMIF-dependent ASD.

Title: Maternal Fmr1 deficiency dysregulates offspring sociability and oxytocinergic signaling in the VTA

Authors: D. DUNN[1], E. TINCHER[1], M. RUSSELL[1], B. KHEYFETS[1], S. BOUKOBZA[1], G. COSTE[1], B. SULAMAN[1], J. KEE[1], K. NEWHALL[1], ***B. ZUPAN**[2];
[2]Psychological Sci., [1]Vassar Col., Poughkeepsie, NY

Abstract: Impaired social interaction is a core dimension of neurodevelopmental disorders. Neuropeptide oxytocin (OXT) signaling in the VTA is critical for mediating rewarding aspects of social behavior. Specifically, OXT modulates activity of VTA dopamine neurons whose projections to the NAc bidirectionally modulate duration of social interaction. The mouse model of Fragile X Syndrome (FXS) exhibits abnormal sociability, and our research suggests that this phenotype is programed in part by maternal *Fmr1* deficiency. We've reported that haploinsufficiency of maternal *Fmr1* (*Fmr1*$^{+/-}$) is sufficient to induce hypersociability in genetically normal (wild-type (WT); *Fmr1*$^{+/y}$) male offspring, indicating developmental sensitivity to maternal FMRP levels. We've also reported that intranasal (IN) OXT administration increases sociability in WT controls, but not in hypersocial mice, actually decreasing social interaction in WT mice from FMRP deficient dams. Here, we asked whether maternal FMRP-programmed sociability is associated with dysregulated OXT signaling in the VTA. We found that IN OXT increases VTA cfos expression and sociability in control mice, confirming that IN OXT modulates activity in this brain region. Interestingly, blocking VTA OXT receptors (R) with a highly selective antagonist prior to IN OXT administration failed to block OXT-mediated increase in social interaction. Rather, it mimicked it - intra-VTA administration of the antagonist increased social interaction time and decreased avoidance of a novel conspecific. We then administered OXT directly into the VTA and found that, like IN administration, intra-VTA OXT increased sociability and decreased avoidance in WT control mice, but failed to modify sociability in maternal FMRP-programmed mice. Varying doses of atosiban, another OXTR antagonist, blocked OXT-mediated effects on sociability in WT control, but had no effect on social behavior in maternal FMRP-programmed WT mice. We found no differences across groups in the number of OXT+ neurons in the PVN nor in the number of PVN neurons innervating the VTA. A semiquantitative fluorescence in situ hybridization analysis of OXTR gene expression in dopaminergic and GABAergic neurons of the VTA also revealed no differences across groups. In sum, our data shows that the lack of oxytocin-induced effects on sociability in maternal FMRP-programmed mice is not mediated by altered OXT innervation of the VTA or OXTR expression in this region. Rather, it suggests that dysregulated oxytocinergic signaling is mediated by a functional deficit in OXTRs, although we cannot yet exclude the possibility of an arginine vasopressin receptor-mediated effect.

Nacional Autónoma de México, Queretaro, Mexico

Abstract: Autism spectrum disorder (ASD) is a disease characterized by reduced social interaction and stereotypic behaviors and related to macroscopic volumetric changes in cerebellar and somatosensory cortices (SPP). Epidemiological and preclinical models have confirmed that a proinflammatory profile during fetal development increases ASD susceptibility after birth. Here, we aimed to globally identify the effect of maternal exposure to high-energy dense diets, which we refer to as cafeteria diet (CAF) on peripheral and central proinflammatory profiles, microglia reactivity, and volumetric brain changes related to assisting defective social interaction in the mice offspring. We found a sex-dependent effect of maternal exposure to CAF diet or inoculation of the dsARN mimetic Poly (I:C) on peripheral proinflammatory and social interaction in the offspring. Notably, maternal exposure to CAF diet impairs social interaction and favors an increase in anxiety in male but not female offspring. Also, CAF diet exposure or Poly (I:C) inoculation during fetal programming promote peripheral proinflammatory profile in the ASD-diagnosed male but not in females. Selectively, we found a robust accumulation of the monocyte chemoattractant protein-1 (MCP-1) in plasma of ASD-diagnosed males exposed to CAF during fetal development. Biological assessment of MCP-1 signaling in brain confirms that systemic injection of MCP-1-neutralizing antibody reestablished social interaction and blocked anxiety, accompanied by a reduction in cerebellar lobule X (CbX) volume and an increase volume of the primary somatosensory (SSP) cortex in male offspring. These data highlight the contribution of diet-dependent MCP-1 signaling on volumetric brain changes and microglia morphology promoting ASD-like behavior in male mice.

Title: Altered excitatory/inhibitory balance in the prefrontal cortex of a mouse model of autism: from neuronal excitability to cerebellar modulation in vivo.

Authors: *D. DI DOMENICO[1], E. PALI[1], M. CONFORTI[1], T. SODA[1], I. MONTAGNA[1], S. TRITTO[1], E. D'ANGELO[1,2], F. PRESTORI[1], L. MAPELLI[1];
[1]Brain and Behavioral Sci., Univ. of Pavia, Pavia, Italy; [2]Brain Connectivity Ctr., IRCCS Mondino Fndn., Pavia, Italy

Abstract: Autism spectrum disorders (ASD) are characterized by altered social interaction and repetitive behavior and are supposed to affect prefrontal cortex and cerebellum. IB2 KO mice provide a good ASD model, since the human IB2 orthologous gene is usually co-deleted with SHANK3 in the Phelan-McDermid syndrome. Here, we characterized the prelimbic cortex (PrL) activity and its control by cerebellar stimulation in IB2 KO and WT mice. *In vivo* single unit (SU) recordings of putative PrL pyramidal neurons were performed to characterize spontaneous activity and responses to electrical stimulation of the cerebellar dentate nucleus (DN) under urethane anesthesia (in 13 KO and 15 WT SUs). IB2 KO SUs showed lower basal frequency (KO=0.7±0.1Hz, WT=1.1±0.1Hz; p=0.03) and a reduced response to DN stimulation (KO=-2.5±0.3sp/bin, WT=-3.5±0.3sp/bin; p=0.06). Local superfusion of dopaminergic D1 and D2-like receptor blockers (SCH23390 and Sulpiride) either decreased or increased the basal firing rate, compatible with the heterogeneous distribution of D1/D2-like receptors in PrL pyramidal neurons, with no significant differences between WT and KO. The interplay between the GABAergic and dopaminergic systems was evident in the correlation between the effects of GABA-A (with SR95531) and D1/D2-like receptors blockade, that was investigated by sequentially blocking D1/D2-like and GABA-A receptors. Importantly, inhibition block had a stronger impact on KO than WT, both on basal firing rate (KO=417±128%, WT=157±53%; p=0.04) and on responses to DN stimulation (KO=420±118%, WT=165±68%; p=0.005). Since

the blockade of inhibition revealed an hyperexcitability of IB2 KO pyramidal neurons, *ex vivo* experiments were performed to get deeper insight on neuronal and local microcircuit changes. Voltage sensitive dye imaging in acute PrL slices revealed an increased excitatory/inhibitory (E/I) balance in KO, characterized by larger excitation cores (KO=399±41µm, WT=246±28µm; p=0.02) with little lateral inhibition in PrL columns. Accordingly, whole-cell patch-clamp recordings of layer V pyramidal neurons showed a significantly increased excitability of KO neurons, an upward shift in the frequency/intensity plot (KO=11.2±1.2Hz, WT=4.7±2.2Hz; p=0.03), and a larger inward current density. While the experimental assessment of D1/D2-like and GABA-A receptors functions *ex vivo* is ongoing, our preliminary results suggest that PrL neurons hyperexcitability might be compensated *in vivo* by mechanism boosting inhibitory modulation. Further investigations are warranted to investigate the balance between primary and compensatory changes in the PrL of IB2 KO mice.

Title: The role of autism-associated postsynaptic density SHANK2 protein in modulating novelty-induced arousal transitions

Authors: *P. N. NEGRON-MORENO[1], Y.-H. JIANG[2];
[1]Neurosci., [2]Genet., Yale Univ., New Haven, CT

Abstract: Organisms strategically use internal states and external information to execute differential behaviors and state transitions depending on specific contexts. Arousal states, in particular, are known to be essential for survival and adaptation in response to sensory input, emotional burden, physiological needs, and changes in the environment. Although previous studies have suggested that the anterior cingulate cortex (ACC) maintains sustained arousal in novel environments and is involved in attentional-state switching, the mechanisms by which neural ensembles and molecular networks mediate arousal states are not well understood. SHANK2 is a scaffolding protein located at the postsynaptic density of excitatory neurons that is involved in synaptic regulation through the formation and stabilization of synapses during development. SHANK2 is predominantly expressed in the cortex with high expression in the ACC. In this study, we sought to investigate the role *SHANK2* plays in modulating novelty-induced arousal using the *Shank2* complete knockout mouse model with a deletion of exon 24 (*Shank2*Δe24). To assess novelty-induced arousal, we developed a modified behavioral paradigm

where mice are challenged with a Novelty-Habituation-Novelty scheme. We found that most mice, regardless of genotype, extensively explore an object on the first day of exposure. *Shank2*$^{\Delta e24-/-}$ mice spend significantly more time exploring and interacting with the object after initial and repeated exposures. These data suggest that *Shank2*$^{\Delta e24-/-}$ mice have an increased arousal response to novelty and a persistent interest in familiar objects. Yet, this response is not due to a long-term or short-term memory impairment since *Shank2*$^{\Delta e24-/-}$ mice have a normal novelty recognition index at both a 5min and 24h recall. Due to the role of the ACC in modulating novelty-related behaviors and arousal, we sought to remove *Shank2* from this region using the *Shank2* conditional knockout line (*SHe24*^{flox}). Our preliminary data suggest that ACC-Cre mice have an increased arousal response toward a novel object evidenced by significantly more time spent exploring the object and an increased number of interactions. Taken together, our data suggest that *Shank2* in the ACC may play an important role in achieving an appropriate arousal response toward novelty. Future work using fiber photometry and circuit manipulation techniques to evaluate 1) how the lack of *Shank2* affects the neural dynamics of the ACC and 2) how *Shank2* might mediate appropriate novelty-induced arousal state transitions.

Title: Amantadine Has Efficacy to Reduce Restrictive-Repetitive Behavior in BTBR Mice

Authors: *S. GREENE[1], G.-A. ALCALA[2], A. ONTANON[3], A. C. SHAKOCIUS[4], I. PARK[3], E. REED[3], A. JOHNSON[3], I. BUSTAMANTE[3], M. SCHILLERSTROM[3], B. GINSBURG[4], G. GOULD[5];

Abstract: The goal of this study was to determine if the drug amantadine, usually used to control some viral infections and dyskinesia in Parkinson's disease, would have any efficacy to reduce

the restrictive-repetitive behaviors characteristic of autism spectrum disorders (ASD). Males of the inbred strain BTBR typically bury lots of marbles relative to male C57BL/6J but this behavior in females is less well characterized. The study hypothesis was that sub-chronic amantadine treatment would be more effective than acute treatment, and higher doses would be more effective than lower doses to reduce marble burying. Mice, both male and females, were used as subjects, and the drug was injected daily at a dose of 50 or 150 mg/kg for 6 days. These doses resulted in steady state serum levels of (mean ± S.E.M.) 260 ± 58 and 693 ± 40 ng/ml amantadine, respectively. Ten each male and female mice per dose of amantadine were tested for marble burying on Day 1 and again on Day 6. On Day 1, male BTBR buried more marbles than female BTBR mice, but on Day 6 this difference was not evident because control females were burying more marbles. In both males and females, amantadine at a dose of 150 mg/kg/day reduced marble burying significantly relative to the control treated groups. Overall, amantadine may be useful to ameliorate restrictive-repetitive behaviors that occur in autism and other psychiatric disorders, a purpose different from its current use to reduce dyskinesia.

Title: Modulation of the maternal gut microbiome with probiotics during pregnancy prevents autism-like phenotypes in environmental and idiopathic mouse models

Authors: *I. J. BOLDING[1,2], L. M. MATZ[1,2], C. M. DI GESU[5], R. FULTZ[6], K. L. HOFFMAN[3,4], J. F. PETROSINO[3,4], S. A. BUFFINGTON[1,2];

Abstract: Disruption of the maternal gut microbiome during pregnancy is associated with adverse neurodevelopmental outcomes. We previously showed that maternal high-fat diet (MHFD) in mice induces gut dysbiosis and social dysfunction in male and female offspring across two generations (F_1, F_2), and that supplementation of offspring drinking water with *Limosilactobacillus* (*L.*) *reuteri* upon weaning rescues social dysfunction and selectively remodels the female gut microbiome by promoting expansion of short-chain fatty acid (SCFA)-producing taxa. We hypothesized that targeted remodeling of the maternal gut microbiome during pregnancy would improve neurobehavioral outcomes in offspring born to obese dams. We therefore developed a maternal probiotic cocktail (MPC) consisting of seven immunomodulatory taxa and administered it to maternal regular diet (MRD) control and HFD-fed dams during pregnancy and lactation. Antenatal targeting of the maternal gut microbiome was sufficient to restore neurotypical social behavior of male and female MHFD + MPC lineage offspring (F_1) compared to MHFD lineage offspring, demonstrated by restored sociability and preference for social novelty in Crawley's three-chamber assay, and increased number of contacts and interaction times in the reciprocal social test for MHFD + MPC male and female offspring, respectively. Importantly, probiotic treatment of MRD controls displayed normative behavior. Metataxonomic 16S rRNA gene amplicon sequencing of stool collected from MHFD and MHFD + MPC lineages revealed few changes in alpha diversity, suggesting that MPC produces functional changes that prevent the onset of autism-like phenotypes in offspring born to HFD-fed mice. Thus, we performed metabolomics of dam and offspring serum and stool, revealing significant fold changes in the MHFD + MPC lineage compared to the MHFD lineage including changes in bile acids, carbohydrate utilization, and fatty acid synthesis and metabolism. Collectively, these results suggest that increasing biosynthetic potential for SCFAs through probiotic supplementation results in an improved serum metabolome, and that therapeutic targeting of the maternal gut microbiome may represent a promising strategy to lower neurodevelopment risks associated with in utero environmental exposures including infection, overnutrition, and particulate matter. We are currently testing the efficacy of a maternal probiotic in genetic and idiopathic mouse models for ASD. Our results link the maternal lineage to instability of descendant microbial communities and maladaptive social behavior and highlight the interaction between host genetics and host microbiota.

Title: Cntnap2 affects conditioned fear memory during early development

Authors: *H. JANOUSCHEK, R. J. TAUGHER-HEBL, A. BERNS, A. TOWNSEND, A. K. EAGEN, M. JONES, H. STEVENS, D. LANGBEHN, J. WEMMIE;
Univ. of Iowa, Iowa City, IA

Abstract: The circuitry that underlies Pavlovian fear conditioning has been suggested to undergo marked changes during brain development. During rodent late pre-weaning and early post-weaning period, these changes include alterations in several molecular mechanisms underlying synaptic plasticity and neuron morphology. The contactin-associated protein-like 2 (CNTNAP2) is a neurexin, which has been associated with neurodevelopmental disorders, synapse formation and stabilization. It is highly expressed in the limbic circuitry, including the amygdala and the hippocampus. Therefore, it is feasible that CNTNAP2 differentially affects fear learning or fear memory recall during brain development. To explore this possibility, we tested Pavlovian fear conditioning in 18-day-old (P18) wildtype (*Cntnap2*$^{+/+}$) mice and *Cntnap2* deficient (*Cntnap2*$^{-/-}$) littermate controls. We then tested cue-evoked freezing and its persistence in the same cohort of mice using mixed effects linear regression analyses. P18 *Cntnap2*$^{-/-}$ mice didn't differ significantly from their *Cntnap2*$^{+/+}$ littermates during fear conditioning. However, knockout mice performed significantly worse on cue-evoked freezing 24 hrs. after training. Interestingly, 1 to 2 weeks later, the persistence of cue-evoked freezing in *Cntnap2*$^{+/+}$ mice declined more than in *Cntnap2*$^{-/-}$ mice, largely eliminating the genotype difference, and suggesting that although memory was initially impaired in the *Cntnap2*$^{-/-}$ mice, it may be more stable. Previous studies suggested CNTNAP2 is involved in spine stability in adult animals. Therefore, one potential explanation for our results might be genotype differences in spine stability which is a future direction for investigation. Together these data provide the first evidence for CNTNAP2 dependent effects on Pavlovian fear conditioning early during development.

Abstract: Loss of function mutations in genes encoding lysine methyltransferases responsible for trimethylation of histone 3 on lysine 4 (H3K4me3), H3K4me3 readers and demethylases are associated with a range of neurodevelopmental conditions, including autism spectrum disorder (ASD) and intellectual disability (ID). *KDM5B* mutations have been reported in patients with ASD, ID and developmental delay. Many of the ASD-associated mutations identified in *KDM5B* are within or around the catalytic domain of the protein, implicating H3K4me3 demethylase activity in ASD pathogenesis. We hypothesized that a deficiency in the demethylation activity of KDM5B will lead to a dysregulated H3K4me3 epigenome, abnormal neurodevelopmental gene expression and ASD-like behaviours in mice. We obtained a mouse line, *Kdm5b*$^{\Delta ARID/\Delta ARID}$, with a deletion of exons 2-4, resulting in reduced KDM5B protein with a complete loss of demethylase activity. Homozygous mice exhibited increased brain-to-body weight ratios, suggesting neurodevelopmental defects. To investigate the in vivo function of the protein in the developing brain, H3K4me3 levels were measured in the neocortex of postnatal day 5 (P5) mice by western blot. H3K4me3 levels were significantly increased, compared to wildtype (WT) littermates. Next, we investigated whether homozygous mice showed ASD-associated behavioural phenotypes. We observed reduced ultrasonic vocalizations in juvenile mutant mice. Adult mice did not show differences in socio-communicative or anxiety behaviours, but mutant mice displayed increased repetitive behaviours and reduced performance on the accelerating Rotarod. High resolution structural MRI revealed volumetric alterations in adult mutant mice compared to WT littermates . Finally, we confirmed by RNAseq that the increased H3K4me3 levels observed in *Kdm5b*$^{\Delta ARID/\Delta ARID}$ mice resulted in altered gene expression in the neocortex. The top biological pathways affected in mutant samples included developmental and signalling-associated genes. In conclusion, our results indicate that the lack of KDM5B demethylase activity leads to altered levels of H3K4me3, neurodevelopmental phenotypes and dysregulated gene expression in the neocortex.

Title: The NO Answer for Autism Spectrum Disorder

Authors: *M. K. TRIPATHI[1], S. K. OJHA[1], M. KARTAWY[1], W. HAMOUDI[1], A. CHOUDHARY[2], S. STERN[2], A. ARAN[3], H. AMAL[1];
[1]faculty of medicine, Hebrew Univ., Jerusalem, Israel; [2]Sagol Dept. of Neurobiology, Fac. of Natural Sci., Univ. of Haifa, Haifa, Israel; [3]Neuropediatric Unit, Shaare Zedek Med. Ctr., Jerusalem, Israel

Abstract: Autism spectrum disorders (ASDs) include a wide range of developmental disorders that share a core of neurobehavioral deficits manifested by abnormalities in social interactions, deficits in communication, restricted interests, and repetitive behaviors. Several reports showed that mutations in different high-risk ASD genes, including SHANK3 and CNTNAP2, lead to ASD. However, the underlying molecular mechanisms have not been deciphered, and no effective pharmacological treatment has been established for ASD. Recently, we reported a dramatic increase in nitric oxide (NO) levels in different ASD mouse models. NO is a multifunctional neurotransmitter that plays a key role in different neurological disorders. However, its functional role in ASD has not yet been fully investigated. Here, we conducted a multidisciplinary comprehensive study using cellular and mouse models, as well as clinical samples and human iPSCs to investigate the role of NO in ASD. Our study showed that treating wild-type mice with an NO donor led to an ASD-like phenotype, which has been confirmed biochemically and behaviorally. High levels of nitrosative stress biomarkers were found in the cortex and the striatum of both the Shank3 and Cntnap2 ASD mouse models. Pharmacological intervention with a neuronal NO synthase (nNOS) inhibitor in both models reversed the molecular, synaptic, and behavioral ASD-associated phenotypes. These findings were validated in primary neuronal cultures as well as genetically in Shank3 and nNOS double-knocked down human SHSY5Y cells. Importantly, treating iPSC-derived cortical neurons from patients with SHANK3 mutations with the nNOS inhibitor showed similar therapeutic effects. Clinically, we found a significant increase in nitrosative stress biomarkers in the plasma of low-functioning ASD patients, compared with typically developed volunteers. An innovative mass spectrometric method, SNOTRAP, was utilized to identify the S-nitrosylated proteins to identify NO-mediated post-translational modifications in the clinical plasma samples. Bioinformatics revealed that the complement systems as well as the synaptic and neuronal development processes were enriched in the ASD group. This novel work reveals that NO plays a significant role in ASD development. Our important findings will open future and novel directions to examine NO in diverse mutations

on the spectrum as well as in other neurodevelopmental disorders and psychiatric diseases. Finally, it suggests a novel strategy for effectively treating ASD.

Title: Autism-associated KCND2 mutation induces multiple behavioral abnormalities in heterozygous knock-in mice

Authors: *H. H. JERNG, P. J. PFAFFINGER;
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The *KCND2* gene encodes the Kv4.2 voltage-gated potassium channel that forms the somatodendritic subthreshold A-type current (I_{SA}) important for regulating membrane excitability, repetitive firing, action potential backpropagation, and signal integration and processing. A missense mutation in KCND2 (Kv4.2/V404M) was identified in patients with early-onset epilepsy, autism, and global developmental delay (Lee et al, 2014; Zhang et al, 2021); however, a direct link between the V404M mutation and the disease phenotype has not been firmly established. To investigate the potential role of the V404M mutation in disease etiology, we generated heterozygous V404M knock-in C57BL/6J mice using CRISPR technology and observed their development and behavior in comparison against age-matched and sex-matched wild-type controls (male and female: wild-type, n=5 each; V404M, n=4 or 5 each). The V404M heterozygotes exhibit marked mortality during early development (~50% mortality), decreased body weight of males (25-30%), and a myriad of behavioral changes. In the open field assay, V404M mice display notable anxiety with hyperactivity (increased moving time: male, $p < 0.01$; female, $p < 0.01$) (greater distance traveled: male, $p = 0.03$, female, $p < 0.01$) and prominent thigmotaxis (increased margin time: male, $p < 0.01$; female, $p = 0.05$). In a conditioned fear (CF) assay, 24 hours after two rounds of training, V404M mice show little to no freezing response to the same environmental context (male, $p = 0.035$; female, $p = 0.01$) and

reduced response to the cued tone (male, $p = 0.01$; female, $p = 0.01$). In a Morris's water maze (MWM) assay, after four days of training mice were tested for their ability to remember the location of the hidden platform. In the MWM probe trials, V404M mice display thigmotaxis with undirected search behavior and spend less time in the platform zone compared to wild-type mice (male, $p = 0.05$; female, $p < 0.01$). Finally, male V404M mice show significantly reduced interest in social interactions in 3-chamber Crawley test (decreased partner cup time, $p = 0.02$). In conclusion, our results indicate that the V404M mutation produces a spectrum of behavioral changes in mice that likely have important implications for understanding the human disorder.

Title: Evolutionary constraint genes implicated in neurodevelopmental disorders across 2,054 rhesus macaque genomes

Authors: M. WOODBURY-SMITH[1,2], M. UDDIN[3], J. VELTMAN[1], *Y. KIKUCHI[1]; [1]Biosci. Institute, Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Cumbria, Northumberland Tyne and Wear NHS Trust, Newcastle upon Tyne, United Kingdom; [3]Col. of Medicine, Mohammed Bin Rashid Univ. of Med. and Hlth. Sci., Dubai, United Arab Emirates

Abstract: Significant progress has been made in understanding the genetic basis of neurodevelopmental disorders (NDDs), which are chronic, childhood-onset conditions that affect cognition, communication, and behaviour. These disorders are among the most severe from a public health perspective, and it is hoped that further research will lead to new therapeutic and intervention strategies. However, there are still significant gaps in our understanding of the link between genotype, neurobiology, and clinical phenotype, which means that new models are needed to advance our understanding. Rhesus macaques (*Macaca mulatta*) have been extensively used for preclinical neurobiological research because of their remarkable similarities to humans in neurobiology and sophisticated social and cognitive behaviours that cannot be captured by other experimental animals. Consequently, nonhuman primates offer the opportunity to understand the neurobiology of NDDs. We used the macaque Genotype And Phenotype (mGAP) resource (v2.0), which consists of 2,054 macaque genomes, to examine patterns of evolutionary constraint in known human neurodevelopmental genes. Residual variation intolerance scores (RVIS) were calculated for all annotated autosomal genes (N=18,168) and Gene Set Enrichment Analysis (GSEA) was used to examine patterns of constraint across the neurodevelopmental genes. We demonstrated that the patterns of constraint across autosomal genes are positively

correlated in humans and macaques (Pearson's product-moment correlation = 0.42, *P* = 2.2e-16), and those genes implicated in autism spectrum disorder (ASD), epilepsy, intellectual disability (ID) and schizophrenia (SZ) all exhibit significant constraint as evidenced by both GSEA and their significant over-representation among the top 2% constrained genes. Moreover, a small number of key NDD genes that are highly intolerant to mutation in humans showed no evidence of similar intolerance in macaques (*CACNA1D*, *CNTNAP2*, *MBD5*, *AUTS2* and *NRXN1*). The presence of pathological mutations in NDD genes among macaques, and the evidence of similar constraints in these genes to humans, provide a strong rationale for further investigation of genotype-phenotype relationships in nonhuman primates. This highlights the importance of identifying phenotypic behaviours associated with clinical symptoms, elucidating the neurobiological underpinnings of neurodevelopmental disorders, and developing primate models for translational neuroscience research to advance approaches for precision medicine and gene therapy interventions.

Title: Preclinical study of deep brain stimulation for severe self-injurious behaviors associated with Autism Spectrum Disorder

Authors: *K. ZHANG[1,4], R. MATIN[1,4], M. EBDEN[1], C. GORODETSKY[2], F. VENETUCCI GOUVEIA[1], G. M. IBRAHIM[3,4];

Abstract: Intractable self-injurious behaviour (SIB) is common in children with Autism Spectrum Disorder (ASD) with limited treatment options. Severe SIB is associated with physical injury, distress, repeated hospitalizations and reduced quality of life for children and their caregivers. Deep brain stimulation (DBS) - a neurosurgical procedure that involves implantation of electrodes and delivery of electric current into specific brain targets to therapeutically alter neural function - is an emerging treatment option for severely affected children. SIB is thought to result from dysfunctions in structures along the fronto-limbic-striatal network, thus, targeting these areas with DBS may reduce the severity and/or frequency of SIB. Neuromodulation within the fronto-limbic-striatal network has been successful in alleviating symptoms of SIB; however, the neural underpinnings of this treatment are poorly understood. Preclinical studies are required to better understand its mechanisms of action. The inbred BTBR T+ Itpr3tf/J (BTBR) mouse strain is commonly used for investigations of ASD as these mice display distinctive phenotypic

traits that constitute a reliable face-validity for modeling SIB and ASD. Notably, they exhibit excessive repetitive self-grooming; a behaviour that is comparable to SIB. To explore the effects of DBS of the fronto-limbic-striatal network on SIB and autism-relevant phenotypes, we used the BTBR mouse model of ASD and administered chronic high-frequency stimulation via implanted electrodes. Animals were tested for: I) excessive self-grooming, II) general locomotion and anxiety (open field test), III) socialization (three-chambered social approach test), and IV) repetitive behaviour (marble burying test). Neurocircuitry influenced by DBS of the fronto-limbic-striatal network was assessed using high-resolution magnetic resonance imaging. The chronic DBS treatment reduced injurious self-grooming and repetitive behaviours. Using deformation-based morphometry and MAGeTbrain (Multiple Automatically Generated Templates Brain Segmentation Algorithm) pipelines, we observed distinct volumetric changes along the neurocircuitry involved in regulating SIB. These preclinical results with mouse models of ASD provide insights into the plasticity induced by chronic high-frequency stimulation of the fronto-limbic-striatal network and has high translational potential.

Univ., Jeonju, Korea, Republic of

Abstract: The earliest diagnosis of autism spectrum disorder (ASD) dates back for over several decades. Nevertheless, the etiology of ASD development is still poorly understood, given its complexity as a multi-symptomatic behavioral disorder. Some transgenic mice models, such as the *Cntnap2* knockout (KO) mice, have exhibited ASD-like phenotypes in animal sociability paradigms, imparting valuable insights on ASD pathophysiology. This may provide an

opportunity for identifying detectable protein-based biomarkers, which may contribute to the development of early-onset ASD diagnostic methods. Herein, we performed an integrated approach for analyzing blood and brain proteomes from *Cntnap2* KO mice and/or patients diagnosed with ASD. Furthermore, functional enrichments and protein-protein interactions (PPIs) were determined through gene ontology (GO) and pathway analysis. 91 common differentially expressed proteins (DEPs) were determined between the proteomes obtained from *Cntnap2* KO mice and ASD patient blood. GO and pathway analysis revealed that hemostasis-related mechanisms were highly enriched in these DEPs. Comparison of the hemostasis-related proteome subset obtained from blood with published cortical proteomes of *Cntnap2* KO mice revealed that Filamin-A (FLNA) and Transferrin (TRF) were commonly upregulated and 4F2 cell-surface antigen heavy chain (SLC3A2) was commonly downregulated across the datasets. Mutations and/or dysregulations in genes that code FLNA, TRF, and SLC3A2 were previously found to potentially result in adverse neurodevelopmental consequences. Previous studies showed that mutations in *Flna* may influence SHANK3 (SH3 and multiple ankyrin repeat domains 3), whose mutation may also result in ASD-like phenotype in mice, while abnormal iron metabolism due to *Trf* dysregulation was found in autistic children. Reports describing the deletion or mutation of *Slc7a5* (solute carrier transporter 7a5), which encodes LAT1 (large neutral amino acid transporter 1) that can heterodimerize with SLC3A2, revealed ASD-like phenotypes in both mice and humans, including the detection of *Slc3a2* genetic variants in ASD patients. Further studies are currently underway that are geared towards the validation of these DEPs in other ASD animal models by correlating their expression levels with ASD-like phenotypes. Overall, our preliminary findings may further support the probable roles of neural and peripheral mechanisms associated with hemostasis, amino acid transport, and iron metabolism in the occurrence of ASD, rendering FLNA, SLC3A2, and TRF as potential biomarkers for early-onset ASD diagnosis.

Title: Phenotypic Rescue via mTOR inhibition in neuron specific PTEN knockout mice

Authors: *A. D'AMORE, M. SUNDBERG, R. LIN, E. LUBBERS, H. HING CHEONG LEE, M. SAHIN;
Neurobio., Boston Children's Hosp., Boston, MA

Abstract: BACKGROUND: Germline *PTEN* mutations are commonly associated with PTEN Hamartoma Tumor Syndrome (PHTS), characterized by benign tumor-like malformations in the body. PHTS exhibits high rate of neurological comorbidities, including ASD, however the relevance of neuronal *PTEN* mutations in PHTS remains unclear. In this study, we: 1) generate *Synapsin-1^{Cre};PTEN$^{f/f}$* (Syn-PTEN KO) mice, 2) characterize this line's development, including survival and transcriptomic analyses, 3) generate and characterize Syn-PTEN KO mouse primary neuronal cultures, and 4) treat with Everolimus to test for phenotypes rescue.
METHODS: We crossed *PTEN$^{f/f}$* and *Synapsin-1^{Cre}* to generate Syn-PTEN KO mice. We measured body weight, brain:body weight ratio and survival of the resultant litters in all genotypes (HOM, HET, WT). Everolimus (3mg/kg, IP) was administered to HOM mice starting at P7, 3x/week. Western blot and RNA-seq were performed on brain tissue. Primary neuronal cultures were dissected from E18.5 pups and firing activity parameters were measured at baseline and post-treatment using the MEA system. Immunostaining for Synapsin1/PSD95/MAP2 expression was performed to quantify synapses in vitro.
RESULTS: We found significant reduction in body weight and lifespan and increased brain:body weight ratio in HOM mice compared to HET or WT control. Everolimus improved lifespan but not weight of HOM mice. HOM neuronal cultures showed increased weighted mean firing
rate and number of bursts compared to HET or WT controls. This network hyperactivity phenotype was partially rescued with everolimus. Synapsin1 and PSD95 were significantly increased on MAP2 neurites in HOM neurons, and were rescued upon everolimus treatment. RNA-seq revealed ~600 differentially regulated genes in HOM mice compared to control. Gene ontology analyses indicated myelin and extracellular matrix (ECM) are amongst the major subclasses of upregulated genes. Immunostaining confirmed significant increase in myelin and perineuronal nets in HOM mice.
CONCLUSION: We successfully generated a novel neuronal-specific PTEN knock-out mouse model. Syn-PTEN KO mice exhibited profound neurological and molecular pathology culminating in premature lethality. Everolimus only partially rescued these phenotypes. Primary HOM neuronal cultures demonstrated hyperactive firing properties as well as excitatory synaptic marker increase, and both were partly rescued by Everolimus. Our data suggests that mTOR inhibition only provides partial rescue of PTEN pathology, likely due to downstream targeting. Alternative approaches targeting upstream of mTOR might be tested in the future.

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder that manifests as impairments in social interactions, and restricted repetitive patterns of behaviors, interests, or activities. According to 2020 CDC estimates, U.S. reported ASD diagnosis in 1/36 children. The ability to identify therapeutic strategies to target the disease relies heavily on the existence of animal models that capture the disease phenotype. The BTBR T+ Itpr3tf/J mouse has been proposed as an idiopathic model of ASD. We compared male BTBR and C57BL/6J mice (n=12/group) aged 8-10 weeks, on a battery of behavioral tests (open field, Y-maze, self-grooming, reciprocal social interaction, marble burying) and using *in vivo* 1H-magnetic resonance spectroscopy (MRS). Memantine, a therapeutic agent proposed for the treatment of core symptoms of ASD, with previously demonstrated efficacy in this model was used as a reference compound.
Our findings revealed no significant differences in activity measures during the Open field assay, between the BTBR and C57 mice. In the Y-maze test for spatial reference memory, vehicle treated C57 mice displayed increased preference for the novel arm relative to the familiar arm, an outcome that was not observed for BTBR mice. In the self-grooming assay, the BTBR mice spent more time grooming compared to C57 mice. During social interaction test that quantified both social and non-social behavior, no clear deficit in social behavior was observed for BTBR mice. Among nonsocial behaviors, exploration was higher in vehicle treated BTBR mice compared to their C57 counterparts. Self-directed grooming in the presence of conspecific, was lower among vehicle treated, BTBR individuals relative to C57 mice. In the marble burying test, memantine treated BTBR mice buried fewer marbles compared to their vehicle treated counterparts. MRS data captured the model phenotype for BTBR mice that displayed higher levels of glutamine, glutamate + glutamine, glucose, phosphocreatine, creatine + phosphocreatine but lower lactate levels compared to C57 individuals. Among BTBR mice, positive control memantine attenuated glucose levels, caused GABA to decrease, further reduced the lactate levels, and increased glutamate + glutamine levels, relative to the vehicle treatment. Altogether, the BTBR mice expressed deficit in short-term spatial memory, increased self-grooming and altered behavior in social contexts compared to C57 mice. In addition, striatal MRS showed alterations in several metabolites. Behavioral phenotypes observed in BTBR mice capture a subset of the key deficits of ASD and can prove to be a useful model for identification of therapeutic interventions.

Title: Deletion of SHANK3 gene leads to alterations in the morphology of astrocytes

Authors: *S. SUBA, D. BALLINAS, A. MCDONALD, T. DEEMYAD;
Otolaryngology, Head and Neck Surgery, Johns Hopkins Univ., Baltimore, MD

Abstract: Synaptic connections in the brain consist of the presynaptic axon, the postsynaptic dendrite and the ensheathing astrocytic process. Astrocytes are morphologically complex, non-neuronal cells that play critical roles in synapse assembly, maturation and function. Many autism risk genes encode proteins that play critical roles in regulating the formation, maturation and function of synaptic connections in the brain, yet the underlying molecular mechanisms of autism are poorly understood. SH3 and multiple ankyrin repeat domains 3 (SHANK3) encodes different isoforms, including Shank3 deltac and Shank3b that stand as a prominent candidate in autism spectrum disorder. RNA sequencing of mouse and human brains revealed expression of SHANK3 gene in both neurons and astrocytes. Previous studies have shown that the loss of the Shank3 deltac isoform does not affect the size of astrocyte domains or cell body size in the hippocampus. However, the impact of eliminating the Shank3b isoform on astrocyte maturation, particularly within the cortical circuit, has not been clearly understood. Here, using electron microscopy and immunohistological assays we identified the developmental trajectory of astrocytes in auditory and somatosensory cortices of Shank3b KO mice. Our preliminary data obtained from Shank3b KO mice indicates a notable increase in the cell body density of astrocytes, particularly in layers 4 and 5 of the auditory and somatosensory cortices. These findings are observed both in adult mice as well as during the critical period of development. Furthermore, the sholl analysis conducted on the astrocytes reveals that the maximum increase in distal processes, leaflets, occurs at a distance of 200 nm from the soma. This indicates that the structural complexity of astrocytes and their perisynaptic territories, as reflected by the number of processes intersecting, is significantly altered in the absence of the Shank3b isoform. Taken together, these findings suggest that the elimination of the Shank3b isoform may indeed have an impact on the maturation of astrocytes within the cortical circuit, specifically in the auditory and somatosensory cortices.

Title: The effect of sulforaphane on autism spectrum disorder behaviors in BTBR mice

Authors: *S. RIEBESELL, N. TOUMANIOS, E. CRAIG, M. SCHMID, R. FREEDMAN, M. POMPY, C. CULLIGAN, C. MCGEARY, L. A. GABEL;
Lafayette Col., Easton, PA

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by restrictive behaviors and social deficits. BTBR T + Itpr3tf/J (BTBR) mice exhibit traits, such as poor social interaction and repetitive behaviors, with face validity to the diagnostic criteria for autism. At the cellular level, ASD is believed to be associated with oxidative stress, which leads to inflammation. Sulforaphane (SFN), a chemical derived from cruciferous vegetables, has been shown to have neuroprotective effects based on its antioxidant and anti-inflammatory properties. The purpose of the current study was to determine the effects of SFN on core symptoms of ASD and comorbidities, such as anxiety, hyperactivity, and impaired memory, in BTBR mice. We found that in the marble-burying task, BTBR mice buried significantly more marbles compared to controls (C57BL/6 [Bl6]), revealing a repetitive behavior phenotype of the BTBR strain, which was attenuated by self-administration of 50 mg/kg of SFN. Additionally, BTBR mice exhibited increased hyperactivity on the Y-maze based on a significant increase in the total number of entries compared to the Bl6 mice, which was ameliorated with SFN treatment. Lastly, SFN treatment increased social interaction in BTBR mice on the three-chamber task but decreased sociability for the Bl6 strain. However, BTBR mice treated with vehicle did not significantly differ from Bl6 mice suggesting they did not exhibit a sociability deficit, contrary to prior findings. We investigated the effect of SFN treatment on autistic-like behaviors and comorbidities in BTBR mice. Our results provide support for the efficacy of SFN treatment on repetitive behaviors and hyperactivity, but it is unclear whether SFN treatment will improve sociability based on the results from this study. BTBR mice did not exhibit impaired sociability on the three-chamber task, however, SFN treatment increased sociability in BTBR mice while decreasing sociability in Bl6 mice. Future studies will need to examine additional measures of sociability to confirm these findings, however, it is possible that BTBR mice may exhibit some, but not all, autistic-like behaviors to make it a suitable model of ASD.

Title: Developmental Trajectory and Mechanisms of Genotype- and Sex-Dependent Differences in Auditory Sensitivity and Temporal Processing in a PTEN-deletion model of ASD

Authors: *K. CROOM[1], J. A. RUMSCHLAG[2], M. A. ERICKSON[1], D. K. BINDER[1], K. M. HUBER[3], K. A. RAZAK[1];
[1]Univ. of California, Riverside, Riverside, CA; [2]Med. Univ. of South Carolina, Charleston, SC; [3]Univ. of Texas Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: The current study aims to identify the developmental trajectory and mechanisms of genotype- and sex-dependent differences in auditory sensitivity and temporal processing in the PTEN-deletion (phosphatase and tensin homolog missing on chromosome 10) mouse model of autism spectrum disorder (ASD). ASD is currently diagnosed in approximately 1 in 44 children in the US and encompasses a wide array of debilitating symptoms, including sensory deficits. Sensory deficits early in development may lead to the broader symptomology in adolescents and adults with ASD, including abnormal language development. Auditory temporal processing is crucial for speech recognition and language development and deficits are hypothesized to cause language impairments in ASD. The mechanisms underlying sensory deficits may show sex-dependency. PTEN has sex-dependent interactions through its regulation of estrogen receptor α (ERα) and is also an ASD-linked gene, providing the opportunity to test whether and how sex-differences in sensory processing abnormalities may arise during development in an ASD model. We recorded epidural electroencephalography (EEG) signals from the frontal (FC) and auditory (AC) cortex in developing and adult Nse-cre PTEN mice, which removes PTEN in specific cortical layers (layers III-V) and the dentate gyrus. Temporal processing is measured using a gap-in-noise-ASSR (auditory steady state response) stimulus paradigm. The experimental manipulation of gap duration and modulation depth in the syllabic range of speech allows us to measure cortical entrainment to rapid gaps in sounds. We quantified temporal processing using inter-trial phase clustering (ITPC) values that account for phase consistency across multiple trials. The results show sex differences in resting power distribution in young mice (p21). Female, but not male, PTEN KO mice have increased beta power. This abnormal power distribution remains throughout development in females. Both male and female PTEN KO mice show diminished ITPC in their gap-ASSR responses in the AC and FC compared to control mice at all ages tested. These deficits become more prominent in adult (p60) mice, with KO mice having increased absolute resting and sound evoked power but significantly decreased ITPC compared to controls. These data suggest that auditory temporal processing deficits in PTEN ASD model mice are present from an early age and may contribute to abnormal development of speech recognition and language function in ASD. Future studies will include targeted treatments to gain insight into underlying mechanisms, critical windows of treatment and potential treatments in PTEN model mice.

Title: Characterization of transglutaminase role in Drosophila melanogaster neurodevelopment and behaviour

Authors: *I. ALMONACID-TORRES, M. GONZÁLEZ-RAMÍREZ, P. GÓMEZ-FETT, C. OLIVA, M. ANDRÉS, J. M. CAMPUSANO;
Celular and Mol. Biol., Pontificia Univ. Católica de Chile, Santiago, Chile

Abstract: Transglutaminase 2 (TG2), a member of the transglutaminase family, plays a keyrole in several disorders including cancer progression, celiac and cardiovasculardiseases, among other conditions. It has been also suggested that TG2contributes to several brain disorders including neurodegenerative diseases andCNS injury, due to its ability to crosslink proteins into insoluble aggregates.Although recent reports support that TG2 plays a role in neural development, thisis still under investigation. In the *Drosophila melanogaster* genome there is onlyone transglutaminase (TG) gene which might be responsible for all actionsplayed by this enzyme family in other animals. In this exploratory research wehave asked whether flies deficient in TG expression exhibit behavioralphenotypes which could be linked to CNS structural alterations.We studied behavioural phenotypes in flies globally deficient in TG expression -Tg^{d01144} and *Tg-CRIMIC* mutants- or bearing a neuron specific deficiency for theTG enzyme. Female and male flies at different ages (3-5 and 8-10 days aftereclosion) were studied.Our data show that TG homozygous mutant animals exhibit reduced lifespan ascompared to heterozygous and control flies. TG mutant animals exhibit impairedstartle-induced climbing behaviour, while they show reduced locomotion whenthey are allowed to freely-move in a behavioral arena alone. TG mutant animalsalso exhibit increased centrophobism, which reflects anxiety. Additionally, the TGmutant flies exhibit reduced interaction time with their peers, which suggestasocial behavior.These behavioral phenotypes are accompanied by modifications in fly brainanatomy, evidenced by structural changes in the mushroom bodies, an importantassociation area in the fly brain.In conclusion, our data support that TG is a relevant enzyme in brain formationand operation.Supported by Fondecyt 1231556 (JMC).

Abstract: Autism Spectrum Disorder (ASD) is a heterogenous group of neurodevelopmental disorders that is characterized by impairments in social interactions, communication, and the presence of stereotypic behaviors. ASD affects 1 in every 36 children in the United States and is four times more prevalent in boys than in girls. Both genetic and environmental factors converge on deficits in the GABAergic system, suggesting that inhibitory interneurons might be particularly susceptible and contribute to ASD pathophysiology. Several studies, including our own, have demonstrated that 10-20% of mothers of a child with ASD harbor brain-reactive antibodies (IgG). One target of these antibodies is Caspr2, a protein involved in neural development and synaptic transmission, and present in up to 40% of mothers with anti-brain antibodies and an ASD child. We have developed a model in which female mice are immunized with Caspr2 and harbor endogenous polyclonal anti-Caspr2 IgG throughout gestation. Male, but not female offspring, display ASD-like behaviors and exhibit brain abnormalities including a reduction in the GABAergic parvalbumin interneurons (PV) in the cortex and hippocampus. We did not observe changes in the total GABAergic, nor in somatostatin interneurons suggesting that exposure in utero to anti-Caspr2 IgG selectively affects PV interneurons. The reduction in PV interneurons in Anti-Caspr2 male mice cannot be explained by a reduction in progenitors or altered migration as number of proliferating cells in the medial ganglion eminence (MGE) and the number of migratory interneurons were similar between Control and Anti-Caspr2 mice. Single nucleus transcriptomics of hippocampal GABAergic interneurons revealed significant alterations in gene pathways that are associated with neural transmission and CNS development. Furthermore, immunofluorescent imaging of synaptic protein expression in these mice revealed a reduction of perisomatic inhibitory synapses onto CA1 pyramidal neurons. We next sought to understand how these deficits in PV interneurons might affect neural activity in the hippocampus. We implanted multi-electrodes in Anti-Caspr2 male mice targeted to the CA1 region and calculated relative power in the gamma band. Anti-Caspr2 male mice exhibited a significant increase in mid and high gamma oscillations compared to Control mice. Since PV interneurons contribute to hippocampal network synchrony, and dysregulation of these cells is a proposed mechanism underlying ASD; ongoing studies are focused on the trajectory of PV

interneuron development and the effect of exposure in utero to anti-Caspr2 IgG on the intrinsic physiology of PV interneurons.

Title: Characterizing the Impact of Developmental Cc2d1a Reduction as a Novel Mouse Model of ASD/ID

Authors: A. T. HELLER[1], A. BHATTACHARYA[1], S. S. RAUF[1], *M. MANZINI[2];
[1]Child Hlth. Inst. of New Jersey, [2]Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract: Intellectual disability (ID) and Autism Spectrum Disorder (ASD) are highly heterogenous neurodevelopmental disorders that are thought to affect early brain development. Previous research has identified *CC2D1A* loss of function (LOF) as a cause of 100% penetrant ID, and highly penetrant ASD. Existing mouse models of *Cc2d1a* LOF rely on the conditional knockout (cKO) of *Cc2d1a* within specific cell types after birth due to early postnatal lethality of global knockouts (KOs). But cKO models have limited translatability to patients with *CC2D1A* LOF due to conditional and postnatal removal of the gene.
Our lab generated a mouse line tagged with both the V5 and HA epitope tags to improve endogenous CC2D1A detection but found that the tags lead to protein degradation. Homozygous CC2D1A-V5-HA mice ($Cc2d1a^{V5\text{-}HA}$) bypass postnatal lethality with a ~86% reduction of CC2D1A but did not recapitulate any of the ASD/ID-like behavioral deficits seen in cKOs. To investigate this phenotypic expression threshold, we generated a mouse line with severe haploinsufficiency (~92% protein reduction) of *Cc2d1a* by breeding a *Cc2d1a* KO allele with $c2d1a^{V5\text{-}HA}$, to obtain $Cc2d1a^{-/V5\text{-}HA}$ compound heterozygous (compHET) mice. These mice are viable and show no gross motor or sensory deficits. Behavioral analysis on a pilot cohort of male and female *Cc2d1a* compHET mice suggests male-specific deficits in sociability, social novelty preference, and spatial memory. While male-specific deficits have been seen in *Cc2d1a* cKOs before, these compHET males show a trend toward more severe social and cognitive deficits. Immunoblot analysis on the hippocampus and cortex of these males suggests CREB activation deficits different from those seen in previous *Cc2d1a* cKO models. While previous research on cKOs has implicated the PKA/CREB pathway, compHET males did not show changes in PKA

activation or cAMP levels. Instead, compHET males had decreased ERK1/2 and CaMKII activation in the cortex as well as reductions in CaMKII activation in the hippocampus. This preliminary, but growing data, suggests this severe developmental reduction of *Cc2d1a* in the mouse has unique neuronal mechanisms driving the ASD/ID-like phenotypes. The investigation of this model can help us better understand some of the mechanisms driving ASD and ID in *CC2D1A* LOF patients.

Title: Gestational influenza A virus disrupts downstream maternal and fetal immune profiles in a dose- and time-dependent manner

Authors: *A. OTERO[1,2], R. GONZALEZ-RICON[1,2], I. CHALEN[1,3], A. ANTONSON[1,3]; [2]Neurosci. Program, [3]Animal Sci., [1]Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: Epidemiological studies link neurodevelopmental disorders (NDDs) with exposure to maternal viral infection in utero. The hypothesized mechanism governing this link comes from animal models that initiate maternal inflammation with a non-pathogenic viral mimic to induce an acute immune response. These studies indicate that maternal intestinal T helper 17 (T_H17) cells are activated to produce interleukin (IL)-17, and this pro-inflammatory cytokine is implicated as a major driver of fetal brain abnormalities. Priming of T_H17 cells is also observed following respiratory influenza A virus (IAV) infection; however, whether these T_H17 cells might be driving fetal brain abnormalities during gestational IAV infection has never been examined. We aim to determine how IAV infection during pregnancy impacts maternal intestinal immune cells and if IAV-mediated activation of these cells is sufficient to result in aberrant brain development. To test our hypothesis, we inoculated pregnant C57BL/6NTac mice on gestational day (GD)9.5 with H3N2 IAV strain X31. Maternal serum, lungs, and intestine, placentas and fetal brains were collected on GD11.5 and 16.5, two- and seven-days post inoculation (dpi) to evaluate peak innate and adaptive immunity, respectively. Pregnant dams received 10^4 $TCID_{50}$ X31 ($X31_{hi}$; n=12, n=10), 10^3 $TCID_{50}$ X31 ($X31_{mod}$; n=14, n=9), or a mock-inoculation with saline (control; n=13, n=10) across three identical replicates per end point. Lung histopathology scores, viral expression, and inflammatory genes were upregulated in a dose- and time-dependent manner. Respiratory IAV infection led to colonic shortening at both time points despite no detection of virus in the intestine. Morphological changes were accompanied by upregulation of

T_H17 cell gene markers in the intestine at the high viral titer only. This includes genes encoding RORγt and IL-6, indicating priming of naïve T cells into T_H17 cells. Flow cytometric analyses of intestinal T_H17 cells at 2 and 7 dpi revealed a complex dose-dependent phenotypic shift. Placental immune transcripts were altered in a dose-dependent manner, demonstrating possible sequestering of adaptive immune cells and recruitment of neutrophils at the maternal-fetal interface. Immunohistochemistry revealed no changes in fetal microglial colonization patterns or proliferative capacities at GD11.5. Ongoing studies will analyze the fetal brain at GD16.5. So far, our data show that a higher infectious dose of gestational IAV is necessary to induce downstream immune changes, confirming the use of live pathogens in NDD modeling to evaluate the complete immune response and improve translation to the clinic.

Title: Perirhinal cortex dysfunction drives spatial learning deficits in the Scn2a mouse model of autism spectrum disorder

Authors: *R. E. KEITH[1], J. A. MEZA[2], M. W. ANTOINE[3];
[1]Section on Neural Circuits, Natl. Inst. on Alcohol Abuse and Alcoholism, Fairfax Station, VA;
[3]Section on Neural Circuits, [2]Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder which often results in cognitive deficits, including that of spatial learning. Over 100 genes increase susceptibility to developing ASD. One such gene, *SCN2A*, codes for the alpha subunit of voltage gated sodium channel $Na_v1.2$, a protein critical for action potential back propagation. Loss of function mutations in *SCN2A* are highly penetrant for ASD, with up to 50% of patients diagnosed. Yet, much remains unknown about which brain regions are impaired by *SCN2A* loss and how subsequent activity changes drive ASD-related behaviors. To address this knowledge gap, we assessed spatial learning and whole-brain activity in mice haploinsufficient for *Scn2a* (*Scn2a*$^{+/-}$) and tissue-specific *Scn2a*-conditional *floxed* (*Scn2a*$^{fx/+}$) mutants. Consistent with prior work, *Scn2a*$^{+/-}$ mice exhibited a spatial learning deficit. Whole-brain light-sheet imaging for cFos (a neural activity marker) in *Scn2a*$^{+/-}$;FosGFP mice revealed hypoactivity in 31 brain areas, which were enriched in cortical areas implicated in spatial learning. We thus used an *Emx1*^{Cre} driver to reduce *Scn2a* in excitatory pyramidal neurons of cortex and hippocampus, and this recapitulated the learning deficit and neural hypoactivity in 15 cortical areas. We hypothesized

these 15 regions act as a spatial learning network. By comparing the pattern of Cre recombination in Cre driver lines which restrict reductions in *Scn2a* to cortical layers and hippocampus to spatial learning, we excluded hippocampus and instead implicated perirhinal cortex as a potential causal node for the spatial learning deficit. As *Scn2a* loss may impair the neuronal depolarization needed for long-term potentiation (LTP), a correlate of learning, we measured theta-burst LTP in cortical and hippocampal specific conditional mutants for *Scn2a*. The presence of spatial deficits co-associated with LTP impairments in perirhinal cortex but not hippocampus. Further, by chemogenetically increasing depolarization in cortical pyramidal neurons of $Emx1^{Cre};Scn2^{+/-}$ mice, we normalized activity within the 15 cortical regions, restored perirhinal cortex LTP, and rescued learning. We implicated perirhinal cortex as crucial for spatial learning by selectively reducing *Scn2a* in perirhinal cortex, via stereotaxic injection of Cre virus, which impaired learning, and, vice versa, selectively increasing perirhinal cortex activity of $hM3Dq^{fx/+};Scn2a^{+/-}$ mice rescued spatial learning. This research identifies a critical locus in cases of *Scn2a* haploinsufficiency that may be targeted to improve learning deficits in ASD and, perhaps, other neurodevelopmental disorders.

Title: Tcf4 mutations cause dysregulation of the oligodendrocyte linage in a human model of autism spectrum disorder.

Authors: *A. ROMERO-MORALES[1,2], G. SHIM[1], S. SRIPATHY[1], S. STUMP[1], J. BOHLEN[1], B. J. MAHER[1,2,3];
[1]Lieber Inst. for Brain Develop., Baltimore, MD; [2]The Solomon H Snyder Dept. of Neurosci., [3]Dept. of Psychiatry and Behavioral Sci., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Pitt-Hopkins Syndrome (PTHS) is a rare form of autism spectrum disorder (ASD) characterized by developmental delay, breathing abnormalities, seizures, lack of speech, and distinctive facial features. PTHS is caused by de novo mutations in TCF4, a key transcription factor that orchestrates multiple neurodevelopmental programs. Previous studies using PTHS mouse models showed dysregulation in the density and maturity of oligodendrocytes which resulted in myelination deficits, however, confirmation of these phenotypes in a human context is currently lacking. Here, we have studied a collection of induced pluripotent stem cells (iPSCs) from PTHS patients, which harbor various types of disease-causing mutations in TCF4 that result

in the expression of putative dominant-negative proteins or haploinsufficiency. To determine if patient-specific mutations in TCF4 result in dysregulation of the OL lineage we first differentiated iPSC using a two-dimensional oligodendrocyte differentiation protocol. We observed that PTHS patient cell lines show a reduction in the expression of mature oligodendrocytes genes, which is consistent with phenotypes observed in mouse models of PTHS. In addition, using a previously described three-dimensional differentiation protocol that generates human oligodendrocytes (hOLS), we observed a significant variation ($p=0.0103$ for Genotype interaction, two-way ANOVA) in the diameter hOLS derived from PTHS that appears specific to patients harboring mutations expected to result in TCF4 haploinsufficiency. Together, these results suggest that TCF4 is a critical regulator of OL development and therefore predicts myelination deficits as a potential pathophysiological mechanism underlying neurodevelopmental abnormalities in PTHS.

Title: Differential plasticity in nucelus accumbens group 1 metabotropic glutamate receptors following limited- versus extended-access to cocaine self-administration

Authors: *B. R. FINE-RAQUET, L. METKO, M. BERGMANN, T. MAXIM, M. B. GHASEMZADEH;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Repeated high-dose cocaine abuse results in drug addiction in humans demonstrating loss of control for drug use concurrent with gradual increase in drug intake, intense craving, and withdrawal symptoms. In preclinical studies, high-dose cocaine intake can be modeled by extended-access cocaine self-administration in rodents (LgA, 6hr daily). The persistent propensity to relapse during abstinence is often associated with drug-related cues and has been a significant barrier to the treatment of addiction. Addiction studies suggest that glutamatergic signaling has an important role in cocaine addiction, particularly in drug seeking and relapse. Hence, significant effort has been invested to harness glutamatergic mechanisms for treatment of cocaine addiction. However, this research has not yet resulted in an FDA-approved treatment. The goal of the present research project is to investigate the role of group 1 metabotropic mGlu1/5 receptors (mGluR1/5) in regulation of cocaine intake and seeking. Male Sprague-Dawley rats were trained to self-administer cocaine (FR1; 1.0 mg/kg/200µl/inf) during either 2hr (ShA) or 6hr sessions (LgA) for 14 days. Subsequently, animals remained in the home cage for 3, 10, or 60 days. Following abstinence period, rats were tested for cocaine seeking under

context-primed extinction condition after systemic administration of either saline or an mGluR1/5 antagonist [JNJ16259685 (0.015 mg/kg, sc) or MTEP (3 mg/kg, ip)]. Systemic blockade of mGluR5 during short abstinence periods (3 or 10 days) reduced drug-seeking only in ShA rats without affecting LgA animals, while mGluR1 blockade was effective in both treatment groups at both withdrawal times. However, systemic blockade of either receptor led to a significant reduction in drug-seeking after a long abstinence period (60 days) in both ShA and LgA treatment groups. While intracerebral infusion of MTEP (3 μg/side) after 10 days of abstinence into either NAcore or NAshell leads to a decrease in drug-seeking in ShA rats, inhibition of NAshell mGluR1 does not block drug seeking. Interestingly, inhibition of mGluR5 in NAcore or NAshell following 10 days of abstinence was not effective in reducing drug-seeking in LgA rats. Data suggest that high-level cocaine intake produces a transient intake-dependent plasticity in NA mGluR5, but not in mGluR1 function. Moreover, our data point to both NAcore and shell as anatomical substrates contributing to selective modulation of mGluR5 function in LgA rats. These observations suggest that systemic activation of mGluR5, during early abstinence period may ameliorate the persistent drug craving present during prolonged periods of abstinence.

Title: An activity-dependent local transport regulation via local synthesis of kinesin superfamily proteins (KIFs) underlying cognitive flexibility

Authors: *S. IWATA[1,2], M. MORIKAWA[2], T. SASAKI[1], Y. TAKEI[1];
[1]Anat. and Neurosci. Lab., Univ. of Tsukuba, Tsukuba, Japan; [2]Structural Cell Biol. Lab., The Univ. of Tokyo, Bunkyo-ku, Japan

Abstract: Multiple neuronal functions require decentralized processes including activity-dependent localized protein synthesis. However, how local protein synthesis drives the dendritic remodeling is still elusive. Kinesin superfamily proteins (KIFs) are microtubule-based motor proteins that transport various types of cargos to a specific area where they function, even to the distal neurites if necessary. This intracellular transport system is essential for neuronal morphogenesis, function, and survival. KIF17 and KIF5A are abundantly expressed in neurons and have been suggested to transport NMDAR and AMPAR in neuronal dendrites, respectively.

Calcium-calmodulin-dependent protein kinase II (CaMKII)-dependent phosphorylation of KIF17 triggered by NMDAR-mediated activity regulates its capacity for binding/release of NR2B-containing vesicles, and acute increase in intracellular Ca^{2+} through NMDAR regulates the speed of AMPAR transport. Thus, we hypothesized that KIF17 and KIF5A might be functionally regulated by NMDAR-mediated neuronal activity. Here, we show that KIF17 is rapidly degraded by the proteasome and subsequently synthesized at dendritic shafts in an NMDAR-mediated activity-dependent manner. Accompanied by the degradation of KIF17, its transport is temporarily dampened in dendrites. We also report that activity-dependent local KIF17 and KIF5A synthesis driven by its 3' untranslated region (3'UTR) occur at dendritic shafts, and the newly synthesized KIF17 moves along the dendrites. Furthermore, hippocampus-specific deletion of *Kif17* 3'UTR disrupts KIF17 synthesis induced by fear memory retrieval, leading to impairment in extinction of fear memory. These results suggest that the regulation of the transport by KIF17 and KIF5A is driven by the single dendrite-restricted mechanism including local protein synthesis that underlies cognitive flexibility. This model could help further understanding how a single dendrite serves as the computational unit for the memory process.

Title: Ketamine induces direct presynaptic enhancement of glutamate release

Authors: *A. ESHRA[1], N. LIPSTEIN[2], S. HALLERMANN[3];
[1]Univ. of Leipzig, Leipzig, Germany; [2]Leibniz-Forschungsinstitut for Mol. Pharmacol., Berlin, Germany; [3]Univ. Leipzig, Leipzig, Germany

Abstract: Ketamine exerts rapid and sustained antidepressant effects via mechanisms involving sustained alteration of glutamatergic signaling, yet the immediate effects of ketamine on presynaptic function are poorly understood. Dissecting this effect is particularly difficult because of the ketamine-induced neuronal circuit potentiation which occurs via alteration of postsynaptic glutamate receptors. To unequivocally isolate the presynaptic mechanisms of ketamine and rule out potential neuronal network effects, we here used direct presynaptic recordings at a bona-fide cerebellar synapse in the intact brain tissue where the cell soma was removed. We performed 238 presynaptic recordings in 5 independent blinded experimental datasets and found that ketamine has a prominent direct effect on presynaptic release. We show that ketamine induced an enhancement of presynaptic release by approximately 30% within 30 minutes. The enhancement of release was sustained for at least 30 minutes after ketamine washout. Comparative

experiments with MK-801 revealed no effect on presynaptic function indicating that NMDA-receptors blockade in itself does not enhance presynaptic release. Further mechanistic analysis indicated that the ketamine-induced enhancement of presynaptic release is due to an increase in both calcium influx and the number of presynaptic release sites. Our results thus show that ketamine potentiates glutamate release via direct presynaptic mechanisms.

Title: Silica nanoparticles decrease glutamate uptake in blood-brain barrier components

Authors: *F. R. E. D. SANCHEZ;
Toxicology, Ctr. for research and advanced studies from national polytechnic institute, Mexico city, Mexico

Abstract: Silica nanoparticles (SiO_2-NPs) have been widely used in biomedical applications and directed to enter the circulatory system; however, little is known about the potential adverse effects of SiO_2-NPs exposure on the blood-brain barrier (BBB) transport systems that support the critical barrier function between the central nervous system (CNS) and the peripheral circulation. This study investigated whether SiO_2-NPs disrupt the transport systems expressed by BBB cell components. First, we evaluated the cytotoxic effect of SiO_2-NPs endothelial (HBEC) and astrocyte (U-87MG) cell lines. Transport kinetics was measured, and the exposure effect of SiO_2-NPs on glutamate transport activity was evaluated in both cell lines. Exposure of cell lines to different SiO_2-NPs concentrations (0.4, 4.8, 10 y 20 µg/ml) and times (3 and 6 hours) resulted in no changes in cell viability. We found that the radio-labeled D-aspartate ([^{3}H]-D-Asp) uptake is sodium-dependent, at least in part, and downregulated by its own substrate (glutamate). Furthermore, SiO_2-NPs exposure on endothelial and astrocytes decreases [^{3}H]-D-Asp uptake at different concentrations (2.4, 4.8, 6.4 y 10 µg/ml). Interestingly, a decrease in the transporter catalytic efficiency, probably linked to a decrease in the affinity of the transporter was detected upon SiO_2-NPs exposure. These results demonstrate that SiO_2-NPs could disrupt BBB function and can help to understand the effects of air pollution on the CNS.

Title: Kir4.1 channels shape astrocyte membrane potential and modulate glutamate uptake: implications for traumatic brain injury

Authors: *J. GARCIA[1], M. ARMBRUSTER[1], C. DULLA[1], D. K. MULKEY[2], S. NASKAR[3]; [1]Tufts Univ. Grad. Program In Neurosci., Boston, MA; [2]Univ. Connecticut, Univ. of Connecticut Physiol. & Neurobio., Storrs Manfld, CT; [3]Tufts Univ. Sch. of Med., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Glutamate, the primary excitatory neurotransmitter in the central nervous system, is essential for normal brain function. In the healthy brain, once released from neurons, glutamate is transported into astrocytes by the excitatory amino acid transporters (EAATs) GLT-1 and GLAST. Previously, using iGluSnFr-based glutamate imaging and electrophysiology in the healthy adult mouse cortex, we have shown that glutamate uptake slowed up to threefold following bursts of neuronal activity. We suspect that this occurs because neuronal activity generates action potentials, causing focal increases in extracellular potassium ($[K^+]_e$). This increase in $[K^+]_e$ drives local astrocyte depolarization, causing voltage-dependent inhibition of EAATs and prolonging extracellular glutamate transients. We hypothesize that EAATs drive uptake while Kir4.1 shapes activity-dependent slowing of glutamate. In this study, I employed the controlled cortical impact (CCI) model of TBI in mice. TBI affects over 60 million people worldwide and multiple studies show that glutamate levels are increased in the human brain after TBI, as well as in animal models and in patients are associated with increased mortality. Three days after CCI I found significantly elevated glutamate decay time constants and increased peak glutamate response in acute cortical slices. This effect was decreased 7 and 14 days after injury. The slowing of glutamate uptake was largely similar in the healthy and injured brain for all time points. IHC and single-cell RNA sequencing data show significantly decreased levels of astrocyte-specific GLT1 and GLAST that return to sham levels 7 and 14 days after injury. Interesting Kir4.1 expression remains largely unchanged for all time points. Additionally, using a $Kir4.1^{fl/fl}$ mouse model and an astrocyte-specific Cre-virus I have conditionally and focally knocked out Kir4.1. Previously, using Genetically Encoded Voltage Indicators (GEVI), we reported report large, rapid, focal, and pathway-specific depolarizations in peripheral astrocyte processes (PAPs) during neuronal activity. We have shown blocking Kir4.1 using Ba^{2+} increases activity-induced PAP depolarization and overexpression of Kir4.1 decreases activity-induced PAP depolarization. I utilized GEVIs, to enable the measurement of V_m at PAPs. Conditional knockout of Kir4.1 resulted in a significant increase in GEVI $\Delta F/F_0$, suggesting that Kir4.1-medicated K^+ influx helps minimize activity-dependent PAP depolarization. We are currently expanding our work to include single-cell patch-clamp and glutamate imaging to further investigate the direct effect of potassium buffering on glutamate dynamics.

Title: Redox-dependent activation of protein kinase C and neurotransmitter transporter trafficking

Authors: *S. RADHAKRISHNAN[1], S. G. AMARA[2];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]NIMH, NIMH, Bethesda, MD

Abstract: Plasma membrane neurotransmitter transporters clear neurotransmitters from the extracellular space and play a key role in regulating neuronal signaling. The neuronal excitatory amino acid transporter 3, EAAT3, is essential for glutamate clearance and modulation of glutamatergic tone. EAAT3 also transports cysteine into the cell where it serves as a rate-limiting substrate for the synthesis of glutathione, a key neuronal antioxidant. EAAT3 mutations are associated with several neuropsychiatric disorders such as schizophrenia and obsessive-compulsive disorders that may be due to its role in glutamate or cysteine transport. The activity of plasma membrane transporters can be altered by changes in transport kinetics, expression levels and trafficking to and from the plasma membrane. Using surface biotinylation assays and radiolabeled glutamate uptake studies, we confirmed that activation of protein kinase C (PKC) can increase cell surface localization of EAAT3 in Neuro2A cells and mouse primary cortical neurons, as previously reported in other cell lines. Redox-triggered mechanisms can influence signaling through PKC by altering the catalytic properties or the subcellular compartmentalization of various PKC isoforms. This suggests a mechanism whereby EAAT3 trafficking could be modulated by cellular redox stress and PKC activation to increase cysteine import. We observed that oxidizing agents such as hydrogen peroxide can enhance PKC activation and surface expression of EAAT3 in both EAAT3-transfected Neuro2A cells and in primary cultures of mouse cortical neurons. To further understand the specific subcellular localization of this PKC activation, we targeted the genetically-encoded fluorescent PKC sensor, CKAR to lipid raft and non-raft membrane using a Lyn Kinase and KRAS targeting motif, respectively. The activation of PKC with hydrogen peroxide caused an increase in PKC activation at the non-raft membrane but did not cause a significant increase near the lipid raft. This PKC activation was reversed with the pre-application of a PKCθ selective inhibitor. We also observed that pre-application of a PKCθ selective inhibitor reduced a PMA-mediated increase in glutamate uptake in EAAT3-transfected Neuro2A cells. From previous research, we know that EAAT3 associates with non-raft membranes suggesting that this targeted PKC

activation could be relevant to understanding the redox mediated increase of EAAT3 at the membrane. Taken together our observations suggest specific subcellular localization for the redox mediated activation of EAAT3 trafficking to the membrane and the potential involvement of the PKCθ isoform in regulating EAAT3.

Title: Deletion of xCT exclusively on immune cells is not sufficient to obtain preservation of hippocampus-dependent memory

Authors: *L. DE PAUW[1], J. O. ADEYEMI[1], O. LARA[1], P. JANSSEN[1], L. MACKENS[1], A. VILLERS[2], H. SATO[3], M. DE RIDDER[4], G. ATES[1], L. RIS[2], A. MASSIE[1];

Abstract: The cystine/glutamate antiporter system x_c^-, is expressed on glial cells of the central nervous system (CNS) as well as cells related to the immune system. Imported cystine serves as building block for glutathione, while exported glutamate can modulate glutamatergic neurotransmission and alter the excitotoxic threshold in the CNS. We recently showed that xCT deletion (specific subunit of system x_c^-) results in lifespan extension as well as protection against age-related hippocampal dysfunction, memory loss and exacerbated inflammatory responses. Given the influence of blood-borne factors on brain aging, and given that exposure to low-grade peripheral inflammation seems to be sufficient to induce impaired neurogenesis and cognitive function, we hypothesized that the absence of system x_c^- on the cells of the peripheral immune system alone might be sufficient to obtain the beneficial effects seen in $xCT^{-/-}$ mice.
We generated chimeric mice in which system x_c^- is exclusively present on or absent from the peripheral immune cells, by performing bone marrow transplantations (BMT). Adult (8w) male Ly5.1 mice and $xCT^{-/-}$ mice underwent BMT with either xCT wild type ($xCT^{+/+}$) or $xCT^{-/-}$ donor BM from 14-16w old male mice. At 6 and 14 months post-BMT, mice were tested in a battery of

behavioral tests to evaluate locomotor function, memory, anxiety- and depressive-like behavior, after which mice were sacrificed to evaluate neuroinflammation and -degeneration. Hippocampal neurotransmission was analyzed through slice electrophysiology experiments at 15 months post-BMT.
Although we did see aging effects on the behavior of the mice for both recipient groups, the genotype of BM cells did not induce major changes in hippocampal neurotransmission or spatial memory in both recipient groups. Moreover, aging induced an expected increase in number of microglia and cortical thinning in all groups, without any striking differences induced by the lack of xCT on immune cells. It should be noted, however, that the performance of irradiated $xCT^{-/-}$ mice, independent of the BM genotype, is overall poor compared to Ly5.1 recipient mice as well as to our previous observations in $xCT^{-/-}$ mice, suggesting an increased sensitivity for irradiation induced (brain) damage.
So far, we can conclude that the absence of xCT exclusively on the cells of the peripheral immune system is not sufficient to protect mice against age-related cognitive decline and/or neuroinflammation nor is the presence of xCT exclusively on immune cells sufficient to induce either of these characteristics.

Title: Optimization and characterization of a bone marrow transplantation mouse model and its use to study the role of system x_c^- in LPS-induced neuroinflammation

Authors: *P. JANSSEN[1], L. DE PAUW[1], M. MAMBRETTI[1], O. LARA[1], J. WALCKIERS[1], L. MACKENS[1], I. ROOMAN[1], H. SATO[2], B. GUILLAUME[3], M. DE RIDDER[4], G. ATES[1], A. MASSIE[1];

Abstract: System x_c^-, a cystine/glutamate antiporter with xCT as specific subunit, is mainly expressed in the brain and on cells of the immune system. xCT has been proposed as a promising target to reduce (neuro)inflammation but its specific function on immune cells remains unclear. To study the involvement of immune cell xCT in the protective effects against LPS-induced neurological dysfunction that we previously observed in $xCT^{-/-}$ mice, we first optimized a protocol to generate bone marrow (BM) chimeras. Using 2x550cGy total body irradiation (TBI), we obtained a robust and stable model reaching near complete BM replacement with maximal survival. Since long-term consequences of TBI and bone marrow transplantation (BMT) performed on healthy adult mice have been poorly studied, contrary to the consequences of radiation on the juvenile body and brain, we next characterized the effects of the procedure on the overall health and brain of C57BL/6 mice. We found a persistent decrease in weight along with long-term impact on locomotion after TBI/BMT. Although the TBI/BMT procedure did not lead to mood disturbances 2- or 16-months post BMT, long-term spatial memory of the irradiated mice was impaired. While altered memory function after irradiation has been linked to neurodegeneration and neuroinflammation, we did not observe this at the timepoints we investigated. Yet, higher levels of hippocampal IgG in aged BMT mice suggest an enhanced age-related increase in blood-brain barrier permeability, potentially contributing to the observed memory deficit. Thus, although overall health of the mice did not seem to be impacted by TBI and BMT, TBI-induced impairment of locomotion and spatial memory could bias the behavioral read-out obtained from mouse chimeras with different genetic backgrounds that might display altered susceptibility to radiation-induced damage. Finally, we injected lethally irradiated Ly5.1 mice with $xCT^{-/-}$ or $xCT^{+/+}$ BM cells with a sublethal dose of LPS (5mg/kg) and found that mice lacking xCT only on their immune cells already recovered from LPS-induced hypothermia within 24h, contrary to $xCT^{+/+}$ BMT mice. Moreover, preliminary findings show that neuroinflammation was slightly attenuated in $xCT^{-/-}$ BMT mice one week post LPS injection as observed in the expression of pro-inflammatory cytokines and microglia activation in the hippocampus. However, while some minor beneficial effects of lacking xCT on immune cells could be seen during the LPS challenge, it seems that targeting xCT in the brain is required to reach significant protection against (neuro)inflammation.

Title: Tackling pancreatic cancer from different angles: compartmentalized role of xCT in supporting tumor growth and inflammation-related comorbidities in mice

Authors: *O. LARA[1], P. JANSSEN[1], M. MAMBRETTI[1], L. DE PAUW[1], G. ATES[1], L. MACKENS[1], J. DE MUNCK[1], J. WALCKIERS[1], Z. PAN[1], P. BECKERS[2], E. ESPINET[3], H. SATO[4], M. DE RIDDER[5], D. L. MARKS[6], K. BARBÉ[1], J. AERTS[1], E. HERMANS[2], I. ROOMAN[1], A. MASSIE[1];

Abstract: While targeting of xCT, the specific subunit of the cystine/glutamate antiporter system x_c^-, has been reported to have cytotoxic effects on tumor cells, most of the studies ignore the possible involvement of this antiporter in cancer-related (neurological) comorbidities. Cachexia, a metabolic disorder characterized by loss of muscle mass and anorexia, as well as depression are frequently associated with (pancreatic) cancer and are both related to peripheral and central (in hypothalamus and hippocampus, respectively) inflammation. As xCT is also present in the brain and on immune cells, thereby modulating glutamatergic neurotransmission, behavior and inflammatory responses, we studied the impact of genetic xCT deletion in a murine pancreatic cancer model, not only on tumor growth but also on (neuro)inflammation, cachexia and mood disturbances. We used male mice with genetic deletion of xCT ($xCT^{-/-}$) and wildtype $xCT^{+/+}$ littermates, as well as Ly5.1 males that were sublethally irradiated and transplanted with bone marrow (BM) originating from $xCT^{+/+}$ or $xCT^{-/-}$ mice. xCT knockout Panc02 cells -generated using CRISPR/Cas9- were injected intraperitoneally in mice. To assess cachexia, food intake and muscle mass were assessed. Anxiety-like behavior was analyzed using the open field test, and the tail suspension test and forced swim test were performed to assess depressive-like behavior. Tumor xCT deletion resulted in a significant reduction of tumor burden, while only targeting xCT in the host had reduced benefit. Yet, the latter was sufficient to attenuate the tumor-related increase in systemic inflammation and immunosuppressive regulatory T (Treg) cells. This effect was only partly mediated by xCT on the immune cells, as we could only observe a reduced Treg population -and not reduced inflammation or tumor growth- in BM chimeras with specific immune xCT deletion. Besides affecting peripheral inflammation, xCT deletion in the host or tumor differentially modulated neuroinflammation. Hypothalamic inflammation was reduced in mice grafted with xCT deficient tumors, in line with improved cachexia parameters, whereas hippocampal inflammation was slightly attenuated by xCT deletion in the host, and was accompanied by reduced anxiety- and depressive-like behavior in tumor-bearing $xCT^{-/-}$ mice compared to $xCT^{+/+}$ mice. Taken together, targeting xCT in pancreatic cancer has beneficial effects on systemic and central inflammation, leading to attenuated cancer-related comorbidities. Novel and specific xCT inhibitors will thus have added beneficial effects in the central nervous system, beyond direct growth inhibition of pancreatic tumors.

Title: The new mechanisms to regulate L-glutamate transporters - the interaction of polyunsaturated fatty acids and Leucine 434

Authors: K. TAKAHASHI[1], L. CHEN[2], M. WU[2], M. SAYAMA[2], M. KATO-HAYASHI[3], T. IRIE[1], T. OHWADA[2], ***K. SATO**[1];

Abstract: Astrocytic excitatory amino acid transporter 2 (EAAT2) playsa major role in removing the excitatory neurotransmitter L-glutamate (L-Glu)from synaptic clefts in the forebrain to prevent excitotoxicity.Polyunsaturated fatty acids such as docosahexaenoic acid (DHA, 22:6 n-3)enhance synaptic transmission, and their target molecules include EAATs. Here,we aimed to investigate the effect of DHA on EAAT2 and identify the key aminoacid for DHA/EAAT2 interaction by electrophysiological recording ofL-Glu-induced current in *Xenopus* oocytestransfected with EAATs, their chimeras, and single mutants. DHA transientlyincreased the amplitude of EAAT2, but tended to decrease that of EAAT1, anotherastrocytic EAAT. Single mutation of leucine (Leu) 434 to alanine (Ala)completely suppressed the augmentation by DHA, while mutation of EAAT1 Ala 435(corresponding to EAAT2 Leu434) to Leu changed the effect from suppression toaugmentation. Other polyunsaturated fatty acids (PUFAs) (docosapentaenoic acid,eicosapentaenoic acid, arachidonic acid, and a-linolenic acid) similarlyaugmented the EAAT2 current and suppressed the EAAT1 current. Finally, ourdocking analysis suggested the

most stable docking site is the lipid crevice ofEAAT2, in close proximity to the L-Glu and sodium binding sites, suggestingthat the DHA/Leu434 interaction might affect the elevator-like slide and/or theshapes of the other binding sites. Clustering of accessible conformations ofDHA in water indicated the probability of U-shaped DHA is highest, which wasconsistent with the structure suggested by the docking study. Collectively, ourresults highlight a key molecular detail in the DHA-induced regulation ofsynaptic transmission involving EAATs. Title: Contribution of synaptic glutamate vs. spiking activity to cerebral vascular responses in awake mice

Authors: *J. PERETIN[1], A. VAZQUEZ[2];
[1]Dept. of Neurosci., [2]Dept. of Bioengineering and Radiology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The brain accounts for roughly 20% of bodily metabolic demands, with the majority being accounted for by neuronal energy consumption for processes such as synaptic transmission, which has been reported to be more metabolically demanding than spike generation. Energy substrates necessary for these processes are delivered by the vasculature, but the impact of synaptic and spiking activity on blood supply has not been fully characterized. Insight into this relationship may be relevant to understanding brain metabolism in both normal and diseased brain states. In this study, we investigated the role of synaptic and spiking activity on local vascular changes in awake mice using fluorescent markers for extracellular glutamate (n=7) and intracellular calcium (n=3), respectively. Simultaneous measurements of vascular changes were obtained using hemoglobin absorption or fluorescent tracers as vascular agents. Low- and high-resolution imaging experiments were conducted during whisker stimulation and ongoing resting state conditions. Under lower resolution wide-field imaging, whisker stimulation produced a mean increase of 0.25% in glutamate signal and 2.91% in neuronal calcium signal relative to baseline. Under high-resolution two-photon imaging, the mean increase in glutamate fluorescence was 5.67% and was 28.93% for neuronal calcium fluorescence. These fluorescent responses to a single whisker puff exhibited mean decay time constants of 26.8 ms for glutamate

and 36.9 ms for calcium by wide-field imaging, with similar results using two-photon microscopy. Robust vascular changes were observed for all experiments. To determine the contribution of synaptic and spiking activity on vascular changes, we used a linear convolution model to predict vascular changes from these neural events. Explained variance (R^2) analyses were performed, and it was determined that the glutamate signal tended to be a better predictor of the evoked hemodynamic response when compared to the calcium signal. These findings suggest that synaptic glutamate activity may be more correlated with and predictive of cerebral blood flow changes than spiking activity, which could have implications in many neurodegenerative diseases associated with synaptic or vascular dysfunction.

Title: Clinical rTMS Therapy Differentially Modulates Glutamatergic Neurometabolites: A Meta-Analytic Synthesis of ^{1}HMRS Studies in Psychiatric Populations

Authors: *M. PECSOK[1], A. MORDY[2], M. CRISTANCHO[3], D. OATHES[3], D. R. ROALF[3]; [1]Neurosci. Grad. Group, Univ. of Pennsylvania Neurosci. Grad. Group; Perelman Sch. of Med., Philadelphia, PA; [2]Dept. of Psychiatry, Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [3]Dept. of Psychiatry, Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Background: Repetitive transcranial magnetic stimulation (rTMS) alleviates symptoms of major depressive disorder (MDD) and other psychiatric disorders but the neurobiological mechanisms of its clinical efficacy remain to be fully determined. Growing evidence from proton magnetic resonance spectroscopy (^{1}HMRS) studies suggests that rTMS alters the balance of excitatory and inhibitory neurometabolites.
Methods: Eligible studies that quantified Glutamate (Glu), Glutamate/Glutamine (Glx), or GABA levels before and after administration of rTMS were sourced from PubMed, MEDLINE, PsychInfo, Google Scholar, and primary literature following PRISMA guidelines. Data were pooled using a random effects model, Cohen's d effect sizes were calculated, and moderators were assessed. It was hypothesized that rTMS would increase glutamatergic neurometabolite concentrations at the rTMS target (DLPFC) and downstream regions. **Results:** Within-subjects data from 229 cases encompassing 42 neurometabolite effects (k) were included. Real rTMS in

clinical responders (N=151; k=28 effects) increased glutamatergic neurometabolites (d=0.20 [95% CI:0.04,0.35], p=0.01). No change was seen clinical non-responders (N=54 participants; k=7; d=0.48 [95% CI:-0.44,0.34], p=0.81) or sham rTMS participants (N=25 participants; k=7; d=0.033[95% CI:-0.34,0.40], p=0.86). Glu was significantly increased in downstream regions after rTMS (k=8, d=0.29 [0.013,0.58], p=0.04). Effect size was associated with the number of rTMS pulses patients received (p=0.05). **Conclusions and Relevance:** Clinical rTMS is associated with a small, distributed, and dose-dependent increase in glutamatergic neurometabolites, suggesting that rTMS may improve psychiatric symptoms by inducing synaptic plasticity and altering neurometabolism. Future studies should explore target and downstream effects, investigate behavioral implications of neurometabolite changes, and leverage ultra-high field MRI techniques for improved spatial resolution.

Title: Transcriptomic signatures of basal forebrain cholinergic neurons across lifespan

Authors: *M. R. ANANTH, R. KIM, D. A. TALMAGE, L. W. ROLE;
NINDS/NIH, Bethesda, MD

Abstract: Basal forebrain cholinergic neurons (BFCNs) are distributed throughout the base of the forebrain and send widespread projections throughout the brain. These neurons have been found to be critical in coordinating neuronal activity to promote attention and facilitate learning. While previously regarded as a uniform cluster of cells, growing evidence supports the assertion that subsets of BFCNs uniquely participate in cognitive behaviors. In addition, we have found region-specific vulnerability across cholinergic axonal arbors, where some projections deteriorate far sooner and to a much greater degree than others. Several factors could contribute to this heterogeneity across BFCN subpopulations including birthdate, projection target and gene expression profiles. Understanding the factors underlying BFCN diversity is critical to understanding the role of acetylcholine in cognition and its vulnerability in cognitive decline. In these studies, we first asked if cholinergic neurons could be distinguished by unique gene expression profiles, and second, whether any functionally unique clusters were specifically vulnerable across lifespan. Given the sparsity of BFCNs throughout the basal forebrain, a detailed classification of this population has been challenging thus far. To overcome this, we used a genetic strategy where cholinergic nuclei were specifically labeled with a nuclear

membrane targeted GFP. Using FACS, we isolated nuclei from dissections of the full anterior to posterior extent of the basal forebrain and enriched for cholinergic nuclei based on GFP expression. Libraries were prepared using 10X Chromium technology and sequenced using the Illumina sequencing platform. Our preliminary dataset included over 30 thousand GFP-captured cells in young male and female mice. After standard QC, we filtered our results toward ChAT-expressing nuclei. We performed clustering analysis to reveal several distinct cholinergic neuron clusters, representing far more diversity across the basal forebrain than initially hypothesized. Identified clusters include those highly NGFR and LHX8 expressing with varying Zic4 expression (which denotes septal and non-septal lineages) and some unexpected populations with low NGFR expression. Using Seurat, we identified biomarkers for each of our isolated cholinergic neuron clusters. Ongoing analyses investigate the patterning of these clusters spatially across the basal forebrain and the selective vulnerability of these subpopulations with age.

Title: Evaluation of the morpho-electrical properties of basal forebrain cholinergic projection neurons

Authors: *G. WATKINS, N. DESAI, L. JIANG, F. LUO, R. KIM, D. TALMAGE, L. ROLE; NIH/NINDS, Bethesda, MD

Abstract: Acetylcholine is essential for proper development and function of the mammalian brain. Cholinergic innervation is provided by projections of the basal forebrain cholinergic neurons (BFCNs), which send axons to diverse structures throughout the brain. BFCNs are often subdivided into anatomically defined populations. Those located in the medial septum and the vertical limb of the diagonal band of Broca (MS/vDB) send projections to several target regions essential for learning and memory such as the hippocampal/subicular complex and the entorhinal cortex. Characterizing the role of MS/vDB cholinergic projections to the ventral subiculum is of particular interest, as it is one of the primary outputs of the hippocampus. Although disruption of normal cholinergic activity to both the hippocampus and the subiculum has been shown to contribute to learning and memory deficits, less is known about the properties of the MS/vDB cholinergic neurons themselves, or how they may differ from other BFCNs. To address this question, whole-cell recordings of ~30 cholinergic MS/vDB neurons were made from acute slices of adult mice in order to measure cell-intrinsic electrical properties. Following recording,

tissue was fixed so that neurons could be relocalized and reconstructed to measure morphological features. Electrical and morphological properties were then analyzed by UMAP and compared to data from cholinergic neurons in the nucleus basalis/substantia innominata (NBM/Si) and ventral pallidum (VP). We found that BFCNs from the three anatomical subregions separate into non-homogenous populations based on their basic properties; furthermore, within each nucleus, the projection target did not seem to correlate with any specific properties. Despite the differences in target, cholinergic neurons in MS/vDB share many electrical properties with those in NBM/Si, although the AP kinetics of MS/vDB neurons are slightly slower. When compared with cholinergic neurons in VP, which share many targets with those in NBM/Si, MS/DB cholinergic neurons have a longer AP latency, higher AP threshold, and a lower maximum firing rate.

Title: Comparative physiology and morphology of BLA projecting cholinergic neurons in mouse and macaque

Authors: *F. LUO, N. DESAI, L. JIANG, G. WATKINS, L. BAI, R. KIM, D. TALMAGE, L. ROLE;
Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: Cholinergic projection neurons in the basal forebrain (BF) are essential to learning and memory. BF cholinergic projection neurons (BFCN) are organized along the rostro-caudal axis of the adult mammalian forebrain, and include the medial septum, diagonal band (vertical and horizontal limbs), the substantia innominata, ventral pallidum (VP/Si_a), and nucleus basalis of Meynert (NBM/Si_p). These cholinergic projection neurons participate in an array of cognitive functions through the action of acetylcholine released at pre and post synaptic sites within multiple cortical and subcortical regions. Recent studies indicate that key determinants of BFCN fate include birth order and location, i.e., early-born cholinergic neurons are more caudally located, in contrast to later born rostral BFCNs *(see Ananth et al. Nat. Rev. Neurosci, 2023*). Despite temporal and spatial differences in origin, both VP and NBM/Si_p cholinergic fibers densely innervate the basal lateral amygdala (BLA). NBM/Si_p cholinergic inputs to the BLA are thought to be engaged in the acquisition and retention of emotional memories. The VP/Si_a cholinergic projection to BLA differentiates innate positive from negative valence stimuli. We

have conducted comparative studies of cholinergic neurons along the rostro-caudal extent of the BF in mouse and macaque. First we asked whether morphological and physiological profiles of mouse BFCNs correlate with A-P location (~birthdate) and/or their projection targets, comparing BLA projecting VP vs. NBM/Si_p neurons. Using retro-bead labeling of cholinergic projection neurons to the BLA we assessed 19 parameters by patch clamp recording. Biocytin injection was followed by relocalization, IHC confirmation and comparison of the electrophysiological and morphological profile of ~60 VP and NBM/SI cholinergic neurons, the majority of which shared the common projection to the BLA. To our surprise the most robust differences of electrophysiological and morphological features were found by comparing BLA projecting VP vs. BLA projecting NBM/Si_p neurons (i.e. independent of target). In a parallel study of the BLA projecting NBM cholinergic neurons from macaque, we found significant differences in most of the 19 physiological parameters tested compared with mouse. Sorting by bregma, dimensionless clustering analysis may suggest some AP-related features of the electrophysiology; comparison of monkey vs mouse somatodendritic morphology is underway. Ongoing work extends the mouse macaque comparison to other BLA projecting BFCNs and to include cortical targets. (Approved by NIH/NINDS ACUC; supported by NINDS IRP)

Abstract: Disruption of cholinergic fibers of passage to the prefrontal cortex by aspiration removals of orbitofrontal cortex in rhesus macaques Authors: A. Mohanty, B. E. Hines, M. A. G. Eldridge, E. A. Murray
Abstract The study of anthropoid nonhuman primates has provided valuable insights into frontal cortex function in humans, as these primates share similar frontal anatomical subdivisions. Causal manipulation studies have been instrumental in advancing our understanding of this area. One puzzling finding is that macaques with bilateral damage to the orbitofrontal cortex (OFC) made by aspiration, which directly removes the cortex, exhibit a different set of behavioral impairments than macaques with excitotoxic lesions of the same region. Specifically, rhesus

monkeys with bilateral aspiration removals of OFC are impaired on tests of cognitive flexibility and emotion regulation, whereas those with bilateral excitotoxic lesions of OFC are not (Rudebeck et al., *Nat. Neurosci.*, 2013). This discrepancy is attributed to the inadvertent disruption of fibers of passage by aspiration lesions but not by excitotoxic lesions. The underlying question is: Which fibers of passage are responsible for impairments in cognitive flexibility and emotion regulation when compromised? One candidate is the cholinergic fibers, originating in the nucleus basalis magnocellularis (NBM) and passing nearby or through OFC on their way to other frontal cortex regions (Kitt et al., *Brain Res*. 1987). To investigate this possibility, unilateral aspiration lesions were performed in the OFC of three rhesus monkeys, and the cholinergic innervation, as measured by AChE expression, of the anterior cingulate cortex (ACC) was compared between hemispheres with and without OFC. The assessment revealed diminished AChE expression in the ACC of hemispheres with OFC lesions, particularly in layers I and III/V. This disparity was more pronounced in the rostral ACC and less so in the more caudal regions. No difference was observed in cholinergic staining in the striatum, which receives cholinergic innervation from local interneurons. These findings suggest that aspiration lesions of the OFC disrupt cholinergic fibers of passage, potentially explaining the significant impairments in cognitive flexibility and emotion regulation observed in comparison to excitotoxic lesions. Further research is necessary to demonstrate a causal relationship between the interruption of cholinergic innervation in the frontal cortex and its effects on behavior.

Title: Differential cholinergic modulations of dentate semilunar granule cell and granule cell excitability and synaptic inhibition

Authors: *A. HUANG[1], M. AFRASIABI[2], B. SWIETEK[3], V. SANTHAKUMAR[4];
[1]UC Riverside, Santa Ana, CA; [2]Pharmacology, Physiol. and Neurosci., Rutgers, New Jersey Med. Sch., Newark, NJ; [3]Rutgers, Newark, NJ; [4]Mol. Cell and Systems Biol., Univ. of California, Riverside, Riverside, CA

Abstract: The dentate gyrus (DG) is a sparsely firing region of the hippocampus critical for processing and formation of episodic memory. Recent studies have characterized two classes of DG projection neurons, granule cell (GC) and semilunar granule cell (SGC) which differ in morphology, location, and intrinsic physiology. As information about the preferential role of SGCs in memory engrams and synaptic physiology emerges, it remains unknown whether memory related neuromodulators such as acetylcholine (ACh) differentially impact GCs and SGCs physiology. Here we conducted whole-cell recordings from GCs and SGCs in hippocampal slices from male and female Wistar rats (P28-41) to examine cholinergic modulation of intrinsic physiology and synaptic inhibition. In both GCs and SGCs, the muscarinic ACh receptors (mAChRs) agonist, oxotremorine (oxo-M, 10μM), increased firing frequency in response to current below 160pA and decreased firing at current injections over 200pA. The mAChR dependent increase in firing was coupled to depolarizing plateau potentials (DPP) during current injections at rheobase, while decline in firing at high current injections resulted from depolarization block. Although mAChR agonist caused persistent firing and lowered action potential threshold in both cell types, it elicited greater increase in firing in SGCs than in GCs. Blocking transient receptor potential canonical isoforms 4/5 (TRPC4/5) channels, known to be activated downstream of mAChRs in GCs, with the selective antagonist M084 (10μM) did not alter firing frequency or action potential threshold in either cell type. However, preapplication of TRPC4/5 antagonist prevented the mAChR mediated reduction in action potential threshold without preventing DPP in both GCs and SGCs. These findings indicate that cholinergic regulation of DPP and action potential threshold likely involve distinct molecular mechanisms. Since SGCs and GCs differ in inhibitory inputs and interneurons show cell type specific cholinergic modulation, we next examined the effect of carbachol (CBC, 10 μM), a nonselective cholinergic agonist on synaptic inhibition onto GCs and SGCs. Although CBC reduced the amplitude of afferent evoked inhibitory synaptic currents in both cell types, it selectively reduced both frequency and amplitude of spontaneous inhibitory synaptic events in GCs but not SGCs. Together these studies demonstrate that cholinergic agonists preferentially enhance SGC excitability and impair GC inhibition which could contribute to the preferential recruitment of SGCs during memory formation.

Title: The septal-hippocampal cholinergic pathway in cue-conditioned threat learning

Authors: *C. ZHONG, N. S. DESAI, D. A. TALMAGE, L. W. ROLE;
NIH/NINDS, Bethesda, MD

Abstract: The cholinergic fibers of the medial septum/diagonal band of Broca (MS/DB) project to the hippocampal formation. Previous studies indicated that MS/DB cholinergic inputs to the ventral hippocampus (vHipp) are engaged in auditory cued fear memory but the precise spatial and temporal profile of acetylcholine (ACh) release and signaling remains unclear. To define specific roles for cholinergic regulation of vHipp mediated cue-conditioned threat learning, we have combined imaging of a genetically encoded calcium indicator (GCaMP, axonGCaMP) and an ACh sensor (Red-GRAB$_{ACh1.7}$), with transcriptional activity markers. Mice went through a classic auditory cue-conditioned fear training and recall paradigm (tone paired to shock and then recall to tone alone). Following different aspects of this paradigm the animal was sacrificed and we imaged cholinergic neurons within acute MS/DB slices or cholinergic projections within the vHipp. With GCaMP6f expressed specifically in cholinergic neurons in Chat-Cre mice, and a tTA-dependent activity labeling system (Robust Activity Marker, or RAM) to label neurons activated during the training session, we found: 1) increased number of RAM labeled cholinergic neurons after cue conditioned fear training; 2) a transient (up to 5 hours post training) increase in Ca^{2+} dynamics, measured as amplitude and frequency of Ca^{2+} oscillations, in RAM labeled cholinergic neurons; 3) 24 hours after training, Ca^{2+} dynamics were significantly enhanced in RAM labeled cholinergic neurons following tone alone (recall) presentation, as compared to RAM labeled cholinergic neurons without tone recall or in untrained mice in response to tone alone. Further studies examine the spatial and temporal profile of septal-hippocampal cholinergic transmission in vHipp using axonGCaMP6s (MS/DB projections) and ACh sensor. Opto-stimulation of cholinergic axons leads to increase of cholinergic axonal Ca^{2+} activity and elicits ACh release in vHipp. Ongoing studies examine the precise frequency and amplitude dependence of optogenetic stimulation on the response kinetics of cholinergic axonal activity and ACh release in vHipp.

Title: Effects of Vesicular acetylcholine transporter overexpression on synaptic activity in Drosophila melanogaster

Authors: *K. ROSIKON[1], H. O. LAWAL[2], B. CHURCH[1];
[2]Biol., [1]Delaware State Univ., Dover, DE

Abstract: Impairment in cholinergic neurotransmission is associated with normal and pathological aging, making cholinergic release a subject of high interest. However, the precise role of changes in central acetylcholine release in mediating behaviors that range from locomotion to cognition has not been fully elucidated. The vesicular acetylcholine transporter (VAChT) is present in many species, including worms, flies, and humans, and is responsible for the packaging of acetylcholine for exocytotic release. Although there is a plethora of knowledge about the molecular machinery that regulates ACh, the exact manner in which VAChT, an essential component of ACh regulation, alters ACh-linked neuronal function remains a subject of active investigation. Here, we use the overexpression of VAChT as a tool to increase the amount of ACh released into the synaptic cleft. And we are measuring the effect of that altered state on synaptic activity using two key behavioral circuits, locomotion and cognition. We report that increased levels of VAChT do not affect locomotion in young flies but do so with age. Moreover, VAChT overexpression leads to a deficit in immediate recall, an important measure of cognitive capability in Drosophila. We also show that a vast increase in VAChT expression leads to an accumulation of the protein in synaptic vesicles and at the plasma membrane. We present an analysis of the effects of different levels of overexpression of VAChT on synaptic activity to ascertain whether those effects are dependent on the degree of VAChT overexpression. Taken together, these data provide further evidence for a role of central cholinergic release in the mediation of key neuronal functions and uncover insights into mechanisms that regulate acetylcholine exocytosis from neurons in the central nervous system.

Title: Effects of changes in vesicular acetylcholine transporter expression on the regulation of cholinergic pathway components

Authors: R. NEMAT, *H. LAWAL;
Delaware State Univ., Dover, DE

Abstract: Effects of changes in vesicular acetylcholine transporter expression on the regulation ofcholinergic pathway components Rohina Nemat and Hakeem O. LawalDelaware Center for Neuroscience Research, Department of Biological Sciences, Delaware StateUniversity, Dover DelawareCentral cholinergic neurotransmission is essential for the regulation of cognition and other acetylcholine-linked behaviors. Consequently, alterations in neuronal cholinergic signaling lead to an impairment inlearning and memory, although the

mechanism through which this deficit occurs is still not fully understood.The vesicular acetylcholine transporter (VAChT) mediates the packaging and transport of acetylcholine(ACh) for exocytotic release. And while much is known about the molecular machinery that regulates ACh,the precise manner in which VAChT, an essential component of ACh regulation, alters ACh-linked neuronalfunction remains a subject of active investigation. Here, we use the overexpression of VAChT (using aconstruct that we have reported on previously) as a tool to increase the amount of ACh released into thesynaptic cleft. And we are measuring the effect of that altered state on synaptic activity using a biochemicalapproach. We have optimized an assay that allows us to reliably measure cholinergic pathway componentsACh and choline from as little as ten *Drosophila* heads. Using this assay, we report the surprising data thatwhile VAChT overexpression does not increase total head ACh levels, there is an increase in choline levels,suggesting that there are homeostatic consequences for changes in VAChT expression. We also presentpreliminary findings from similar experiments with *Vacht* mutants that have reduced transporter expression.Taken together, these data provide further insight into the severe consequences that follow a disruption inVAChT expression and form a basis for more detailed optical and electrophysiological studies aimed atdissecting in cholinergic function neural circuits.

Title: Interactions between metabotropic acetylcholine and glutamate receptors for the enhancement of dendro-somatic coupling of cortical pyramidal tract neurons

Authors: *A. BRONEC[1], M. SUZUKI[2], T. A. ZOLNIK[3], M. E. LARKUM[1];
[1]Humboldt Univ. of Berlin, Berlin, Germany; [2]Univ. of Amsterdam, Amsterdam, Netherlands; [3]Charité Universitätsmedizin Berlin, Berlin, Germany

Abstract: In the somato-sensory cortex, the distal apical dendrites of cortical layer 5 pyramidal neurons (L5p) receive feedback inputs from higher-order cortical and thalamic regions, which convey important information related to reward, memory, and behavioral context. The impact of these feedback inputs on the somatic activity of these neurons depends on the dendro-somatic coupling, which represents how effectively dendritic depolarization propagates toward the soma and evoke somatic action potentials (APs). A previous in vivo study revealed that general anesthesia suppresses the dendro-somatic coupling of these neurons. Additionally, metabotropic receptors for acetylcholine (mAChRs) and glutamate (mGluRs) were found to significantly

influence this coupling, but the underlying mechanisms and potential receptor interactions remain unclear. To address these questions, we used whole-cell recording, cell-type-specific expression of optogenetic actuator, and pharmacological application of metabotropic receptor agonists. We generated a mouse model by crossing the Sim1-Cre KJ18 transgenic mouse line with the Rosa26-ChR2 reporter line Ai32 to selectively express channelrhodopsin2 (ChR2) in the pyramidal tract (PT) neurons of L5p. Optogenetic stimulation using blue light was specifically applied to the distal apical dendrites. We used carbachol for mAChRs and (S)-3,5-DHPG for mGluRs to manipulate each type of metabotropic receptorOur preliminary findings from 8 PT neurons obtained from 7 mice showed that bath applications of 3 μM carbachol enhanced dendro-somatic coupling. Optogenetic stimulation of distal tuft dendrites evoked an increase in somatic activity in the presence of carbachol (n=6/8 neurons with an average increase of 43.48%) which supports previous in vivo investigations. Simultaneous application of DHPG (0.75 μM) and carbachol (3 μM) elicited more APs compared to carbachol alone (n=6/8 neurons with an average increase of 23.66%), suggesting potential interactions between the two types of metabotropic receptors. Further data collection and analysis, as well as investigation into downstream mechanisms such as IP3-mediated intracellular calcium release, will be conducted to better understand these interactions.

Title: Inhibition of the TRPM3 ion channel is involved in opioid-induced itch

Authors: N. KIM[1], Y. YUDIN[2], C. BURTON[1], H. HU[1], Z. KISS[1], S. SU[1], ***T. ROHACS**[3]; [2]Rutgers New Jersey Med. Sch., [1]Rutgers New Jersey Med. Sch., Newark, NJ; [3]Rutgers Biomed. Hlth. Sci. - Newark, Newark, NJ

Abstract: Itch, or pruritus, is a significant side effect of neuraxial morphine therapy that often leads to cessation of opioid administration. Transient Receptor Potential Melastatin 3 (TRPM3) is a heat-activated ion channel expressed in various tissues, including peripheral sensory neurons of the dorsal root ganglia (DRG), spinal cord, and brain. Activation of opioid receptors and other Gi-coupled receptors, robustly inhibits TRPM3 through direct binding of G-protein βγ subunits to the channel protein. Even though Gβγ inhibition is robust and well-documented, its physiological relevance is not well understood. To better understand the in vivo relevance of this

inhibition, we generated a mouse model in which we deleted the exon encoding for the ten-amino-acid Gβγ binding site (TRPM3$^{\Delta Ex17}$). In DRG neurons of TRPM3$^{\Delta Ex17}$ mice, Ca^{2+} signals induced by the TRPM3 agonist pregnenolone sulfate (PregS) were not inhibited by the μ-opioid receptor agonist DAMGO, indicating that Gβγ inhibition is absent. Scratching behavior induced by intrathecal injection of morphine was significantly reduced in TRPM3$^{\Delta Ex17}$ mice compared to wild-type littermates. Intrathecal injection of the TRPM3 inhibitor primidone evoked itch, indicating that the channel inhibition is sufficient to induce itch by itself. Co-injecting PregS with morphine reduced itch, offering a potential therapy for opioid-induced itch. Itch induced by intradermal injection of DAMGO was also reduced in TRPM3$^{\Delta Ex17}$ mice. Intradermal primidone did not induce scratching behavior, indicating that TRPM3 inhibition alone is not sufficient to induce itch locally. Analgesia induced by systemic or intrathecal morphine on the other hand was largely maintained in TRPM3$^{\Delta Ex17}$ mice, indicating that Gβγ inhibition is dispensable for the analgesic effects of opioids.

Title: The effect of heated propofol on the activation of human TRPA1

Authors: *C. SUDA[1], Y. TAKAYAMA[2], M. TOMINAGA[3], T. AKASE[1];
[1]Nursing, Yokohama City Univ., Kanagawa, Japan; [2]Showa Univ. Sch. of Med., Shinagawa, Japan; [3]Natl. Institue for Physiological Sci., Okazaki Inst. Integrative Biosci, Okazaki, Japan

Abstract: Propofol, an intravenous anesthetic, has a side effect of local pain at the injection site. Although various treatments for this pain have been investigated, this side effect has not been yet completely resolved. This pain is caused by propofol action on Transient Receptor Potential Ankyrin 1 (TRPA1), which is expressed in perivascular sensory nerve endings. While TRPA1 was initially reported to be activated by noxious cold stimulus, it has been recently understood that TRPA1 is a heat sensor. However, it is unclear whether propofol at different temperatures alters the pain intensity upon injection. Therefore, the aim of this study was to determine the effects of propofol at different temperatures on human TRPA1 activity. These findings may be useful for establishing a simple method of care to reduce vascular pain. Using HEK293T cells transfected with *hTRPA1*, membrane currents were measured with a whole-cell patch-clamp method. As propofol, 1% Diprivan® Injection (Sandoz K.K.) was diluted to 0.01 %. Intralipos® Injection 20 % (Otsuka Pharmaceutical Co., Ltd.) was used as the solvent and diluted to 0.1 %.

To evaluate the effect of temperature changes on hTRPA1, Diprivan was perfused after precooling or preheating the solution. First, the effect of Diprivan on hTRPA1 activity was examined in the range of approximately 10 - 45 °C. The results showed that the hTRPA1 currents activated by Diprivan were small at temperatures above 35 °C. Then, the effect of thermal stimulation on hTRPA1 activation by Diprivan was examined. The chamber solution was preheated to 35°C and then chilled to 25 °C before Diprivan application. The hTRPA1 currents were observed upon Diprivan application in this condition. Next, the chamber solution was preheated to 35 °C and then 35 °C or 25 °C Diprivan was applied. The hTRPA1 currents were smaller with 35 °C Diprivan than with 25 °C Diprivan. In the case of 35 °C Diprivan application, no AITC-induced responses were observed.
In this study, we found that hTRPA1 currents were very small when heated Diprivan (> 35 °C) was applied. The hTRPA1 can be actived by Diprivan when earlier heat-activated currents were inactivated by reduced solution temperature. This suggests that thermal stimulation may suppress pain induction by continued inhibition of hTRPA1 activation by propofol.

Title: Roles of TRP channels in spiking and calcium responses of cold nociceptors in Drosophila larva

Authors: *A. SAKURAI[1], N. V. MAKSYMCHUK[1], S. M. KOROGOD[2,1], Y. SHAMS[1], J. M. LETCHER[1], D. N. COX[1], G. S. CYMBALYUK[1];
[1]Georgia State Univ., Atlanta, GA; [2]Intl. Ctr. for Mol. Physiol., Kiev, Ukraine

Abstract: In *Drosophila* larvae, multidendritic primary sensory neurons tile the lumen of the body wall. In cold-nociceptive Class III (CIII) neurons, several TRP channels, including TRPA1 and PKD2, have been implicated in the cold-temperature sensitivity (Turner et al. 2016, Cox lab unpublished results). Here we conducted electrophysiological recording and Ca^{2+} imaging using CIII-specific expression of GCaMP6m and gene-specific RNAi knockdown of each TRP channel and further performed biophysical modeling to investigate the roles of TRP channels in encoding cold temperature.
CIII neurons exhibited a spiking response to rapid temperature decrease (2-6°C/sec) from 24°C to 10°C (Maksymchuk et al., 2022). Approximately half of the neurons showed bursts of spikes forming the spike rate peak. Following the peak, the spike rate settled at a lower steady-state frequency. In response to the temperature drop, we observed a rise of intracellular Ca^{2+},

beginning in the axon and then spreading to the cell body and dendrites. The axonal Ca^{2+} signal exhibited the highest rate of increase approximately 3 sec after the stimulus onset. In contrast, the cell body and dendrites showed slower Ca^{2+} responses, with the highest rate of increase occurring around 10 sec after the stimulus onset.
TRPA1-knockdown led to lower spike frequency than controls, accompanied by the reduced occurrence of bursts during the rapid temperature drop and markedly reduced the rate of rise in the soma Ca^{2+} signal. In contrast, PKD2-knockdown maintained initial bursting but showed significantly attenuated tonic spiking activity during the sustained low temperature; it did not affect the rate of rise in the soma Ca^{2+} signal but resulted in a significant increase in latency. Blocking action potentials with tetrodotoxin (TTX) diminished the axonal Ca^{2+} signal, but the soma and dendrites still exhibited Ca^{2+} signals of approximately half the original size. Both TRPA1- and PKD2-knockdown reduced the Ca^{2+} signals in TTX.
Based on the experimental results, we developed biophysical two-state models of the TRPA1 and PKD2 currents with their temperature-dependent activation as well as Ca^{2+}-dependent activation and inactivation processes. The model reproduced the CIII responses to the used temperature change protocols. The results highlight the critical role of TRPA1 in encoding the rate of temperature change with transient bursting activity, while PKD2 in sensing the temperature magnitude. The rise in intracellular Ca^{2+} concentration in the soma and dendrites appeared to originate mainly from axonal spiking and also via the TRPs-mediated Ca^{2+} influxes occurring independently of the spikes.

Title: Antioxidant and cytoprotective effects of salvianolic acid derivatives on rat osteoblast cell

Authors: *A. KHAN[1,2], T. SARAVANAN[2], F. DEBA[2];
[1]Univ. of Texas, Tyler, Tyler, TX; [2]Univ. of Texas, Tyler, TX

Abstract: Osteoarthritis (OA) is a pervasive degenerative joint disorder which **is characterized by oxidative stress, synovial fluid inflammation, apoptosis in chondrocytes, cartilage degradation, bone sclerosis, and osteophyte formation.** Reactive oxygen species (ROS) production due to oxidative stress is the primary cause of many pathological disease processes. Approximately 32.5 million US adults are suffering from this disease. An understanding of molecular and cellular pathways and their association with joint tissues is necessary to develop

new therapeutic approaches for the prevention and treatment of OA. **Most of the** over-the-counter **non-steroidal anti-inflammatory drugs** are used to treat OA. Natural compounds with medicinal properties have been valuable and effective sources for the treatment of various diseases since ancient times. Salvianolic acid is one of the natural phenolic compounds of the plant Radix *Salvia miltiorrhiza* having antioxidant, anti-inflammatory, antimicrobial, anesthetic, and cytotoxic properties. There is a critical need for new drug planning to focus on the specific mechanisms of oxidative interaction in targeted TRPA1 ion channels and intracellular ion signaling, which will interact with other TRP channel subunits to regulate pathological diseases. In our experiment, we found that the rise of intracellular calcium ions in rat osteoblast cells due to excessive free radicals generated by H_2O_2 was suppressed by Salvianolic Acid-B. Therefore, this pilot project aims to identify Salvianolic acid analogs as lead compounds that target the TRP channel, which is one of the key pathway players in producing arthritis pain and other pathogenesis.

Title: Scn1b is required for proper mechanosensory signaling in mouse mechanoreceptors and nociceptors

Authors: *K. NGUYEN, Y. BABA, D. BAUTISTA, E. LUMPKIN;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Voltage-gated sodium channels (VGSC) are key regulators of neuronal excitability, and it is well-established that distinct subtypes of sensory neurons express different pore-forming alpha subunits. By contrast, we currently have little understanding of how modulatory beta subunits govern excitability in different sensory neuron subtypes. In a previous screen for genes that confer susceptibility to chemotherapy-induced peripheral neuropathy, a top hit was *Scn1b*, which encodes the β1 subunit of VGSC. SCN1B regulates the excitability of neurons and cardiomyocytes, and mutations in this gene underlie several rare human congenital diseases, including severe childhood epilepsies and cardiac dysfunction. Moreover, *Scn1b* global knockout mice die by P21 due to epilepsy. Recent studies show that *Scn1b* transcripts are highly expressed in touch receptors and proprioceptors of the dorsal root ganglia. To validate these findings, we used RNAscope to examine *Scn1b* expression in sensory neurons. *Scn1b* puncta were observed in all neurons but were enriched in the large-diameter myelinated subset as determined by co-

labeling with α-NEFH, a marker of myelinated neurons and an analysis of somatal diameters of *Scn1b*-positive and negative cells (median somatal diameter, *Scn1b*-pos.*:* 23 µm, n=185 neurons; *Scn1b*-neg.*:* 18 µm, n=132 neurons; P<0.0001, Mann-Whitney test). To determine the role of SCN1B in sensory neurons, we generated a somatosensory neuron-specific knockout of *Scn1b* by crossing $Scn1b^{fl/fl}$ mice with $Pirt^{Cre}$ mice. $Pirt^{Cre+};Scn1b^{fl/fl}$ conditional knockout (CKO) mice are viable, fertile and exhibit normal locomotor and exploratory behavior, as assessed with the open-field test (N=8 mice). Next, we assessed the effects of *Scn1b* deletion on A-fiber excitability using an *ex vivo* skin-saphenous nerve preparation. The mechanical threshold of A-fibers was significantly increased in CKO mice compared with littermate controls (CONT) (median von Frey threshold, CONT: 0.69 mN, N=4 mice, 66 fibers; CKO: 1.6 mN, N=8 mice, 57 fibers; P=0.002, Mann-Whitney). We also found that the instantaneous firing frequency was significantly lower in CKO mice compared with CONT (mean±SD, CONT: 215.6±186.7 Hz; CKO: 122.0±116.5 Hz; P=0.03; Student's t test, unpaired, two-tailed). By contrast, the mean conduction velocities of A-fibers did not differ between genotypes (P=0.56; Student's unpaired *t* test, two tailed). Together, these findings suggest that SCN1B is required to properly initiate mechanically evoked action potentials in mechanoreceptors and mechanonociceptors but has little effect on action potential propagation in these myelinated sensory afferents.

Title: Molecular docking of capsaicin at epithelial membrane model TRPV1 receptor

Authors: *C. A. ZERÓN ALVARADO[1], A. CARRASCO CARBALLO[2], L. MARTÍNEZ MENDIETA[3], V. G. S. ALATRISTE BUENO[4];
[1]Lab. de Neuroendocrinología, Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [2]Lab. de Elucidación y Síntesis orgánica, [3]Lab. de Neuroenquímica, [4]Lab. de Neuroendocrinología, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The transient receptor potential vanilloid subtype 1 (TRPV1) is a transmembrane receptor with ion channel activity that allows the passage of cations, mainly calcium. The TRPV1 can be activated by capsaicin, the main component of chili peppers. The TRPV1 has been found on sensory fibers as well other cells. Different effects with respect to capsaicin concentration have been shown in different biological tissues. The TRPV1 activation by low concentrations of capsaicin promotes cell proliferation and differentiation, however high concentrations promote cell death. In the uterus, the expression of the TRPV1 has been demonstrated, but its function is poor understood. The uterus is an organ that is constantly undergoing regeneration, mainly luminal and glandular epithelial cells, so the TRPV1 may play

an important role in uterine cell development. In this work, an *in silico* molecular docking study was performed to identify the capsaicin binding site on the TRPV1 in an epithelial membrane model. The docking was performed on the Schrödinger platform. With the Protein Preparation Wizard tool, the crystallized structure of the tetrameric squirrel TRPV1 (PDB: 7LR0) was optimized to a physiological pH (pH=7.40). The capsaicin molecule (PubChem CID: 1548943) was loaded in Ligprep and macromodel tool. The probable binding areas such as the transmembrane and intracellular areas were selected in Glide tool by XP Molecular docking. Subsequently, the embedding of the TRPV1 in an epithelial membrane model was performed. The aims of embed the TRPV1 into an epithelial membrane was to assimilate *in vivo* molecular interactions in uterus. As a result, we found five capsaicin binding sites in the TRPV1 receptor. Four sites were found in the transmembrane zone with the following binding energies: Site 1: -8,092 Kcal/mol, Site 2: -8,097 Kcal/mol, Site 3: -7,078 Kcal/mol and Site 4: -7,598 Kcal/mol. One site was found in the cationic pore with a binding energy of -8,083 Kcal/mol. The dissociation constant (K_D) of each binding site was obtained with values of 2.0 μM, 2.0 μM, 10.4 μM, 4.5 μM and 2.0 μM respectively. According to our results, the sites with the best affinity are the transmembrane sites 1 and 2 and the cationic pore site. In our work we have found Different sites of activation for capsaicin in the TRPV1, we demonstrate the sensitivity for molecular interactions of the TRPV1 according to the concentration used. These results indicate possible reference capsaicin concentrations to test for TRPV1 stimulation in uterine cells.

Title: Tentonin 3/TMEM150C comprises a pore-forming subunit with unique structure

Authors: *S. PAK, H. RYU, J. WOO, G.-S. HONG, K. HAN, T. KIM, U. OH;
Korea Inst. of Sci. and Technol. (KIST), Seoul, Korea, Republic of

Abstract: Abstract : Tentonin 3(TTN3/TMEM150C) is a mechanosensitive (MS) channel with slowly-adapting (SA) kinetics. TTN3 mediates various physiological functions such as proprioception, baroreceptor reflex, and insulin secretion from pancreatic beta cells. Compared to other MS channels, TTN3 displays a unique biophysical property including the SA-type MS

currents as well as specific inhibition from a mutant conotoxin, NMB-1. Even with these distinctive characteristics, however, its role of as a *de novo* MS channel or molecular structure as an ion channel was not yet determined. When purified TTN3 proteins were incorporated to the lipid bilayer, spontaneous as well as stretch-induced single channel currents were evoked, suggesting that TTN3 forms a pore-forming, *de novo* MS channel. In addition, the Western blot analysis combined with crosslinking maneuver elicited a tetrameric complex of TTN3. A deep learning-based protein structure prediction algorithm, AlphaFold2, predicted a monomeric structure of TTN3. With this monomeric structure, molecular dynamics algorithms predicted several tetrameric configurations of TTN3. These putative configurations predicted key residues residing in the putative pore opening. We mutated these residues and selected one configuration whose mutation led to a complete blockade of mechanosensitivity. The selected tetrameric configuration showed a rectangular shape with a central pore. The transmembrane alpha helices, S1, S2, S5, and S6 of each subunit interact with the membrane lipids and surround the pore, whereas S3 and S4 constitute an ion conducting pathway. Mutations of residues lining the putative ion conducting pathway reduced MS channel currents. These results suggest that these residues are key components of an ion conducting pore and that the predicted structure may represent a native structure of TTN3.

Title: Comparative Transcriptome Profiling of Multiple Human Induced Pluripotent Stem Cell Derived Sensory Neuron Populations and Functional Validation of Pain Targets on Automated Patch Clamp Systems

Authors: *V. TRUONG[1], A. RANDOLPH[2], I. LU[2], R. CERONE[2], A. OBERGRUSSBERGER[3], R. HAEDO[2], T. STRASSMAIER[2], P. WALSH[1];

Abstract: Nociceptors are a subset of sensory neurons that relay painful stimuli from the peripheral tissues. Multiple nociceptor subtypes exist and can respond to different thermal, mechanical, or chemical noxious stimuli. Recent findings with transcriptomics have identified gene expression patterns that classify these sub-types by different ion channels including Nav1.7, Nav1.8, Nav1.9, TRPV1, TRPA1, P2X3, HCN and a number of others that have been implicated in pain. In this study, we have identified a method to rapidly generate a novel TRPA1+ human induced pluripotent stem cell (hiPSC)-derived sensory neuron population and thoroughly

characterized it molecularly and functionally. Neurons were matured through four weeks and samples were processed on a weekly basis for bulk RNA sequencing and RNAscope. We found that this population was more similar to primary human DRG than other hiPSC-derived sensory neurons with RNA data sets publicly available, and specifically looked at differences in expression of ion channels, GPCRs, neuropeptides, and cell adhesion molecules. We also quantified this population via RNAscope and found 60% of the neurons express TRPA1+. Using high throughput automated patch clamp electrophysiology, we also explored properties of: voltage-gated sodium and potassium ion channels; TRP, GABA, and P2X ligand-gated ion channels; hyperpolarization-activated, cyclic nucleotide-gated channels; and mechanosensitive Piezo channels. Excitability properties in current clamp mode including resting membrane potential, spontaneous and evoked action potentials were also studied. These results were compared to a different hiPSC-derived sensory neuron population to determine the optimal sub-type and for target discovery and validation in high-throughput pain drug discovery screens.

Title: A specific blocker of Tentonin 3, NMB-1 and its blocking molecular mechanism

Authors: ***S. LIM**, U. OH;
Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Tentonin3 (TTN3/TMEM150C) is a mechanosensitive ion channel that exhibits unique biophysical, structural, and physiological functions distinct from Piezo channels. Notably, deep learning algorithms combined with molecular dynamics predict a putative TTN3 structure, which shows a tetramer with rectangular shape and a pore in the center. TTN3 elicits slowly-

adapting (SA) inactivation kinetics upon mechanical step stimuli. TTN3 mediates proprioception, baroreceptor reflex, and insulin release from pancreatic beta cells. Despite in depth studies on biophysical and functional aspects of TTN3, its specific inhibitor has not been identified. NMB-1, a conopeptide analogue, is known to selectively block the slowly adapting mechanically activated current in DRG neurons . As TTN3 confers SA-type mechanosensitive (MS) currents in DRG neurons , we hypothesized that NMB-1 may block TTN3. Indeed, NMB-1 blocked MS currents of TTN3. NMB-1, however, failed to block Piezo1 MS currents. Because NMB-1 is a conopeptide with 19 amino acids, we mutated functional residues such as bulky residues and positively charged residues to determine key residues for the blocking activity. Furthermore, we identified a structure of NMB-1 and predicted the location of its binding to TTN3. As TTN3 mediates numerous physiological functions, the identification of a specific blocker and its interaction mechanism would lead to the development of useful tools for clinical use.

Title: Lung-brain communication in the onset of respiratory viral infection

Authors: *S. MONROE[1], N. NANDURI[2], F. ULLOA SEVERINO[3], S. BILBO[2];
[1]Neurobiology, Cell. and Mol. Biol., [2]Duke Univ., Durham, NC; [3]Cell Biol. Dept., Duke Univ. Med. Ctr., Durham, NC

Abstract: Society faces increasing burden from respiratory immune challenge including respiratory viral infection. Respiratory viral infection, including with influenza A virus, can cause changes in brain function and understanding the link between lung and brain health is critical to anticipating the shifting health needs of our society. It is unknown how lung-brain communication impacts the progression of respiratory viral infection, or how different communication mechanisms are prioritized as inflammatory response progresses. Using a mouse model of infection with the influenza A strain PR8, this project explores immune signaling in either direction of the lung-brain axis. Preliminary data shows that during PR8 infection, changes in central nervous system (CNS) occur prior to inflammatory gene upregulation in lung tissue. The source and outcome of these acute phase CNS changes remains unknown. Pulmonary neuroendocrine cells are also the only cells in the lung epithelium directly innervated by the vagus nerve, making them a likely candidate to send rapid signals from the lung to the brain. PNECs can be manipulated by using cre-dependent tools in calca^{cre} mice to determine whether

these cells contribute to the CNS response to acute PR8 infection. Ablation of PNECs prior to infection reduces both proliferation of PR8 and inflammatory gene upregulation in lung tissue. This may also lead to a reduction in CNS response to infection. The ultimate role of CNS changes during acute PR8 infection remains unknown. Fos2A-iCreER (TRAP2) mice allow for the "capture" of neuronal ensembles using an inducible cre system to deliver a gene of choice. By delivering chemogenetic receptors to the neuronal population that responds to PR8, it is possible to later reactivate these neurons to determine whether they influence the immune outcome of infection. Preliminary data shows that the insular cortex has notable neuronal activity during the acute phase of PR8 infection, making it a promising region for implementation of this technique. Altogether, this research explores the connection between lung and brain health, focusing on these organs influence each other's immune states in the acute phase of respiratory infection.

Title: Unraveling itch and pain sensations by in vivo voltage imaging

Authors: *Y. ZHANG[1], H. SON[1], J. SHANNONHOUSE[1], R. GOMEZ[1], M.-K. CHUNG[2], J. PLATISA[3], V. A. PIERIBONE[4], Y. KIM[1];

Abstract: Both itch and pain are unpleasant sensations caused by exposure to certain chemical irritants, injuries, or inflammation. Despite itch and pain sensations being distinguishable in behavioral readouts, itch and pain signals are difficult to discern in functional studies with traditional electrophysiology and calcium imaging due to similar discharge patterns, represented as action potentials and intracellular calcium transients, respectively. Thus, little is known of how somatosensory neurons transmit and process itch and pain information *in vivo*. Here, we generated and characterized a knock-in mouse line with Pirt-driven expression of Marina, a positively tuned genetically-encoded voltage indicator, in primary sensory neurons. Pirt-Marina mice enable optical reporting of touch, itch, and nociceptive sensations *in vivo* and subtype-

specific action potential patterns in the trigeminal and dorsal root ganglia neurons. Our results suggest that neuronal firing encoded by noxious or pruritic stimuli are processed differently when they pass through soma of primary sensory neurons within ganglia. The pain signals are encoded by neuronal action potential firing activity, but itch sensations are by variable subthreshold voltage dynamic changes and their summation. This novel Pirt-Marina mouse line provides optical access to dynamic neuronal activity and plasticity in the peripheral nervous system with high temporal accuracy, fidelity, and reliability, greatly expanding our knowledge of how somatosensory neurons differentiate and encode itch, pain, and other sensations in live animals.

Title: Resurrected from obscurity: the forgotten Goldman-Hodgkin-Katz (GHK) current equation: stable spike firing in ultrathin axons.

Authors: *O. KOTLER[1], M. GUTNICK[2], I. FLEIDERVISH[1];
[1]Physiol. and Cell Biol., Ben Gurion Univ. of the Negev, Beer Sheva, Israel; [2]Koret Sch. of Vet. Med., Hebrew Univ. of Jerusalem, Rehovot, Israel

Abstract: In the 1940s, two equations emerged that describe the relationships between current and voltage across a membrane. The more famous equation, the GHK *voltage* equation, reconciled the Nernst potentials of the various ion species with their partial permeabilities. The less famous GHK *current* equation described the non-linear relationship between current and voltage for different concentration gradients. Hodgkin and Huxley, who did not benefit from modern computers, knew the GHK current equation and its ramifications. However, they preferred to use a simplified linear model for their equations, and this estimation fit their data well. Recently, several studies have used the Hodgkin-Huxley style linear conductance models to study the excitable properties of very thin axons. They found that high-frequency repetitive firing in these fibers could cause the Na^+ concentration gradient to dissipate, drastically compromising spike generation and propagation. However, we now show that when the current-voltage relationship is described using the GHK current equation, the Na^+ current in the voltage range relevant to the action potential (AP) generation is barely affected by dramatic changes in $[Na^+]_i$. Thus, whereas the linear model predicts that a 10-fold increase in $[Na^+]_i$ leads to an 80% decrease in inward current at 0 mV and an equivalent slowing of the rate-of-rise of an AP, the

non-linear GHK current equation predicts only ~ 20% change. This dramatic difference is significant because so much of the recurrent activity in many brain areas is via axons with diameters less than 0.5 microns. Since experimental access to these compartments is very limited, we must rely on computational models for insight. In summary, by placing the voltage range of the AP in a region that is relatively resistant to changes in Na^+ concentration gradient, evolution has ensured stable interaction of neurons in highly active complex local networks.

Title: Using Real-Time Dynamic Clamp to Determine the Effects of State-Dependent Toxin Action on Action Potential Behavior in Living Neurons

Authors: B. K. PANAMA[1], ***M. W. NOWAK**[2], S. ACHARYA[2], C. BASS[2], L. KORBEL[2], R. L. RASMUSSON[2,1], G. C. L. BETT[2,1];
[1]Jacobs Sch. of Med., SUNY at Buffalo, Buffalo, NY; [2]Cytocybernetics, Pendleton, NY

Abstract: Ion channel dysfunction leading to aberrant neuronal function underlies many neurological diseases (e.g., epilepsy, neuropathic pain) and Pharma has devoted considerable effort in developing drugs targeting ion channels. A critical aspect is understanding which ion channel state (closed, open, inactive) must be blocked in order to normalize neuronal function. The aim of these studies is to utilize real-time dynamic clamp to express virtual sodium channel models of state-dependent drug block into living neurons and assess the effects on action potential (AP) behavior. We compared the effects of the late Na channel current potentiator ATX-II with virtual expression of a neuronal Na channel with a persistent late current model (I_NaP, Herzog et al., 2021) on AP behavior in human pluripotent stem cell-derived GABAergic neurons (hiPSC-GNs) (iCell-GABA Neurons, Fujifilm Cellular Dynamics Inc, Madison, WI). Electrophysiological recordings were performed using the whole-cell ruptured patch clamp configuration and real-time dynamic clamp was implemented using the Cybercyte system (Cytocybernetics, Inc., Buffalo, NY). As with previous studies, due to the lack of expression of background K^+ currents, the stable recording of APs in hiPSC-GNs required the electronic expression of a Goldman-Hodgkin-Katz outwardly rectifying K^+ current to adjust the depolarized resting membrane potential (RMP) (29.4±1.2 mV, n=21) to a more physiological value (60.5±0.5 mV, n=21). This allowed for the recording of stable evoked APs (stimulus: 0.3-1.0 nA for 0.3-1.5 ms). APs measured in the presence of 100 nM ATXII altered the AP morphology with a significant prolongation of the AP duration at 90% repolarization (APD90)

(Control: 6.3±1.0 ms, ATXII: 12.4±2.6 ms, n =4, paired t-Test, $p<0.05$). To model the effect of ATXII, we blocked the endogenous Na current with 100 nM TTX and virtually expressed I_NaP. Similar to ATX-II, INaP virtual expression also altered AP morphology and prolonged the APD90 (Control: 12.3±3.3 ms, INaP: 43.5±8.1 ms, n =6, paired t-Test, $p<0.05$). Our data demonstrate that dynamic clamp can be utilized to determine the effects of state-dependent toxin action on neuronal AP behavior. Further studies will examine the effects of virtual expression of Markov I_Na models with state-dependent actions on neuronal AP behavior. This approach can be utilized in developing drugs that target ion channels in which efficacy and normalization of aberrant neuronal function are dependent on block of a specific ion channel state.

Title: Presynaptic leak channel NALCN regulates vesicular glutamate transport and vesicle release

Authors: *T. WU, D. LI, Y. DARWISH, T. XIAO, H. HUANG;
Tulane Univ., New Orleans, LA

Abstract: At chemical synapses, Ca^{2+} triggers and modulates neurotransmitter release. The action potential-triggered high-concentration Ca^{2+} transients are required for rapid exocytosis, while a low concentration of basal Ca^{2+} can modulate subsequent release via vesicle recruitment, priming and sensitization, thus controlling the strength of synaptic transmission. The Ca^{2+} channels activated by action potentials that trigger neurotransmitter release have been extensively studied. However, little is understood about the ion channel that sets resting Ca^{2+} level and modulates neurotransmitter release, especially at glutamatergic synapse. Here we report that the Na^{+} leak channel, non-selective (NALCN) is expressed in the calyx of Held terminals and controls the presynaptic resting membrane properties. NALCN is Na^{+}-permeable

that controls the presynaptic resting Na^+ level and, by activating vesicular Na^+/H^+ exchanger, regulates vesicular glutamate transport. NALCN is also Ca^{2+}-permeable and regulates resting Ca^{2+} level and glutamate release. NALCN is tightly coupled with release machinery and regulates both the amplitude and frequency of miniature excitatory postsynaptic current (mEPSC). Moreover, blocking NALCN decreases synaptic strength and disrupts reliable neurotransmission during prolonged high-frequency signaling. Therefore, this work demonstrates that the activity of presynaptic NALCN regulates both vesicular glutamate transport and neurotransmitter release in the mammalian central nervous system.

Title: Exploring Time-Dependent Modulation of Active Zone Protein Accumulation by the NALCN Channel Pore Unit

Authors: *R. KARATEPE;
Univ. of Hlth. Sci., Istanbul, Turkey

Abstract: Synaptic dysfunction has been implicated in a range of neurological disorders, including epilepsy, movement disorders, and intellectual disability. At our institute, we have identified several patients harboring mutations in genes that have the potential to be important players in synapse function, NALCN channel being one of them.NALCN channel is a sodium leak channel composed of the NALCN protein, which forms the pore region, and two accessory subunits, UNC80 and UNC79. Previous research has demonstrated that NALCN leak channel localizes to synapses in Drosophila, and disruption of its components leads to altered locomotor activity and disturbances in circadian rhythm.The objective of this study was to investigate the impact of silencing the pore region of the sodium leak channel NALCN on synaptic protein abundance. To achieve this, we employed immunohistochemistry and imaging techniques using Drosophila larvae as a model organism. By silencing the expression of the NALCN channel pore region, specifically the NALCN ortholog na, in motoneurons, we aimed to identify changes in synaptic protein intensity and synapse (active zone) number.While the number of active zones remained constant in both the motoneuronally silenced na larvae and the wild-type larvae, we observed time-dependent oscillation of synaptic marker bruchpilot (brp) and glutamate receptors, at the neuromuscular junction. Surprisingly, this oscillatory pattern was reversed when silencing the NALCN ortholog na in motor neurons.Our findings indicate that the NALCN channel

component na plays a crucial role in regulating time-dependent levels of brp and glutamate receptors in Drosophila. Understanding the mechanisms underlying these changes could provide valuable insights into the pathogenesis of some synaptic disorders.

Authors: *Y. OGAWA[1], M. N. RASBAND[2];
[1]Baylor Col. of Med., Houston, TX; [2]Neurosci., Baylor Col. of Med. Dept. of Neurosci., Houston, TX

Abstract: The axon initial segment (AIS) is important for the generation and propagation of action potentials, and regulation of neuronal polarity. Although it is well established that AnkyrinG (AnkG) and β4-Spectrin play key roles in the formation and maintenance of the nodes of Ranvier and AIS, the molecular composition of these domains remains incompletely understood. We recently used proximity biotinylation and proteomics approaches to identify candidate AIS and nodal proteins. To validate and investigate these candidates, we developed an AAV-mediated CRISPR-based genome editing method which allows for high-throughput analysis in both cultured neurons and brain. Using this high-throughput knock-in screening strategy, we found several new AIS proteins. For subsequent functional analysis of these new AIS proteins, we also developed a simplified AAV production method which allows high-throughput and efficient knockout or overexpression in cultured neurons. Together, these methodologies are flexible and efficient for the analysis of proteins associated with a variety of subcellular structures and can be used to address a broad spectrum of neurobiological questions.

Title: Biophysical properties of sodium channels in dopaminergic midbrain neurons defined by axonal projections.

Authors: *M. JAHNKE[1], J. MANKEL[2], J. ROEPER[2];
[1]Inst. of Neurophysiol., Frankfurt am Main, Germany; [2]Inst. of Neurophysiol., Johann Wolfgang Goethe-University Frankfurt, Frankfurt, Germany

Abstract: The midbrain dopamine (DA) system is critical for various essential brain functions such as working memory, movement control, motivation, and reward-based learning. Dysfunction of distinct DA subpopulations respectively contributes to major disorders such as Parkinson disease, schizophrenia, or drug addiction. Midbrain DA neurons release DA within their specific axonal target areas, which include the nucleus accumbens (NAc) subregions and the dorsal striatum. DA levels in these areas depend on both the action potential discharge patters in the projecting DA neurons and local control mechanisms at the distal axon. To further define the biophysical properties of projection-specific DA subpopulations we studied their respective voltage-gated sodium (Na^+) channels.Using nucleated outside-out patches previous studies investigated the differences between the functional characteristics of voltage-gated Na^+ currents in midbrain GABAergic and DA neurons (Seutin and Engel., 2010; Ding et al., 2011) and DA neurons of the ventral tegmental area (VTA) and substantia nigra (SN) (Yang et al., 2019). However, sodium current properties of projection-defined DA subpopulations have yet to be described. For that purpose, we combined axonal retrograde tracing with nucleated outside-out patch clamp recordings of labelled DA neurons in adult male C57Bl6N mice.As a first step, we recorded voltage-gated Na^+ currents of NAc-core and NAc-medial shell-projecting DA subpopulations. These two subpopulations in the VTA both belong to a extended-firing range DA phenotype (Lammel et al., 2008, Knowlton, Ziouziou et al. 2021). As expected we observed no significant differences in the functional properties of their Na^+ currents (activation 10-90% rise time (at - 20 mV): NAc-core: 263.2 ± 43.5 µs, n = 11, N = 4; NAc-medial shell: 251.1 ± 36.6 µs, n = 22, N = 5; p = 0.84; inactivation 10-90% rise time (at - 20 mV): NAc-core: 2.12 ± 0.71 ms, n = 11, N = 4; NAc-medial shell: 4.16 ± 0.8 ms, n = 21, N = 5; p = 0.1; Na^+ current density (at - 20 mV): NAc-core: 22.6 ± 8.1 pA/pF, n = 10, N = 4; NAc-medial shell: 27.5 ± 4.4 pA/pF, n = 21, N = 5; p = 0.57). Next, we will explore Na^+ current properties in nucleated outside-out patches of NAc-lateral shell-projecting DA neurons, which are a distinct VTA/SN DA subpopulation characterized by a compressed firing-range phenotype.

Title: Pharmacologically Targeting the Nav1.6:GSK3β Protein Complex to Mitigate Hyperexcitability in Early-Stage Alzheimer's Disease

Authors: *T. J. BAUMGARTNER, II, N. M. DVORAK, N. A. GOODE, A. K. SINGH, Z. HAGHIGHIJOO, Z. HAGHIGHIJOO, P. A. WADSWORTH, F. LAEZZA;
UTMB, Galveston, TX

Abstract: Despite global initiatives to elucidate the pathophysiology of Alzheimer's disease (AD), there is an unmet need for disease-modifying AD therapeutics. Numerous studies show a causal relationship between hippocampal hyperactivity and the onset of cognitive impairments during early-stage AD. Voltage-gated Na+ channels (Nav channels) are transmembrane proteins with critical regulatory roles in synaptic function and neuronal firing. Importantly, Nav1.6 plays a critical role in action potential initiation due to its localization at the axon initial segment, and therefore serves as an attractive target for modulation of neuronal excitability. The Nav1.6 channel is regulated through its interactions with various auxiliary proteins and signaling molecules. Studies from our lab revealed that glycogen synthase kinase 3β (GSK3β) directly binds and phosphorylates the Nav1.6 C-terminal domain (CTD), indicating that GSK3β regulates the Nav1.6 channel via a dual-function mechanism including phosphorylation and complex formation. Functionally, genetic silencing of GSK3β suppresses Nav1.6-encoded currents, while GSK3β overexpression stimulates Nav1.6 activity and promotes maladaptive firing of neurons. Critically, overexpression and dysregulation of GSK3β is observed in the hippocampus of AD brains. This evidence suggests that dysregulated GSK3β-mediated modulation of Nav1.6 facilitates neuropathological phenotypes associated with the early-stage AD. Using the split-luciferase complementation assay, we have identified a small molecule ligand, 1063, that significantly inhibits Nav1.6:GSK3β complex assembly compared to vehicle control. Furthermore, 1063 reduces Nav1.6-mediated sodium currents in a manner reminiscent of GSK3β knockdown. Using *ex vivo* patch clamp electrophysiology in 2-4 month old 3x-Tg-AD mice, we show that hyperexcitability in the CA1 region of the hippocampus is mitigated with knockdown of GSK3β, and that the effects of 1063 in this region are dependent on the presence of GSK3β. Mutagenesis screening indicated that the Nav1.6:GSK3β complex is mediated by residues of the GSK3β axin-binding domain. Functional studies revealed that expression of the GSK3β axin-binding domain is sufficient to inhibit GSK3β-induced upregulation of Nav1.6-mediated currents in heterologous cells, suggesting that residues within this region are required for GSK3β's functional effects on the channel. Cooperatively, these results illustrate a novel, druggable interface between Nav1.6 and GSK3β that holds potential as a disease-modifying target for early-stage AD.

Title: Possible roles for the sodium leak channel (Nalcn) in serotonergic (5-HT) dorsal raphe (DR) neurons: Implications for hypocretin/orexin (OxR) and alpha1 (Adra1) receptor signaling

Authors: *S. JAVED[1], E. BERRY[2], M. ISHIBASHI[4], C. S. LEONARD[3];
[1]Physiol., [3]Dept Physiol, [2]New York Med. Col., Valhalla, NY; [4]Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: Serotonergic DR neurons provide extensive ascending innervation of brain regions that influence many functions including those that regulate mood, reward, feeding and metabolism, sleep and arousal, and sensory and motor systems. Moreover, regulation of extracellular 5-HT levels is critically implicated in the etiology and treatment of major psychiatric illness, including depression. Thus, factors that influence the firing of these neurons will widely impact CNS function. The orexin/hypocretin and noradrenergic systems can potently depolarize and induce firing in these 5-HT neurons by GPCR-activation of noisy cation-permeable ion channels that are effectors for the convergent signaling of OxRs and Adra1 on these neurons, although the identity of these channels is not known. By leveraging published gene expression profiles of 5-HT neurons, we identified several candidate cation channels including the sodium leak channel (Nalcn), which regulates resting membrane potential and can couple to GPCRs to alter neuronal excitability in some neurons. Initial immunocytochemistry experiments suggested that Nalcn protein is present in serotonergic DR neurons. However, subsequent knockout experiments utilizing AAV delivery of Cre-recombinase to $Nalcn^{fl/fl}$ mice revealed an incomplete absence of Nalcn immunostaining in Cre-expressing neurons, suggesting a lack of antibody specificity. To test for the presence of functional Nalcn channels, we are using whole-cell patch clamp recordings from DR neurons in brain slices obtained from $Nalcn^{fl/fl}$ mice. Our preliminary data indicate the presence of a small TTX-insensitive, Na^+-dependent current (12.3 ± 2.2 pA, N = 5) at -70 mV in putative 5-HT DR neurons, which was revealed by lowering extracellular Na^+ from 151.2 mM to 27.2 mM with NMDG substitution in the ACSF. This Na^+-dependent current was increased to 39.8 ± 6.1 pA at -70 mV (N = 5) following application of the Adra1 agonist phenylephrine (3 uM). To determine if these currents are mediated by Nalcn, we are now examining these currents in mice selectively lacking Nalcn in 5-HT neurons. We anticipate these findings will delineate the potential roles of Nalcn in regulating membrane

potential and excitability of 5-HT DR neurons. Understanding these molecular mechanisms could therefore provide valuable therapeutic targets for modulating the many functions engaged by 5-HT DR neurons.

Title: Modulation of voltage-gated sodium (Na_v) channel inactivation, medium spiny neuron excitability, and motivation-related behavior through pharmacologically targeting the $Na_v1.6$/fibroblast growth factor 14 complex

Authors: *N. M. DVORAK[1], P. A. WADSWORTH[1], D. S. ENGELKE[2], A. SINGH[1], N. NGUYEN[3], P. WANG[1], H. CHEN[1], R. T. POWELL[3], C. STEPHAN[3], F. DO MONTE[2], J. ZHOU[1], F. LAEZZA[1];

Abstract: Voltage-gated Na^+ (Na_v) channels enable the initiation and propagation of action potentials. While the α subunit is sufficient for ion conduction, the full physiological function of Na_v channels is dependent upon protein:protein interactions (PPI) with auxiliary proteins. In the brain, $Na_v1.1$, $Na_v1.2$, and $Na_v1.6$ are the primary isoforms expressed, and they differ with respect to their cellular and subcellular distributions. In medium spiny neurons (MSN) of the nucleus accumbens, which is a central hub of reward circuitry, the $Na_v1.6$ channel is the primary isoform expressed and its activity is regulated by the auxiliary protein fibroblast growth factor 14 (FGF14). Here, we explore the druggability of the FGF14/$Na_v1.6$ complex in an effort to fine-tune reward circuitry that is corrupted in an array of psychiatric disorders. To that end, we screened ~45,000 small molecules for effects on FGF14/$Na_v1.6$ complex assembly. In cell screening, in tandem with protein:ligand binding studies, functional validation modules, and molecular modeling, identified a class of four compounds targeting the intermolecular interaction between $FGF14^{R117}$ and the $Na_v1.6^{D1846:R1866}$ salt bridge. From this class, 1028 was selected as the representative ligand on account of its superior potency. Mutation studies revealed that 1028 modulated FGF14/$Na_v1.6$ complex assembly through a mechanism dependent upon an intact interaction between $FGF14^{R117}$ and the $Na_v1.6^{D1846:R1866}$ salt bridge. Functionally, 1028 was shown to cause a depolarizing shift in the voltage-dependence of inactivation of $Na_v1.6$-mediated sodium current through a mechanism dependent upon an intact interaction between the III-IV

linker and C-terminal domain. 1028's effects on $Na_v1.6$ channel inactivation correspondingly resulted in increased activity of MSNs *ex vivo* and *in vivo*. Behaviorally, electrophysiological changes conferred by 1028 were shown to correlate with alterations in behaviors associated with motivation. Collectively, these results demonstrate that the FGF14/$Na_v1.6$ complex is amenable to small molecule modulation and that it could serve as a therapeutic target for psychiatric disorders.

Title: Fgf14 derived ligand differentially regulates $na_v1.2$ and $na_v1.6$ function

Authors: ***P. ARMAN**[1], C. A. LUPASCU[2], Z. HAGHIGHIJOO[1], N. GOODE[1], Y. XUE[1], P. WANG[1], H. CHEN[1], D. ANTUNES[3], M. MIGLIORE[2], F. LAEZZA[1];
[1]Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br., Galveston, TX; [2]Inst. of Biophysics, Dept. of Physical Sci. and Technologies of Matter, Natl. Res. Council (CNR), Genoa, Italy; [3]Univ. of Houston, Houston, TX

Abstract: Voltage-gated Na^+ channels (Na_v) are the molecular determinants of action potential initiation and propagation because of their role in mediating ionic flow (Na^+). Among the nine voltage-gated Na^+ channels, $Na_v1.2$ and $Na_v1.6$ are of particular interest in the central nervous system because of their role in modulating forward ($Na_v1.6$) and backward ($Na_v1.2$) action potential propagation. In pyramidal neurons, the interplay between $Na_v1.2$ and $Na_v1.6$ is complex with reduction or complete loss of $Na_v1.2$ producing a paradoxical increase in excitability, contrary to the reduction of excitability observed when $Na_v1.6$ is absent. Although the α-subunit can sufficiently confer transient Na^+ currents (I_{Na}), in vivo these channels are modulated by auxiliary proteins like intracellular fibroblast growth factor 14 (FGF14) through protein:protein interactions (PPIs). Previous studies have identified ZL0177, an FGF14 ligand derived from a short amino acid sequence mapped to the FGF14/$Na_v1.6$ PPI, as a functional modulator of $Na_v1.6$. In this report, ZL0177 was chosen for selectivity evaluation against $Na_v1.2$ and $Na_v1.6$. We observed statistically significant changes in peak I_{Na} density as well as shifts in both $V_{1/2}$ of activation and steady-state inactivation that were isoform specific. To that end, ZL0177

effectively decreased $Na_v1.6$ and $Na_v1.2$ mediated peak I_{Na} density, while causing statistically significant shifts in $V_{1/2}$ of activation that were isoform specific when compared to their corresponding controls. In addition, ZL0177 caused a selective shift in $V_{1/2}$ of steady-state inactivation for $Na_v1.2$, with no effect in $Na_v1.6$. Computational investigations using AlphaFold (AF) models of $Na_v1.2$ and $Na_v1.6$ revealed isoform specific interactions of ZL0177 with the inactivation gate and C-terminal domain (proximal:$Na_v1.2$ vs. distal: $Na_v1.6$). Complementary computational neuronal models of pyramidal neurons predict that ZL0177 results in distinct phenotypic variations in intrinsic excitability by selectively modulating $Na_v1.2$ and $Na_v1.6$ in an isoform specific manner. These findings support the distinct roles of $Na_v1.2$ and $Na_v1.6$ channels, raising the need for the development of isoform-specific probes to interrogate Nav channel function *in vivo*.

Title: Mechanism of inhibition by polysorbate 80 on the sensory and cardiac sodium channels

Authors: *R.-E. KIM[1,2], J.-S. CHOI[1,2];
[1]The Catholic Univ. of Korea, Bucheon-si, Gyeonggi-do, Korea, Republic of; [2]Integrated Res. Inst. of Pharmaceutical, The Catholic Univ. of Korea, Bucheon-si, Gyeonggi-do, Korea, Republic of

Abstract: Polysorbate 80 (PS80) is a non-ionic detergent derived from polyethoxylated sorbitan and oleic acid. It is widely used in pharmaceuticals, foods, and cosmetics as an emulsifier. $Na_v1.7$ is a peripheral sodium channel that is highly expressed in sympathetic and sensory neurons, and it plays a critical role in determining the threshold of action potentials (APs). We found that PS80 either abolished APs or increased the threshold of the APs of dorsal root ganglions. We thus investigated whether PS80 inhibits $Na_v1.7$ sodium current using a whole-cell patch-clamp recording technique. Also, we wondered whether PS80 has similar effects on $Na_v1.5$ sodium current important for generating action potentials in cardiomyocytes. PS80 decreased the peak currents in a concentration-dependent manner on both channels, and the

inhibition by PS80 was more potent when the holding potentials were more depolarized. The blocking of $Na_v1.7$ and $Na_v1.5$ currents by PS80 was not reversible at a holding potential of −90 mV but completely reversible at −120 mV, where the channels were mostly closed. The activation rate and the voltage dependency of activation curves for $Na_v1.7$ and $Na_v1.5$ were not changed by PS80. However, PS80 hyperpolarized the voltage dependency of the steady-state inactivation curves, slowed the recovery from inactivation, and produced robust use-dependent inhibition, suggesting it preferentially binds to the inactivated state. Our results indicate that PS80 has concentration-, state-, and use-dependent inhibitory effects on $Na_v1.7$ and $Na_v1.5$ channels, which may have potential implications for the peripheral nervous system and cardiac function even below commercial concentrations.

Title: Peptide-based probe reveals a scaffolding function of GSK3β in the Nav1.6 macromolecular complex

Authors: *A. K. SINGH, N. M. DVORAK, Z. HAGHIAHIJOO, M. BERNABUCCI, J. SINGH, Z. LIU, Y. XUE, J. ZHOU, F. LAEZZA;
Pharmacol. & Toxicology, Univ. of Texas Med. Br. (UTMB), Galveston, TX

Abstract: Kinase signaling pathways regulating ion channel macromolecular complexes play a crucial role in fine-tuning neuronal activity and remodeling synapses. Yet, the molecular underpinnings of activity-dependent signaling mechanisms regulating these molecular complexes are still poorly understood. In recent studies conducted in the nucleus accumbens (NAc), we have shown that vulnerability to depression-like and stress-induced disorders induces a form of maladaptive plasticity consisting of hyperexcitability of medium spiny neurons (MSNs). Vulnerability in these cells is mediated by the increased interaction between glycogen synthase kinase 3β (GSK3β) and the C-terminal domain (CTD) of the voltage-gated Na+ channel Nav1.6. A decoy peptide mimicking the Nav1.6 segment interacting with the kinase or in vivo genetic silencing of GSK3β were found to be sufficient to prevent MSN maladaptive plasticity. Building

on these results, we hypothesized that inhibition of the GSK3β/Nav1.6 protein-protein interaction complex could counteract GSK3β-dependent maladaptive plasticity of MSNs. To that end, we developed a series of peptide-based probes capable of modulating the scaffolding function of GSK3β in the Nav1.6 channel complex. Molecular docking, split-luciferase complementation (LCA), intrinsic fluorescence, surface plasmon resonance (SPR), whole-cell patch-clamp electrophysiology in heterologous cells, and in the ex-vivo acute slice preparation as well as viral vector-based in vivo gene silencing were implemented for discovery and validation studies. Probe ZL141 was found to significantly inhibit GSK3β/Nav1.6 complex formation using the LCA and to bind to GSK3β using SPR. In addition, whole-cell patch-clamp recordings in HEK293 cells stably expressing Nav1.6 showed that ZL141 regulates peak current density, voltage-dependent activation, and steady-state inactivation curves as well as long-term inactivation of Nav1.6 in a GSK3β-dependent manner. Preliminary studies employing GSK3β in vivo genetic silencing and ex vivo slice recordings of MSN in the NAc support the mechanism of action of ZL141 observed in heterologous cells. These studies lay the groundwork for the development of novel neurotherapeutics based on modulation of non-enzymatic activity of GSK3β in the brain.

Title: Inhibition of Sympathetic Nerve Mediated Contraction of Human and Guinea Pig Blood Vessels by Selective $Na_V1.7$ Blockers

Authors: *J. S. KIM[1], S. MEEKER[1], T. S. ZABKA[2], D. H. HACKOS[2], B. J. UNDEM[1]; [1]Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Genentech Inc, South San Francisco, CA

Abstract: We quantified the effect of blocking $Na_V1.7$ with two highly selective $Na_V1.7$ blockers on sympathetic nerve-evoked adrenergic contractions of blood vessels isolated from guinea pigs and humans. We isolated pulmonary arteries from human lungs (obtained via NIAA) and the abdominal aorta from guinea pigs. The smooth muscle tension was quantified using standard tissue bath technology. The intrinsic nerves were stimulated with electrical field stimulation (EFS, 12V, 1msec, 10Hz) for 30 sec. This causes rapid contraction in all tissues, which was entirely prevented with alpha adrenoceptor antagonists (1 μM prazosin). The contractions were quantified as the % of a maximal obtainable adrenergic contraction evoked by 100 μM phenylephrine added at the end of the experiment. Genentech Pharmaceuticals provided a highly selective $Na_V1.7$ blocker (GNE8493; 500-5000 fold selective for $Na_V1.7$ over other Na_Vs), while SiteOne Pharmaceuticals provided another mechanistically distinct, highly selective $Na_V1.7$ blocker (ST2262; 1000-fold selective for $Na_V1.7$ over other Na_Vs) (Sci Rep. 10:14791, 2020). We previously published that the parasympathetic neurons in human and guinea pig airways express only $Na_V1.7$, making the parasympathetic cholinergic contractions of the airways a useful tissue level "bioassay" for $Na_V1.7$ activity (see JPET,361: 172-180, 2017). The potencies (-log M IC_{50}) of GNE8493 and ST2262 at blocking $Na_V1.7$- dependent parasympathetic contractions of human bronchi averaged 6.7 ± 0.4 (n=8) and 6.2 ± 0.1 (n=13), respectively. The EFS-induced activation of sympathetic nerves caused contractions of human pulmonary arteries averaging 12 ± 3% and 0.7 ± 0.3% in the absence and presence of GNE 8493, respectively ($P<0.01$); and 8 ± 1% and 0.7 ± 0.3% in the absence and presence of ST2262 ($P<0.01$), respectively. Since ST2262 has a relatively low affinity for rodent and guinea pig $Na_V1.7$, we limited our studies to GN8493 in guinea pigs. GN8493 abolished the $Na_V1.7$ responses in the airway parasympathetic nerves with a -log (M) IC_{50} of 5.8 ± 0.2 (n=6). The sympathetic contraction of the isolated abdominal aorta was similarly blocked with a -log (M) IC_{50} of 6.4 ± 0.3. Single neuron RT-PCR revealed that 11 of 11 neurons isolated from guinea pig stellate ganglia express $Na_V1.7$ mRNA. These data support the hypothesis that pharmacologically blocking $Na_V1.7$ with selective inhibitors is likely to reduce sympathetic tone in certain vascular beds.

Title: $Na_V1.1$ selective potentiators increase pv^+ fast-spiking interneuron excitability, normalize inhibition/excitation imbalance and restore motor performance in a mouse model of dravet syndrome

Authors: *S. THOUTA, M. WALDBROOK, K. BURFORD, C. DUBE, M. SORIANO, R. DEAN, V. LOFSTRAND, H. CLEMENT, S. WESOLOWSKI, J. EMPFIELD, J. GILBERT, J. JOHNSON JR, S. GOODCHILD;
Xenon Pharmaceuticals, Burnaby, BC, Canada

Abstract: Loss-of-function variants of *SCN1A* cause Dravet Syndrome and generalized epilepsy with febrile seizures plus (GEFS+), by decreasing $Na_v1.1$ expression and function of inhibitory interneurons. The resulting hypo-excitability of interneurons reduces inhibitory input onto excitatory neurons, leading to epilepsy and other co-morbidities. To date, there are no subtype selective potentiators of Nav1.1 channels clinically available that directly address the underlying mechanisms of the disease. We have identified potent, isoform-selective, brain penetrant small molecule potentiators of $Na_V1.1$ channels with good drug-like properties that increase Nav1.1 current and restore the firing activity of parvalbumin-expressing, fast-spiking GABAergic interneurons in Dravet Syndrome mice ($Scn1a^{+/-}$). The firing properties of excitatory neurons were not affected by the compounds. Wild-type interneurons were similarly not affected by the compound. Furthermore, we also show that the compounds normalize the imbalance in spontaneous excitatory and inhibitory synaptic input to pyramidal neurons in $Scn1a^{+/-}$ mice. When tested *in vivo*, these compounds suppress seizures in an $Scn1a^{+/-}$ mouse 6 Hz seizure model and improve motor dysfunction in the rotarod assay. In conclusion, our precision medicine approach, that specifically targets the pathophysiological deficit in Dravet Syndrome, may provide a novel approach to control seizures and to ameliorate other co-morbidities

Abstract: Entrapment neuropathies occur when the nerve becomes compressed between other structures in the body and are the most common type of neuropathic pain. Previous studies have

shown that in preclinical models of entrapment injuries there is an increase in $Na_V1.8$ trafficking and insertion in the membrane. This increase in $Na_V1.8$ channel activity is believed to underly neuropathic pain. Our lab previously identified the WW domain-containing scaffold protein called Magi1 as the putative scaffold protein responsible for $Na_V1.8$ stabilization in the nociceptor membrane (PMID: 30860870). Using the sciatic nerve cuff model of entrapment injury in male and female mice, we used both a genetic approach and a pharmacological approach to investigate the role of the Magi1-$Na_V1.8$ interaction in neuropathic pain. The Hargreaves thermal, von Frey fiber mechanical, and dynamic weight-bearing sensitivity assays were used to confirm and monitor neuropathic pain. After Magi1 was genetically knocked down unilaterally in the sciatic nerve, we found that there was an increase in the thermal withdrawal latency in neuropathic mice compared to the scrambled shRNA-treated mice. We also saw an increase in the percent weight borne on the ipsilateral paw in the Magi-1 knockdown mice compared to scrambled shRNA-treated mice. For von Frey sensitivity, there was an increase in the withdrawal threshold of the Magi1 knockdown mice. We noted sex differences in response to the Magi1 knockdown. In a parallel set of experiments, we injected a lipidated $Na_V1.8$ WW domain peptidomimetic into the ipsilateral paw. We found in an increase in thermal withdrawal latency in the peptide treated mice compared to the scrambled peptide treated mice that lasted for >21 days. There was also a similar increase in the paw withdrawal threshold in von Frey sensitivity. We also saw a change in the percent weight borne on the ipsilateral paw in the NaV1.8 WW peptide treated mice compared to scrambled control. Pharmacologically targeting the $Na_V1.8$ interaction with Magi1 is analgesic in mice undergoing nerve entrapment neuropathic injury. Future studies will look at the effect this peptidomimetic has on other chronic pain models.

Abstract: Pathogenic variants of the *SCN2A* gene, coding for the $Na_V1.2$ voltage gated sodium channel alpha subunit, can cause a wide phenotypic spectrum, including mild epilepsy, different types of developmental and epileptic encephalopathies (DEEs) or different types of neurodevelopmental disorders without epilepsy. Functional studies have shown that variants implicated in infantile-childhood onset DEEs or neurodevelopmental disorders cause loss of function (LoF), but the genotype-phenotype relationships within these variants are not clear yet. We have investigated functional effects of 14 of these variants (7 of them not yet published) in transfected cell lines and neurons in primary culture, either expressing the mutant in isolation or co-expressing mutant and wild-type $Na_V1.2$, to reproduce the conditions of heterozygosis. We observed that all the mutants show LoF when expressed in isolation, either because of reduced current density or because of modifications of gating properties. Notably, when co-expressed with the WT, mutants causing autism spectrum disorder (ASD) without epilepsy induced negative dominance by reducing the current density of the WT and leading overall to more than 50% reduction in current density. Differently, those causing schizophrenia or DEEs did not show negative dominance. Mutagenesis experiments showed that the negative dominant effect of the ASD mutants depends on regions in the channel protein that have been implicated in the interaction of two Na^+ channel alpha-subunits. Moreover, radioactive binding experiments in cell lines and STED super-resolution microscopy experiments in neurons showed that ASD mutants are not targeted to the plasma membrane.Thus, we have disclosed a novel specific pathological mechanism for *SCN2A*/$Na_V1.2$ variants involved in ASD without epilepsy. Our results are consistent with a mechanism in which ASD mutant alpha subunits, interacting with the WT alpha subunit, reduce the targeting of the alpha subunit dimers to the plasma membrane.

Title: An optical analysis of the Na^+ influx, of the Ca^{2+} influx and of the action potential shape in the axon initial segment of neocortical pyramidal neurons in a $Na_V1.2$ knock-out mouse

Authors: *F. ABBAS[1], L. BLÖMER[1], M. SIMONTI[2], S. CELESTE[2], M. MANTEGAZZA[2], M. CANEPARI[1];

Abstract: ***An optical analysis of the Na^+ influx, of the Ca^{2+} influx and of the action potential shape in the axon initial segment of neocortical pyramidal neurons in a $Na_v1.2$ knock-out mouse*** **Fatima Abbas**, **Laila Ananda Blömer**, **Martina Simonti**, **Sandrine Cestele**, **Massimo Mantegazza**, **Marco Canepari**The voltage-gated Na^+ channel (VGNC) $Na_v1.2$ is one of the two Na^+ channels expressed in the axon initial segment (AIS) of pyramidal neurons, responsible for the generation of the action potential (AP). Several neuronal disorders are associated with constitutive spontaneous mutations of the *SCN2A* gene leading to loss of function of the $Na_v1.2$ VGNC. Thus, heterozygote $Na_v1.2$ knock-out (*Scn2a*$^{+/-}$) mice are considered animal models to investigate the physiological changes associated with these channelopathies. Here we present the results of an analysis of AIS Na^+ and Ca^{2+} influx, as well as AIS APs, in layer-5 neocortical pyramidal neurons of a *Scn2a*$^{+/-}$ mouse. The analysis, performed using ultrafast imaging techniques (50-100 µs time resolution), was carried out in brain slices prepared from mice during the third and fourth postnatal week, when the *Scn2a*$^{+/-}$ mouse displays autistic-like phenotype associated with impaired memory and reduced reactivity to stressful stimuli [1]. The Na^+ influx in the proximal part of the AIS was slightly smaller in *Scn2a*$^{+/-}$ mice with respect to wild-type (*Scn2a*$^{+/+}$) mice. Since we recently reported that $Na_v1.2$ VGNCs also mediate a Ca^{2+} current that shapes the generating AP [2], we also performed a comparative analysis of Ca^{2+} current and AP waveform in *Scn2A*$^{+/-}$ and *Scn2a*$^{+/+}$ mice to investigate whether the $Na_v1.2$ loss of function can lead to a change in the AP shaping during its generation. As we also found a slight decrease of $Na_v1.2$ Ca^{2+} influx in *Scn2a*$^{+/-}$ mice, we conclude that this analysis can be considered as a first step to correlate the behavioral dysfunction with the cellular event of AP generation, also opening the gate to future utilizations of the technique for therapeutic assessments. Title: A new mouse model of non-syndromic autism spectrum disorder carrying the human negative-dominant mutation L1314P of the SCN2A/$Na_v1.2$ sodium channel

Authors: *M. SIMONTI[1], S. CESTÈLE[1], F. DUPRAT[1], I. LÉNA[1], M. MANTEGAZZA[1,2]; [1]Inst. of Mol. and Cell. Pharmacol. (IPMC), Univ. Cote d'Azur, CNRS, Valbonne - Sophia Antipolis, France; [2]Inserm, Valbonne - Sophia Antipolis, France

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by social communication deficits, impaired social behaviour and stereotypies. Genetic variants in the *SCN2A* gene (encoding the voltage-gated sodium channel $Na_v1.2$) cause different neurodevelopmental diseases with or without epilepsy, and are among those with the strongest association with ASD. Functional studies that we performed co-expressing mutants and wild type $Na_v1.2$ in transfected cells to mimic heterozygosis have shown that variants causing ASD without epilepsy (non-syndromic) selectively induce negative dominance, leading to an overall >50% reduction of $Na_v1.2$ function. We generated a novel heterozygous knock-in mouse carrying one of these mutations that cause negative dominance and ASD, L1314P. We characterized behavioural features of these mice through a battery of tests at young (P23-44) and adult (>P70) age. *Scn2a*$^{L1314P/+}$ young male mice present some stereotyped repetitive behaviours and cognitive deficits in risk-assessment and decision-making processes, recapitulating some of the main symptoms observed in ASD patients. To determine the neuronal mechanism that generates these features, we performed whole-cell patch-clamp recordings in brain slices obtained from pups (postnatal day, P5-9) and young mice (P25-30). We evaluated potential impairments in layer 5 pyramidal neurons (PYRs) of the medial prefrontal cortex caused by the mutation in heterozygous *Scn2a*$^{L1314P/+}$ mice. Our results show that immature *Scn2a*$^{L1314P/+}$ PYRs are hypoexcitable, with reduced action potential amplitude and velocity, but without any differences in the voltage threshold. Thus, our novel mouse model is a relevant ASD model. It can be used to shed light on pathological mechanisms that are specific to ASD and to develop new targeted therapeutic strategies.

Title: Modeling disease phenotypes of autism-associated voltage-gated sodium channel Nav1.2 mutations using advanced human brain assembloids

Authors: *X. CHEN, J. ZHANG, K. WETTSCHURACK, M. I. OLIVERO ACOSTA, M. EATON, M. WANG, E. N. CREAGER, M. S. HALURKAR, Z. QUE, B. DEMING, J. WU, Y. ZHAO, Y.-E. YOO, Y. YANG;
Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN

Abstract: The utilization of three-dimensional (3D) human brain organoids for the investigation of neurological disorders has experienced a remarkable surge in recent years. Organoids, derived from human induced pluripotent stem cells (hiPSCs), are widely recognized as a promising model for studying human neurodevelopmental disorders and developing new treatments for clinical translation. One notable gene implicated in neurodevelopmental disorders, such as autism and epilepsy, is *SCN2A*, which encodes the voltage-gated sodium channel Nav1.2 mediating neuronal action potential firing in the brain. Mutations in this *SCN2A* gene give rise to dysfunction in the Nav1.2 channel. Notably, various mutations in this gene can lead to intricate alterations in neuronal excitabilities, sometimes even resulting in contrasting phenotypes. *SCN2A*-C959X, known as a protein-truncating/loss-of-function (LoF) mutation, has been identified in children with severe autism but with no disease-modifying treatment exists. Therefore, it is imperative to determine how the *SCN2A*-C959X mutation impacts neural activity, with the ultimate goal of mitigating these *SCN2A*-associated impairments. To gain a better understanding of how *SCN2A*-C959X contributes to circuit dysfunction and impairments, we are constructing an advanced *in vitro* 3D human organoid model known as "assembloids" to partially recapitulate the key circuits in the human brain. By using assembloids, we are conducting molecular, imaging, and electrophysiological studies to elucidate how Nav1.2 deficiency renders disease phenotypes at both the single neuron and cross-brain region circuitry levels. In summary, with this current study focusing on a typical *SCN2A* protein-truncating mutation, specifically *SCN2A-C959X*, our innovative approach employing assembloids composed of 3D human brain organoids and connecting circuitry offers a promising avenue to explore the impact of *SCN2A* LoF mutations on neuronal function and circuit impairments. We aim to unravel the underlying mechanisms of Nav1.2 deficiency-related diseases to help develop novel therapeutic strategies.

Title: Role of I_h current in the intrinsic excitability of auditory cortex of fmrp knockout mice

Authors: *C. MORENO, D. RIQUELME, C. CEA, E. LEIVA;
Univ. of Santiago de Chile, Santiago, Chile

Abstract: Fragile X syndrome (FXS) is a neurodevelopmental disorder caused by an increase in the CGG codon repeats (over 200 repeats) in the promoter of the fmr1 gene, that leads to a silencing of the gene and a loss of expression of the Fragile X Mental Retardation Protein (FMRP). FXS patients presents auditory hypersensitivity caused by a decrease in the excitability of neurons in layer 2/3 and 5 in the auditory cortex due to an increase in the excitability of the neurons downstream the auditory cortex, altering the auditory processing of external stimuli. In this regard, it has been described that in FMRP KO mice, the I_h current, composed by the HCN channels, is decreased. The I_h current is critical to modulate excitability, synaptic integration and filter capabilities in the neurons; in this context, we investigated the role of I_h current in the homeostatic regulation of the intrinsic excitability of pyramidal neurons in the layer 2/3 and 5 of the auditory cortex. In this work, using a combination of patch-clamp and immunofluorescence, we found that neurons in the auditory cortex of Fmr1KO mice have an increased synaptic activity with a decreased action potential firing frequency, a hyperpolarized resting membrane potential and a decreased membrane resistance and sag, suggesting a homeostatic compensation through a decrease in intrinsic excitability. Additionally, we found a decreased HCN1 expression in layer 1 of the auditory cortex; however, the inhibition of the I_h current with ZD7288 did not reverse the changes observed in the firing frequency, nor other parameters related to the intrinsic excitability. These results show that not only I_h current participates in the homeostatic plasticity of Fmr1KO mice, but other conductances may contribute to this phenotype. This study shed light on the mechanism of homeostatic compensation through changes in ion channel activity, its expression and how it contributes to the altered neuronal processing in FXS.

Title: Evaluation of tetracycline-controlled overexpression of human K_V1.1 to alleviate disease phenotypes in Na_V1.2-deficient mice

Authors: *B. DEMING[1], J. ZHANG[2], M. HALURKAR[2], E. PEREZ-REYES[3], Y. YANG[2]; [1]Purdue Univ., west lafayette, IN; [2]Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN; [3]Univ. of Virginia, Charlottesville, VA

Abstract: The CDC estimates that 1 in 36 children have ASD in the United States. A major characterization of ASD is social abnormalities. Genetic variants in *SCN2A*, a gene encoding the voltage-gated sodium channel Na_V1.2, have been identified as a leading monogenic cause of ASD; however, there are few FDA-approved drugs to aid with the social impairments seen in *SCN2A*-deficiency-related ASD patients. We have established a *Scn2a* deficient mouse model, which displays social deficits and neuronal hyperexcitability. We identified that this mouse model has a significant downregulation of multiple voltage-gated potassium channels (K_V), especially K_V1.1, in the brain. We further showed that the application of 4TFMPG, a K_V1.1 channel opener, corrects the hyperexcitability in neurons of Na_V1.2-deficient mice, further supporting a key role of K_V1.1 in mediating the disease phenotypes. However, even though 4TFMPG showed promise in rescuing the neuronal phenotypes *ex vivo*, it is a tool compound. Thus its bioavailability and *in vivo* safety are unknown. With growing FDA approval, Adeno-Associated Viruses (AAVs) based gene therapies to deliver a genetic payload to neurons are booming. In particular, an AAV with a Tet-on system driving expression of human K_V1.1 has recently been developed for potential clinical trial use by Dr. Perez-Reyes at UVA. Originally designed to treat seizures, this system utilizes a reverse Tetracycline-controlled transcriptional activator to drive the expression of *KCNA1* to produce exogenous Kv1.1 in the presence of a tetracycline, such as doxycycline. In this study, we tested whether the tetracycline-controlled overexpression of human K_V1.1 could rescue behavioral and neuronal phenotypes in Na_V1.2-deficient mice. Our preliminary results suggest that the overexpression of K_V1.1 in Na_V1.2-deficient mice alleviates the social deficits. Furthermore, we are examining the neuronal excitability in *Scn2a*-deficient mice transduced with AAV-K_V1.1. We anticipate our study would expand the utility of Kv1.1-based gene therapy to potentially alleviate disease phenotypes seen in *SCN2A*-related ASD.

Title: Modeling epilepsy-related SCN2A variant L1342P with CRISPR/Cas9-edited human-induced pluripotent stem cell-derived cortical spheroids

Authors: *M. OLIVERO ACOSTA[1], Z. QUE[2], M. WANG[3], J. ZHANG[2], C. OTTERBACHER[3], X. CHEN[2], T. NGUYEN[4], B. DEMING[5], K. WETTSCHURACK[4], J. WU[6], Y. YANG[2];

Abstract: Recent developments in stem cell technology have provided new avenues for studying neurological disorders via the generation of human neuron-based models, aiming to explore disease mechanisms and test for interventions. The SCN2A gene encodes for voltage-gated sodium channel Nav1.2, a protein that mediates action potential firing. SCN2A pathogenic mutations have been associated with epilepsy. An example is L1342P, identified in several patients with severe seizures that are hard to treat with current medications (Que, Olivero-Acosta et al., 2021). Given that no disease-modifying treatment exists, there is an urgent need to generate novel tools to probe at the variant-specific disease mechanisms and screen for efficient therapies. In our recent work, we have demonstrated that hiPSC-derived 2D- neuronal monolayers carrying the CRISPR/Cas9-edited L1342P-mutant channel display hyperexcitability (Que, Olivero-Acosta et al., 2021). However, the L1342P variant's impact on neurodevelopment in the more physiologically relevant 3D models, such as cortical spheroids, remains unknown. Human cortical spheroids are 3D aggregates that resemble the human cortex. This model is characterized by a neuroectoderm-like epithelium that matures over time, spawning cortical neurons that arrange themselves in patterns observed in the postnatal brain (Sloan et al., 2018). They are composed mainly of glutamatergic neurons (Yoon et al., 2019), and when mature, they display robust electrical activity. In the present study, we describe the use of CRISPR/Cas9-edited hiPSCs to generate cortical spheroids carrying the epilepsy-related SCN2A-L1342P variant to study its effect on neuron development and other disease phenotypes. Techniques used include advanced microscopy imaging, patch-clamp, and microelectrode array (MEA) recordings. Our results will provide insight into how disease-causing Nav1.2 genetic variants may affect neuronal excitability and development, as well as establish a cutting-edge 3D cortical spheroid platform suitable for testing novel interventions.

Title: Cholinergic transmission modulates TRPM4 channel trafficking in cortical neurons

Authors: ***P. LEYTON**[1], D. RIQUELME[2], E. LEIVA-SALCEDO[2];
[1]Biol., [2]Dept. of Biol., Univ. of Santiago of Chile, Santiago, Chile

Abstract: Neuronal excitability is determined by the type, density, and localization of ion channels, transporters, and receptors in the neuronal plasma membrane. One regulator of excitability is cholinergic transmission, working directly on channels or through second messengers. Recently we found that TRPM4 is activated by cholinergic stimulation, through Gq-coupled M1, M3, and M5 muscarinic receptors, which increases neuronal excitability. TRPM4 is a non-selective, Ca^{2+} activated, and monovalent cation permeant channel which is expressed in several brain regions such as prefrontal cortex, CA1 hippocampus, olfactory neurons among others. In pyramidal neurons it presents a somatodendritic expression with an intense perinuclear signal, which strongly suggests its presence in intracellular compartments. In this work, we explore the mechanism by which TRPM4 increases neural excitability after cholinergic stimulation by investigating the change in the trafficking of these ion channels. Using a combination of immunofluorescence, confocal microscopy, and fluorescent recovery after photobleaching (FRAP) assay, we investigated the localization of TRPM4 in mice cortical neuron cultures on four regions: plasma membrane, early endosome, Golgi apparatus, and endoplasmic reticulum and found that cholinergic stimulus increases TRPM4 levels in Golgi and plasma membrane. Moreover, we found in FRAP assay that cholinergic stimulation decreases the time constant of TRPM4 translocation to the plasmatic membrane suggesting an increase in the incorporation of channels to the membrane. Together, these results shed light on the mechanism of cholinergic modulation of neuronal excitability through the regulation of TRPM4 trafficking.

Title: Microglial over-pruning of synapses during development in autism-associated SCN2A-deficient mice and human cerebral organoids

Authors: *J. WU[1], J. ZHANG[2], Y.-E. YOO[2], Z. QUE[2], K. WETTSCHURACK[2], B. DEMING[2], N. CUI[2], M. I. OLIVERO ACOSTA[2], M. HALURKAR[2], Y. YANG[2];

Abstract: Microglia play a pivotal role in regulating synaptic remodeling. Studies have demonstrated that microglia are capable of modulating synapses, performing crucial functions such as pruning excessive spines in normal development and neurological disorders like autism and schizophrenia. Recent large-scale human genetic studies have demonstrated mutations in the *SCN2A* gene as the leading cause of monogenic autism. SCN2A encodes voltage-gated sodium channel Nav1.2, expressed in the central nervous system mediating action potential initiation, propagation, and backpropagation. The majority of these *SCN2A* mutations identified in children with autism are either loss-of-function or protein-truncating, collectively referred to as *SCN2A* deficiency. Our recent studies found that Nav1.2-deficient mice displayed severely impaired learning and memory. We further demonstrated that hippocampal neurons have reduced spine density, and microglia engulfed excessive post-synapses throughout development and into adulthood in the hippocampal region of Nav1.2-deficient mice. Treatment with PLX3397, which is CSF1R specific inhibitor used to ablate microglia, has been shown to result in about 95% elimination of microglia brain-wide. Moreover, we observed that the dendritic spine density and miniature excitatory postsynaptic currents (mEPSC) of Nav1.2-deficient neurons can be rescued toward the WT level by PLX3397. To extend our findings from rodents to human cells, we established a human cortical organoid model carrying an *SCN2A* protein-truncating mutation C959X identified in children with profound autism. We found that human microglia display increased elimination of post-synapse in cortical organoids carrying the *SCN2A*-C959X genetic mutation. Our research has established the crucial role of microglia in autism-associated models across multiple species, ranging from mice to human cells.

Abstract: The loss-of-function mutations in the *SCN2A* gene, which encodes a sodium channel critical for action potential initiation and propagation, have been implicated in neurodevelopmental disorders including autism spectrum disorder (ASD) and epilepsy. We established a preclinical mouse model to investigate the impact of *Scn2a*-deficiency and demonstrated that *Scn2a*-deficient mice exhibit major disease phenotypes. However, the cellular heterogeneity within the brain and molecular alteration underlying these phenotypes at a single-cell resolution has not been thoroughly explored. In this study, we conducted single nucleus RNA sequencing (snRNA-seq) on the medial prefrontal cortex (mPFC) of wild-type (WT) and homozygous *Scn2a*-deficient (HOM) mice to examine the effects of *Scn2a*-deficiency on gene expression and the composition of different cell populations. The mPFC brain region was chosen due to its role as a critical hub for social behavior and higher cognitive functions in ASD. Our preliminary analysis revealed differential proportions of cell types in the mPFC between WT and HOM groups. Further analysis of differential gene expression is ongoing to identify cell-type-specific gene expression differences. Together, our findings will reveal gene expression profiles and differential proportions of cell types in the mPFC region of *Scn2a*-deficient mice, advancing our understanding of the underlying pathology of disease phenotypes due to *Scn2a*-deficiency. We anticipate that these findings could serve as a foundation for the development of novel therapeutic interventions toward new molecular targets in a cell-type-specific manner.

Title: Splicing and phenotypic consequences of SCN2A splice-site genetic variant identified from a child with autism

Authors: K. WETTSCHURACK[1], ***M. S. HALURKAR**[1], M. I. OLIVERO ACOSTA[1], N. LANMAN[2], W. SKARNES[3], Y. YANG[1];

Abstract: *SCN2A* encodes the alpha subunit of the voltage-gated sodium channel Nav1.2, which is essential for proper neuronal function. Mutations in *SCN2A* have been associated with a range of neurodevelopmental disorders, including autism spectrum disorder and epilepsy. In this study, we aimed to investigate a specific splice-site variation (SCN2A c.3973-1GtoA) using induced pluripotent stem cells (iPSCs). The c.3973-1GtoA variation was recently identified from a child with autism spectrum disorder (ASD). This variation occurs in the conserved splice site before Exon 22. While it is suspected that mutations in a highly conserved splice site will affect the splicing and assembling of exons in the mRNA, how exactly c.3973-1GtoA affects the splicing and function of Nav1.2 to alter neuronal activity is unknown. We have used CRISPR/Cas9 editing techniques to engineer the c.3973-1GtoA variation into a reference iPSC cell line, of which a GCaMP6 biosensor was engineered in the AAVS1 safe harbor. We then differentiated these engineered iPSCs into cortical neurons that are known to express Nav1.2. Using mRNA/cDNA extracted from the differentiated cells, our preliminary data suggest that c.3973-1GtoA variation leads to a shortened *SCN2A* mRNA. The analysis of the neuronal activity in neurons carrying c.3973-1GtoA is ongoing using a GCaMP6-based Calcium signal biosensor. Our results will shed light on the transcriptional and phenotypic changes in neurons by the c.3973-1GtoA variation, allowing us to identify key disease phenotypes for testing personalized therapeutic interventions.

Title: Effects of cocaine self-administration on nucleus accumbens core astrocyte calcium dynamics

Authors: *E. V. HARDER[1], J. W. VANRYZIN[2], S. O. AHAOTU-SIMELANE[2], K. J. REISSNER[1];
[1]Psychology and Neurosci., [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Psychostimulant use disorders are a major public health concern within the United States. Recent evidence suggests that astrocytes are significantly implicated in cocaine-related changes in the brain underlying relapse and drug dependence. Previously, we found astrocytes in the nucleus accumbens (NAc) core are profoundly structurally impaired following long-access (LgA, 6 h/day, 10 days) cocaine self-administration and 45 days of forced abstinence, as evidenced by a ~40% reduction in surface area, volume, and synaptic colocalization. Considering that astrocytes are positioned to sense neuronal activity at the synapse and accordingly respond by modulating synaptic function, surprisingly little is known about how cocaine-mediated changes can affect astrocyte function and therefore, their ability to regulate synaptic transmission. We hypothesize that cocaine self-administration results in decreased NAc astrocyte responsiveness to input from prelimbic cortex glutamatergic afferents. To test this hypothesis, we used a combination of DREADD-mediated synaptic transmission and GCaMP8s astrocyte calcium imaging in acute brain slices. AAV5-GfaABC1D-GCaMP8s provides 90+% specific expression in rat astrocytes. Using this indicator, we found in acute slices from drug-naïve animals that stimulation of prelimbic to NAc core projections by 1 mM CNO significantly changes astrocyte calcium event frequency in the NAc core, and that the directionality of this change depended upon whether regions of interest (ROIs) were tracked across baseline and 1 mM CNO conditions or whether ROIs were selected independently in each condition based on activity. Further, we find that cocaine self-administration and abstinence results in NAc core astrocyte calcium event frequency that is significantly reduced at baseline but significantly increased during prelimbic to NAc core stimulation, when selecting ROIs independently based on activity. These changes in astrocyte calcium activity may have important implications for astrocyte ability to regulate synaptic function following a history of cocaine. Ongoing work aims to delineate the neurotransmitter systems responsible for these effects and downstream consequences on synaptic transmission. These results provide insights into how functional changes in astrocytes may underlie relapse behaviors.

Title: Astrocytic LRRK2 Controls Astrocyte Morphology and Synaptic Connectivity

Authors: *S. WANG[1], D. SIVADASAN BINDU[1], C. TAN[1], K. SAKERS[1], T. TAKANO[2], M. RODRIGUEZ[1], K. DIMOND[1], S. H. SODERLING[1], A. R. LA SPADA[3], C. EROGLU[1];

Abstract: Astrocytes tightly control neuronal connectivity and function in the brain through direct contact with synapses. These glial cells become reactive during disease pathogenesis, including Parkinson's disease (PD). However, it remains unknown if astrocyte dysfunction is an initiating factor of PD pathogenesis and whether astrocytes can be targeted to stop or reverse the synaptic dysfunction seen in PD. Using *in vitro* and *in vivo* methods, we found that the PD-linked gene Lrrk2 controls astrocyte morphology via regulating the phosphorylation of ERM proteins (Ezrin, Radixin, and Moesin), a structural component of the perisynaptic astrocyte processes. ERM phosphorylation is robustly elevated in mice and humans carrying the LRRK2 G2019S Parkinsonism mutation. Importantly, the reduction of the ERM phosphorylation, specifically in the LRRK2 G2019S in adult astrocytes, is sufficient to restore excitatory synapse number and function deficits in the LRRK2 G2019S knock-in mouse cortex. These results show a role for Lrrk2 in controlling astrocyte morphogenesis and synaptogenic function and reveal that early astrocyte dysfunction in PD could be causal to disruptions in cortical excitatory synaptic connectivity. The astrocytic dysfunction can be corrected by dampening ERM phosphorylation, pinpointing astrocytes as critical cellular targets for PD therapeutics.

Title: Astrocytic cannabinoid receptor 1 promotes resilience by dampening stress-induced blood-brain barrier alterations

Authors: K. DUDEK[1], S. E. J. PATON[1], A. COLLIGNON[1], M. LEBEL[1], O. LAVOIE[1], J. BOUCHARD[1], F. NEUTZLING KAUFMANN[1], L. DION-ALBERT[1], V. CLAVET-FOURNIER[1], L. BANDEIRA BINDER[1], C. Abstract: Major depressive disorder (MDD) is a leading cause of disabilities worldwide, with one out of five individuals affected throughout their lifetime. Blood-brain barrier (BBB) alterations contribute to stress vulnerability and development of depressive behaviors. In contrast, neurovascular adaptations underlying stress resilience remain unexplored. The BBB is a dynamic frontier responsible for regulation of molecular exchange between the periphery and the brain, critical for the maintenance of its homeostasis. We observed that high expression of astrocytic cannabinoid receptor 1 (CB1, encoded by the *Cnr1* gene) in the nucleus accumbens (NAc) shell, particularly in the endfeet ensheathing blood vessels, is associated with resilience despite chronic social stress exposure. The endocannabinoid system is a crucial regulator of stress responses, and its disruption is associated with depressive behaviors in both clinical and preclinical studies. Perivascular astrocytic CB1 remain understudied despite perfect positioning to modulate BBB properties during stress exposure and in mood disorders. Viral-mediated overexpression of *Cnr1* in astrocytes of the NAc shell has baseline anxiolytic effects and dampened stress-induced anxiety- and depression-like behaviors. It also reduced astrocyte inflammatory response and morphological changes following an immune challenge with the cytokine interleukin-6, linked to stress susceptibility and mood disorders. At the preventive and

therapeutic level, physical exercise and antidepressant treatment increased perivascular astrocytic *Cnr1* in mice. Loss of *CNR1* was confirmed in the NAc astrocytes of individuals with MDD. These findings suggest a role for the astrocytic endocannabinoid system in stress responses and possibly, human depression, via BBB modulation.

Title: Uncovering cell-specific mechanisms of adolescent cannabis-induced behaviors: a novel role for astrocytes

Authors: *J.-M. N. FERLAND[1], Y. HURD[2];
[1]Icahn Sch. of Med. at Mount Sinai Friedman Brain Inst., Brooklyn, NY; [2]Icahn Sch. of Med. at Mount Sinai Friedman Brain Inst., New York, NY

Abstract: Cannabis is one of the most popular drugs of abuse worldwide. One unintentional consequence of shifts in attitudes towards cannabis after legalization and decriminalization efforts is a rise in use amongst adolescents, including occasional and frequent use. Despite positive perceptions of cannabis, use during adolescence when the brain is still undergoing significant maturation is associated with increased risk for developing psychopathologies including Cannabis Use Disorder (CUD). Clinical data shows a strong link between regular cannabis use and several behaviors associated with addiction including increased emotional dysregulation, anxiety, and risky decision making. Furthermore, emerging data now indicate that use of high potency products (which now dominate the market) increase the risk of developing CUD. However, the causal relationship between adolescent cannabis exposure, THC potency, and these behavioral outcomes remains highly debated, and the mechanisms underlying THC-induced phenotypes are poorly understood. Using a rat model, we assessed the relationship between adolescent THC exposure and dose on addiction-related behaviors in adulthood. Compared to low dose and control animals, exposure to high dose THC during adolescence significantly increased stress reactivity, risky decision making, and THC-induced cognitive deficits in adulthood---phenotypes linked to CUD. RNA sequencing and immunohistochemistry analyses of the basolateral amygdala, a region critically implicated in stress responsivity and

cognition, revealed that astrocytes were specifically associated with high dose THC-induced stress reactivity, including downregulation of genes that regulate astrocyte glutamate homeostasis, calcium signaling, and astrocyte morphology. Impairments in decision making and impulse control after adult re-exposure to THC also correlated to astrocyte plasticity *Gfap* expression in the basolateral amygdala and prelimbic cortex. These data reveal an emerging role for astrocytes in adolescent THC-induced behaviors. Ongoing studies are examining the relationship between decision making and edible THC consumption, the impact of adolescent THC exposure on these outcomes, and the unique role astrocytes play in cognitive vulnerability to CUD-like phenotypes.

Title: High-throughput assessment of astrocyte morphology in the ventral striatum reveals striking heterogeneity during heroin withdrawal and relapse.

Authors: *A. KRUYER;
Univ. of Cincinnati, Cincinnati, OH

Abstract: Astrocytes regulate excitatory activity at striatal synapses via gliotransmission, glutamate uptake, and spatial buffering of glutamate spillover. Astrocyte insulation of synapses in the nucleus accumbens is dynamic and circuit-selective after addictive drug use, and astrocyte adjacency to different synaptic subtypes tunes synaptic activity necessary for drug seeking. Given the critical effects of astrocyte structural plasticity on neural circuit activity in the striatum, we developed a high-throughput machine-learning approach to assess astrocyte structural heterogeneity within and across ventral striatal nuclei based on astrocyte expression of the cytoskeletal marker GFAP. This deep-learning framework permits automated detection of GFAP-immunolabeled astroglia despite near-adjacency of densely tiled cells. Next, we applied automated segmentation of individual astrocytes and classified astrocytes according to brain region and drug treatment groups based on consistent and identifiable features. Assessment of astrocyte features across striatal subregions revealed structurally unique astrocyte subpopulations across adjacent portions of the nucleus accumbens that were uniquely altered after withdrawal from heroin use and during seeking. Our approach also indicated that astrocyte network connectivity was significantly reduced across the ventral striatum after chronic heroin use, highlighting important avenues for future research.

Title: Cocaine induced microglia pruning of astrocytes

Authors: A. TESTEN[1], T. J. BELLINGER[1], J. W. VANRYZIN[1], H. WANG[1], J. P. FRANKLIN[1], M. GASTINGER[2], *K. J. REISSNER[3], ***K. J. REISSNER**[1];
[1]Psychology and Neurosci., UNC, Chapel Hill, NC; [2]Biptplane, USA, Lancaster, PA; [3]UNC-CH, Chapel Hill, NC

Abstract: Accumulating evidence indicates effects of illicit drug use on astrocytes. In particular, both the structure and function of nucleus accumbens (NAc) astrocytes are significantly impaired by rat cocaine self-administration. We recently reported that 10 days of long-access (6h/day) self-administration access followed by 45 days of home cage access results in a ~40% reduction in surface area, volume, and synaptic colocalization of NAc astrocytes (Kim et al., 2022 eNeuro). To evaluate the nature of these observed structural deficits more fully, we developed a novel approach to perform three-dimensional branching complexity analysis of individual astrocytes. This analysis revealed cocaine-dependent reductions in the number of astrocyte branches and segments, with no effect on segment length, suggesting that reductions in morphometric features may be driven by branch loss rather than overall shrinkage of segments. In order to explore whether loss of astrocyte peripheral processes might occur as a consequence of microglia pruning, we analyzed Iba-1 labeled microglia for evidence of astrocyte-derived Lck-GFP inclusions at withdrawal day 45 following cocaine versus saline self-administration. We indeed observed inclusions of fluorescent astrocyte membranes within microglia, which were significantly more prevalent in the cocaine versus the saline group. Further, inclusions were positive for a complement component 3 (C3) protein, suggesting implication of a complement-dependent pathway in pruning. To confirm this, we blocked C3 receptor interactions using neutrophil inhibitory factor (NIF) peptide across abstinence following cocaine self-administration. Administration of intra-NAc NIF peptide significantly impaired behavioral measures of cocaine seeking, and normalized the structure of NAc astrocytes. These results indicate astrocytes as a target of microglia phagocytosis, and indicate microglia-mediated phagocytosis as a contributing mechanism to drug seeking behaviors.

Title: Nucleus accumbens astrocytes regulate social behavior in rats

Authors: *J. W. VANRYZIN, K. J. REISSNER;
Dept. of Psychology and Neurosci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Appropriate social behavior is necessary for health and survival of many animal species and is often disrupted in psychiatric disorders such as schizophrenia, autism spectrum disorder, and depression. Successful social interactions require not only processing of social information, but also proper integration of social reward. The nucleus accumbens (NAc) is a critical integrative hub in the brain's reward circuitry that has also been shown to be essential for processing social information. Within the NAc, astrocytes are uniquely positioned to sense and regulate a diversity of incoming circuit projections and neurotransmitters. Yet how astrocytes accomplish such a feat and how astrocyte signaling, in turn, affects neuronal circuit activity during social behavior are largely unknown. To this end, we aimed to test the hypothesis that NAc astrocytes dynamically regulate the expression of social behavior in the rat. We first utilized an AAV to overexpress the human plasma membrane calcium-transporting ATPase2 (PMCA2) specifically in NAc astrocytes under the control of the GfaABC1D promoter, to deplete NAc astrocyte Ca2+ signaling. Ca2+ depletion significantly increased the amount of time rats spent interacting with a novel conspecific in an open-cage social test, while also increasing the social preference index in a 3-chamber social preference test. Conversely, activating NAc astrocyte Ca2+ signaling, using an AAV to express the HM3D(Gq) DREADD construct, significantly decreased social interaction time in an open-cage social test when the animals received CNO as compared to saline trials. However, CNO treatment did not affect social preference index in the 3-chamber test. Together, these findings demonstrate that NAc astrocytes can bidirectionally modulate social interaction in the rat via Ca2+. Current studies are underway using fiber photometry with GCaMP8s to measure NAc astrocyte Ca2+ responsiveness to social interaction, in order to characterize the precise nature of the dynamics between NAc astrocyte and neural activity in real-time during social investigation. Collectively, these studies aim to provide novel insight into how social information is processed and integrated with reward circuitry in the brain.

Title: Striatal astrocytic mechanisms underlying the development of compulsive heroin seeking habits

Authors: *T. HYNES[1], M. PUAUD[2], B. J. EVERITT[3], M. FOUYSSAC[2], D. J. BELIN[1]; [2]Psychology, [1]Univ. of Cambridge, Cambridge, United Kingdom; [3]Downing Col., Univ. Cambridge, Cambridge, United Kingdom

Abstract: The development of compulsive heroin seeking is underpinned by a functional coupling of the ventral and the dorsolateral striatum. This coupling has been shown to involve dopaminergic processes, but the cellular and molecular mechanisms they engage have not been fully elucidated. We hypothesised that astrocytes and their striatal syncytium may play a critical role. Astrocytes express dopamine transporter and their syncytium tiles the striatum, thus positioning them well to functionally bridge dopaminergic activity across striatal territories. To investigate this hypothesis, we deployed our novel rodent model of compulsive heroin seeking alongside spatial transcriptomics, virally mediated gene transfer, and classical pharmacology. We first determined the spatiotemporal profile of the functional recruitment of the striatal astrocytic syncytium over the course of the development of compulsive heroin seeking. RNAScope analysis revealed that compulsive heroin seeking was associated with decreased dopamine transporter (DAT) mRNAs in both the anterior dorsolateral striatum (aDLS) and the nucleus accumbens core (NAcC). In contrast, a short-term history of heroin self-administration under continuous reinforcement was associated only with decreased DAT mRNA expression NAcC. Western blots of astrocytes cultured from striatal grafts of individuals had a history of heroin self-administration or a well-established compulsive heroin seeking habit confirmed that the alterations observed in mRNA were also present at the protein level. This pattern of astrocytic DAT regulation suggests that volume-transmitted dopamine could be biased toward the aDLS in the early stages of heroin use, thereby facilitating the transition to compulsive heroin seeking.We next asked whether astrocytes of the NAcC played a causal role in the functional recruitment of the aDLS in dopamine-dependent compulsive heroin seeking. In separate groups of rats, we tested the influence of chronic inhibition (using a virally transduced calcium extruder) or activation (using hM3Dq) of NAcC astrocytes on the functional engagement of the aDLS dopamine-dependent habits following a prolonged history of heroin seeking. This bidirectional modulation of NAcC astrocytes differentially impacted the sensitivity of heroin seeking to bilateral delivery of a dopamine receptor agonist into the aDLS, providing causal evidence for the role of NAcC astrocytes in the development of aDLS-dependent heroin seeking habits.

Title: Striatal astrocytes in dopamine regulation: A new perspective on behavior state transitions and interaction with striosomes.

Authors: *I. LAZARIDIS[1], G. AHN[1], E. HUESKE[1], A. MATSUSHIMA[1], M. SUR[2], A. M. GRAYBIEL[1];
[1]McGovern Inst. for Brain Res., [2]The Picower Inst. for Learning and Memory, MIT, CAMBRIDGE, MA

Abstract: Introduction: The striatum, a core structure in the basal ganglia, plays vital roles in motor control and reward-related learning. Emerging evidence suggests a complex interplay between striatal astrocytes, dopamine, and striosomes within the striatum. Striosomes modulate dopamine regulation by projecting onto dopamine-rich neurons in the substantia nigra pars compacta (SNpc). We hypothesize that astrocytes can potentially affect, either directly through gliotransmitter release or through dopamine regulation, striatal pathway function and can ultimately modulate decision-making behaviors. **Methods:** Our study employed optogenetic stimulation of SNpc dopamine neurons while recording concurrent astrocyte activity. Using two-color photometry imaging, we achieved simultaneous imaging of dopamine release and astrocyte activity in the dorsolateral striatum (DLS) and dorsomedial striatum (DMS) in freely moving mice during a decision-making maze task. Behavioral recordings with DeepLabCut facilitated the labeling and detailed behavioral clustering. We also demonstrated simultaneous imaging of astrocytes and striosomal SPNs at single-cell resolution with a miniaturized endoscope and widefield imaging. **Results:** Astrocyte responses to optogenetically induced dopamine release revealed a strong response of astrocytes to dopamine that mimicked the relationship of endogenous striatal dopamine release and astrocyte activity. Importantly, our simultaneous imaging of astrocytes and dopamine release in freely moving mice revealed a bidirectional interaction. Paired pulse ratio experiments revealed a refractory period in both DLS and DMS astrocytes, but with distinct characteristics. The abolishment of astrocyte response to optogenetically induced dopamine under anesthesia suggests potential indirect effects of dopamine on astrocytes. Finally, we found a correlation between astrocyte activity and task performance, indicating a decrease in astrocyte peak probability during engagement and increased astrocyte calcium activity during behavioral state transitions between task engagement

and free exploration. **Conclusion:** Our findings indicate that striatal astrocytes play an integral role in modulating the dopamine system and suggest potential interaction with striosomal functions. These results underscore the possible influence of astrocytes in modulating dopamine's effects within the dorsal striatum, and their potential involvement in regulating the balance between exploitation and exploration or engagement.

Title: Using an astrocyte-specific RiboTag AAV to investigate cocaine-mediated effects on nucleus accumbens astrocyte gene expression

Authors: *J. P. FRANKLIN[1], K. J. REISSNER[2];
[1]Neurosci. Ctr., [2]Psychology and Neurosci., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Substance abuse continues to be a national public health issue, as substance-related overdose deaths have increased over time. Particularly, there were approximately 1.4 million individuals who were diagnosed with cocaine use disorder (CUD) in 2021 and roughly a 72% increase in cocaine-related overdose deaths from 2014 to 2020. However, an FDA-approved treatment for CUD is lacking. Hence, it is of great importance to investigate mechanisms of CUD and relapse. Historically, neurons have been central to studies on mechanisms of drug abuse, with limited emphasis on the role of glial cells. However, accumulating studies reveal dysregulated glial cell function is associated with substance abuse. We recently reported that astrocytes within the nucleus accumbens (NAc) are significantly (~40%) decreased in surface area, volume, and synaptic colocalization after long-access self-administration of cocaine (6hr/day) followed by protracted abstinence (45d) (Kim et al., eNeuro 2022). However, the underlying mechanisms for these structural changes in NAc astrocytes are unknown. My research utilizes an unbiased transcriptomic approach to identify differentially expressed genes in NAc astrocytes following cocaine self-administration and prolonged abstinence. We hypothesize that cocaine alters expression of astrocyte genes, which mediates the observed decreased NAc astrocytic phenotype and contributes to drug-seeking behaviors. We have employed astrocyte-specific AAV5-GfaABC1D-Rpl22-HA (Addgene #111811) to

immunoprecipitate mRNAs from NAc astrocytes following long-access cocaine vs. saline self-administration, at withdrawal days 1 and 45 for RNA-Seq analyses. Results indicate significant differences in NAc astrocyte gene expression following cocaine self-administration at abstinence day 1. The majority of differentially expressed genes showed decreased expression, with a few genes significantly upregulated in cocaine-administering rats. Gene ontology analyses showed that the identified differentially expressed genes were primarily involved in cellular processes including transcriptional regulation and GTPase activity, among others. Extended comparative analysis of long abstinence is ongoing. Near term studies will also analyze expression changes in female rats, as our lab has demonstrated sex differences in cocaine induced NAc astrocyte structural changes (Kim et al., eNeuro 2022). Ultimately, these studies will provide insight to how cocaine affects astrocytes, both structurally and functionally, and how NAc astrocyte dysfunction increases susceptibility to augmented drug-seeking behaviors across abstinence.

Abstract: Drug addiction represents an enormous healthcare burden. To better understand its biological underpinnings, investigations of the transcriptional response to drugs of abuse have demonstrated lasting changes in gene expression throughout the brain's reward circuitry. Historically focused on neurons, emerging evidence increasingly indicates that astrocytes are also involved in disorders of the nervous system, including addiction. However, the astrocyte-specific transcriptome and its regulation following exposure to drugs of abuse have not yet been investigated. We utilized whole cell sorting of astrocytes and RNA-sequencing to characterize the astrocyte transcriptome in several key brain regions involved in reward-processing, including the nucleus accumbens and prefrontal cortex, following cocaine self-administration, withdrawal, and "relapse" in mice. We determined that astrocytes exhibit a robust transcriptional response,

including regionally- and contextually-specific transcriptional signatures. Interestingly, bioinformatic analysis revealed CREB as a highly-ranked predicted upstream regulator, and CUT&RUN-sequencing identified increased association of CREB bound at DNA in astrocytes following cocaine administration. Viral-mediated manipulation of CREB activity selectively in NAc astrocytes, in combination with a variety of addiction-related behaviors including conditioned place preference and self-administration, reveals that astrocytic CREB increases the rewarding and reinforcing properties of cocaine. Interestingly, this effect is sex-specific, with no change in preference found in females. Together, these data demonstrate that the astrocyte transcriptome responds robustly to cocaine administration and indicates, for the first time, that CREB is a cocaine-induced transcriptional regulator in astrocytes that increases the rewarding properties of cocaine. These findings are particularly interesting, as previously published work demonstrates opposite effects with neuronal CREB in NAc: increased neuronal CREB activity results in cocaine aversion. Ongoing studies are investigating the molecular mechanism by which astrocytic CREB regulates addiction-related behaviors.

Title: Reducing Astrocyte-calcium Signaling in the Nucleus Accumbens Increases Cocaine Self-administration Behavior

Authors: *G. A. LARAIA, J. W. VANRYZIN, K. J. REISSNER;
Psychology and Neurosci., Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Accumulating evidence suggests that astrocytes are critical for reward processing and are implicated in substance use disorders in the brain. Rat cocaine self-administration is associated with long-lasting changes in astrocyte structure and activity, particularly within the nucleus accumbens (NAc). Moreover, pharmacological manipulation of astrocytes can reduce cocaine seeking behaviors. A critical component of astrocyte function is signal transduction via Ca2+ signaling. In order to investigate the role of nucleus accumbens astrocyte Ca2+ signaling in cocaine self-administration and seeking, we employed AAV5 hPMCA2 (CalEx) under control of the astrocyte-specific GfaABC1D promoter, to deplete NAc astrocyte Ca2+. AAV5 GfaABC1D-Lck-mCherry was employed as negative control. Following jugular catheterization and viral

infusion, rats were trained in either short-access (ShA, 2h/day) or long-access (LgA, 6h/day) cocaine self-administration, followed by home cage abstinence. No effect of hPMCA2 was observed during ShA self-administration; however, hPMCA2 expression resulted in a significance increase in cocaine self-administration during LgA access. Following 45 days of abstinence, no difference was observed between hPMCA2 and Lck-mCherry rats in cocaine seeking behavior. Specificity of expression was confirmed using immunohistochemistry. These results collectively indicate that depletion of NAc astrocyte Ca2+ results in modified reward processing under conditions of extended access. Future studies using behavioral economics may more fully detail the nature of the modified reward processing, and the role of astrocyte Ca2+ signaling in substance use disorders.

Title: Role of GSCAN Identified Genes in the Astrocytic Response to Nicotine

Authors: *A. LOMBARDI[1,2], M. BOWER[2], C. BORSKI[2,3], K. KASTENGREN[2,3], M. EHRINGER[2,3], J. STITZEL[2,3], C. HOEFFER[2,3];

Abstract: Improved understanding of nicotine neurobiology is needed to reduce or prevent chronic addiction, the detrimental effects of nicotine withdrawal, and increase successful cessation of use. Nicotine use Genome wide association studies (GWAS) suggest an astrocytic role for nicotine responses. Previously, we found that *Akt2* expression is restricted to astrocytes in mice and humans and may play a role in the nicotinic responses of astrocytes. The current study aims to identify additional astrocyte-expressed genes that alter nicotine's effect on astrocytes and contribute to nicotine use behaviors. To identify genes of interest (GOI)s, we selected genes from TWAS results from the GWAS & Sequencing Consortium of Alcohol and Nicotine use (GSCAN) significantly associated with cigarettes per day (CPD) and smoking cessation (CS) that were also expressed in human and mouse astrocytes. The genes that met these criteria were further prioritized by whether they also were associated with CPD and SC in additional analyses including Pascal, DEPICT, and fine mapping. Using a CRISPRi approach to knockdown GOI expression, we are screening 25-50 of these smoking-related, astrocyte-expressed genes. Using area analysis, we are assessing the role of the GOI on astrocyte size and morphology in primary mouse astrocyte cultures following nicotine treatment. The screen will identify GOIs for generating new mouse models to assess the role of the astrocyte-expressed

gene on nicotine behaviors and *in vivo* astrocyte response to nicotine. We have already found a promising gene target, *Clusterin*, that when knocked down blunts the astrocytic response to nicotine. These results will allow for the identification of potential novel drug targets and will improve the current understanding of the astrocytic response to nicotine.

Title: Measures of Astrocyte Morphology Subtly Altered in a Rat Model of Alcohol Use Disorder

Authors: *S. P. GUERIN, K. NIXON;
Univ. of Texas at Austin, Austin, TX

Abstract: Excessive alcohol consumption consistent with an alcohol use disorder (AUD) can lead to cognitive impairments that may be caused by structural changes in the brain. These changes can include reactivity in glial cells such as astrocytes. This study investigates morphological changes in astrocytes of male and female rats exposed to ethanol using GFAP to label branches and S100B to label the soma. Adult rats (n=8 per group, PND 65-70; ~240g females, ~350g males) were subjected to 4 days of binge-like alcohol exposure. Rats received ethanol (25% w/v in Vanilla Ensure Plus) or isocaloric control diet 3 times/day for 4 days. Doses of ethanol were adjusted based on a behavior intoxication (9.2 ± 1.4 g/kg/day for males; 9.5 ± 1.2 g/kg/day for females) resulting in blood ethanol concentrations that were similar for both sexes (338.8 ± 70.2 mg/dl for males; 354.3 ± 29.7 mg/dl for females). Withdrawal behaviors were observed from 10-27 hours (30 min on/off) after the last dose of ethanol. Following a week of abstinence from ethanol, animals were transcardially perfused, brains were removed and postfixed in PFA, and sectioned in 12 series at 40µm. A laser scanning confocal microscope was used to take 60x z-stacks of the hilus of the hippocampus, the entorhinal cortex, and the basolateral amygdala. Imaris software was used to reconstruct all GFAP labeled filaments from S100B labeled starting points, which allows for better discrimination of individual astrocytes compared to methods that use GFAP only. Measures of astrocyte morphology were examined, including the area of each astrocyte and the sum of branch lengths. When examining the sum of filament branch lengths in astrocytes, there was a main effect for ethanol treatment in the entorhinal cortex ($p<0.001$) and an interaction effect between sex and treatment ($p<.05$), with

ethanol-exposed female rats having a significant increase in length compared to controls ($p<0.001$). Astrocyte area was also significantly altered by ethanol treatment in the entorhinal cortex ($p<0.05$), but only ethanol-exposed males had a significant increase in area compared to controls ($p<0.05$). There were no significant morphological differences in the amygdala or hippocampus, and astrocyte number was not altered in any of the brain regions. Changes to morphology in the parameters examined were subtle: although morphological parameters were increased in nearly all brain regions, most of these changes were not statistically significant. These results suggest that the phenotype of alcohol-induced reactive astrocytes is unique compared to other pathologies where more robust changes to GFAP are observed.

Title: The effect of Early-Life Stress on lateral hypothalamic astrocytes and sleep-wake behaviours.

Authors: *L. DEPAAUW-HOLT, S. HAMANE, A. BOSSON, B. ROGERS, C. MURPHY-ROYAL;
Neurosci., Ctr. hospitalier de l'Université de Montréal, Montreal, QC, Canada

Abstract: Astrocytes regulate several important processes in the brain to maintain synaptic transmission and behaviour. The metabolic support role of astrocytes has been shown to coordinate many complex behaviours including sleep-wake cycles. Specifically, astrocytes in the lateral hypothalamus modulate the excitability of orexin neurons by dynamically controlling the availability of energy substrates across night and day to drive sleep-wake cycles. Furthermore, local energetic substrate shuttling to neurons is significantly impaired in conditions of stress, in a glucocorticoid dependant manner. Considering the overwhelming prevalence of sleep-wake perturbations in stress related psychiatric disorders, **we hypothesise that stress, specifically elevations in blood glucocorticoids, impacts lateral hypothalamic astrocytes to influence sleep-wake behaviours.** To determine the impact of stress we employed an early life stress (ELS) paradigm, which significantly increases blood glucocorticoids in adulthood. We then examined the effects of ELS induced elevations in blood corticosterone on astrocyte morphology in the lateral hypothalamus. ELS increased nuclear translocation of astrocyte glucocorticoid receptors, suggestive of increased receptor activity in these cells, that was associated with

reduced expression of astrocytic proteins linked to metabolic support function. Next, we examined the impact of ELS on lateral hypothalamic-dependent behaviours and determine the role of astrocyte-specific glucocorticoid signalling in mediating stress-induced sleep-wake disturbances. To directly implicate astrocyte glucocorticoid receptors in ELS induced behavioural dysfunction we carried out stereotaxic surgeries injecting AAV2/5-GfaABC1D-Cre into the lateral hypothalamus of glucocorticoid receptor (*Nr3c1*)-floxed mice. Following astrocyte-specific GR-Knock Out (KO), we observed a significant alteration in lateral hypothalamus-dependent behaviours in a sex-specific manner, without any alterations in anxiety-like behaviours or basal metabolic function. In sum, these data identify a unique role for astrocyte glucocorticoid receptors in stress-induced sleep-wake behavioural impairment. Our preliminary observations suggest that ELS perturbs astrocyte metabolic network function which in turn can influence the supply of energy substrates to orexin neurons and underlies stress-induced behavioural dysfunction.

Title: Early-life adversity induces blood-brain barrier alterations contributing to stress responses in adulthood

Authors: *J. L. SOLANO LÓPEZ[1,2], B. DAIGLE[1,2], M.-È. BOSSÉ[1,2], V. LÉVESQUE[1,2], A. CADORET[1,2], L. BANDEIRA BINDER[1,2], M. LEBEL[2], C. MENARD[1,2];
[1]Univ. Laval, Quebec, QC, Canada; [2]CERVO, Brain Res. Ctr., Quebec, QC, Canada

Abstract: Early-life adversity (ELA) events, like physical and emotional abuse or parental neglect, can occur during critical developmental stages, altering the vulnerability threshold to stressful events. Indeed, ELA can calibrate an individual's future response to stress, by either improving or impairing coping abilities and in some cases, lead to the development of major depressive disorder (MDD) in adulthood. Neurovascular adaptations modulate cognition, stress responses, and mood. Loss of blood-brain barrier (BBB) integrity, which is formed by endothelial cells, astrocyte endfeet ensheathing the vessels, pericytes, and a basement membrane, has been implicated in affective disorders, such as depression, which can arise from chronic

stress. Alterations in astrocyte endfeet have been described in rodents after chronic stress exposure and in MDD postmortem brain samples. During childhood, the BBB goes through critical maturation stages, but it remains unknown if ELA could impact the brain vasculature making it vulnerable to subsequent challenges. The long-term effects of ELA and its interaction with chronic social defeat stress (CSDS) were thus evaluated. Male and female mice were exposed at post-natal day 10, to a 10-day ELA period of maternal separation and limited bedding/nesting. At the end of the ELA period, the animals were group-housed with access to a house, toys, bedding, and nesting material. Subsequently, during adulthood, the animals were subjected to 10-day CSDS (week 8). 24h after the last defeat bout, the stress response was tested with a social interaction test, and anxiety with the elevated plus maze. Punches from brain areas regulating reward, mood, and emotions were collected for qPCR analysis. Interestingly, ELA induced anxiety-like behaviors in males but not in females. ELA combined with CSDS did not exacerbate vulnerability to stress, in fact, it increased the proportion of resilient animals in both males and females. BBB transcriptomic profiling revealed sex-specific differences in astrocytic function, endothelial tight junctions, and glucocorticoid signaling. ELA and/or CSDS exposure produced distinct patterns of neurovascular gene expression. These results indicate that ELA can modulate stress responses when facing emotional challenges in adulthood, possibly through long-lasting changes of BBB properties via the glucocorticoid system and astrocyte's function. It also suggests that access to an enriched environment after ELA could dampen its deleterious impact later in life.

Abstract: Both human and rodent studies have provided compelling evidence for the long-lasting effects of adverse early-life experiences, highlighting enhanced susceptibility to subsequent stressors presented later in life. ELS has widespread effects across the brain and can influence many neural circuits including those involved in threat detection, emotion, cognitive processing, and reward seeking behaviors. Research in this domain has predominantly focused upon investigating the effects of stress on neuronal cells and the consequences for behaviour. However, the links between stress, brain circuits and behaviour remain tenuous, and the contribution of distinct brain cells, including astrocytes, remains largely untested. Glial cells, which comprise approximately half the cell population in the brain have been shown to directly regulate synaptic transmission and plasticity, thereby influencing many discrete behaviours. Despite the abundance of research suggesting important roles for astrocytes in regulating affective states, fear, and reward seeking behaviors, whether astrocyte dysfunction prompts stress-induced behavioral impairments remains unknown. To answer this question, we performed behavioural tests targeting the lateral amygdala, a brain region involved with threat detection and associative learning that is acutely sensitive to stress. Using auditory discriminative fear conditioning, an amygdala-dependent behavioural task, we find that ELS impairs discrimination of neutral from aversive auditory cues. This was associated with impaired synaptic plasticity in cortico-amygdala circuits, recorded in acute brain slices. We characterised the impact of ELS on astrocytes in the lateral amygdala revealing changes in specific proteins associated with morphological reorganisation and astrocyte network function. Genetic disruption of astrocyte function, specifically in the lateral amygdala, recapitulated ELS-induced behavioural and synaptic phenotypes, supporting the hypothesis that astrocytes strongly contribute to the impact of stress on neural circuits. Finally, we reveal that attenuating glucocorticoid signalling in lateral amygdala astrocytes fully rescued the impact of ELS on cognition, with a marked improvement in auditory discrimination. Together, these findings identify astrocytes as key elements regulating amygdala-dependent affective memory and highlight astrocytes as central mediators of the long-term impact of stress on amygdala circuit function.

Title: Stress causes abnormalities in the production and release of beta hydroxybutyrate in hepatic cells and astrocytes

Authors: *S. SATO, Z. YU, H. TOMITA;
Tohoku Univ., Sendai, Japan

Abstract: Beta-hydroxybutyrate (BHB) is a major ketone body synthesized mainly in the liver mitochondria and is associated with stress and severity of depression in humans. It is known to alleviate depressive-like behaviors in mouse models of depression. It has also been shown to be produced not only in the liver but also in astrocytes, but the effect of stress on the production function is unknown. First, we used nuclear magnetic resonance spectroscopy to analyze and measure plasma BHB, ketogenic and glucogenic amino acids selected from the Tohoku Medical Megabank Project Community-Based Cohort Study. The Center for Epidemiologic Studies Depression Scale (CES-D) was utilized to select adult participants with depressive symptoms (CES-D $\geq$ 16; n = 5722) and control participants (CES-D < 16; n = 18,150). We observed significantly reduced plasma BHB (Tukey-Kramer HSD post hoc test: $P < .008$), leucine ($P < .001$), and tryptophan ($P < .008$) levels in participants with depressive symptoms. Second, we used acute and chronic social defeat stress (SDS) in C57BL6/N mice to investigate the effect of stress on BHB production. For the chronic SDS session, the C57BL/6 mice were exposed to a different CD1 aggressor mouse for 10 min every day for 10 consecutive days by removing the clear, perforated plexiglas divider. The acute SDS session was composed of three 10-min exposures to SDS, within a single day, and 5-min intervals between each exposure. BHB levels in serum ($n = 15$, $P < .001$) and mitochondria of prefrontal cortex (PFC) ($n = 10$, $P < .001$), but not in hepatic mitochondria, were significantly increased after acute SDS. After chronic SDS, BHB level in liver mitochondria was significantly reduced (control: $n = 18$, SDS: $n = 35$, $P < .01$), whereas no significant difference in serum and PFC mitochondria. In addition, transcription levels of monocarboxylic acid transporter 1 (Mct1), major molecules relevant to BHB transporter, were significantly decreased in the liver (control: $n = 10$, SDS: $n = 9$, $P < .001$) and PFC (control: $n = 12$, SDS: $n = 20$, $P < .05$) after chronic SDS exposure. Furthermore, we administered corticosterone, a stress hormone, to the human astrocytoma U251-MG cells. Corticosterone induced significantly higher amounts of BHB in the mitochondria ($n = 6$, $P < .05$) and cytoplasm ($n = 6$, $P = .05$) but not in the culture medium. In addition, the transcript level of the BHB transporter Mct2 ($n = 12$, $P < .001$) and Mct4 ($n = 12$, $P < .01$) were significantly decreased by corticosterone treatment. Our findings suggest that stress causes abnormalities in the production and release of BHB in the hepatic cells and astrocytes, potentially associated with the dysfunction of monocarboxylate transporters.

Title: Effect of Stress and Corticosterone on Astrocyte-Neuron Lactate Shuttle in Depression

Authors: *F. CHAMAA, **X. LIN**, H. FIUMELLI, P. J. MAGISTRETTI;
King Abdullah Univ. of Sci. and Technol., Thuwal, Saudi Arabia

Abstract: Depression, a psychiatric disorder influenced by stress and high corticosterone levels, has been associated with reduction in brain glucose metabolism (Su et al. BMC Psychiatry 2014). The astrocyte-neuron lactate shuttle (ANLS) plays a crucial role in this context, and its dysfunction has been implicated in the pathophysiology of depression (Carrard et al. Mol Psychiatry, 2021). Our objective is to explore the impact of stress and corticosterone on the impairment of astrocyte-neuron metabolic coupling and the potential for restoration through lactate treatment, both *in vitro* and *in vivo*. The antidepressant effect of lactate has been previously shown in three models of depression in mice, the forced swim test, the open space forced swim test and chronic corticosterone treatment (Carrard et al. Mol Psychiatry 2018 and 2021). In the present study, prolonged exposure of mouse neocortical astrocytic cultures to corticosterone resulted in the upregulation of thioredoxin-interacting protein (TXNIP), a pathological marker associated with dysfunction in glucose and lipid metabolism. Furthermore, corticosterone led to a decrease in glucose uptake in these cells, along with downregulation of glucose transporter-1 (GLUT-1) expression at the cell membrane level, and lactate monocarboxylate transporter-4 (MCT-4) at both the mRNA and protein levels. Moreover, there was a reduction in lactate release from astrocytes, indicating impairment in the ANLS. *In vivo* experiments using mouse models of chronic unpredictable stress (CUS) or corticosterone-induced depression demonstrated increased anxiety and social avoidance, as evidenced by behavioral tests including the social interaction test. Treatment with lactate in both models promoted resilience to stress and anxiety, while also rescuing social avoidance to levels comparable to control mice. Currently, we are examining changes in the expression of genes related to energy metabolism in the hippocampus and prefrontal cortex in the two depression models, with or without lactate treatment. The alterations observed in astrocytes suggest that the ANLS pathway is a crucial target in stress and mood disorders.

Title: The Role of Astrocyte Calcium Signaling in Anxiety-like Behavior

Authors: *E. KIM[1], M. MA[2], X. YU[1];
[1]Neurosci. Program, [2]Sch. of Mol. & Cell. Biol., UIUC, Urbana, IL

Abstract: Anxiety disorders are one of the most common psychiatric diseases and are highly comorbid with other mental health diseases, such as major depressive disorder (MDD) and bipolar disorder (BD). Studies showed that patients with anxiety disorders have a detrimental impact on the quality of life across their lifespan. Unfortunately, current anxiolytic medications are ineffective since around half of patients fail to respond to initial treatment. In order to develop novel therapeutic treatments for anxiety disorders, understanding the neurobiological mechanism is crucial. The medial prefrontal cortex (mPFC) enacts an essential role as a central hub of microcircuits that regulate emotions including anxiety. The dysfunction of the mPFC has been reported in both human anxiety disorder patients and animal models. For example, in a rodent anxiety model induced by social defeat stress (SDS), increased glutamatergic neurotransmission was shown in mPFC. Until now, most studies have focused on neuronal changes to apprehend the mechanisms underlying anxiety disorders, while little is known about non-neuronal changes. Neurons are not the only cells in the brain controlling emotions. Astrocytes are one of the most abundant cells in the brain and interact closely with neurons and other glial cells. Dissimilar to neurons, astrocytes utilize intracellular calcium signals rather than electrical signals to interact with other cells. Previous studies have shown that altered astrocyte calcium signaling in the striatum caused synaptic and circuit-level changes, ultimately leading to abnormal repetitive behavior. However, the role of astrocytes in mPFC and their effects on anxiety-like behavior are largely unknown. To address this question, a newly developed transgenic mouse line $CalEx^{flox}$ that can extrude intracellular calcium signals in astrocytes was executed to validate astrocyte function in the mPFC and anxiety-like behavior. We believe that comprehending the contribution of astrocyte calcium signaling in anxiety-like behavior would be conducive to providing potential therapeutic targets for anxiety disorders.

Abstract: Astrocytes are increasingly being recognized as having important roles in regulating the functional output of neuronal circuits, e.g., by sensing and modifying synaptic activity. In the hippocampus, astrocytes have been found to modulate long-term potentiation in CA1 and dentate gyrus (DG), and it has been reported that in a mouse model of Alzheimer's disease loss of tau homeostasis in dentate gyrus hilar astrocytes results in spatial memory deficits. Our previous studies have shown that additional copies of the *Gldc* gene encoding the glycine-degrading enzyme glycine decarboxylase, which in the brain is expressed only in astrocytes, resulted in a deficit in long-term potentiation in the dentate gyrus and schizophrenia-like phenotypes. These findings raise the question whether functions of the DG relating to learning and memory and to anxiety-related behaviors may be modulated by astrocytes. To evaluate the functional significance of the activity of astrocytes in dentate gyrus, we expressed the calcium extrusion pump hPMCA2w/b (CalEx) in dentate gyrus astrocytes. CalEx removes calcium from the astrocytes and thus disrupts any calcium-dependent astrocytic function. A viral construct expressing CalEx or tdTomato (for control group) with the astrocyte-specific *Gfa*ABC$_1$D promoter was stereotaxically injected into the DG hilus of 3 months-old male and female C57BL/6J mice. After a recovery period of 3 weeks behavioral experiments were performed, including elevated plus maze, open field test, light/dark box, Y-maze, social interaction test, Morris water maze, as well as latent inhibition and Pre-pulse inhibition / startle habituation tests. In the elevated plus maze test, female mice injected with CalEx-expressing virus showed less anxiety-like behaviors compared to mice injected with the control virus. CalEx-expressing mice also displayed enhanced performance in reversal learning phase of the Morris water maze and a latent inhibition deficit. We propose that astrocytes in dentate gyrus may modulate anxiety-like behavior in mice, and that normal astrocytic function is essential for some aspects of memory tasks facilitated by the dentate gyrus and possibly play a critical role in memory tasks that involve memory interference.

Abstract Chronic stress is a major precursor to various neurodegenerative disorders. Emerging evidence suggests that chronic stress is associated with increased inflammation in the brain. However, the bidirectional association between inflammation and chronic stress has yet to be fully understood. Microglia and astrocytes are key inflammatory regulators in the brain. When activated by inflammation, microglia and astrocytes become neurotoxic and proinflammatory. In this study, we aimed to evaluate the chronic stress-induced inflammation in the hippocampus by examining the morphological and molecular changes of microglia and astrocytes. We conducted the Unpredictable Chronic Mild Stress (UCMS) paradigm to model chronic stress, and lipopolysaccharide (LPS) administration to induce systemic inflammation in mice. Sholl analysis was performed to analyze microglia and astrocytes morphology. Chronic stress induced morphological changes in astrocytes similar to systemic inflammation in the hippocampus. Hippocampal astrocytes were highly ramified with increased branches and branching points from the cell body compared to the control group. However, unlike astrocytes, chronic stress did not induce morphological changes in hippocampal microglia. The finding of this study suggests that chronic stress induces inflammation in the hippocampus through astrocyte activation.

Title: Prefrontal Cortex Astroglia Modulate Anhedonia-like Behavior

Authors: *S. A. CODELUPPI[1], M. XU[2], Y. BANSAL[1], A. E. LEPACK[2], V. DURIC[3], M. CHOW[1], J. MUIR[4], R. C. BAGOT[4], P. LICZNERSKI[2], S. L. WILBER[2], G. SANACORA[2], E. SIBILLE[1], R. S. DUMAN[2], C. J. PITTENGER[2], M. BANASR[1];

Abstract: Astroglia loss and decreased expression of specific markers expressed by GFAP (glial fibrillary acidic protein)-astroglia have been found in key brain regions such as the prefrontal cortex (PFC) in MDD patients and rodent chronic stress models. In this study, we examined the consequences of PFC GFAP-astroglia ablation on depressive-like behaviours and potential reversal of chronic stress-induced deficits by enhancing PFC GFAP-astroglia activity. GFAP-cre mice infused in the PFC with an AAV5-DOI-CMV-DTR (diphtheria toxin (DT) receptor) were behaviourally assessed following i.p. injection with DT in several tests measuring anhedonia- and anxiety-like behaviors. We found that PFC astroglial ablation induced significant anhedonia- but not anxiety-like deficits. We also infused wild-type mice with an AAV5-GFAP-DREADD (designer receptor exclusively activated by designer drug) Gq in the PFC to activate GFAP-astrocytes upon clozapine-N-oxide administration. While PFC GFAP activation had no effects at baseline (no stress condition), it reversed the anhedonia-like deficits induced by chronic stress exposure. No reversal of anxiety deficits was observed. After validating increased astroglia activity using Ca^{2+} fiberphotometry following GFAP+ cell activation with CNO we used the same technique to assess in parallel changes in neuronal and astroglial in animals subjected to acute and chronic stress. Our results demonstrate that cortical GFAP-astroglia loss is sufficient to induce anhedonia, that chronic stress-induced anhedonia-like deficits can be reversed by increased GFAP-astroglia activity and that astroglial and neuronal activity are effect by chronic stress. Altogether, our work suggests a critical role of astroglia in the expression and the treatment of key symptoms of MDD.

Title: Microglial Regulation of Motor Cortical Excitability in TDP-43 related neurodegeneration

Authors: *M. XIE, A. UMPIERRE, Y. LIANG, K. HARUWAKA, S. ZHAO, L. WANG, J. ZHENG, D. BOSCO, P. PALLEGAR, A. NGUYEN, L.-J. WU;
Mayo Clin., Rochester, MN

Abstract: Motor cortical hyperexcitability, a well-documented phenomenon observed in the presymptomatic stage of TDP-43 related neurodegeneration, including amyotrophic lateral sclerosis (ALS). However, the underlying mechanisms responsible for sensing and regulating this early motor cortical dysfunction remain unclear. Microglia, the principal resident immune cells in the central nervous system, have recently gained attention for their role in monitoring and modulating neuronal activity under both physiological and pathological conditions. In this study, we investigated the potential involvement of microglia in sensing and regulating neuronal activity and shaping the function of motor cortical circuits in TDP-43 neurodegeneration by using a novel mouse model (rNLS8). We performed longitudinal calcium imaging in awake mice using *in vivo* two-photon microscopy combined with silicon probes to record neuronal activity in the motor cortex and found a dynamic change in neuronal activity during disease progression. Specifically, we observed neuronal hyperactivity at initial stage. Intriguingly, upon microglia ablation, we observed a dramatic calcium overload in motor cortical neurons, leading to a decrease in survival. To elucidate the underlying mechanisms, we examined microglia activation during disease progression and observed significant activation accompanied by distinct morphologies, suggesting functional heterogeneity of microglia in ALS. Furthermore, we performed spatial RNA sequencing to decode the transcriptional profile of the activated microglia. Additionally, we observed direct interactions between microglia and the apical dendrites of motor neurons, implying a complex interplay between microglia and neurons. Together, our results reveal that microglia may mediate neuroprotection by dampening motor cortical excitability in the hTDP-43 overexpression model of ALS-like motor neuron degeneration. This comprehensive investigation may contribute to the early diagnosis of ALS, while also uncovering novel targets for preventing motor neuron degeneration and impeding disease progression.

Alcohol exerts diverse effects on the human brain, including alterations in neurotransmitter release and neuroinflammation, which contribute to the development and progression of alcohol use disorders (AUD) in humans. Numerous gene variants linked to AUD have been identified using genome-wide association studies (GWAS). Leveraging insights derived from these GWAS, integrating these variants by creating polygenic risk scores (PRS) has the potential prediction of outcomes associated with AUD. However, the cellular and molecular mechanisms underlying the interaction between ethanol and PRS on AUD in human remains enigmatic.Microglia, resident immune cells within the central nervous system, play a critical role in AUD by regulating neuroinflammatory responses. Here, we utilized induced pluripotent stem cell (iPSC)-derived microglia obtained from individuals with high PRS (HiPRS) and low PRS (LoPRS) of AUD and investigated the impacts of ethanol. Human microglia were generated from yolk sac embryoid bodies derived from 12 iPSC lines (6 HiPRS and 6 LoPRS, both males and females). The application of 20 mM and 75 mM for 7 days led to a significant increase in microglia expressing the active marker $CD68^{+}$, with no notable distinction observed between the HiPRS and LoPRS lines. Interestingly, the HiPRS-microglial cells displayed enhanced phagocytic activity following EtOH exposure, while the LoPRS-microglial cells exhibited reduced phagocytic capacity. Using RNAseq, we identified abundant differentially expressed genes (DEGs) that have the potential to explain the differences in low vs. high AUD PRS human microglial cells. Notably, these DEGs were predominantly enriched in processes associated with extracellular matrix organization, integrin-mediated signaling pathways, and regulation of calcium ion transport. In conclusion, our findings suggest that genetic backgrounds play important roles in determining their response to EtOH exposure. This research provides novel insights into the intricate connection between genetic factors and microglial function in AUD.

Title: Nmes1 is a regulator of neuro-inflammation in cultured murine microglial cells

Authors: *J. SINZI[1], B. BISHOP[3], S. EWING[2], D. DONLEY[2];

Abstract: Beta-amyloid42(Aβ42) is a peptide that accumulates in the brain of Alzheimer's disease (AD) patients and is closely associated with disease-potentiating pro-inflammatory responses of microglial cells. While the inflammatory response to Aβ42 is extensively studied, the precise mechanisms and cell signaling pathways that trigger and regulate this response remain poorly understood. Consistent with prior literature, our preliminary data identified Normal mucosa of esophagus-specific1(NMES1) as a putative regulator of microglial activation in response to Aβ42. NMES1 is a mitochondrial cytochrome c oxidase subunit that is increased in cultured microglia by Aβ42. Consistent with its anti-inflammatory properties, NMES1, replaces the NDUFA4 subunit of cytochrome c oxidase, resulting in lower efficiency of electron transport. Paradoxically, decreased mitochondrial respiration is often associated with elevated inflammation, but increased NMES1 is implicated in suppression of inflammation. Therefore, we modulated NAMES1 expression in cultured microglial cells with and without Aβ42 stimulation. Herein we report on the impact of NMES1 of inflammatory markers and metabolic regulation in microglia. Notably, we found that knockdown of NMES1 by silencing RNA, resulted in an increase of the expression of CD68, a marker of inflammatory activation. Together our data is consistent with NMES1 acting as an inflammatory braking mechanism. Overall, we postulate that NMES1 has been previously underappreciated as an inflammatory regulator in microglial cells. However, more work is required to investigate the impact of NMES1 on microglial activation and proinflammatory responses during disease.

Title: Iron suppresses the microRNA, mir-147b in cultured microglia cells, potentiating pro-inflammatory activation to beta-amyloid in vitro

Authors: *B. BISHOP[1], S. EWING[2], E. MORGAN[3], M. VARGUS[3], D. DONLEY[3];
[1]Harding, Searcy, AR; [2]Biol., [3]Harding Univ., Searcy, AR

Abstract: Iron dysregulation in microglia cells promotes dystrophy and modulates activation in response to disease stimuli such as beta-amyloid. Accumulation of beta-amyloid results in chronic microglia activation linked with the progression of Alzheimer's disease (AD). In addition, the buildup of iron is associated with AD progression, and preliminary data finds that iron potentiates microglial activation in response to beta-amyloid. The mechanism(s) of how elevated iron and beta-amyloid converge to induce microglia dysfunction is unclear. To study this intersection, microglia were cultured in iron for three days, then treated with/without beta-amyloid. We completed a proteomic analysis to identify potential intersection points of beta-amyloid and iron. Normal mucosa of esophagus-specific gene 1 (NMES1) was solely identified as being altered between cells stimulated with iron, beta-amyloid, and iron/beta-amyloid. The host gene for the NMES1 protein is *C15orf48,* and it also produces the microRNA mir-147b. NMES1 is a subunit of mitochondrial cytochrome c oxidase and an inflammatory regulator. Our data suggest that iron attenuates the ability of *C15orf48*/NMES1 to regulate microglial activation. Based on the literature and preliminary data, we hypothesize that mir-147b may be a critical mediator of inflammation that is affected by iron. To study this, we transfected cultured microglia with a mir-147b inhibitor. We found that inhibition of this microRNA potentiates the functional response of microglia to beta-amyloid, suggesting its role as an inflammatory regulator. Herein, we specifically report on the impact of mir-147b on oxidative stress and mitochondrial metabolism - which have both been suggested as potentiators of inflammation in AD. More research is needed to fully elucidate the role of mir-147b on microglial activation and to determine the mechanism by which iron alters mir-147b expression. Our data expands on the current understanding of the mechanisms underlying microglial activation states and suggests that iron dysregulation in microglia may be impairing important inflammatory regulators, such as mir-147b, in the context of beta-amyloid activation.

Title: Regulation of C15orf48 controls microglial inflammation: a role for methylation?

Authors: *G. BING[1], B. BISHOP[2], D. DONLEY[1];
[1]Harding Univ., Searcy, AR; [2]Biol., Harding, Searcy, AR

Abstract: The *C15orf48* gene encodes the NMES1 protein and the microRNA mir-147b, which both are associated with facilitating inflammatory responses of microglia. Microglial cells act as the resident immune cells of the central nervous system. Chronic neuroinflammation resulting, in part, from microglial activation is a pathological hallmark of neurodegenerative diseases, including Alzheimer's Disease (AD). Despite this, if and how *C15orf48* mediates microglial activation is not well understood. There is evidence of transcriptional dysregulation in AD, both globally and at the *C15orf48* locus. Upon stimulation of cultured microglial cells with beta-amyloid, we found that *C15orf48* expression increased, but the addition of iron attenuated the response. This preliminary finding identifies *C15orf48* regulation as a potential intersection point of disease-associated pathways. In cancer cells, the NMES1 gene has been found to be heavily methylated, suggesting that this may be one mechanism of regulation. However, we also identified dysregulation of putative *C15orf48* transcription factors as a result of inflammatory stimuli. Herein, we report the impact of iron and beta-amyloid on regulation of *C15orf48*. It is known that methylation and transcription factor expression are key regulators of gene expression but more research to examine these factors in the context of *C15orf48* expression. This work will provide insight on the significance of *C15orf48* in directing inflammatory responses of microglia.

Title: Effects of early immune activation on microglial metabolism, cytokine release and synaptic pruning

Authors: *A. CAMPOS SALAZAR[1], S. ATI[2], D. M. NGUYEN[2], J. DZIABIS[2], B. DEVLIN[2], C. J. SMITH[3], E. BORDT[4], S. D. BILBO[2];

Abstract: Early immune activation impacts brain development leading to behavioral impairment. For instance, lipopolysaccharide (LPS) administration at postnatal day 9 leads to male-specific social behavior deficits and mitochondrial changes in microglia. Our laboratory has described a metabolic shift towards glycolysis in microglia underlying early immune activation with LPS administration at postnatal day 9. This metabolic shift highlights the role of mitochondrial respiration and suggests that microglial functions such as synaptic pruning and cytokine expression can be impacted. My goal is to investigate the effects of early immune activation on microglial functions and mitochondria respiration during development and whether these outcomes are impaired persistently later in life. Male and female postnatal day 9 mice were subcutaneously administered 10 mg/kg LPS. Using the three-chamber sociability test, only LPS-treated male mice showed reduced social investigation times compared to saline. Two microglial functions are analyzed in this study: cytokine release and synaptic pruning. Because we have previously shown that the anterior cingulate cortex (ACC) is a critical node in the social behavior network during development, our experiments are initially performed in the ACC 24 hours after LPS injection. Cytokine profiling for pro-inflammatory and anti-inflammatory cytokines is performed using the MesoScale Discovery platform. Changes in synaptic pruning are investigated in the ACC by quantification of synaptic material inside microglial lysosomal content. Mitochondrial respiration is measured by oxygen consumption rate using the seahorse platform. In isolated microglia from the prefrontal cortex, we expect that LPS administration reduces mitochondrial reliance and increases glycolysis. The correlation between mitochondria respiration status and cytokine profile or synaptic pruning in microglia will crystallize the relationship between microglial metabolism and *in vivo* functions. Finally, to evaluate long-term changes, morphometric parameters such as volume and length of microglial mitochondria from ACC of postnatal day 70 mice are quantified using immunohistochemistry. Our study will strengthen the notion that impairment of mitochondrial respiration driven by early immune activation controls microglial functions such as cytokine release and synaptic pruning *in vivo*.

Title: Evaluation of microglial-vascular interactions and glial reactivity through morphometric image analyses in a murine model of intranasal nicotine-derived nitrosamine ketone (NNK) treatment using intravital microscopy

Authors: *L. F. OCHOA[1], P. P. VILLARREAL[2], O. D. SOLOMON[5], F. XIA[3], W. ZHANG[3], G. VARGAS[4];
[1]Neurobio., Univ. Of Texas Med. Branch, Galv Neurosci. Grad. Program, Galveston, TX; [2]Neurobio., [3]Ophthalmology & Visual Sci., [4]Neurosci. Cell Biol. and Anat., Univ. of Texas Med. Br., Galveston, TX; [5]The Univ. of Texas Med. Br., Galveston, TX

Abstract: Cigarette Smoke (CS) significantly impacts global quality of life and mortality rates. Nicotine-derived nitrosamine ketone (NNK), a prominent toxin and nicotine metabolite present in CS and e-cigarettes, has been associated with neuroinflammation and lung cancer due to its ability to form DNA adducts and activate nicotinic receptors. Prior investigations using a humanized flow-based in vitro blood-brain barrier (BBB) model have shown that CS extract exposure triggers pro-inflammatory reactions, disrupts BBB function, and compromises endothelial cell viability. However, the specific effects of NNK on the BBB, vascular dynamics, and in vivo microglial dynamics in relation to the vasculature are currently unclear. In this study, we employed 2-photon microscopy (2P) to examine in vivo cellular responses to intranasally administered NNK. Transgenic mice were treated with NNK for acute (4 days) and chronic (12 weeks) exposures. To quantitatively investigate microglial and cerebrovascular dynamics 2P imaging and NNK treatment were done on *CX$_3$CR-1^{GFP}* mice with IP-delivered Evans Blue (EB). Volumetric scans and time series captured spatial features and dynamic responses. Machine learning (ImageJ plugin), combined with an in-house image processing algorithm that segmented features through a combination of morphological and spectral (filter-based) information was used to isolate individual biological components that included microglia soma, microglial processes, engulfed EB localized within the soma, engulfed EB localized to glial processes, and the vasculature, leading to analysis of reactivity, phagocytic activity, and vascular interactions. NNK groups showed disrupted BBB, increased vessel-associated microglia, heterogeneous microglial morphology (reactive near vessels, homeostatic far from vessels), vasoconstriction, vasodilation, microbursts, increased EB uptake in microglia soma and processes compared to PBS controls. The algorithm was similarly applied in a non-GFP neurodegenerative mouse model (3xTG-AD) treated with NNK. EB labeled vessels and autofluorescence delineated cell-like bodies in the parenchyma consistent with lipofuscin spectral properties. This led to analyses indicating NNK-treated mice exhibited heightened vascular leakage, vasospasms and lipofuscin deposition. In summary, we show that implementing segmentation approaches that leverage morphometry in addition to traditional filter-defined channels provides a powerful way to dissect key image features for assessment of the cerebrovascular microenvironment, revealing responses following exposure to a nicotine-associated carcinogen.

Title: Microglial morphological and phenotypical changes across abstinence following long-access cocaine self-administration

Authors: *T. BELLINGER[1], A. TESTEN[2], J. W. VANRYZIN[3], K. J. REISSNER[4];
[1]Dept. of Pharmacol., Univ. of North Carolina Chapel Hill, Chapel Hill, NC; [2]UNC Neurosci. Ctr., UNC, Chapel Hill, NC; [4]Dept. of Psychology and Neurosci., [3]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: A reactive microglial response to drugs of abuse has been implicated in the development and persistence of substance use disorders. However, the full scope of cocaine-mediated microglia responses to rat cocaine self-administration is understudied. Given this, we sought to determine the timeline of nucleus accumbens microglia morphology across abstinence in adult male rats. We utilized a long-access cocaine self-administration paradigm, in which adult male Sprague Dawley rats self-administered cocaine or saline for six hours per day for ten days. Nucleus accumbens core microglia were then analyzed at abstinence days 1, 30, and 45 (AD1/30/45). Immunohistochemistry was performed to detect microglia marker Iba1 and lysosomal marker CD68, together with astrocytes transduced for AAV5 GfaABC1D Lck-GFP. A Zeiss LSM 800 confocal microscope was used to acquire 63x z-stack images. Bitplane Imaris software was utilized to construct three-dimensional filament reconstruction of individual microglia. A number of morphometric features of microglia were collected, including surface area, volume, soma area, soma volume, soma sphericity, and filament number. In the AD1 cohort, a significant decrease was observed in filament number, area to volume ratio, and filament number of dendrite branch points, with a significant increase in soma sphericity. However, results from AD45 (long abstinence) revealed no significant differences in microglia morphometric measurements between cocaine and saline groups. Colocalization of Iba1 with astrocytic Lck-GFP and CD68 was also performed across abstinence, to determine whether microglia phagocytosis might contribute to previously reported astrocyte hypotrophy. AD1 data illustrate a significant increase in somatic Lck-GFP+ inclusions in microglia of cocaine-administered animals compared to saline animals, but no effect of cocaine on colocalization between Iba1 and CD68, or total Lck-GFP inclusions. AD45 data revealed significantly increased colocalization in cocaine-administering rats of Iba1 with Lck-GFP and Iba1 with CD68, with a significant increase in number and volume of Lck-GFP+ inclusions within microglia, suggesting that microglia phagocytosis is heightened at AD45 in cocaine animals. A small but significant increase in the number of microglia as a function of cocaine were observed at all time points. Structural and colocalization analysis of AD30 is ongoing. Cumulative results from this study demonstrate that microglial morphological responses and evidence of microglial phagocytosis are variable across abstinence.

Title: Assessing microglia in the Suprachiasmatic Nucleus, Anterior Hypothalamus and Cortex under control and excitotoxic conditions at different times of day

Authors: *D. ACHARYYA, R. A. PROSSER;
Univ. of Tennessee, Knoxville, Knoxville, TN

Abstract: Various pathological conditions generate excitotoxic conditions resulting in cell death. We have found that the suprachiasmatic nucleus (SCN) is more resistant to excitotoxic damage compared to the anterior hypothalamus (AH) and cortex. We have also found time-of-day differences in excitotoxic susceptibility in all three regions. Given that excitotoxic stimuli induce changes in microglia activity, we are investigating whether differences in microglial responses may contribute to the SCN's excitotoxic resiliency and to the day-night susceptibility differences we have observed. Here we investigated overall microglial numbers and morphology (ramified vs. amoeboid), expression of the pro-inflammatory (CD86) vs. anti-inflammatory microglial cell markers (CD206), and release of cytokines from acute brain slices under control and excitotoxic conditions at different times of day. We hypothesized that distinct microglial activity contribute to regional and time-dependent differences in excitotoxic resiliency.To begin assessing regional differences in microglial number, morphology, and pro- vs. anti-inflammatory state,we prepared acute coronal brain slices containing the SCN/AH or cortex from adult male C57Bl/6 mice. At Zeitgeber time 6 (ZT6, where ZT0 = lights-on; ZT12 = lights-off) the slices were left untreated or exposed to NMDA for 1h. Three hours after the treatment ended, the slices were processed for immunohistochemistry and double-stained for the pan-microglia marker IBA1 and either CD86 or CD206. To investigate differences across 24h, we used the same experimental procedure, except that the slices were treated or left untreated at different times of the day: ZT6, ZT12, ZT16 and ZT23. Lastly, we used the same experimental set-up except that we collected media perfusates from acute slices after control/NMDA treatment at ZT6 to assess cytokine release.Our data show that NMDA shifts SCN microglia to a more amoeboid morphology and increases microglia numbers in the cortex. NMDA also decreases the percentage of CD86-expressing microglia in the SCN and AH compared to cortex. We also see differences in microglial morphology between the SCN and AH under control conditions across the 24 hrs. Our cytokine data are still being collected and analyzed. Thus, there appear to be regional differences in microglial activity that could contribute to variability in excitotoxic responses.

Title: Enhanced expression of microglial Clec7a in the mesial temporal lobe epilepsy

Authors: *T. KAWANA[1], Y. IKEGAYA[1,2], R. KOYAMA[1,2];
[1]pharmaceutical science, Tokyo Univ., Bunkyo-ku, Tokyo, Japan; [2]Univ. Tokyo, Inst. For AI and Beyond, Tokyo, Japan

Abstract: Medial temporal lobe epilepsy (mTLE) is a chronic neurological disorder characterized by seizures resulting from neuronal hyperexcitation. Approximately one third of individuals with mTLE exhibit resistance to antiepileptic seizure medications (Thurman et al., Epilepsia, 2011; Chen Z et al., JAMA Neurol, 2018). Recently, the involvement of glial cells, such as microglia and astrocytes, in the pathogenesis of mTLE has garnered attention. Glial cells play a pivotal role in maintaining neuronal activity, and it has been postulated that their dysfunction contributes to the development of epileptic seizures. For instance, it has been hypothesized that an exaggerated inflammatory response in microglia might increase neuronal excitability and exacerbate epileptic symptoms (Vezzani et al., Nat Rev Neurol, 2011). However, the precise mechanisms underlying this phenomenon remain elusive, necessitating a comprehensive understanding of the molecular mechanisms by which microglial responses in mTLE contribute to epilepsy pathogenesis (Hiragi et al., Cells, 2018; Andoh et al., Journal of Clinical Medicine, 2019).Here, we performed RNA sequencing on the hippocampus from the mTLE mice to identify microglial genes involved in the pathogenesis of mTLE. We focused on Clec7a, a microglial gene whose expression is upregulated in mTLE. Clec7a is a single transmembrane receptor expressed in myeloid cells. Previous studies have indicated that Clec7a is specifically upregulated in microglia in neurodegenerative diseases such as Alzheimer's disease (Keren-Shaul et al., Cell, 2017). However, the role of microglial Clec7a in central nervous system (CNS) diseases remains unclear (Deerhake et al., Trends Immunol, 2021). Immunohistochemical staining revealed enhanced expression of Clec7a in microglia in the hippocampus two weeks after inducing seizures in the mTLE mouse model. Using single-cell RNA sequencing-based analysis and primary cultures of microglia, we found that the expression of the proinflammatory cytokine TNFα is upregulated downstream of Clec7a. Furthermore, pharmacological investigations employing a glial co-culture system revealed that Clec7a leads to the phosphorylation of ERK in microglia. These findings suggest that in the context of mTLE, microglial Clec7a contributes to microglial survival, proliferation, and inflammatory responses,

potentially influencing neuronal cell death in the hippocampus and the development of epileptic seizures.

Sch., Newark, NJ; [9]Dept. of Biol., The Univ. of Texas At San Antonio, San Antonio, TX

Abstract: Cerebral malaria (CM) is the most lethal form of malaria due to a *Plasmodium falciparum* infection involving systemic inflammation. Children under the age of five residing in Africa south of the Sahara are most susceptible to developing this condition. It is a condition associated with neurological deficits that are evident even in survivors. Experimental models of CM indicate this condition involves hypercoagulation and microgliosis, studied previously in late disease. The role of microglia in disease pathogenesis, as well as the interplay between coagulation and microgliosis, have not been elucidated. This study sought to investigate the role of microglia in eCM and how the microglial responses relate to hypercoagulation. Intravital multiphoton microscopy (IVM) was performed on IL-10$^{-/-}$CX3CR1$^{GFP/-}$CCR2$^{RFP/-}$ and IL-10$^{-/-}$ murine models infected with *Plasmodium chabaudi* to investigate the interplay between coagulation and microglial-vascular responses. Additionally, a study was performed to deplete microglia using Pexidartinib, a CSF-1R inhibitor incorporated into a custom chow. In comparisons between infected and uninfected animals, IVM coupled with immunohistochemistry

indicated significant reactive microglia near vessels while microglia further away from vessels are less reactive. Studies also indicated in infection an increase in vessel associated microglia and revealed microglia associated with intravascular CCL5+thrombi. Moreover, results showed microglia were actively engulfing fibrinogen and also suggestive of microglial-vascular interaction at play. Findings of microgliosis, coagulation, and associations between microglia and vessels increased in late disease (D7) vs early (D3). Depletion of microglia resulted in increased disease severity denoted by a rapid decline of clinical scores and exacerbated hypothermia beyond that experienced without Pexidartinib. Notably, sagittal brain sections exhibited increased widespread hypercoagulation in the infected microglia-depleted group vs. infected normal chow group (percent area mean: uninfected, normal chow= 8%, infected normal chow= 15%, infected Pexidartinib chow= 25%, P=0.01), suggesting that microglia play an important role in controlling the effects of coagulation to maintain homeostasis.

Title: Effects of combined gestational exposure to air pollution and maternal stress on microglial interactions with social circuits in male and female offspring

Authors: *M. C. STOEHR[1], J. XUE[1], J. BABALOLA[1], E. T. HICKEY[1], D. M. NGUYEN[2], S. D. BILBO[2], C. J. SMITH[1];
[1]Psychology and Neurosci., Boston Col., Chestnut Hill, MA; [2]Psychology and Neurosci., Duke Univ., Durham, NC

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social interaction, repetitive behaviors, and a sex bias in prevalence (higher in males). Air pollution and maternal stress during pregnancy are both risk factors for ASD. Air pollution disproportionately impacts communities that also experience high levels of psychosocial stress and these exposures may combine to increase overall risk. However, the biological mechanisms by which these exposures increase ASD risk are not fully understood. The social decision-making network (SDMN) is a set of interconnected brain regions critical to the control of social behaviors across many species. Oxytocin (OT) and vasopressin (AVP) are closely related nonapeptides whose receptors are highly expressed within the SDMN and regulate social behavior. Microglia, the resident immune cells of the brain, sculpt neural circuits during development and respond to environmental signals like air pollution. Therefore, we aimed to

investigate whether prenatal exposure to air pollution and maternal stress might alter microglial sculpting of OT and/or AVP in the SDMN. Our lab utilizes a mouse model in which pregnant dams are exposed to combined diesel exhaust particles (DEP) and maternal stress (MS). In the DEP/MS model, we previously found that male offspring show social behavior deficits and shifts in microglial morphology and gene expression. Here, we exposed dams to either DEP/MS or control (CON) and then cross-fostered pups to determine the importance of the postnatal environment. We assessed microglial density and morphology in 3 subregions of the prefrontal cortex and in the lateral septum (LS). We found that in the prelimbic cortex microglial density is lower following DEP/MS as compared to CON ($p = 0.01$). In the LS, microglial density tended to be lower following DEP/MS ($p=0.06$), and density was significantly increased in DEP/MS pups who were cross-fostered to a CON dam on the day of birth ($p=0.04$). Currently, we are investigating whether there are changes in microglial morphology within the PrL and LS. We are also characterizing microglial interactions with OT and AVP systems in critical nodes of the SDMN throughout development and how DEP/MS exposure alters these interactions.

Title: Early life hormone manipulation in rats alters microglial activation in adulthood

Authors: *L. K. DAVIS[1], J. S. DARLING[2], L. K. FONKEN[2];
[1]Univ. of Texas at Austin Dept. of Neurosci., Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Microglia play a critical role in the central nervous system during health and disease. Sex differences in microglial activation and morphology have been observed across development, raising valuable questions about the role of sex hormones in microglial function and pathology. Although it is known that hormones are crucial for the appearance of sex differences in microglial function, it is unclear whether sex differences are due to organizational effects of early life hormones or if sex differences in microglia result from the activational wave of hormones during puberty. Understanding the role of hormones on microglial physiology and function may have important implications for treating nervous system disorders. In this study, we examined the role of hormones on microglial activation and morphology across the lifespan. F344 x Brown Norway F1 rats were subcutaneously injected with vehicle or hormone treatments on postnatal day (P) 0 and 1. Females were treated with testosterone to masculinize them; males were treated with the androgen antagonist, Flutamide, to feminize them. Brain tissue was

collected across the lifespan: prepubertal (P30), adulthood (P150), and aged (P700), and microglia were isolated for *ex vivo* assays and immunohistochemistry. Microglia were isolated using a Percoll density gradient and plated with lipopolysaccharide (LPS) before being assessed for proinflammatory cytokine gene expression. We report that early hormone treatment did not affect rat physiology or microglial activation at P30. However, by adulthood, there were changes in physiology and microglial activation such that microglia isolated from vehicle-treated males had elevated pro-inflammatory cytokine gene expression, while flutamide-treated males have reduced inflammatory cytokines. Although female physiology was affected by hormone treatment in adulthood, such that testosterone-treated females were significantly larger than vehicle-treated females, female microglia did not appear affected by hormone treatment. These results suggest that the activational wave of hormones during puberty may be critical for the appearance of sex differences in microglial activation, especially in males. Ongoing work is examining how adult microglial morphology is affected by hormone treatment, as well as assessing how early life hormone treatment alters sex differences in age-related cognitive decline in our aging rats (P700).

Title: Role of synaptic refinement in the pathophysiology of stuttering disorders

Authors: *A. ADECK[1], M. WEINHOLD[3], M. MILLWATER[2], S. SHEIKHBAHAEI[1]; [2]Natl. Inst. of Neurolog. Disorders and Stroke, [1]NIH, Bethesda, MD; [3]Natl. Inst. of Health, Natl. Inst. of Neurolog. Disorders and Strokes, Bethesda, MD

Abstract: Stuttering, a prevalent neurodevelopmental speech disorder, significantly impacts approximately 1% of the adult population in the United States. It manifests as recurrent disruptions in the natural rhythm of speech, characterized by silent blocks, word repetitions, and elongated sounds. Synaptic refinement plays a crucial role in brain development, orchestrating the elimination and preservation of specific synapses in response to fluctuations in neural activity. Disruptions in this process have been associated with neurodevelopmental disorders such as autism spectrum disorder (ASD), attention deficit hyperactivity disorder (ADHD), and Tourette Syndrome. Imaging data in human suggested a deficit in synaptic refinement in individuals who stutter, however, direct experimental evidence has been limited. In this study, we employed viral-vector-assisted circuit mapping, advanced electron and light microscopy, and 3D computer-assisted cellular reconstruction techniques to investigate synaptic pruning in a

mouse model of stuttering (Gnptab-mutant mice). Since reactive microglia cells contribute to synaptic pruning process, we reconstructed microglia cells (immunostained by Iba1 marker) as well as vesicular glutamate transporter 2 (VGLUT2) and vesicular GABA transporter (VGAT) as synaptic proteins in postnatal (P)- 7, 15, and 21. We then examined the localization of VGLUT2 and VGAT with Iba1+ microglia cells. Our preliminary data suggest higher levels of VGAT and VGLUT2 localization within IBA1+ cells in control mice (by 35%, n=10-12 microglia per group per region) compared to *Gnptab-mutant* mice at all ages. The observed pruning deficit may lead to excess synapses. Critical components for neuronal communication, which can significantly impact brain function. Given the integral role of microglia in synaptic pruning during the critical period, our data propose that these glial cells may have a significant involvement in the pathophysiology of stuttering disorder.

Title: Adipose tissue-derived extracellular vesicles; effects of aging and inflammation in obesity and prediabetes

Authors: *A. ALLOUCH[1,2], S. E. ELZINGA[1,2], R. E. HENN[1,2], E. GLASS[3,4], R. PARENT[3,4], K. GUO[5], F. E. MENDELSON[1,2], J. M. HAYES[1,2], I. WEBBER-DAVIS[1,2], G. G. MURPHY[3,4], J. HUR[5], E. L. FELDMAN[1,2];
[1]Neurol., [2]NeuroNetwork for Emerging Therapies, [3]Mol. and Integrative Physiology, Div. of Cardiovasc. Med., [4]Michigan Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [5]Biomed. Sci., Univ. of North Dakota, Grand Forks, ND

Abstract: Inflammation, particularly adipose tissue inflammation, is commonly associated with multiple diseases and disorders, including obesity, prediabetes, type 2 diabetes, and aging. This inflammation is thought to promote the neurological complications that are common in these disorders. Adipose tissue-derived extracellular vesicles (EVs) are key mediators of cell-cell communication. EVs can cross the blood brain barrier and may promote central nervous system

(CNS) inflammation, potentially via activation of the primary immune cells of the CNS, the microglia. Therefore, our goal was to assess potential inflammatory effects of age and obesity/prediabetes on microglia-adipose crosstalk via EVs. To do this, we induced obesity/prediabetes by feeding young adult (5 weeks of age) or middle aged (1 year of age) male C57BL/6 mice either standard diet (SD) or high fat diet (HFD) for 13 weeks. Metabolic and cognitive phenotyping was performed at terminal and fresh epididymal white adipose tissue from these animals (n=3/group) was used to isolate EVs. HFD-fed animals developed cognitive impairment, which was aggravated by age. We also showed adipose tissue hypertrophy in HFD animals, which was similar in both age groups. Cognitive deficits were accompanied by changes in CNS inflammatory profiles, which varied dependent upon age. Complimentary *in vitro* work in a human microglial cell line (SV40; applied biological materials, British Columbia, Canada) was used to characterize adipose-microglial crosstalk by treating microglia for 24 hours with adipose tissue-derived EVs. Western blots of microglial NFκB protein expression showed increased expression in cells treated with adipose tissue-derived EVs from adult HFD mice, as well as EVs from aged SD fed animals relative to adult SD controls. These data indicate that HFD and age promote cognitive impairment and inflammatory changes. HFD and age may also disrupt adipose-microglia crosstalk via EVs, contributing to an inflammatory environment in the CNS.

Title: Microglial priming in orbital frontal cortex of alcohol use disorder

Authors: *L. QIN, R. P. VETRENO, L. G. COLEMAN, Jr, F. T. CREWS;
Univ. North Carolina, Sch. Med., Chapel Hill, NC

Abstract: Microglia and proinflammatory gene expression are altered by alcohol treatment of rodents and in post-mortem human brain of alcohol use disorder (AUD). In this study we extended previous studies to better characterize microglia in AUD cortex using immunohistochemical (IHC) assessment of cellular proteins and PCR determination of microglial gene mRNA. Interestingly, microglial markers showed increases in expression in AUD patients, although not all showed increases in both IHC staining and mRNA. The microglial marker genes Iba-1, P2RY12 and CD68 showed significant increases in staining in

AUD compared to controls, but no change in mRNA (Aif1, P2ry12, CD68). The resting microglial marker TMEM119 was decreased in AUD brain, both staining and mRNA. Microglial priming marker CD11b was increases in AUD, both staining (MAC1, OX42) and mRNA (CD11b) suggesting AUD microglia are sensitized to proinflammatory activation. CCR2, a monocyte-microglial receptor, showed increases in both cell numbers by IHC as well as mRNA consistent with migration of monocytes into AUD brain. TREM2, Dap12, IL15, and C1q were not different between controls and AUD. These studies are consistent with proinflammatory priming of microglia in AUD increasing oxidative stress which we assessed using the DNA oxidation marker 8-OHdG+IHC. We found 8-OHdG increased with age in both controls and AUD, with AUD showing higher levels across the ages studied. These findings support ethanol priming of microglia to proinflammatory-oxidative stress phenotypes in AUD cortex that are reflected in increased levels of 8-OHdG, a marker of DNA oxidative damage. Priming of microglia likely contributes to AUD neuropathology.

Title: Senescent glial cells drive NMO pathogenesis

Authors: *Y. ZHU[1], L.-J. WU[2], V. A. LENNON[3], T. CHEN[2], F. QI[2];
[1]Physiol. and Biomed. Engin., [3]Neuroimmunology Laboratory, Dept. of Lab. Med. & Pathology, [2]Mayo Clin., Rochester, MN

Abstract: Neuromyelitis Optica (NMO) is a debilitating autoimmune disorder characterized by severe visual loss and paralysis. Effective treatments for NMO are limited, highlighting the need to understand the underlying mechanisms driving its development. Cellular senescence, a stable cell cycle arrest triggered by external stresses, has recently emerged as a potential contributor to various neurological disorders. Senescent cells secrete a range of inflammatory molecules known as the senescence-associated secretory phenotype (SASP), which can impact neighboring cells, alter tissue microenvironments, and induce dysfunction. In the previous study, we have established a mouse model of NMO by infusing either IgG from pooled NMO patients' serum or AQP4-specific monoclonal IgG into the spinal subarachnoid space of mice without exogenous complement. The detailed mechanisms are yet to be determined. To begin exploring the underlying mechanisms, we utilized mass cytometry (CyTOF) for single-cell proteomic analysis of cellular and molecular changes in NMO pathology. We found an accumulation of senescent glial cells, specifically astrocytes and microglia, in the progression of NMO in mice, suggesting their crucial role in the disease pathology potentially triggered by Aquaporin 4 depletion due to IgG binding. Furthermore, we observed a direct correlation between the increased population of

these senescent cells, known for their inflammatory properties, and the prevalence of immune cells in the spinal cords of the NMO mice models, as well as an inverse relationship with the loss of oligodendrocytes. Collectively, our study indicates a novel mechanism that senescent astrocytes activate microglia, instigating microglial senescence, which subsequently promotes immune cell infiltration and oligodendrocyte loss. By elucidating the interplay between senescent glial cells and NMO, this study aims to identify potential therapeutic targets for the treatment of NMO, with broader implications for autoimmune neurological disorders.

Title: Lox-1 mediates inflammatory activation of microglia through the p38-mapk/nf-κb pathways under hypoxic-ischemic condition

Authors: *M. ITOH[1], Y. AOKI[2];
[1]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Pediatrics, Univ. of Miyazaki, Miyazaki-shi Kiyotake-cho Kihara, Japan

Abstract: Background and aim Microglial cells play an important role in the immune system in the brain. Activated microglial cells are not only injurious but also neuroprotective. We confirmed marked lectin-like oxidized low-density lipoprotein receptor-1 (LOX-1) expression in microglial cells in pathological lesions in the neonatal hypoxic-ischemic encephalopathy (nHIE) model brain. Here, we investigated a novel role of LOX-1 and the molecular mechanism of LOX-1 gene transcription microglial cells under hypoxic and ischemic conditions. **Methods** We isolated primary rat microglial cells from 3-day-old rat brains. We treated primary rat microglial cells with oxygen glucose deprivation (OGD) as an in vitro model of nHIE. Then, we evaluated the expression levels of LOX-1, cytokines and chemokines in cells treated with or without siRNA and inhibitors. We performed a luciferase reporter assay and chromatin immunoprecipitation assay. In addition, we analyzed reactive oxygen species and cell viability. **Results** We found that OGD treatment induced LOX-1 expression and inflammatory mediators, such as the cytokines of IL-1β, IL-6 and TNF-α and the chemokines of CCL2, CCL5 and CCL3. Then, the LOX-1 signal transduction pathway was blocked by some inhibitors suppressed the production of inflammatory mediators. We found that NF-κB and HIF-1α bind to the promoter region of the *OLR-1* gene. Moreover, we demonstrated that LOX-1 in microglial cells was autonomously overexpressed by positive feedback of the intracellular LOX-1 pathway.

Conclusion The hypoxic/ischemic conditions of microglial cells induced LOX-1 expression and activated the immune system. LOX-1 and its related molecules or chemicals may be major therapeutic candidates.

Title: A unique population of senescent microglia in neurodegeneration

Authors: *V. DURAN LAFORET, T. E. FAUST, C. HUNG, R. M. BEITER, D. P. SCHAFER;
Univ. of Massachusetts Chan Med. Sch., Worcester, MA

Abstract: Senescence is a physiological process, which has historically been associated with aging and an inability to undergo cell division. At the same time, senescent cells enter a chronic inflammatory state, which includes secretion of the senescence-associated secretory phenotype or SASP, a cocktail of secreted inflammatory mediators (cytokines, matrix metalloproteases, etc.), which impacts the function of surrounding cells. In addition to aging, recent evidence now implicates senescent cells in neurodegeneration in diseases such as Alzheimer's Disease and Multiple Sclerosis. However, it remains to be determined where these senescent cells are localized in the brain during neurodegeneration and whether senescence influences the molecular phenotype of these cells. We are now using MERFISH (multiplexed error robust fluorescence in situ hybridization), an innovative spatial transcriptomic technique to measure the copy number and spatial distribution of 100's of senescence-related genes directly in human and mouse brain tissue. In the process, we have identified that the distribution of senescence cells is highest in Alzheimer's disease-relevant neurodegeneration vs. normal aging or acute neuroinflammation. Further, of the cell types that have this senescent signature, microglia are the most pronounced. We are now working towards identifying senescence-related secreted factors from microglia that influence neurodegeneration.

Abstract: Microglia, the brain's resident immune cells, participate in a variety of processes such as synaptic pruning and axon growth cone guidance during neurodevelopment, as well as brain sexualization, resulting in adult sexual behaviors. While the male microglial transcriptome assumes a short-lived, pro-inflammatory phenotype in response to a neonatal surge of estradiol (E2), female microglia exhibit persistent inflammatory gene expression beginning in early adolescence. This sustained inflammatory state may be linked to the female bias of neurodegenerative diseases. The current study investigates neonatal E2 exposure in specifying the microglial-mediated response to neurodegenerative disease processes in 5xFAD mice. Utilizing a previously established neonatal E2 administration paradigm, we masculinized female 5xFAD mice, and evaluated changes in the microglial transcriptome using qPCR.

Title: Elucidating the role of NFκB in inflammasome-mediated microglial inflammation

Authors: *K. SANCHEZ[1], **J. HULSE**[2], G. A. ROSENBERG[3], K. BHASKAR[2];
[2]Mol. Genet. and Microbiology, [3]Neurol., [1]Univ. of New Mexico, Albuquerque, NM

Abstract: Amyloid-β plaques and tau neurofibrillary tangles are the primary pathological components of Alzheimer's dementia (AD). Neuroinflammation has recently been implicated as another key driver of pathology in AD and occurs in response to these danger-associated molecular patterns. Microglia, the innate immune cells of the brain, assemble a multiprotein complex called the inflammasome composed of the NACHT, LRR, and PYD domain-containing protein 3 (NLRP3); the apoptosis-associated speck-like protein containing a CARD (ASC); and inflammatory caspase-1. Oligomerization of ASC and pro-caspase-1 leads to the activation of caspase-1, which can facilitate the cleavage of interleukin-1β (IL-1β) and IL-18. This "ASC-speck" is secreted into the extracellular space and is capable of cross-seeding amyloid-β in a prion-like fashion and contributing to an inflammatory milieu that worsens tau and amyloid-β pathology. Our preliminary studies indicate that ASC-specks also serve as a danger signal; ASC-specks stimulate the release of chemokines and cytokines such as TNFα, IL6, and CXCL1 in primary murine microglia. However, the pathway responsible for the release of these proteins is unknown. Due to previous work related to ASC-specks in the peripheral immune system, we hypothesized that the nuclear translocation of NFκB stimulates the release of proinflammatory chemokines and cytokines in the presence of ASC-specks. C20 immortalized human microglia and BV2 immortalized murine microglia were stimulated with purified ASC-specks and the nuclear translocation of NFκB was compared and evaluated in both human and murine immortalized cell lines through the use of immunocytochemistry and CX7 Cellomics High Content Screening. The release of proinflammatory cytokines and chemokines involved in inflammasome maturation such as IL-1β and IL-18 were evaluated using ELISA. We will report our findings indicating that externally released ASC-specks induce an inflammatory response in microglia. This study provides key insights into how the ASC-speck serves as a danger signal to drive neuroinflammatory processes involved in AD pathology.

Title: Mediation of IRF7 transcriptional regulation through a novel long non-coding RNA

Authors: *S. CIECHANOWSKI[1], N. MATHY[4], O. BURLEIGH[2], X.-M. CHEN[5], K. DRESCHER[3], A. SHIBATA[2];

Abstract: Systemic immune responses due to viral infection significantly contribute to the neurodegeneration seen in various diseases. Microglia participate in antiviral immune responses and promote both neurorecovery and neurotoxicity. Long noncoding RNAs (lncRNAs) are transcripts that lack coding potential and perform regulatory activities through interactions with RNA-binding proteins, such as transcription factors. Our previous work shows that lncRNAs can regulate microglial antibacterial responses, so we hypothesize that lncRNAs are also important in microglial antiviral immunity. In vivo and in vitro FBV/nJ mouse systems were used to study whether Theiler's murine encephalomyelitis virus (TMEV) altered lncRNA expression in microglia. Post-TMEV infection, lncRNA Nostrill expression significantly increases 3.9 ± 0.8fold in TMEV-infected and chronically demyelinated brain, 3.0 ± 0.04fold in infected primary microglia, and 2.8 ± 0.1fold in infected microglial cell lines, compared to uninfected controls (n=3, ±=SEM, $p<0.05$). Upregulation of Nostrill in response to TMEV is dependent upon NFκB signaling, as NFκB inhibitors block TMEV upregulation of Nostrill. TMEV-mediated NFκB signaling significantly upregulates gene transcription of interferon response factor 7 (IRF7) to ~22fold in primary microglia and to ~14fold in microglial cell lines as compared to unstimulated controls (n=3, $p<0.05$). Silencing of Nostrill using siRNA constructs blocks upregulation of IRF7 following infection of microglial cell lines with TMEV. Overexpression of Nostrill significantly increases IRF7 gene transcription without (~2fold) or with (~8fold) TMEV infection, as compared to controls (n=3, $p<0.05$). Following TMEV infection in microglial cell lines, qRT-PCR analysis showed an increase in infection burden with silencing of Nostrill (2.7 ± 0.3fold), and a reduced viral burden with the over expression of Nostrill (0.4 ± 0.1fold), as compared to control (n=3, ±=SEM, $p<0.05$). Nostrill has also been shown to bind to the p65 subunit of NFκB by RIP. ChIP analyses suggest that Nostrill targets p65 to promoter regions of IRF7. These data indicate that viral-induced upregulation of Nostrill is necessary and sufficient for regulation of IRF7 gene transcription and IRF7-related microglial antiviral immune responses. An increased understanding of the regulatory factors of microglial antiviral activity is critical for understanding immune responses in the CNS that contribute to neurodegeneration.

Title: Novel spatial quantification showed glial-neuron interaction after TBI

Authors: *T. GREEN[1], L. BEAUREGARD[1], S. MURPHY[2], M. OPP[1], R. ROWE[1];
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Cumberland Biol. and Ecological Researchers, Longmont, CO

Abstract: Introduction: Traumatic brain injury (TBI) causes dysfunction of orexin/hypocretin neurons, which contributes to post-traumatic sleep-wake disturbances. Injury-induced glial activation in proximity to orexin neurons may exacerbate dysfunction and promote neuronal apoptosis. Using a modified Sholl analysis, we investigated spatial relationships among hypothalamic orexin neurons, microglia, and astrocytes, and hypothesized that activated microglia and astrocytes would surround orexin neuronal cell somas following focal TBI. Methods: Mice received a controlled cortical impact (depth -1 mm) or sham surgery. At 3 days post-injury, brains were harvested, cryosectioned, and co-labeled for orexin neurons, astrocytes, and microglia. Z-stacked images were taken spanning the lateral hypothalamus. Concentric rings were placed on approximately 3 neurons per image (n=127 neurons), spanning 50µm from the soma center, in 3µm increments. The number of intersections on concentric rings surrounding the neuron were recorded for both microglia and astrocytes. This approach showed the proximity of glia to the orexin neuron soma. Nearest-neighbor glial morphology measurements are ongoing. Results: After TBI, as the frequency of microglial intersections proximal to the neuron increased, astrocyte intersections also increased both contralateral ($p=0.020$) and ipsilateral ($p=0.025$) to the injury. Astrocytes were further from orexin neurons compared to shams in the contralateral hypothalamus, ($p=0.029$) and in the ipsilateral hypothalamus ($p=0.004$). In the ipsilateral hemisphere, where neuropathology is routinely observed, astrocytes were closer to orexin neurons after TBI. Conclusions: Our results indicate an increased localization of astrocytes to orexin neurons after TBI. We demonstrate a novel Sholl analysis modification for examining the spatial relationships between any cell types in biological tissue.

Title: Agmatine modulates microglial activity in nucleus accumbens of fentanyl self-administration mice

Authors: *C. BARAJAS[1], C. PETERSON[2], K. F. KITTO[1], G. L. WILCOX[4], C. A. FAIRBANKS[3];

[2]308 Harvard Street SE, [3]Univ. of Minnesota, [1]Univ. of Minnesota, Minneapolis, MN; [4]Univ. Minnesota Med. Sch., Univ. Minnesota Med. Sch., Minneapolis, MN

Abstract: Chronic pain affects a significant fraction of the world population and is one of the major contributors to the global burden of disease. Opioid medications are commonly prescribed for the treatment of pain but carry high risk for addiction and overdose. Therefore, development of new medications with reduced risk of addiction and opioid use disorder is a high national priority. It is well established that the neuroplastic changes underlying chronic pain and addiction are dependent on activation of the N-methyl-D-aspartate (NMDA) receptor. Microglia also contribute to this neuroplasticity through interactions with neurons in CNS areas implicated in reward, such as the nucleus accumbens (NAc), and pain, such as the spinal cord. The decarboxylated form of L-arginine, agmatine, antagonizes the NMDA receptor and inhibits NMDA-evoked current, behavior, and NO production. Agmatine also inhibits the development of chronic pain and manifestations of chronic opioid exposure, but without the associated motor toxicity commonly observed with NMDA receptor antagonists. Therefore, agmatine-based therapeutics could provide an effective therapy for pain or opioid addiction with potentially limited side effects. Despite the potential of agmatine as a therapeutic, it is not yet clear whether the actions of agmatine on pain and reward circuitry involve microglia. To evaluate the effects of agmatine on microglia reward circuit remodeling, female ICR mice (21-30g) were separated into experimental groups and were able to press either for oral fentanyl reward (10 ug/mL) or inactive control over 12 hours of nightly access. Prior to each session, mice were treated (i.p.) with either agmatine (30 mg/kg) or saline. Agmatine-treated subjects had significantly decreased responding as compared to their saline controls. Brains were collected and immunohistochemical staining for Iba1, a microglial marker, in the NAc was conducted. Initial analysis demonstrated distinct morphological identities of microglia in NAc of mice treated with agmatine vs. those treated with saline. Saline-treated mice had increased microglia in the activated amoeba form compared to agmatine-treated mice. In contrast, agmatine-treated mice had increased microglia in the resting ramified form. These exploratory data suggest that agmatine may prevent neuroplastic remodeling through anti-inflammatory mechanisms.

Abstract: Endothelin-1 as an Activator of Pro-inflammatory Microglia Cells in Multiple Sclerosis Shakira Bou, José Alvarado, Diego Capo, Jean P. Moliere, Claudia P. Arenas and Yaritza Inostroza-Nieves

Abstract

Objective: Demonstrate that high levels of ET-1 contribute to the progression of MS by studying the activation of microglia cells *in vitro*.

Background: Multiple sclerosis (MS) is a neurodegenerative autoimmune disease characterized by inflammation, demyelination, and axonal degeneration. In MS patients, demyelination is associated with activated microglia, which are the resident innate immune cells of the central nervous system and play an important role in inflammatory responses. ET-1 is a potent vasoconstrictor that has been documented in MS by inducing severe and prolonged cerebral vasoconstriction. However, the mechanism of how ET-1 activates a proinflammatory response is unknown.

Methods: To study ET-1 levels in MS, we used C57BL/6 mice with or without induced experimental autoimmune encephalomyelitis (EAE), and the score history was taken. The brain ET-1, TNF, and iNOS levels were measured by qPCR and ELISA. To investigate ET-1's role in microglia activation, HMC3 cells were treated with ET-1 in the presence or absence of endothelin receptor B (ETRB) antagonist, BQ788. TNF levels were measured using ELISA. Nitric Oxide (NO) production was measured using Griess Reagent. ROS production was measured using the MUSE Oxidative Stress kit.

Results: We found that the ET-1 gene and protein were upregulated by 1.5 folds (±0.4, $p<0.05$) in EAE mice compared to the control. ET-1 levels were correlated with EAE score at onset ($R2 = 0.9282$, $p<0.05$). In addition, TNF and iNOS were upregulated by 4.6 folds and 3.8 folds in EAE mice, respectively. TNF levels were correlated with ET-1 levels ($R2 = 0.3760$, $p<0.05$). Moreover, ET-1 increases TNF levels by 90% ($p<0.05$) in HMC3 cells, and it was decreased to basal levels in the presence of the ETRB antagonist. iNOS, NO, and ROS production are induced by ET-1 ($p<0.05$), and treatment with the ETRB antagonist was able to decrease them ($p<0.05$).

Conclusion: These data suggest that *in vitro* administration of ET-1 was able to activate microglia, increasing significantly inflammatory cytokines levels and NO and ROS formation. This is a novel mechanism of microglial cell activation and will provide key information to understand MS pathogenesis.

Title: Rit1 deficiency alters cerebral lipid metabolism and reduces white matter tract oligodendrocytes and conduction velocities

Authors: *D. ANDRES[1], L. WU[2], F. WANG[2], C. MONCMAN[2], M. PANDEY[2], H. CLARKE[2], H. FRAZIER[2], L. YOUNG[2], M. GENTRY[2], W. CAI[3], O. THIBAULT[2], R. SUN[2];
[1]Col. of Med., Lexington, KY; [2]Univ. of Kentucky Col. of Med., LEXINGTON, KY; [3]New York Inst. of Technol., Old Westbury, NY

Abstract: Oligodendrocytes (OLs) generate lipid-rich myelin membranes that wrap axons to enable efficient transmission of electrical impulses. Using a *RIT1* knockout mouse model and *in situ* high-resolution matrix-assisted laser desorption/ionization mass spectrometry imaging (MALDI-MSI) coupled with MS-based lipidomic analysis to determine the contribution of RIT1 to lipid homeostasis. Here, we report that RIT1 loss is associated with altered lipid levels in the central nervous system (CNS), including myelin-associated lipids within the corpus callosum (CC). Perturbed lipid metabolism was correlated with reduced numbers of OLs, but increased numbers of $GFAP^+$ glia, in the CC, but not in grey matter. This was accompanied by reduced myelin protein expression and axonal conduction deficits. Behavioral analyses revealed significant changes in voluntary locomotor activity and anxiety-like behavior in $RIT1^{KO}$ mice. Together, these data reveal an unexpected role for RIT1 in the regulation of cerebral lipid metabolism, which coincide with altered white matter tract oligodendrocyte levels, reduced axonal conduction velocity, and behavioral abnormalities in the CNS.

Title: Galactosylceramidase deficiency and pathological abnormalities in cerebral white matter of Krabbe Disease

Authors: D. IACONO[1,2], S. KOGA[3], H. PENG[1,2], J. DAIKER[4], A. R. HERDT[1,2], M. H. GELB[4], D. W. DICKSON[3], ***C. W. LEE**[1,2];

[1]Biomed. Res. Inst. of New Jersey, Cedar Knolls, NJ; [2]Atlantic Hlth. Syst., Morristown, NJ; [3]Neurosci., Mayo Clin., Jacksonville, FL; [4]Univ. of Washington, Seattle, WA

Abstract: Krabbe Disease (KD) is an autosomal recessive disorder resulting from loss-of-function mutations in the *GALC* gene. Functional deficiency of galactosylceramidase (GALC) leads to progressive demyelination in the nervous systems. Psychosine, which can only be degraded by GALC, is a key player in pathologic cascades. Despite the central role of GALC in KD pathomechanism, investigations of GALC protein deficiency are largely absent, due in part, to the lack of sensitive antibodies available. Leveraging custom antibodies that can detect endogenous GALC, we demonstrated that GALC was predominantly localized to oligodendrocytes in cerebral white matter of infant brain. Mature GALC was also quantitatively detected by western blot and correlated to enzyme activity. The common p.Ile562Thr polymorphic variant was associated with reduced mature GALC protein and activity. In three infantile KD brains, homozygous null mutations led to deficiency in total GALC protein and activity. Interestingly, although GALC activity was absent, normal levels of total GALC protein were detected in a later-onset KD brain using our custom ELISA, which suggests its potential use in KD prognosis. Among the infantile KD brains, we quantified a 5-fold increase in psychosine levels, and also a marked increase in acid ceramidase and hyperglycosylated LAMP1 levels in periventricular white matter, a major pathological site, when compared with age-matched normal controls. While near complete demyelination was observed in the infantile KD brains, we quantified that an early-infantile case (10 months) had about 3-fold increase in both CD68-positive globoid cells and CD8-positive T lymphocytes in the white matter, compared with a slower progressing infantile case (21 months). The results suggest a positive correlation between clinical severity and neuropathology. Overall, our findings have advanced the understanding of GALC protein biology in the context of normal and KD brain white matter. We also revealed neuropathological changes that may provide insights to understand KD pathogenesis.

Title: The correlation between in-vitro conduction velocities and myelination provide insights into the role of myelin in nerve signal transmission

Authors: *H. VILA-MERKLE[1], N. W. HANSEN[2], J.-F. PERRIER[2], T. DYRBY[3,1];
[1]Copenhagen Univ. Hosp. Amager and Hvidovre, Hvidovre, Denmark; [2]Dept. of Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [3]Dept. of Applied Mathematics and Computer Sci., Tech. Univ. of Denmark, Kongens Lyngby, Denmark

Abstract: Background: The timely and accurate delivery of information is vital for the proper functioning of the nervous system. This directly depends on the regulation of neuronal conduction velocity, which is necessary to ensure the precise execution of motor skills, sensory integration, and cognitive functions. In vertebrates, rapid signal transmission along nerve fibers is made possible by the myelination of axons. However, alterations in myelin integrity can lead to changes in conduction. To date, the specific mechanisms underlying the systematic regulation of conduction velocity and its relationship with myelin alterations remains poorly understood. The objective of this study was to investigate how acute hypoxia affects action potential conduction in a brain slice preparation, and if these changes are associated with alterations of myelin integrity. Methods: In this study, we used in-vitro extracellular recordings of evoked compound action potentials in mice brain slices to investigate the impact of hypoxia on axonal conduction velocity along the corpus callosum. Additionally, electron microscopy images were collected on the same tissue to correlate the myelin layer structure in relation to function of the hypoxia-induced alterations. Results: After 5 minutes, the hypoxic condition elicited notable alterations in the conduction velocity, as evidenced by changes observed in both the amplitude and latency of evoked potentials following electrical stimulation of the corpus callosum. The observed effects primarily targeted myelinated axons, as evidenced by a distinct shift in conduction velocity alterations favoring a worsening trend in myelinated axons compared to unmyelinated axons. Furthermore, preliminary electron microscopy evidence suggests the presence of alterations, such as loosening, in the myelin layer. However, it is important to consider that further investigations will determine whether the observed myelin alterations was indeed caused by the acute hypoxia. Discussion: In this study, we demonstrate a reduction in conduction velocity among a cohort of myelinated axons, which could be indeed caused by the loosening of myelin due to exposure to hypoxia.

Abstract: Damage to the myelin sheath that protects axons in the central nervous system (CNS) is a hallmark of inflammatory demyelinating diseases such as multiple sclerosis (MS). Cuprizone-induced demyelination in rodents is a widely used model for studying demyelination, remyelination, and related changes in the brain tissue. Cuprizone is a copper chelator, which when added to a rodent's regular diet induces death of mature oligodendrocytes and subsequent demyelination of the CNS. We previously showed that neuronal firing rate is decreased in CA1 and DG areas of the mouse hippocampus within several days following cuprizone ingestion and remains low for multiple weeks. Here, we added longitudinal, label-free monitoring of myelin using third-harmonic generation (THG) in parallel to monitoring of neuronal firing patterns in the same mice and monitoring potential differences between male and female mice. Our data suggest a link between the functional and structural deficits in the mouse hippocampus caused by cuprizone-induced demyelination. Using this integrated structural-functional recording approach, we identified that functional loss of neuronal activity and structural loss of myelin showed a trend towards correlation, but that the functional deficits were apparent much earlier than myelin loss. We also found trends toward functional, but not structural, sex differences, where neuronal firing rates of female mice were decreased more severely during the cuprizone-induced demyelination period than these of males. In summary, the application of nonlinear microscopy methods enables longitudinal detection of same-subject demyelination-related deficits, as well as the ability to link deficit progression with brain function, thereby facilitating a new approach to test the efficacy of neuroprotective treatments and how they may modulate or preserve brain circuits.

Title: Oligodendrocyte precursor cell survival after differentiation increases with quiescence depth and following demyelination

Authors: *M. STOCKTON, E. HUGHES;
Cell and Developmental Biol., Univ. of Colorado, Anschutz Med. Neurosci. Grad. Training Program, Aurora, CO

Abstract: Oligodendrocytes are the myelin-forming cells of the central nervous system. New oligodendrocytes are produced throughout life from oligodendrocyte precursor cells (OPCs) in a process called oligodendrogenesis. Oligodendrogenesis is an inefficient process; most differentiating OPCs die before they generate myelinating oligodendrocytes. In demyelinating diseases, decreased oligodendrogenesis is thought to underlie limited regeneration. However, it remains unclear whether this deficiency is due to inhibited OPC differentiation or reduced survival of OPCs after differentiation. Furthermore, emerging evidence suggests OPCs have functionally distinct populations. Here, we aim to understand the factors and the functional consequences of OPC heterogeneity in health and disease.
To explore OPC heterogeneity, we use longitudinal *in vivo* 2-photon imaging under healthy conditions in young adult mice. Using a "real-time" fate mapping approach (*Olig2-CreER;R26-lsl-tdTom;MOBP-eGFP mice*), we determined proliferation, differentiation, and oligodendrogenesis for individual OPCs over 12 weeks (n=136-197 OPCs / mouse). By examining cell-cycle length for each OPC, we found a subset that existed in a non-proliferative state of quiescence. Therefore, we subdivided the OPC population into 3 groups according to the depth of quiescence: Active OPCs (0-7 days since last division), shallowly quiescent OPCs (8-42 days since last division), and deeply quiescent OPCs (43+ days since last division) to explore functional heterogeneity. In healthy mice, we found that survival after differentiation was higher for deeply quiescent OPCs (47.7±2.2%) compared to shallowly quiescent (14.0±2.3%) and active OPCs (0.0±0.0%). Next, we investigated OPC behaviors following demyelination injury induced by acute cuprizone treatment (0.2% cuprizone diet for 3 weeks; n=4). Two weeks after demyelination, the daily rate of OPC differentiation (1.8±0.1%) was not altered compared to the healthy mice (1.2±0.2%). However, the survival of OPCs after differentiation was increased in cuprizone treated (56.1±9.1%) compared to healthy mice (13.8±5.9%). Survival after differentiation was higher for deeply quiescent OPCs (75.5±9.2%), compared to both shallowly quiescent (42.6±3.2%) and active (3.1±3.1%) OPCs in the demyelinated mice. Finally, we found that the pool of deeply quiescent OPCs produced 58±6.3% of the new oligodendrocytes during remyelination despite only making up 23.6±2.2% of the total OPC population. Together, these data suggest that deeply quiescent OPCs may be a functionally distinct population in the healthy and remyelinating brain.

Title: Asic3 delay nerve regeneration process to prolong mechanical allodynia

Authors: *J.-Y. HSU, W.-H. SUN;
Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan

Abstract: ASIC3 delay nerve regeneration process to prolong mechanical allodynia Jia-Yun Hsu [1] and Wei-Hsin Sun [1,2*1] Program in Molecular Medicine, College of Life Sciences, National Yang Ming Chiao TungUniversity, Taipei 112, Taiwan[2] Department of Life Sciences and Institute of Genome Sciences, National Yang Ming Chiao TungUniversity, Taipei 112, TaiwanNeuropathic pain is triggered by lesions on peripheral or central nervous systemwhich caused spontaneous and abnormal pain sensation, and approximately 7% of theglobal population is affected with long-term physical and mental health condition.Wallerian degeneration as a factor involved in nerve injury-induced pain sensation,including axonal degeneration and Schwann cell degradation. Previous studies haveshown that delayed sciatic nerve degeneration postpones chronic constriction injury(CCI)-induced pain and sciatic nerve regeneration reverses pain. Acid-sensing ionchannel 3 (ASIC3), a proton-gated cation channel, is involved in mechanical allodyniainduced by nerve injury and inflammation. We previously demonstrated that *Asic3*$^{-/-}$mice have less loss of dorsal root ganglion neurons at week 1 post CCI surgery andmore small neuron regeneration at week 8 by lowering M1/M2 ratio on sciatic nerve,which contributes to the relief of mechanical allodynia from week 8. However, theunderlying mechanism for ASIC3-mediated nerve degeneration to relieve pain is stillunclear. We performed CCI on the sciatic nerve as a model of neuropathic pain toexamine temporal changes of the nerve. Here, we found that nerve degeneration beganfrom the injury site to distal stump and then to proximal stump on sciatic nerve, whilethe regenerative process was started from the proximal stump through the injury site todistal stump in CCI mice. Histological analysis of axons reveals that nerve regenerativephase includes two sequential stages: stage I, medium-diameter fiber regeneration andstage II, large-diameter fiber regeneration. ASIC3 deletion slightly slowed down thedegeneration process but facilitated the regeneration process to stage II. The earlyregeneration could partially contribute to the shortening of CCI-induced mechanicalallodynia in *Asic3*$^{-/-}$ mice. Accordingly, ASIC3 modulation on the regeneration processof the sciatic nerve could be critical to the maintenance of mechanical allodynia afternerve injury.

Abstract: Leukodystrophies are a group of genetic diseases that affect the white matter of the central nervous system (CNS). Clinical presentations are variable with over fifty genetic causes identified to date. *De novo* heterozygous stoploss mutations in *CLDN11,* the gene encoding the myelin tight junction protein claudin-11, have recently been identified as the cause of an early-onset neurodegenerative disease termed hypomyelinating leukodystrophy 22 (HLD22). How such mutations in *CLDN11* cause HLD22 is not well understood. To elucidate the pathogenic mechanisms involved, we first established immortalized cell lines with stable expression of wild-type (WT) or mutant (MT) claudin-11. Western blot analysis showed that the stoploss mutation results in the elongation and reduced stability of MT claudin-11. Furthermore, immunofluorescence imaging showed markedly reduced surface abundance of MT claudin-11 relative to WT. Using bafilomycin A1 and lactacystin treatments, we demonstrate that the reduced expression of MT claudin-11 reflects increased clearance through lysosomal and proteasomal pathways. As endoplasmic reticulum (ER) stress has been implicated in the pathogenesis of a number of myelinopathies, we evaluated the response of the immortalized MT and WT claudin-11 cell lines to ER stressors. MT claudin-11 cells showed elevated cell death and reduced viability in response to thapsigargin, suggesting that ER stress may contribute to the pathogenesis of HDL22. Overall, our results to date point to decreased protein stability and increased ER stress as potential mechanisms contributing to the pathogenesis of HLD22.

Title: Elucidating the role of the JAK-STAT cell signaling pathway in oligodendrocyte maturation in vitro

Authors: *S. TYAGI[1], V. SHRIVASTAVA[1], D. DEY[1], S. RANI[1], J. B. SHARMA[2], J. K. PALANICHAMY[1], S. SINHA[1], P. SETH[3], S. SEN[1];

Abstract: Perinatal hypoxic injury in preterm neonates results in neurological deficits. Oligodendrocyte (OL) maturation arrest is usually associated with such deficits. Premyelinating OL predominate in preterm infants, and are particularly vulnerable to hypoxic injury. Understanding the mechanistic pathways of OL development is a prerequisite to developing therapeutic strategies to overcome OL maturation arrest. Analyzing transcriptional datasets (RNA sequencing) in primary OL cells derived from human fetal neural stem cells (FNSCs) revealed the involvement of the JAK-STAT cell signaling pathway in terminal OL maturation. To validate our findings, we used the MO3.13 cell line resembling premyelinating OL, which can be differentiated into mature OL over 7 days, using phorbol 12-myristate 13-acetate (PMA). Morphological changes, increased expression of mature-OL marker MBP (qPCR and ICC) and decreased expression of premyelinating OL markers NG2 and O4 (ICC) confirmed the differentiation of MO3.13 into mature OL (n=5). Flow cytometry indicating increased expression of MBP also confirmed the differentiation (n=3). Upregulation of the ligand IL-6 and the transcription factor STAT3 using ELISA and qPCR respectively, validated the involvement of the JAK-STAT pathway during OL maturation in MO3.13 cells (n=3). Interestingly, while total STAT3 levels remained constant, phosphorylated STAT3 (pY705) levels increased during MO3.13 differentiation, exhibiting the highest expression at day 7, using western blotting (n=3). MO3.13 differentiation was induced using PMA, with and without STAT3 specific inhibitor (Stattic). Flow cytometry demonstrated MBP-positive cells (treated with PMA alone) to be 51% (day 3), 65% (day 5), and 99% (day 7) while they measured 42% (day 3), 46% (day 5), and 49% (day 7) with both PMA and Stattic, thereby confirming the involvement of the JAK-STAT pathway in terminal OL maturation (n=3). Western blotting confirmed an increase in phosphorylated STAT3 (pY705) while total STAT3 remained constant while differentiating MO3.13 with PMA alone (n=3). However, when STAT3 specific inhibitor (Stattic) was added along with PMA, phosphorylated STAT3 (pY705) levels decreased in a time-dependent manner with no expression detected at day 7 (n=3). Morphological changes also confirmed the results. These novel findings highlight the involvement of the JAK-STAT pathway in OL maturation. This may aid in the development of new therapeutic strategies to overcome the OL maturation arrest associated with perinatal hypoxic injury. It may also contribute to developing therapeutics for other demyelinating disorders.

Title: Enteric Glial Cells as a possible source of myelin antigen in Inflammatory Bowel Disorders and Multiple Sclerosis

Authors: *R. BROWN, H. LE, A. NIVEN, A. GAULTIER;
Neurosci., The Univ. of Virginia, Charlottesville, VA

Abstract: Multiple Sclerosis (MS) is a chronic neurodegenerative disorder marked by an autoimmune response against myelin in the Central Nervous System (CNS). There is a link between the gut and MS as patients frequently present with gastrointestinal symptoms, suggesting dysregulation of local motility circuits in the Enteric Nervous System (ENS). Further, patients with Inflammatory Bowel Disorders (IBDs) such as Ulcerative Colitis have an increased risk of developing MS. Enteric glial cells (EGCs) are observed throughout the gastrointestinal tract where they are closely associated with immune cells. EGCs are poised to contribute to T cell-mediated intestinal inflammation, as they express antigen presentation machinery and costimulatory molecules. Although the ENS is devoid of conventional myelin sheaths, EGCs express several myelin proteins such as Proteolipoprotein 1 (PLP1) and Myelin Basic Protein (MBP). Further, PLP1 and MBP are major constituents of myelin in the CNS and are targeted by the immune system in MS. As such, autoimmune reactions initiated by EGC antigen presentation could potentially act to trigger CNS autoimmunity in MS. I have demonstrated that EGCs are capable of antigen presentation via MHC I and MHC II in *vitro.* To model IBD and MS comorbidity, I have utilized rodent models of colitis paired with the MS model, Experimental Autoimmune Encephalomyelitis (EAE). I have observed upregulation of MHC I by EGCs in the Dextran Sodium Sulfate colitis model as well as EAE. However, I see little to no MHC II expression by EGCs in either of these models. Ongoing work includes studying how comorbidity of these models affects EGC MHC I/II expression levels and intestinal T cell clones that recognize EGC derived peptides. I am also further characterizing the functional relevance of EGC antigen presentation in disease states by investigating whether disrupting EGC antigen presentation using genetic mouse models will impact disease severity. These results could provide insights into the role of EGCs in the etiology and pathogenesis of IBDs and MS.

Abstract: Ermin, encoded by the gene *ERMN*, is an actin-binding protein expressed almost exclusively in mature oligodendrocytes, the myelination cells of the central nervous system (CNS). Ermin has been shown to play a role in oligodendrocyte arborisation as well as in maintaining myelin integrity. Mutations predicted to truncate and abrogate Ermin function have been identified in a multi-incident multiple sclerosis (MS) family. Furthermore, we have recently shown that Ermin-deficient mice exhibit a number of myelin abnormalities such as outfolding, fragmentation and altered compaction, as well as increased susceptibility to experimental autoimmune encephalomyelitis, a widely-used model of MS. While nonsense, truncating mutations in *ERMN* are rare, a large number of coding, single-nucleotide variants (SNVs) are substantially more frequent in the general population. In this study, we used *in silico* analyses to identify potentially pathogenic, naturally-occuring SNVs in *ERMN*. We followed this with *in vitro* studies assessing the impact of selected SNVs on Ermin function including measures of cell morphology, expression levels, and actin interactions. Our study uncovered a number of SNVs with marked impact on Ermin-related measures and support further investigation of Ermin variants as a potential risk factor for white matter disorders.

Title: Store-operated calcium entry-dependent signaling in adult OPCs acts to delay oligodendrocyte differentiation following demyelination

Authors: *R. RAVICHANDAR, R. MUTHAIAH, D. SARASWAT, F. GADELKARIM, R. A. SEIDMAN, F. J. SIM;
State Univ. of New York, Univ. at Buffalo, Buffalo, NY

Abstract: One of the hallmarks of multiple sclerosis (MS) is inefficient/failed remyelination that contributes to neurodegeneration. Inhibition of $M_{1/3}R$ in oligodendrocyte progenitor cells (OPCs) promotes differentiation and remyelination. However, the operant downstream mechanisms are poorly understood. $G_{\alpha/q}$ receptor activation triggers endoplasmic reticulum Ca^{2+} release and replenishment via store operated calcium entry (SOCE) modulated by Ca^{2+} sensors, namely STIM1 and STIM2. Our previous gain-of-function studies in human OPCs showed that specific optogenetic activation of SOCE acts to reduce differentiation *in vitro*. As such, we hypothesize that OPC SOCE acts to delay or prevent OPC differentiation and may thereby impair remyelination. In this study, we utilized a tamoxifen inducible cre-lox strategy to conditionally knockout (cKO) SOCE in adult OPCs prior to lysolecithin-induced spinal cord demyelination. *NG2creER;Stim1/2* floxed mice and cre-negative littermates were injected at 8-weeks with tamoxifen. Following demyelination, we analyzed OPC density and proliferation at 5 days post-lesion (dpl). *Stim1* or *Stim2* cKO had no significant effect on the density of $Olig2^+$ cells at 5 dpl and did not alter the proportion of EdU^+ proliferating OPCs. Likewise, the density of $Pdgfra^+$ OPCs was not influenced at 7 dpl. However, at 7 dpl, both *Stim1* and *Stim1/2* cKO mice exhibited increased densities of $CC1^+$ and $Plp1^+$ oligodendrocytes (OLs) as well as increased proportion of $CC1^+$ OLs among the Olig2-defined OL lineage pool (2-way ANOVA, $p < 0.05$). As the individual effects of *Stim2* and the interaction between *Stim1/2* were not significant, these results indicate that *Stim1* alone plays a critical role. Next, to determine whether pharmacological inhibition of SOCE may improve OL differentiation following demyelination, we intraspinally injected a small molecule Orai1 inhibitor CM4620 (Zegocractin) at the time of demyelination in wild-type mice. At 7 dpl, 50 μM CM4620 treatment induced a significant increase in the proportion of mature $CC1^+$ OLs (Tukey $p = 0.017$). Thus, SOCE inhibitor treatment may act in a similar manner to *Stim1* cKO to promote differentiation. Future studies will determine the effects of *Stim1* cKO on remyelination, investigate the mechanisms of action of CM4620, and determine whether systemic treatment can influence remyelination in other models of demyelination. These results indicate that OPC-expressed Ca^{2+} sensing proteins can modulate OL differentiation following demyelination and may offer a novel therapeutic means to enhance myelin repair.

Title: 2-o sulfation of OPC-expressed heparan sulfate impairs oligodendrocyte differentiation following experimental demyelination

Authors: *R. MUTHAIAH[1], R. RAVICHANDAR[1], B. KULKARNI[1], R. JUSZCZAK[1], D. XU[2], F. J. SIM[1];
[1]Pharmacol. and Toxicology, [2]Oral Biol., The New York State Univ. at Buffalo, Buffalo, NY

Abstract: Chronic demyelination in multiple sclerosis (MS) is the result of a failed regenerative process known as remyelination. Remyelination largely occurs via the recruitment and differentiation of parenchymal oligodendrocyte progenitor cells (OPC). Deposition and alterations in the extracellular matrix following demyelination play a significant role in the failure of remyelination in MS and directly influences OPC signaling. We recently described a novel role of heparan sulfate proteoglycans (HSPGs) following experimental demyelination. 6-*O*-endosulfatases (*Sulf1/2*) specifically edit the pattern of 6-*O* sulfation (6S) on HSPGs post-synthetically and are highly expressed by human and mouse OPCs following demyelination. We have previously shown that the conditional knockout (cKO) of *Sulf-1/2* in OPCs accelerated recruitment, differentiation and remyelination following demyelination likely via inhibition of BMP and WNT signaling. In this study, we tested the hypothesis that the synthesis and pattern on sulfation on OPC-expressed HSPGs themselves plays a critical role in OPC function following demyelination and that removal of 2-*O* sulfation (2S) would result in altered OPC recruitment and/or differentiation. Adult *NG2creER;Hs2st1* floxed and cre-negative littermate controls were injected with tamoxifen prior to lysolecithin-induced spinal cord demyelination. Immunofluorescence for highly 2S/6S sulfated HSPG was enriched around a subset of OPCs at 7 days post lesion (dpl) and this was significantly reduced following *Hs2st1* cKO ($p = 0.01$). At 5 dpl, *Hs2st1* cKO did not alter OPC proliferation (%EdU$^+$) but was associated with a small increase in overall Olig2$^+$ oligodendrocyte (OL) lineage cell density. By 7 dpl, when OL differentiation occurs in this model, *Hs2st1* cKO significantly increased both OL lineage density and the proportion of CC1$^+$ mature oligodendrocyte among Olig2$^+$ cells ($p < 0.05$, $n = 5$ / group). Overall, this resulted in a more than 2-fold increase in oligodendrocyte density in *Hs2st1* cKO mice ($p < 0.01$). Ongoing studies will determine whether increased oligodendrogenesis following *Hs2st1* ablation is a direct result of loss of 2S or via a compensatory increase in 6S that is associated with improved remyelination. Together, these studies further implicate the role of HSPG dependent signaling in the context of demyelination and highlight the potential for HS modulators to enhance myelin repair.

Title: Interleukin-12 Mediates OPC Maturation and Myelin Morphogenesis

Authors: A. MERCHAK, ***S. MOY**, A. THAKUR, L. BROWN, T. RAGHAVAN, R. BEITER, E. SLOGAR, A. GAULTIER;
Univ. of Virginia Neurosci. Program, Charlottesville, VA

Abstract: Multiple sclerosis (MS) is a multifaceted, chronic disorder of the central nervous system in which the myelin sheath is destroyed due to an autoimmune response. Despite decades of work, MS has no cure and remains a debilitating disease with an enormous economic and social cost. Research around remyelination and myelin maintenance during disease is ongoing. Harnessing the intrinsic signaling of oligolineage cells to promote maturation and differentiation of oligodendrocyte precursor cells (OPCs) into myelinating oligodendrocytes is one strategy for therapeutic intervention. Interleukin 12 (IL12) is a cytokine produced by macrophages, dendritic cells, and neutrophils in the periphery, and by microglia in the brain to promote T cell differentiation. We aimed to test the effects of IL-12 cytokine signaling in oligolineage cells during pathological demyelination such as that seen in MS. We incubated primary OPCs with IL-12 family cytokine which showed a reduction of relative expression of *Myrf* and *Mbp*, transcripts involved in myelin formation. Primary cultures from IL12Rβ2-/- mice do not differentiate compared to cultures from C57BI/6J mice. We used immunofluorescent imaging to visualize the organization of OPCs and oligodendrocytes within the corpus callosum. Female IL12Rβ2-/- mice have disrupted myelin formation including disorganized axonal tracts and higher counts of OPCs, while male mice showed no differences between IL12Rβ2-/- and their C57BI/6J age-matched counterparts (10-15 weeks old). Taken together, these results suggest that the absence of IL12 shown in our constitutive IL12Rβ2 knockout has a detrimental effect on the maturation and differentiation of OPCs into myelinating oligodendrocytes both *in vitro* and *in vivo*. Conversely, data from the stimulation of cells with IL12 suggests that overproduction of IL12 may also have an inhibitory effect on OPC differentiation, highlighting the necessity of appropriate IL12 levels in the brain. These studies underscore the importance of understanding age-specific differences in neuroimmune signaling to find effective therapeutics for MS and other demyelinating disorders such as Alzheimer's disease.

Title: Voltage-sensitive dye imaging reveals disrupted interhemispheric communication in a cuprizone-induced demyelination mouse model of multiple sclerosis

Authors: *K. TSUKUDA[1,2], M. MIWA[3], M. TAKETOSHI[2], Y. TOMINAGA[2], K. NAKASHIMA[1,2,3], T. TOMINAGA[1,2,3];

Abstract: Multiple sclerosis (MS) is a chronic neurological disease associated with extensive demyelination within the central nervous system (CNS). Although the cause of MS onset is unclear, animal models such as autoimmune encephalomyelitis (EAE) and cuprizone (CPZ)-fed mice induce demyelination and are used as MS pathology. The corpus callosum (CC) plays a critical role in facilitating interhemispheric communication between layer II/III neurons in the cerebral cortex and is frequently affected by demyelination in both animal models and human patients. Although previous studies have investigated the electrophysiological aspects of nerve conduction in models of demyelination within the CC, a comprehensive understanding of its impact on interhemispheric communication remains to be discovered. Therefore, the aim of this study was to investigate the effects of demyelination on interhemispheric communication across the CC by visualizing neural circuit activity using voltage-sensitive dye (VSD). The CPZ-induced model of MS (CPZ mice) was established by subjecting male C57BL/6 mice to a 0.3% CPZ-containing powdered diet for six weeks. Acute coronal brain slices of 350 μm thickness were used in the study, ranging from 1 to -0.5 mm from the bregma. We used a wide-field microscope with an imaging system (MiCAM05, Brainvision Ltd.) that is designed for a large field of view (10 mm). We used SR95331 (Gabazine: GZ; 10 μM), a GABAA receptor inhibitor, to enhance interhemispheric connectivity throughout the experiments. Upon electrical stimulation of cingulate cortex area 1 (Cg1) within the anterior cingulate cortex (ACC), a significant optical excitatory signal propagated across cortical layers toward Cg2 in both control and CPZ mice. In control mice, this propagation resulted in interhemispheric spread across the CC. However, the interhemispheric spread was rarely observed in slices obtained from CPZ mice. These results suggest that the transmission of neural excitation to the opposite side across the CC is reduced due to demyelination. The slices showing decreased interhemispheric connectivity in CPZ mice showed demyelination on histological analysis. These results suggest that demyelination induced by the CPZ mouse model disrupts efficient action potential propagation between the left and right cerebral cortices through the CC. By employing optical imaging techniques, we can gain valuable insights into the pathophysiology of MS and explore potential therapeutic approaches and novel treatments.

Abstract: Glioblastoma (GBM) is a highly aggressive and invasive form of brain cancer. The 5-year survival rate of those diagnosed with GBM is less than 10% and, on average, patients have 12-15 months of survival following final diagnosis. Recent research has implicated mechanobiology in the development of the aggressive phenotype of this cancer, in which biochemical and biophysical cues encoded in the tumor microenvironment may promote cell proliferation and invasion. The extracellular matrix (ECM) is a critical component of the microenvironment and stiffening of the GBM ECM has been shown to enhance GBM cell migration and proliferation. Metabolic reprogramming is likely needed to support this proliferative and migration response but the specific changes as they relate to microenvironmental stiffness are not yet known. The purpose of this study was to investigate the effect of ECM stiffness on the metabolic profile of GBM cells. To do this, we seeded U87MG cells on premanufactured collagen coated hydrogels of 100Pa, 4kPa, and 25kPa stiffness and conducted a variety of assays that included mass spectrometry based metabolomics, label-free two-photon imaging for optical REDOX ratio (NADH/FAD) providing spatial cellular assessment and heterogeneity and morphometry, RNA sequencing, and imaging of cell migration. Results were indicative of metabolic reprogramming stimulated by increased ECM stiffness, which was accompanied by changes in cell morphology and migration. Metabolomic data indicated an increase in key metabolites and amino acids along the aerobic glycolysis and glutamine metabolism pathways as ECM rigidity increased, suggesting that metabolic activity across multiple pathways is affected by ECM rigidity. Both metabolomics data and two-photon imaging of the optical REDOX ratio, identified a decrease in FAD and an increase of NADH as ECM stiffness increased. These results indicated a decrease in oxidative phosphorylation with an increase in ECM stiffness, suggesting ECM stiffening signals for transition from oxidative phosphorylation to glycolysis. RNA sequencing identified over 100 significant changes in RNA expression between both the 100 and 4kPa and the 100 and 25kPa stiffnesses, and provide insight into the effect ECM rigidity has on gene expression relating to metabolism and cell proliferation. This study shows that metabolic reprogramming occurs in U87MG cells toward

increased glycolysis and glutaminolysis as the ECM stiffness increases, indicating a potential link between the biomechanical microenvironment with metabolic activity that could support the aggressive and lethal nature of GBM.

Title: Hypoxic glioblastoma-derived extracellular vesicles induce microglial polarization to pro-tumorigenic phenotype

Authors: *S. PANCHOLI[1], P. PILLAI[2];
[1]Zoology, The M.S. Univ. of Baroda, Vadodara, India; [2]Zoology, Dept. Of Zoology, Vadodara, India

Abstract: Glioblastoma multiforme (GBM) is marked by its highly heterogeneous, immunosuppressive, and hypoxic tumor microenvironment (TME) often resulting into limited success in therapies against GBM. Brain resident immune cells microglia are reprogrammed to an immunosuppressive phenotype by GBM tumor cells via release of extracellular vesicles carrying oncogenic immunomodulatory non-coding molecules such as long noncoding RNAs (lncRNAs). Although many lncRNAs are dysregulated in GBM, much is still unknown regarding its involvement in microglial polarization and pathophysiology. Here, we investigated the involvement of hypoxic glioblastoma-derived extracellular vesicles (GDEVs) in microglial polarization to a pro-tumorigenic phenotype with the enriched expression of H19 lncRNA in glioblastoma-derived exosomes. Human GBM cells (U87MG) were subjected to normoxic and hypoxic stimulus to closely mimic the *in vivo* TME. Results demonstrated the increase in the number of hypoxic exosomes release ($9.8*10^7$ particles/ml) as compared to normoxic ($6.0*10^7$ particles/ml) when characterized through Zeta view (NTA). *In-silico* database search and lncRNA profiling for glioblastoma-derived exosomes identified the enrichment of lncRNA H19 in hypoxic exosomes that is widely known to aid in GBM proliferation. To further study the functional effect of hypoxic exosomes on recipient microglia, we demonstrated nuclear localization of purinergic receptor (P2RY12) in microglia when co-incubated with hypoxic U87MG exosomes. The results obtained are in line with the studies suggesting the association of nuclear localization of P2RY12 with the increase in glioma grade and microglial chemotaxis. Hypoxic conditioned media treatment to microglia for 24 hrs significantly increased the

expression of M2 activated genes CD163, CD206, IL-10, STAT-3, PPAR-γ, ADORA-3, TMEM-119 and reduced phagocytic index thereby suggesting the induction of M2 like phenotype and altered phagocytosis. Together, our findings provide evidence to the involvement of GDEVs in microglial activation which enables us to further study the substantial role of lncRNA H19 in microglial dysregulation and its potential as a key biomarker for GBM.

Title: Antiproliferative and apoptotic effects induced by Ibervillae sonorae root extract in glioma cell lines

Authors: *C. RODRÍGUEZ-PÉREZ[1], M. A. TORRES-RAMOS[2], C. TREJO-SOLÍS[2]; [1]Natl. Inst. of Neurol. and Neurosurg., MEXICO CITY, Mexico; [2]Inst. Nacional de Neurología y Neurocirugía, Mexico City, Mexico

Abstract: Bioactive compounds in medicinal plants may be a good source of new treatments for diseases like cancer. One of the most aggressive nervous system tumors is the glioblastoma multiforme, which, despite new drugs, is still mortal and has a low survival rate. This study aimed to characterize and know the antiproliferative effects of *Ibervillae sonorae* over human glioma cell lines. *Ibervillae sonorae* is a plant from the Northwest of Mexico used traditionally for natives to treat diabetes and dermis infections. Root extracts of *Ibervillae sonorae* were obtained, and their effects on cellular proliferation and apoptosis in LN18 and U87 glioblastoma cell lines were evaluated. The results showed a dose-response and time-dependent effect on cell viability using the MTT assay and the downregulation of PCNA and cyclin D3. Also, the apoptotic cell death by the TUNEL test and western blot for Bcl-2, Bax, and Caspase 3 proteins were observed. The extract doesn't show a cytotoxic effect on the fibroblast BJ cell line.

Title: Extracellular vesicle characteristics in response to iron in glioblastoma cell types

Authors: *E. TUFANO[1], K. PALSA[2], J. CONNOR[2];
[1]Penn State Col. of Med. Neurosci. Grad. Program, Hershey, PA; [2]Neurosurg., Penn State Col. of Med., Hershey, PA

Abstract: Glioblastoma (GBM) is a very aggressive brain tumor with poor survival rates, emphasizing the need to understand the molecular mechanisms behind the disease. Extracellular vesicles (EVs) play extensive roles in GBM progression, including cell migration, invasion, immune responses, and treatment resistance. Iron is a key element that promotes GBM cell proliferation and is preferentially taken up and used by cancer stem cells (CSCs) to promote their growth. However, little is known about how iron impacts GBM EV number, cargoes, and functionality. Iron has been shown to increase CD63 positive vesicle release in several cell types due to the presence of an iron responsive element (IRE) in the 5' untranslated region (UTR) of this protein. Here, we examine the influence of iron on EV release from two GBM cell lines, T387 and LN229, which are CSC and non-CSC lines, respectively. Using Nanoparticle tracking analysis (NTA), we have found that 100 μM of ferric ammonium citrate (FAC) increases EV release in the CSC line after 24 hours compared to the untreated control, but not the non-CSC line. These data are complemented by changes to CD63 expression by Western blot in the CSC line, reflective of the IRE. We further find that these differences in EV release are rescued upon treatment with an EV inhibitor (GW4869) in the CSC cell line, but not the non-CSCs, looking at total EVs by Western blotting. These results suggest key mechanistic differences in EV release in response to iron between these cell populations in the tumor microenvironment (TME), prompting our interest in the related EV cargoes. Differences in iron metabolism between CSC and non-CSCs in GBM have been extensively studied, but the discrepancy in EV characteristics between these cells is a novel concept. Iron has been shown to influence several miRNAs that target iron uptake and release proteins within the parent cell that may be present within the EVs, contributing to altered iron metabolism within the tumor. To understand these differences further, we will interrogate specific miRNA and mRNAs that may contribute to GBM progression through horizontal transfer of cargoes within the TME using RNA sequencing. Together, this project provides a significant contribution to our understanding of how GBM EVs seed new tumor growth in response to high iron conditions, the contribution of iron-induced CSC and non-CSC EVs, and the specific EV cargoes that can be targeted to prevent new growth.

Title: Involvements of decapping scavenger enzyme DcpS in the progression of glioblastoma

Authors: U. KUDO, Y. KUSE, S. NAKAMURA, *M. SHIMAZAWA;
Mol. Pharmacology, Dept. of Biofunctional Evaluation, Gifu Pharmaceut. Univ., Gifu, Japan

Abstract: Glioblastoma (GBM) is a brain tumor derived from astrocytes and is the most poor prognosis cancer type among brain tumors. For GBM, temozolomide, an oral alkylating agent, is used as a first-line treatment, but the 5-year survival rate is only about 10%. Therefore, there is a worldwide expectation to develop new drugs against GBM. In this situation, a new therapeutic target of interest is the regulation of alternative splicing of carcinogenicity. Thus, we focused on RG3039, an decapping scavenger enzyme (DcpS) inhibitor, which can penetrate the blood-brain barrier and be used orally. DcpS binds to the 5' capping structure of mRNA and is involved in mRNA decay. DcpS is also reported to be responsible for the organization of the mRNA splicing complex and is implicated in cell proliferation of acute myeloid leukemia. In this study, we investigated whether DcpS contributes to the progression of GBM.First, bioinformatics analysis using Gliovis, the public database, was used to examine DcpS expression and survival by DcpS expression levels in GBM patients. We further explored the function of DcpS using two GBM cell lines, U87 and GL261. After treatment of U87 and GL261 cells with RG3039, cell proliferation was examined using CCK-8 and BrdU. Also, the expression of cell cycle-related proteins in U87 cells treated with RG3039 was evaluated using Western blot analysis. Furthermore, we examined the effects of siRNA-induced knockdown of DcpS in U87 cells on cell viability and expression of related proteins.Analysis utilizing Gliobis showed that DcpS is highly expressed in GBM patients and that GBM patients with high DcpS expression have lower survival rates than those with low DcpS. The DcpS inhibitor RG3039 significantly reduced cell viability and cell proliferation in U87 and GL261 cells. On the other hand, RG3039 did not decrease cell viability in non-tumor (astrocyte) cells. These results suggest that DcsS plays a particularly important role in survival and proliferation in GBM cells. RG3039 also decreased the expression levels of CyclinB1 and CyclinD1. Furthermore, the knockdown of DcpS in U87 cells reduced cell viability. Interestingly, knocking down DcpS in U87 cells reduced the expression of N-cadherin. N-cadherin is one of the major intercellular adhesion molecules and is known to induce interactions such as proliferation and differentiation in various cancer cells. Taken together, these results suggested that DcpS contributes to GBM progression through the expression of N-cadherin, and DcpS selective inhibitors are expected to be a novel treatment for GBM.

Title: The repetitive evolution of neural stem cells contributes to the recurrence of glioblastoma

Authors: *J. LEE, X. LI;
Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Glioblastoma multiforme (GBM) mostly recurs locally near the resection cavity, causing high lethality of GBM, while primary treatment has been intensified to eradicate the possible residual local tumors. Otherwise, Neural stem cells (NSCs) in the subventricular zone (SVZ) have recently been identified as the cells of origin for human GBM. We hypothesized that the tumor-initiating neural stem cells in the SVZ might evolve repetitively to tumor construction following the removal of primary tumor, leading to the recurrent GBM. To do so, we developed a mouse model harboring the cancer-driving mutations in the NSCs of the SVZ with surgical resection to reflect the brain status after surgical resection of primary tumors, as well as the origin thereof. Therein, the NSCs harboring driver mutations migrated specifically to the RC through the aberrant growth of oligodendrocyte-precursor cells (OPCs). The SVZ-originated cells arriving at the RC newly constituted the locally recurrent GBM around the RC, representing the main pattern of recurrence in GBM. RNA sequencing analysis of longitudinal sampling from the mouse model and the matched primary-recurrence samples of human GBM patients revealed upregulation of the C-X-C Motif chemokine receptor (CXCR) 4/C-X-C motif chemokine ligand (CXCL) 12 axis in recurrent tumors after total resection. The microglia/macrophage activated by the resection can release CXCL12 to drive the aberrant migration of CXCR4-expressing NSC in the subventricular zone. We found that a CXCR4 antagonist inhibited the differentiation to OPC lineages from NSCs and decreased the number of immigrating OPC lineages to the RC in mice. The CXCR4/CXCL12 blockade also reduced mouse tumor development and death rates after resection. Accordingly, this study identifies the noble process of recurrence which the tumor-initiating NSCs can evoke repetitive cyclic evolution to the recurrent GBM even after the complete removal of the tumor. Blocking the CXCL12/CXCR4 pathway could be a potential treatment target to prevent this recurrence.

Abstract: Primary gliomas make up the majority of malignant tumors arising in the central nervous system and are the deadliest form of brain cancer. The current standard of care is surgical resection followed by chemotherapy with temozolomide and radiotherapy. Unfortunately, the recurrence of drug-resistant tumors is common leaving glioblastoma patients with a 5% five-year survival rate. Glioma stem cells (GSCs) are a subset of undifferentiated cells widely believed to drive tumor initiation, therapeutic resistance, and glioma recurrence. Depleting the GSC population in combination with the standard of care could improve current cancer treatments and extend the survival of glioma patients. Oligodendrocyte precursor-like GSCs have been identified as a cellular origin for glioma. Recent findings indicate that the neurotransmitter acetylcholine (ACh) maintains the primitive state of normal oligodendrocyte precursors via muscarinic ACh receptors (mAChRs), preventing cell cycle exit and maturation. Our analysis of publicly available data identified high levels of expression of *CHRM3* (M3mAChR) in adult and pediatric gliomas. CHRM3 expression was largely restricted to the proneural subtype of glioma that is associated with the oligodendroglial precursor gene expression signature. Oligodendrocyte precursor-like GSCs established from malignant oligodendrogliomas arising in mice express *Chrm3* and are responsive to ACh. Pharmacological studies in vitro and in vivo indicated that the FDA-approved anti-muscarinic drug benztropine suppressed GSC proliferation and glioma progression in serially passaged patient-derived glioma xenografts. These studies suggest that the cholinergic microenvironment may influence GSC malignant potential providing a rationale to investigate widely available antimuscarinics as treatments for glioma.

Title: Characterization of Store-operated calcium entry in glioblastoma cell of origin

Authors: *S. KIM[1], S. CHUNG[2];
[1]YONSEI UNIVERISTY, SEOUL, Korea, Republic of; [2]Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Recent scientific advances have been made to unravel the presence of neural circuit between the cortical neurons and brain tumor cells such as glioblastoma. The anatomical niche of brain tumor cells surrounded by the cortical neurons allow a neural influence over the tumor microenvironment and vice versa. So far, little is known about the functional role of the calcium signaling as a switch in the proliferation and migration of glioblastoma cells of origin. In this study, we characterized the glioblastoma cells of origin from the murine models in attempting to investigate the molecular signaling pathway involved. Using calcium imaging study with Fura-2/AM, our results indicated that glioblastoma cells of origin exhibited the store-operated Ca^{2+} entry (SOCE) channels. We found that activating the SOCE by store-depletion caused the calcium influx from the external environment. The blockade with SOCE inhibitor, GSK7975A, showed a significant reduction of the calcium influx in the cells, indicating the engagement of SOCE channels. We conducted these experiments to understand a voltage-independent source of calcium and its regulation in glioblastoma cells of origin where calcium may be a critical messenger to initiate the tumor proliferation and migration. Taken together, our results showed that the SOCE channels regulate the Ca^{2+} signaling of glioblastoma cells of origin, implicating in tumor progression.

Title: Sprouty2 regulates endocytosis and degradation of fibroblast growth factor receptor 1 in glioblastoma cells

Authors: *B. HAUSOTT[1], L. PIRCHER[1], M. KIND[1], J.-W. PARK[2], P. CLAUS[3], L. KLIMASCHEWSKI[1];
[1]Med. Univ. Innsbruck, Innsbruck, Austria; [2]Gachon Univ., Incheon, Korea, Republic of; [3]SMATHERIA gGmbH - Non-Profit Biomed. Res. Inst., Hannover, Germany

Abstract: Endocytic trafficking of receptor tyrosine kinases (RTKs) regulates spatio-temporal intracellular signaling, and aberrant RTK signaling is a common phenomenon observed in glioblastoma (GBM). The Sprouty (SPRY) proteins are evolutionary conserved modulators of RTK signaling. SPRY2 inhibits fibroblast growth factor (FGF) signaling, whereas it enhances epidermal growth factor (EGF) signaling through inhibition of EGF receptor (EGFR) ubiquitination, degradation and endocytosis. In this study, we analyzed the effects of SPRY2 on degradation and signaling of FGF receptor 1 (FGFR1) compared to EGFR using two human GBM cell lines with different endogenous SPRY2 levels. In U251 cells with low endogenous SPRY2 levels, SPRY2 was overexpressed, while in SF126 cells with high endogenous SPRY2 content, SPRY2 was downregulated using short hairpin (sh)RNA. FGFR1 ubiquitination and degradation were analyzed by immunoprecipitation and Western blotting. Transfection with FGFR1-enhanced green fluorescent protein (FGFR1-EGFP) and treatment with Cy3-labeled FGF2 (FGF2-Cy3) was used to study the effects of SPRY2 on FGFR1 endocytosis by confocal microscopy of whole cell images. Western blot analysis was performed to analyze the effects of SPRY2 on FGF2- and EGF-induced signaling. SPRY2 increased EGFR levels but reduced FGFR1 levels by enhanced c-casitas b-lineage lymphoma (c-CBL)-mediated ubiquitination and decreased N-cadherin protein. Furthermore, SPRY2 was present in anti-FGFR1 immunoprecipitates. SPRY2 inhibited clathrin- and caveolae-mediated endocytosis of FGFR1 and uptake of transferrin. FGF2-induced activation of extracellular signal-regulated kinase (ERK) and phospholipase Cγ1 (PLCγ1) was inhibited by SPRY2 whereas EGF-induced ERK and PLCγ1 phosphorylation was enhanced. Together, these results demonstrate a novel role of SPRY2 in degradation and endocytosis of FGFR1. SPRY2 enhanced c-CBL-mediated ubiquitination and degradation of FGFR1 and reduced N-cadherin, which inhibits FGFR1 ubiquitination and lysosomal degradation. Since SPRY2 inhibited FGF2-induced signaling and reduced FGFR1 protein, the inhibitory effect of SPRY2 on FGF signaling may at least in part be due to the enhanced degradation of FGFR1.

Title: Examining the role of BDNF-TrkB.T1 signaling on the brain tumor microenvironment

Authors: *L. MERINO GALAN[1], S. ORTIZ-ESPINOSA[2], M. HATHAWAY[1], A. RAJENDRAN[1,3], G. RUBIO[1], M. SHABAR[3], N. RECHE-LEY[1], H. L. JAGANA[1], S. S. PATTWELL[1,2,3];

[1]Ben Towne Ctr. for Childhood Cancer Res., Seattle Children's Res. Inst., Seattle, WA; [2]Human Biol. Div., Fred Hutchinson Cancer Ctr., Seattle, WA; [3]Univ. of Washingthon, Seattle, WA

Abstract: Gliomas are the most common type of brain tumor in both children and adults. Communication between cancer cells and surrounding non-cancerous cells is a fundamental component of brain cancer pathophysiology. Glioma cells release factors that function as chemoattractants and influence the tumor microenvironment. Reciprocally, the activity of normal cells from the surrounding tumor microenvironment drives the proliferation and growth of glial malignancies through paracrine signaling, brain-derived neurotrophic factor (BDNF) being one of the key secreted factors. BDNF binds with high affinity to the tropomyosin receptor kinase B (TrkB). Recent work from our group has shown that the TrkB.T1 splice variant is upregulated in various human gliomas and that overexpressing TrkB.T1 enhances the tumor aggressiveness *in vivo* and is associated with the downregulation of genes involved in facilitating tumor cell recognition and elimination *in vitro.* However, the role of TrkB.T1 splice variant in this bidirectional communication between glioma cells and the surrounding cells remains unknown. Our aim was to assess if increased levels of TrkB.T1 observed in gliomas harbor a role in modulating immune responses. To explore these mechanisms *in vitro*, 3T3 cells were transduced with pLJM1-lentivirus to overexpress TrkB.T1 and then serum-starved and treated with BDNF. Immunoprecipitation and affinity purification-mass spectrometry (AP-MS) were used to identify TrkB.T1 interactors, and the conditioned media was subjected to a cytokine multiplex analysis. The results show that TrkB.T1 significantly increases key chemokine levels and that it has a unique set of binding partners involved in MHC class II-mediated immune response. In addition, we explored the immune cell heterogeneity associated with increased levels of TrkB.T1 *in vivo* using a glioma mouse model engineered with RCAS/tv-a technology. Taken together, this work shows that the BDNF-TrkB.T1 axis represents a potential target for modulating glioma-immune cell interactions needed to curb disease progression and warrants further investigation.

Title: Elucidating the role of the TrkB.T1-initiated Ca^{2+} mobilization in Rho GTPase activation

Authors: *S. PATTWELL[1], **H. L. JAGANA**[2], M. HATHAWAY[2], A. RAJENDRAN[3], G. RUBIO[2], N. RECHE-LEY[4], M. SHABAR[5], L. MERINO GALAN[2], D. JOHNSON[2];

[2]Ben Towne Ctr. for Childhood Cancer Res., [1]Seattle Children's Res. Inst., Seattle, WA; [3]Univ. of Washington Sch. of Med., Seattle, WA; [4]Stanford Univ., Stanford, CA; [5]Univ. of Washington, Seattle, WA

Abstract: The neurotrophin receptor TrkB, along with its ligand brain derived neurotrophic factor (BDNF) are critical for proper neural development. The TrkB.T1 splice variant has been shown to be involved in glial development and is overexpressed across several cancers including low grade glioma and glioblastoma. TrkB.T1 stimulation by BDNF initiates a signaling cascade that has been shown to increase intracellular calcium in astrocytes. In addition, TrkB.T1 associates with Rho-GDI1 leading to morphological changes in astrocytes and glioma cells. Both calcium transients and Rho GTPases regulate oncogenic phenotypes including invasion and migration. Although links between TrkB.T1 and calcium signaling and TrkB.T1 with Rho GTPase activity have been individually identified, a gap on how they interact to regulate oncogenic characteristics remains. We hypothesize that TrkB.T1 initiated calcium mobilization is uniquely altering Rho activation and thereby regulating oncogenic phenotypes. Affinity purification mass spectrometry was utilized to identify both direct and indirect interacting proteins of TrkB.T1, full length-TrkB (TrkB.FL), and a GFP control. Gene Ontology (GO) analysis of these TrkB.T1 binding proteins revealed statistically significant terms related to GTPase activity, GTP/GDP Binding, Ca^{2+} mobilization, and Ca^{2+} ion binding. Calcium detection assays and calcium indicators facilitated deciphering of mechanistic differences in TrkB.T1-initiated calcium mobilizations in glial cells and and cancer cell lines. An *in vitro* Rho GTPase activity assay determined how changes in Ca^{2+} mobilization affect Rho activity. Deciphering the direct signaling cascade between calcium and Rho GTPases may reveal potential therapeutic vulnerabilities of gliomas. Future investigation into how gliomas are utilizing TrkB.T1 is needed to verify its promotion of oncogenic phenotypes.

Abstract: ASCL1 and OLIG2 are basic-helix-loop-helix transcription factors (bHLH TFs) that are co-expressed in the majority of gliomas, including glioblastomas (GBMs), the most aggressive and heterogenous primary brain tumors. During development, these bHLH TFs bind to DNA E-box motifs to regulate transcriptional programs essential for neuronal and glial cell fate specification, migration, and proliferation, but their combinatorial roles in the development and heterogeneity of GBMs remains to be determined. In this study, we performed ChIP-seq and RNA-seq analyses of human GBMs to identify binding profiles and novel targets of both ASCL1 and OLIG2. We uncovered that ASCL1 and OLIG2 reciprocally interacts at the transcriptional and protein levels, and exhibit significant overlap in binding to transcriptional targets essential for GBM progression. Using loss and gain-of-function approaches, we then directly tested the combinatorial roles of ASCL1 and OLIG2 in brain tumors induced from glial progenitors in the dorsal cortex of a CRISPR/Cas 9 immunocompetent GBM mouse model. We showed that the loss of either *Ascl1* or *Olig2* significantly extended survival but also produced opposing tumor types, with ASCL1 promoting a highly invasive "astrocytoma" tumor type which consistently migrates across the corpus callosum, whereas OLIG2 represses this phenotype in favor of a less invasive "oligodendroglioma" tumor type. Despite these opposing functions, the loss of both *Ascl1* and *Olig2* drastically reduced the efficiency of tumor inductions, with 80% of mice failing to develop brain tumors by six months of age. This highlights the importance yet redundant function of these two bHLH TFs in the initiation of GBMs. Finally, using single cell RNA sequencing, we revealed that GBMs of the mouse model are transcriptionally diverse exhibiting molecular signatures of multiple GBM subtypes and cell types ranging from oligodendrocyte precursor cells to mature oligodendrocytes (OPC/MOL), neural stem cells to astrocytes (NSC/AS), and neurons to microglia. More importantly, tumor cells with high levels of ASCL1 are highly migratory, proliferative, and displayed molecular signatures resembling that of NSC/AS, consistent with ASCL1's role as a marker and regulator of glioma stem-like cells (GSCs). Taken together, this study demonstrates that oncogenic driver mutations lead to dysregulation of ASCL1 and OLIG2, which are then responsible for driving GBM initiation and progression in vivo. Subsequently, the dynamic level, interactions, and direct binding of these two bHLH TFs to each other and downstream target genes then determine the cell types and degree of migration of GBMs in the brain.

Abstract: Glioblastoma is an aggressive form of brain cancer with a very poor prognosis for survival. Understanding the molecular and cellular changes that occur in glioblastoma is crucial for developing effective treatments and understanding disease progression. In this study, we applied 10x Genomics Xenium In Situ technology with the Human Brain Panel to profile gene expression in postmortem healthy and glioblastoma brain cortex samples.
We used a maximum likelihood classifier and performed unsupervised clustering with differential gene expression analysis to identify putative cell types and states. This approach allowed us to map gene expression patterns with high resolution and distinguish between different cell types within and between samples. Our results revealed distinct molecular signatures associated with different cell types in healthy and glioblastoma samples, providing new insights into the cellular changes that occur in this devastating disease. These findings highlight the potential of spatial transcriptomics for advancing our understanding of complex neurological disorders and for identifying new targets for therapeutic intervention.

Title: Synergistic cytotoxic effect of the combination of melatonin with albendazole or albendazole sulfoxide on glioma cells through autophagy and apoptosis

Authors: *M. CERÓN[1,2], V. CHAVARRIA[4], C. RIOS[3], B. PINEDA[5], F. PALOMARES[6], I. ROJAS-TOMÉ[6], H. JUNG[7];

Nacional Autónoma de México, Mexico City, Mexico

Abstract: Introduction. Glioblastoma (GB) is the most aggressive and lethal brain tumor in adults, which presents diffuse cerebral infiltration, drug resistance and high recurrence. Currently, standard treatment involves maximal surgical resection, followed by radiation therapy and concurrent chemotherapy with temozolomide; however, the median overall survival is 12-15 months. New treatments (bevacizumab) have been approved for recurrent patients, but the average survival rate is two years. Therefore, it is necessary to continue exploring therapeutic alternatives that offer better results. Taking into account that the anticancer activity of albendazole (ALB), its active metabolite, albendazole sulfoxide (ALBSO) and melatonin (MLT), has been previously reported in various types of cells, through different mechanisms of action, the main objective of this study was to assess whether the combinations of MLT with ALB or MLT with ALBSO have a synergistic cytotoxic effect on glioma cells. Methods. C6 and RG2 rat glioma cells and U87 human glioma cells were used. Concentration-response curves were prepared in the range of 0.16 to 1.25 μM for ALB, 2.0 to 64.0 μM for ALBSO, and 0.18 to 6.0 mM for MLT. The mean Dose (Dm) values were calculated from which combinations were designed in serial dilutions. Cytotoxicity was evaluated using the MTT assay and drug interaction was determined by the Chou-Talalay method. The mechanisms of cell death, apoptosis, necrosis, (annexin V and 7-AAD) and autophagy (LC3 and AVOS), were evaluated by flow cytometry and immunofluorescence. The cell proliferation was evaluated by crystal violet staining. Results. Our results showed that in all cell lines the drugs exhibited cytotoxic activity in a concentration-dependent manner. The Dm values in lines C6, RG2 and U87, for ALB were 0.6 μM, 0.6 μM and 0.9 μM; for ALBSO, 20.0 μM, 26.0 μM and 36.0 μM; and for MLT, 1.0 mM, 0.9 mM, and 0.9 mM, respectively. Most of the combinations produced a synergistic cytotoxic effect. The combined treatments induced death in all three cell lines, mainly by apoptosis and autophagy. Inhibition of cell proliferation was observed after ALB and ALBSO treatment, as well as with the combination of both compounds with MLT. Conclusions. The synergistic cytotoxic effect of the combination of ALB and ALBSO with MLT could be related to the different mechanisms of action of the molecules. The results are promising since the combinations could be a potential strategy for the treatment of GB, considering that these compounds are less toxic and expensive. Other studies are necessary to evaluate the combinations in in vivo models.

Title: Glioblastoma multiforme cells generate functional cell-cell interactions with native CNS cells in 3D in vitro ultra-soft hydrogels

Authors: M. S. ANDRADE MIER[1], J. SCHENK[3], K. G. HEINZE[3], T. BLUNK[2], *C. VILLMANN[1];
[1]Inst. for Clin. Neurobio., [2]Dept. of Trauma, Hand, Plastic and Reconstructive Surgery, Univ. Hosp. of Wuerzburg, Wuerzburg, Germany; [3]Rudolf Virchow Center, Ctr. for Integrative and Translational Bioimaging, Julius-Maximilians-University Wuerzburg, Wuerzburg, Germany

Abstract: Glioblastoma multiforme (GBM) are the most aggressive brain tumors. Despite the use of standard therapeutic approaches (surgery, chemotherapy, and radiotherapy), patients life expectancy is around 16 months after diagnosis due to GBM´s highly proliferative, infiltrative, and invasive properties. Recently, the interactions of glioma cells with neurons and astrocytes have been brought to the spotlight. Functional pseudo-synaptic cell-cell interactions between glioma cells and native central nervous system cells underlie tumor pathophysiology including invasion, tumor proliferation, and maintenance of an immunosuppressed environment. To further study these mechanisms, disease models that recapitulate the development of GBM are needed. A 3D *in vitro* hydrogel-based culture system was used to establish a model of glioblastoma with a controllable microenvironment. We used a hyaluronic acid-based hydrogel with very low stiffness (≈ 100 Pa) to mimic the mechanical properties and the chemical composition of the brain as hyaluronic acid is one of the major components in the brain extracellular matrix. Previously, it was demonstrated that co-cultures of cortical neurons and astrocytes were able to mature and formed a functional neuronal network. To stay within the murine system, tri-cultures of Gl-261, a mouse glioma cell line, together with primary cortical astrocytes and neurons were established to study functional cell-cell interactions. Immunocytochemical stainings revealed cell-cell contacts between glioma cells and astrocytes (gap-junctions) and neurons and glioma cells (microtubes). If these contact points represent functional interactions is currently under investigation. Confocal live-cell imaging of 3D tri-cultures will be used to track the movement of glioma cells and microtube formation, similarly a functional assessment of gap-junctions can be performed. Finally, calcium imaging will be used to determine if glioma cells integrate into the neuronal network and alter network firing. Altogether, the generated 3D *in vitro* constructs

mimic a “physiological” GBM microenvironment which allow glioma cells to develop functional cell interactions as reported for *in vivo* models. Such models are essential prerequisites to further generate patient-specific approaches to study and understand the disease pathomechanisms.

Title: In vitro investigation of glioma-induced neuronal hyperexcitation using a human neuronal-glioblastoma co-culture model

Authors: *D. YANG[1], A. BAK[2], K. SCHMIED[2], H. KOCH[2], D. FELDMEYER[1], D. DELEV[3]; [1]Inst. of Neurosci. and Med. 10, Res. Ctr. Juelich, Juelich, Germany; [2]Dept of Neurology, Section Epileptology, [3]Dept of Neurosurg., RWTH Aachen Univ. Hosp., Aachen, Germany

Abstract: Glioblastoma is one of the most common and devastating malignant brain tumors, with an extremely poor prognosis, which is reflected in an overall survival of only 15 months despite maximal treatment. Glioma progression can lead to increased neuronal activity, resulting in neuronal hyperexcitability and the development of tumor-induced epilepsy. This clinical complication occurs in 40-80% of glioma patients. To study how glioma growth progressively alters neuron excitability, we transplanted ZsGreen-tagged brain tumor cells into human organotypic brain slice cultures obtained from cortical resection surgeries. We tagged endogenous neurons by introducing mCherry to neurons using Adeno-associated viruses (AAV) transduction. After 2 to 8 days in vitro (DIV), we performed whole-cell patch-clamp recordings from cortical layer 5 pyramidal neurons in tumoral, peritumoral, and non-tumoral areas. Our findings revealed that glioma invasion quickly affected neuronal excitability from the early days of transplantation. Neurons in tumoral and peritumoral areas showed a larger input resistance, broader AP half-width, and smaller rheobase current compared to neurons located in tumor-free area. Additionally, neurons located within the area of the tumor showed a markedly high frequency of excitatory post-synaptic currents (EPSCs). Thus, we successfully established a co-culture model to investigate the effects of glioma on the peritumoral neuronal microenvironment in the human cortex. This model will aid our understanding of how these brain tumor cells can integrate into complex neuronal circuits.

Title: Examining cellular vulnerabilities of glioblastoma across space and time using region-specific human brain organoids

Authors: ***T. N. BHATIA**[1], S. GANTA[1], S. SZABO[5], A. SING[1], A. KING[1], C. SOJKA[1], K. HOANG[2], E. NDUOM[2], T. GARZON-MUVDI[2], R. READ[3], J. OLSON[4], S. A. SLOAN[1]; [1]Dept. of Human Genet., [2]Dept. of Neurosurg., [3]Dept. of Pharmacol. and Chem. Biol., [4]Departments of Hematology, Med. Oncology, and Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA; [5]Georgia Inst. of Technol., Atlanta, GA

Abstract: Glioblastoma multiforme (GBM) is a devastating form of astrocytoma with no known cure. However, these tumors show significant regional bias. For example, most adult GBMs are localized to the frontotemporal lobes of the cerebral cortex. In contrast, adult GBMs are rarer in caudal regions, accounting for only ~1-5% of all cases in the midbrain and hindbrain. Thus, signals from the local environment may influence the biological behavior of GBM cells. However, the mechanisms underlying these phenomena have been difficult to study due to lack of access to functional human brain tissue. To address this question, we use region-specific human induced pluripotent stem cell-derived (hiPSC) brain organoids engrafted with cells harvested directly from surgical GBM resections or with patient-derived glioma stem cells (GSCs). Using RNA-seq and immunostaining we confirmed that forebrain, midbrain, and hindbrain organoids express canonical patterning markers. We dissociated surgical GBM resections and single-cell RNA sequencing confirmed cell type heterogeneity after dissociation. Specifically, immune cells as well as all major CNS cell types, such as microglia, oligodendroglia, astroglia, neurons, and radial glia were observed in dissociated GBMs. We show that dissociated surgical GBM cells and GSCs readily invade organoids patterned to mimic the dorsal cortex (pallium; hCS), ventral cortex (subpallium; hSS), midbrain (hMbS), and hindbrain/spinal cord (hSpS). However, GSCs tended to show a regional preference and occupied greater areas of forebrain *vs.* midbrain/hindbrain organoids. Finally, we report that tumor cells maintain their phenotype within organoids and express markers related to proliferation (Ki67, EdU), stemness (Sox2, Nestin, CD44), and glial precursors (GFAP, PTPRZ1). Currently, we are using single-cell approaches to determine how the host region

microenvironment influences the identity of GBM cells by comparing pre- and post-engraftment transcriptomes. Our findings will help identify novel targets to determine if endogenous defenses preexisting in select regional environments can be harnessed to stave off tumor formation, reduce relapse, or improve patient survival.

Title: Engraftment of Patient Derived Glioblastoma Cell Lines into Brain Region Specific Organoids

Authors: *S. GANTA[1,2], T. N. BHATIA[2], A. KING[2], A. SING[2], R. REED[3], S. A. SLOAN[2]; [1]Emory Univ. Neurosci. and Behavioral Biol., Atlanta, GA; [2]Human Genet., [3]Pharmacol. and Chem. Biol., Emory Univ., Atlanta, GA

Abstract: Glioblastoma (GBM) is the most common malignant brain tumor in adults. GBMs are known for their highly invasive and proliferative properties and are associated with a dismal prognosis (~12-18 months post-diagnosis). Furthermore, these tumors show regional disparities, and the most frequent location for GBMs in adults is the cerebral cortex. In contrast, less than 5% of adult GBMs occur in the cerebellum, brainstem, and spinal cord. The mechanistic underpinnings of the observed regional differences in occurrence remain unclear but may be driven by regional differences in the cellular and molecular profiles of the brain microenvironment. This idea has been difficult to study due to a lack of human-specific models that effectively recapitulate the pathophysiology and biological behaviors of GBMs in region-specific microenvironments. To address these challenges, we employed a patient derived xenograft (PDX) model by engrafting GFP-tagged patient-derived glioma stem cells (GSCs) from three individuals into human induced pluripotent stem cell (hiPSC)-derived cortical and spinal cord organoids. Immunostaining assays were performed at 2, 7, 14, and 21-days post-engraftment to compare the extent of infiltration and proliferation within both the regions. Inter-regional differences were observed specific to each patient engraftment. We are currently determining the proliferative capacities of GSCs within cortical versus spinal cord organoid environments by measuring the co-expression of GFP with proliferative marker Ki67 and 5-Ethynyl-2′-deoxyuridine (EdU). In addition, we tended to observe that GSCs displayed

morphological complexity after entering the organoid environment, potentially suggesting that GSCs differentiate in their post-engraftment setting. To define the cellular and transcriptomic effects of GSC engraftment within organoids, we are performing RNA-sequencing and immunostaining with canonical neuronal, glial, and oligodendroglial markers. By comparing the biological behaviors of GSCs in cortical versus spinal cord organoids, we aim to gain insights into whether GBM's affinity for particular brain regions is intrinsic (driven by genetic mutations) or extrinsic (driven by the regional microenvironment), thus advancing our understanding of this devastating disease.

Title: Functional ultrasound imaging of mouse orthotopic glioma

Authors: A. SHATILLO, ***J. RYTKÖNEN**, T.-K. STENIUS, R. IMMONEN, A. SUHONEN, S. BÄCK;
Charles River Discovery Services, Kuopio, Finland

Abstract: Aberrant vasculature together with neovascularization are hallmark of glioblastoma. Understanding the vasculature of glioma can have a pivotal role in planning therapeutics approaches. The objective of this study was to investigate morphological, vasculature and blood flow changes induced by aggressive tumor growth, using in vivo imaging - magnetic resonance imaging (MRI) and functional ultrasound (fUS) imaging in a mouse model of orthotopic glioma. Human glioblastoma xenografts, U-87M cells 5 x 10^4, were implanted in female NMRI nude mice at the age of 8 weeks. Four weeks after implantation the mice we anesthetized with isoflurane and scanned with 11.7 T small animal MRI (Bruker) for tumor volumetry. Thereafter, the mice were imaged with Iconeus One imaging system (Iconeus, Paris, France) for structural information of brain vasculature and relative cerebral blood volume (rCBV) changes. High resolution vascular imaging was performed after intravenous injection of microbubble contrast agent (SonoVue, sulphur hexafluoride microbubbles).
Four weeks after implantation the average tumor size was 58.8 ± 27.6 mm^3 (mean ± SD, n=7).

Aberrant vasculature was visualized with structural fUS imaging as and the necrotic core of the tumor was observed. A reduced rCBF was observed in ipsilateral hemisphere on the relative power doppler signal timeseries as a lower amplitude and faster decay compared to contralateral side.
As a summary, in vivo fUS imaging is a noninvasive tool to visualize vascular changes induced by aggressive brain tumor growth which are not detectable with conventional imaging methods (CT, MRI, PET, SPECT) and can provide a novel readout for efficacy studies.

Title: Area postrema neurons mediate interleukin-6 function in cancer-associated cachexia

Authors: *Q. SUN, D. VAN DE LISDONK, B. GEGENHUBER, M. WU, J. TOLLKUHN, B. LI;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Interleukin-6 (IL-6) has been long considered a key player in cancer-associated cachexia. It is believed that sustained elevation of IL-6 production during cancer progression causes brain dysfunctions, which ultimately result in cachexia. However, how peripheral IL-6 influences the brain remains poorly understood. Here we show that neurons in the area postrema (AP), a circumventricular structure in the hindbrain, mediate the function of IL-6 in cancer-associated cachexia in mice. We found that circulating IL-6 rapidly enters the AP and activate AP neurons. Peripheral tumor leads to neuronal hyperactivity in the AP, and causes potentiated excitatory synaptic transmission onto AP neurons. Neutralization of IL-6 in the brain of tumor-bearing mice reduces AP hyperactivity, prevents cachexia, and markedly prolongs lifespan. Furthermore, suppression of Il6ra specifically in AP neurons achieves similar effects. Our study

identifies a central mechanism underlying the function of peripheral IL-6, which may serve as a target for treating cancer-associated cachexia.

Abstract: The Glioblastoma multiforme (GBM) tumor microenvironment is highly immunosuppressive, leading to poor clinical outcomes and median survival of less than 15 months. Preclinical syngeneic mouse models are indispensable for analyzing the underlying pathogenesis and immunobiology of GBM, identifying novel therapeutic targets, and evaluating the efficacy of potential therapeutic strategies. In this study, we utilize a spatial phenotyping application that permits comprehensive characterization of key proteins in the microenvironment of healthy and diseased brain tissues. The PhenoCycler-Fusion is a fast spatial biology solution that affords ultra-high parameter single cell spatial readouts. We used this solution for deep phenotyping of over 40 proteins, comprising immune cell lineages, glial cell activation states, as well as markers for tumor, vascular, and neuronal landscapes of the murine GBM models. Via whole-slide spatial phenotyping and single-cell analysis, we were able to isolate distinct microglial, neuronal, and systemic immune subtypes within the GBM tissue microenvironment. Our data provides a comprehensive account of diverse immune cell populations in murine GBM models and may guide informed choices to facilitate immunotherapies in the clinic. Our application has enormous potential to further our understanding of the brain microenvironment in GBM and other CNS related disorders such as Alzheimer's and Parkinson's disease.

Abstract: Glioblastoma, a type of brain tumor, encompasses various histological variants, including the rare gliosarcoma, which is known for its highly aggressive nature and limited number of documented cases. In this report, we present the case of a 31- year- old man who initially manifested a single seizure episode. A month later, he experienced weakness in his left hand, resulting in frequent dropping of objects. Brain MRI unveiled a mass in the right hemisphere that extended across the midline and obstructed the ventricular system. To address this, the patient underwent parieto-temporal resection surgery. Gross specimen histology indicated the coexistence of classic glioblastoma, gliosarcoma and glioblastoma with rhabdoid changes. Considering the aggressive nature of the tumor, adjuvant radiotherapy was administered after the surgical procedure. Histopathological examination indicated a tumor composed of pleomorphic glial cells, fusiform cells, and cells displaying rhabdoid changes, accompanied by areas of necrosis and microvascular proliferation. The tumor exhibited high cellular density, frequent atypical mitosis, and geographic necrosis. Immunohistochemical analysis exhibits positive expression of glial fibrillary acidic protein (GFAP) in neoplastic cells, with focal positivity for isocitrate dehydrogenase (IDH). The Ki67 labeling index, which indicates proliferative activity, was determined to be 40% in the tumor cells. The integrated diagnosis encompassed a gliosarcoma/glioblastoma with rhabdoid changes, wherein the classical glioblastoma component accounted for 30% of the tumor. According to the World Health Organization (WHO) grading system, the tumor was classified as grade 4. Molecular analysis confirmed an IDH wild type status and provided data on hypoxia and reactive gliosis. The therapeutic plan involved initiating volumetric modulated arc therapy (VMAT) with a total dose of 60 Gray, which was well-tolerated by the patient. This case emphasizes the intricate clinical presentation, aggressive histopathological features, and the essential role of radiotherapy following surgery in managing refractory glioblastomas, particularly in young individuals.

Title: Occult gallbladder adenocarcinoma with spinal leptomeningeal spread mimicking Guillain Barré syndrome. Post-mortem case report

Authors: *R. ORTEGA[1], J. E. GARCÍA-BOLL[1], A. A. ANGELES-ROMERO[1,2], K. LÓPEZ-MAGALLÓN[3], E. GÓMEZ-APO[3,4];

Abstract: Guillain-Barré syndrome (GBS) is an autoimmune disorder characterized by acute and subacute polyneuropathy with diverse clinical presentations. While peripheral involvement primarily affecting the myelin sheath is more common, axonal and retrograde involvement represent a less frequent yet aggressive variant. GBS is typically associated with concurrent bacterial and viral infections; however, rare cases demonstrate a cross-reactive response in patients with cancer; notably, lymphatic, hematopoietic, lung, prostate, mammary, and male genital tissues, along with the use of chemotherapeutic agents. Here, we present an unusual case of a 51-year-old woman with a history of obesity and tobacco use, who exhibited rapidly progressive motor axonal demyelinating polyradiculomyelopathy, resulting in ascending weakness, areflexia, quadriparesis, cranial nerve involvement, and dysautonomia. Symptoms did not improved even after plasmapheresis treatment. CT scan revealed diffuse cerebral and cerebellar edema. The patient continued with neurological impairment and died. Remarkably, histopathological examination during autopsy unveiled a moderately differentiated adenocarcinoma of the gallbladder with multi-organ metastases, including the liver, adrenal glands, and ovaries; as well as cervical, peripancreatic, periaortic, and perirenal lymph nodes; and in the central nervous system (basal ganglia, frontal lobe leptomeninges, and spinal cord leptomeninges). Notably, central chromatolysis was observed in the anterior horns of the spinal cord. This atypical case highlights the severe expression of Guillain-Barré syndrome as a paraneoplastic manifestation, particularly in a patient without a history of significant infections.

Title: Lateral proteome transfer between sensory neurons and breast cancer

Authors: *Y. WU, J. C. BORNIGER;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Recent evidence suggests a crucial involvement of the nervous system in the development of cancer. The bidirectional interaction between the nervous system and cancer occurs either through direct membrane contacts or tumor microenvironment. Compared to investigations on nerves-glioma interactions in the brain, studies exploring the role of the peripheral nervous system in the tumor microenvironment outside the brain are relatively limited.
Breast tumor clearing results indicate sensory nerves are the most abundant nerve types in the tumor microenvironment throughout the early to late stages during tumor progression. We have established a co-culture system where breast cancer cells are found in direct contact with primary sensory neurons. Interestingly, a significant increase of proliferation and migration rate of breast cancer cells were observed, particularly when stromal cells are present in the neuron cultures. Through bulk RNA-sequencing analysis, we have identified the upregulation of several key cell signaling pathways involved in cell adhesion, migration, and proliferation in the co-cultured breast cancer cells. Furthermore, using bioorthogonal labeling, proximity labeling enzymes and immunostaining, we demonstrated intercellular protein and mitochondria trafficking between sensory neurons and breast cancer cells. This lateral cellular component transfer may implicate in cellular homeostasis, damaged cell repair, tumor progression and immunoregulation.
To further elucidate the mechanisms underlying this sensory neuron-cancer cell interaction, our research focuses on identifying the specific proteins being trafficked, investigating the structural aspects of the cellular connections involved, and understanding their functional implications. This will be achieved through techniques such as mass spectrometry, electron microscopy, whole-cell patch-clamp recording, microelectrode array, and intravital imaging, etc.
By studying the interactions between the peripheral nervous system and breast cancer within the tumor microenvironment, we aim to gain a comprehensive understanding of the molecular and cellular mechanisms driving breast cancer progression and potentially identify novel therapeutic targets.

Title: Incidence of Intracranial Tumours in Aged Spontaneously Hypertensive Rats

Authors: *A. C. J. KALISVAART[1], F. K. H. VAN LANDEGHEM[4,2], C. WILKINSON[3], F. COLBOURNE[1,2];
[1]Psychology, [2]Neurosci. and Mental Hlth. Inst., [3]Res. Ethics Office, Univ. of Alberta, Edmonton, AB, Canada; [4]Lab. Med. and Pathology, Univ. of Alberta Hosp., Edmonton, AB, Canada

Abstract: Background: Worldwide, annual incidence of intracranial tumours is approximately 20 per 100,000 people, or ~1.6 million based on the current global population. The risk of developing a primary intracranial tumour increases with age. Modelling these cancers accurately using translationally relevant animal models remains a challenge. Therefore, tracking tumour incidence and pathophysiology in laboratory animal species and sub-strains as they age naturally remains a valuable exercise in understanding cancer etiology, and is also relevant to modelling other age-related pathologies; here, we document our observations in aged spontaneously hypertensive rats (SHRs), a laboratory rat strain frequently used in cardiovascular research. **Methods:** Sixty male SHRs were aged to 20-24 months for other experiments. Intracranial tumour incidence was documented upon post-mortem necropsy following either: a) spontaneous death in cage, b) displaying clinical signs (e.g., ataxia, loss of balance/coordination, visual deficits), meeting premature euthanasia criteria, or c) upon serendipitous observation following euthanasia (e.g., no obvious clinical signs). Tissue samples were taken for assessment in consult with a neuropathologist (H&E, immunohistochemistry, transmission electron microscopy). **Results:** In our sample, 18 out of 60 SHRs developed intracranial tumours (30%), at 648 days old on average, or 1.8 years. Of these tumours, 77% were located on the ventral aspect of the brain at the suprasellar region (average volume of 227.7 mm^3), 11% were located on the superior aspect of the cerebellum (495.2 mm^3), and 11% were documented in multiple locations (suprasellar with brain infiltration, 30% of total average coronal section area, 284.9 mm^3 in volume). Suprasellar tumours had a reticulin-positive monomorphic sheet-like or insular-like cellular pattern, with eosinophilic cytoplasm, round to oval nuclei with salt and pepper chromatin, low mitotic activity, and stromal capillary networks. Taken together, evidence so far indicates a neuroendocrine tumour sub-type, but ongoing analyses of other targets remain. **Discussion/Conclusion:** Estimates of lifetime intracranial tumour incidence in other common laboratory rodent strains, such as Sprague-Dawley, Fischer, and Wistar rats, range from 0.5-5%. The comparatively high intracranial tumour incidence rate in our sample suggests that aged SHRs have a greater susceptibility to intracranial tumours versus other laboratory rodent strains, though this requires further investigation. Caution and enhanced monitoring are warranted when using very old SHRs in cardiovascular research to ensure their welfare.

Title: Dura macrophages bypass cerebrospinal fluid barrier to drive leptomeningeal metastasis progression

Authors: *J. ZHAO[1], Y. CHI[2];
[1]Inst. For Translational Brain Research, Fudan Univ., Shanghai, China; [2]Inst. for Translational Brain Research, Fudan Univ., Shanghai, China

Abstract: Leptomeningeal metastasis (LM) is a devastating complication characterized by the infiltration of cancer cells into leptomeninges and the cerebrospinal fluid (CSF). The prognosis of LM is dire with a grim survival of few months, and little progress has been made in improving survival outcomes. The immense number of myeloid cells at CSF barrier provide constant surveillance in the CSF and meningeal space, responsible for maintaining brain homeostasis. However, the myeloid cells have lost their function in controlling LM development, and the underlying mechanism by which tumor cells evade immune surveillance remains poorly understood, posing a significant challenge for the development of effective treatments. Here, we utilize genetic fate-mapping, longitudinal two-photon time-lapse imaging, and single-cell profiling technologies to investigate the precise origin, cellular crosstalk, and molecular landscape of macrophages that inhabit the CSF barrier and contribute to LM progression. Mechanically, we find that LM-associated macrophages (LAMs) originate locally from the dura mater, migrating into the CSF niche via a matrix metalloproteinase 14 (MMP14)-dependent manner. Further, we also identify the CSF-resident LAMs critically require the presence of secreted phosphoprotein 1 (SPP1) for their establishment and recruitment, leading to an immunosuppressed microenvironment. Conversely, suppression of the SPP1-MMP14 pathway via genetic or pharmacological interventions, which blocks the migratory capability of macrophage bypassing CSF barrier, can impede cancer cell proliferation and improve survival in LM mouse models. Together, our findings reveal a private source for LM-associated innate immunity within the meningeal space and supply the potential targets of immunotherapeutic interventions for LM.

Title: Nucleus Tractus Solitarii-specific activation by Tumor Necrosis Factor

Authors: *S. PETRUZZELLI[1], S. S. CHAVAN[2], K. J. TRACEY[2];
[1]Feinstein Inst. for Med. Res., Manhasset, NY; [2]Feinstein Inst. For Med. Res., Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: The inflammatory responses to infection and injury are tightly controlled by neural reflex mechanisms. Proinflammatory cytokines (such as TNF) produced by immune cells during infection and injury, and other inflammatory mediators have been shown to activate sensory signaling in the vagus nerve. However, it remains unclear whether the brain encodes cytokine-specific information. Here, we develop methods to map the neuronal populations in the Nucleus Tractus Solitarii (NTS), a brainstem nucleus that receives sensory input from the vagus nerve. Transgenic targeted-recombination-in-active-populations (TRAP2) mice that expressed tamoxifen-inducible Cre under control of an activity-dependent c-Fos promoter were crossed with a Cre-dependent tdTomato reporter line. These mice (TRAP2/tdTomato mice) were injected with 4-OHT (an active form of Tamoxifen) to induce Cre recombination and tdTomato expression. 30 min later, TNF was administered intraperitoneally to these mice. One week after initial TNF challenge, mice were re-challenged with TNF, and brains were harvested 2 h post for c-Fos immunostaining. Administration of TNF induces increased tdTomato expression (representing increased neuronal activity) in specific neuronal populations in the NTS. Re-challenging with TNF on day 7 revealed that a significant number of neurons TRAPed on day 0 (expressing tdTomato) are reactivated (tdTomato+ and c-Fos+) on day 7. Statistical analysis on double positive data shows a significant difference between the experimental and the control groups ($p= 0.0159$). In addition, re-exposure of mice to TNF results in the recruitment of additional neuronal populations in the NTS, as labeled by cFos only. A population of TNF-responsive neurons is found to be localized in the central and intermedial subnuclei within the NTS. Together, these studies reveal that the TNF-specific information is encoded in the brainstem NTS region.

Title: Disease and stage specific alterations of the oral and fecal microbiota in Alzheimer’s disease

Authors: S. PHILIPPEN[1], A. TROCI[2], P. RAUSCH[2], J. RAVE[1], G. WEYLAND[1], K. NIEMANN[1], K. JESSEN[1], A. FRANKE[2], C. BANG[2], ***T. BARTSCH**[1];

Abstract: The microbiota in the human gastrointestinal tract has been suggested to influence the etiopathogenesis of Alzheimer’s disease (AD). Although alterations in the gastrointestinal microbiome of AD patients have been reported, little is known about the microbiome in different stages of the disease.
Here, we used 16S rRNA analysis of fecal and oral samples from patients with AD and mild cognitive impairment (MCI) (n=84), a group of healthy adults with high-risk genotype (APOE4, n=17) and healthy sex- and age-matched controls (n=50) to characterize the microbial communities in the gut and the oral cavity. We further investigated the relationship of the microbial composition to Alzheimer’s disease specific biomarkers in the cerebrospinal fluid (CSF).
Results show the diversity of the fecal microbial communities to be slightly decreased in the patient cohort and differences in bacterial abundances are identified including Bacteroidetes, Ruminococcus, Sutterella, Porphyromonadaceae. In contrast, the diversity of the oral microbiome is increased in AD patients and at-risk individuals and significantly higher abundance of gram-negative pro-inflammatory Porphyromonas and members of the Proteobacteria, especially Haemophilus, Neisseria and Actinobacillus are observed in the oral microbiota of AD and MCI patients. The abundance of theses dominant bacteria correlates with the CSF biomarker of AD.
The findings show a shift in the microbial composition of AD patients which is already detectable in prodromal stage of MCI. In case of the oral microbiome, alterations are already dominant at the stage of individuals at risk. Altogether, this indicates stage-dependent alterations of the microbial composition in AD pointing towards a bacterial milieu facilitating systemic inflammation which might enhance neuroinflammation and neurodegeneration. Further investigations are needed to understand the dynamics of microbiome changes in the course of AD and its impact of the neurodegeneration in Alzheimer’s disease.

Title: The retina of Octodon degus: A natural model for studying biomarkers associated with diabetes during aging.

Authors: D. NEIRA[1], D. PONCE[1], M. ESCOBAR[3], P. REYES[3], F. MIQUELES[3], C. IBACETA-GONZALEZ[4], J. PORTAL[3], J. MINONZIO[2], J. ARAYA[5], ***A. G. PALACIOS**[1]; [1]Neurosci., [2]Ingeniería Informatica, Univ. de Valparaiso, Valparaiso, Chile; [3]Electronica, Univ. Federico Santa Maria, Valparaiso, Chile; [4]Inst. de Psychiatrie et Neurosciences de Paris, Paris, France; [5]Escuela de Tecnología Médica, Facultad de Salud, Univ. Santo Tomas, Santiago, Chile

Abstract: The Octodon degus, a native rodent from South America, naturally exhibit insulin resistance, positioning it as a valuable animal model in studying the pathophysiology of diabetes mellitus. In our study, young degus (YD, n=4) and adult degus (ADC, n=6) and without cataracts (AD, n=6), were housed under bioethical certification in the animal facility at the Universidad de Valparaiso. These animals underwent retinal physiological evaluations using multi-electrode experiments (252 channels, 20 KHz) from where we measured the micro electroretinogram (µERG), a measure of evoked visual potential to monitor both age-related physiological changes associated with cataracts. For the µERG a-wave response, indicative of photoreceptor activity, the AD group presented a higher at 867±343 µV ON-flash response amplitude compared to 570±293 µV for the YD group and 429±138 µV for the ADC group. In the case of the µERG b-wave response, associated with on-bipolar cell activity, the AD group also demonstrated a higher amplitude of 282±163 µV relative to the YD group 223±98 µV and the the ADC group with the lowest amplitude of 153±59µV ($p<0.0001$). Assessing the OFF-flash response, the amplitude for the µERG a-wave was 228±105 µV for AD, 184±50 µV for YD, and 209±88 µV for ADC. The µERG b-wave showed amplitudes of 602±263 µV for AD, 369±113 µV for YD, and 399±238 µV for ADC. In terms of the cut-off frequency response was highest for the ADC group at 5.0±1.2 Hz, compared to 3.8±0.4 Hz for YD and 3.6±0.5 Hz for ODC ($p<0.001$). An additional

indicator of retinal health status, the receptive field (RF) estimate was determined using a Stimuli Trigger Average (STA). The size of the RF was found to increase in AD degus compared to YD and ADC; displaying diameters of 168.46±70.95 µm, 136.58±29.13 µm, and 128.22±37.20 µm, respectively (mean±SD, $p<0.0001$). Data were analyzed using a two-way ANOVA followed by Tukey's multiple comparisons test for determining statistical significance. In summary, the retinal visual responses and RF characteristics of degus are influenced by age and cataract development. Further investigations are warranted in older degus to elucidate other potential age-related biomarkers.

Title: An improved Caenorhabditis elegans model of alzheimer's disease to monitor neuronal signalling activity

Authors: *V. BAJUSZOVA, N. COHEN, J. JOHNSTON;
Univ. of Leeds, Leeds, United Kingdom

Abstract: Alzheimer’s disease (AD) is the most prevalent form of neurodegenerative disease, characterised by the presence of Aβ plaques and neurofibrillary tangles, mediating memory impairments due to loss of neurons and impairments in neuronal plasticity. The most common model to study the toxic effects of Aβ in AD are transgenic rodents. However, these animals develop cognitive impairments making them suffer. Thus, to reduce and replace the rodent animals used to study these toxic effects, we are developing a *C. elegans* neuronal model of human $A\beta_{1-42}$. Existing Aβ transgenes available for *C. elegans* have fluorescent markers in or near the head preventing functional imaging of neural activity. To overcome this we have created a human $A\beta_{1-42}$ *C. elegans* strain that has a fluorescent co-injection marker in the posterior intestine. As glutamatergic signalling is one of the neuronal subtypes largely affected in AD, we are also generating constructs containing a glutamate and calcium sensor for imaging glutamatergic activity in all glutamatergic neurons and a subset of glutamatergic neurons. Expression of these constructs in the newly generated Aβ strain will allow simultaneous glutamate and calcium imaging to determine the onset of glutamatergic signalling defects and the subtype of glutamatergic neurons affected first.

Abstract: Synaptic changes are thought to underlie learning and memory, with synapse loss being considered the best correlate of memory impairment in Alzheimer's disease (AD). Multiple synapses, such as multi-spine boutons (MSBs), have been linked to learning and memory, however their role is poorly understood, and they are often overlooked in AD research. We have used 3-dimensional electron microscopy, which provides sufficient resolution to unequivocally identify and classify established synapses, to address whether MSBs are affected by memory formation in a mouse model, and if MSBs change in post-mortem AD brain. MSBs account for 20% of all synapses in mouse CA1 stratum radiatum, and their abundance does not change after contextual fear conditioning (CFC). However, CFC decreases the number of synapses per MSB, hence their complexity (n=3-5). Further, AD does not change the abundance of MSBs in transentorhinal cortex and stratum pyramidale, but their complexity is increased (n=3-6). Please note that in these brain regions, synapse number is conserved after CFC and in AD, respectively. Our results suggest that changes in MSBs complexity occur in AD brain, which are the opposite of learning-induced alterations in MSB complexity. The decreased MSB complexity seen after CFC may be needed for memory retrieval, therefore the increased complexity seen in AD is expected to impair memory, most likely the retrieval process, as too many neurons become inter-connected. The role of MSB's in memory will be further investigated by analysing MSB number and complexity in the APP PS1 mouse model of AD.

Title: Tau-mediated neurodegeneration disrupts emergent dynamics but not single neuron activity across sleep-wake states and cell types in a mouse model of tauopathy

Authors: *J. MCGREGOR[1], C. A. FARRIS[1], S. ENSLEY[1], Y. LIU[1], T. TU[1], K. RONAYNE[1], C. WANG[1], R. WESSEL[1], E. L. DYER[2], D. M. HOLTZMAN[1], K. B. HENGEN[1];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Neuronal activity is homeostatically-regulated around set-points of activity at the level of individual neurons and at the level of neuronal networks. These processes are thought to stabilize brain function across sleep-wake states, aging, and in response to perturbations. In the context of neurodegenerative disease, it is likely that these homeostatic mechanisms compensate for perturbations caused by toxic proteins, and only when these mechanisms are overwhelmed do neural dynamics become disrupted and symptoms emerge. However, it is unclear how neuronal activity is regulated around set points in the context of neurodegeneration. We performed chronic, multi-month electrophysiological recordings of ensembles of single units in CA1 of freely behaving wild-type mice (WT) and P301S/E4 mice (TE4), which are a mouse model of tauopathy. We found that the mean firing rate and coefficient of variation of interspike intervals (CV of ISIs) of individual neurons did not significantly differ between genotypes at any age, even late in the disease process. On the other hand, a homeostatic set-point of emergent properties of network dynamics (criticality) was significantly different between genotypes as a function of disease progression. We then developed a machine learning algorithm to automatically classify sleep-wake states from over 20,000 hours of extracted LFP data with an accuracy greater than 90%. We found that mean firing rates and CV of ISIs during wake, NREM, and REM did not significantly differ between genotypes at any age range, yet criticality was significantly altered across both wake and sleep states late in life. Further, we found that TE4 mice displayed a significant disruption of the natural sleep-wake cycle - one of the earliest known behavioral symptoms of neurodegenerative disease - which occurred at nearly the same age as the disruption in criticality. These results suggest that homeostatically-regulated set points of individual neuron activity remain remarkably stable across the sleep-wake cycle, age, and disease states, whereas set points of network activity are sensitive to disease states. The strong correlation between aberrant network activity and early symptoms of disease suggest that measures of network activity may serve as potential biomarkers.

Title: Alteration of sleep oscillations and activity of hippocampal parvalbumin neurons in the 5XFAD mouse model of Alzheimer's disease

Authors: *F. KATSUKI, J. M. MCNALLY, D. GERASHCHENKO, R. E. BROWN; Psychiatry, VA Boston Healthcare System/Harvard Med. Sch., West Roxbury, MA

Abstract: Neuronal network dysfunction is one of the early characteristics of Alzheimer's disease (AD). Another early characteristic of AD is sleep abnormalities, including changes in overall sleep pattern and sleep oscillations such as slow wave (0.5-1 Hz) activity and sleep spindles (10-15 Hz). These abnormalities correlate with the severity of amyloid-β deposition and cognitive impairment at later stages of the disease. However, the relationship between the AD-related cortical network dysfunction and sleep abnormalities is poorly understood. Here, we investigated whether abnormal activity of hippocampal (HPC) parvalbumin (PV) containing neurons during the early stage of AD is relevant to impaired sleep oscillations and cognition. To assess this, we simultaneously performed fiber photometry recordings and local field potential (LFP) recordings in the AD mouse model at different ages.
We performed sleep recordings from 6 5XFAD/PV-cre mice (AD) and 4 control PV-cre mice (Ctr) using LFP electrodes in medial prefrontal cortex (mPFC) and HPC. The fiber photometry recordings were performed in the contralateral side of HPC to identify and record activity of PV neurons in the same mice. Recordings were performed for 24h each month at ages 3-6 months-old (mo). To detect relevant signals in the photometry data, we computed a peak prominence value for each peak in the data and identified those which exceeded a threshold as the prominent peaks. The spontaneous Y-maze alternation task was performed to assess cognition.
The proportion of REM sleep during the 12h light (inactive) phase was significantly lower in the AD mice at 6 mo compared to 3 mo (paired t-test: $p=0.03$). NREM spindle density during the light phase in mPFC was significantly lower at 6 mo in AD mice (paired t-test: $p=0.01$). Decreased slow wave (SW) density (paired t-test: $p=0.01$) and SW-spindle coupling density (paired t-test: $p=0.008$) in HPC were also found at 6 mo in AD mice, while no significant changes were observed in Ctr mice. In fiber photometry data the proportion of prominent peaks detected in HPC PV neurons was decreased in AD mice at 6 mo. The % change in prominent peaks from 3 to 6 mo showed a significant correlation with % change in mPFC spindle density

(r=0.71, p=0.02). Although some AD mice showed a decline in Y-maze performance at 6 mo, the difference was not statistically significant.
The results suggest that changes in activity of HPC PV neurons might be linked to sleep oscillation changes in AD mice. Cognitive decline was not as robust at 6 mo, suggesting that changes in sleep and PV neuron activity observed here could be characteristics of earlier stages of AD before apparent cognitive impairment.

Title: Donor Mouse-derived Interneuron Progenitors Rescue Host Circuit Function in an Alzheimer's Model

Authors: *S. YOKOMIZO[1], M. MACI[1], M. MILLER[1], S. AYGAR[1], D. VOGT[2], J. R. NAEGELE[3], K. KASTANENKA[1];

Abstract: The number of Alzheimer's disease (AD) patients continues to escalate annually. Alzheimer’s patients are starting to gain access to FDA-approved disease-modifying therapies. However, those come with major risks and hence additional therapeutic strategies are needed. Sleep impairments have been identified in addition to memory deficits in Alzheimer’s patients. Disruptions of sleep-dependent brain rhythms, slow oscillations, prevalent during NREM sleep were observed in patients with AD as well as in the mouse models, including APP/PS1 mice. Reduced slow wave power was due to the dysfunction of GABAergic interneurons and low GABA. Thus, we hypothesized that transplantation of healthy Medial Ganglionic Eminence (MGE) inhibitory interneuron progenitors could restore inhibition and rescue cortico-thalamic circuit function driving slow oscillations in APP/PS1 hosts. To that end, healthy donor MGE progenitors were harvested from VGAT-Venus or VGAT-ChR2-EYFP mice and were transplanted into the cortices of host APP/PS1 mice. The viability, maturation, and differentiation of the transplanted donor MGE progenitors were assessed via immunohistochemistry. Furthermore, to determine the functionality of donor inhibitory neurons and their effect on slow oscillations, voltage-sensitive dye imaging was conducted 2 months post-transplantation once the donor cells had time to mature and incorporate into host circuitry.

Furthermore, light activations of ChR2 in APP/PS1 mice transplanted with VGAT-ChR2-EYFP cells were undertaken to measure the effect of optogenetic stimulation on slow oscillations. We found that the transplanted MGE progenitors not only survived but also differentiated into mature interneurons expressing somatostatin and parvalbumin markers within the host mice. Importantly, transplantation of healthy MGE progenitors restored the slow wave power in APP/PS1 mice 2 months post-transplantation. Optogenetic activation of donor interneurons further increased the power of slow oscillations. These results suggest that stem cell therapy with MGE progenitors warrants further investigation and could hold promise as a therapeutic strategy to combat the progression of Alzheimer's disease.

Abstract: N-methyl-D-aspartate receptors (NMDARs) are primary mediators of Ca^{2+} influx into excitatory neurons. According to the Ca^{2+} hypothesis, hyperactivity of NMDARs and excitatory neurons is an initial and chronic pathogenic mechanism of late-onset sporadic AD and related dementia (ADRD). We identified that GluN3A(NR3A), a negative regulatory subunit of NMDARs, is critical for Ca^{2+} homeostasis while its deficiency is a genetic factor contributing to NMDAR-mediated degenerative excitotoxicity and the development of AD/ADRD. Aging GluN3A knockout (KO) mice exhibited moderate but persistent neuronal hyperactivity, elevated intracellular Ca^{2+}, and neuronal loss, accompanied by age-dependent olfactory deficit and psychological/cognitive dysfunctions as well as amyloid/tau pathology. In this study, we use diffusion tensor imaging (DTI) to determine the selective vulnerability of associated neuronal connections between the olfactory system, the vision system, and the hippocampus, which are

critical for sensory memory. The DTI analysis yields valuable phenotypical information, such as early regional atrophy, and quantitative biomarkers that can be analyzed within the context of networks. Ex vivo MR images of all isolated brains were acquired on the 7-T MRI system, using a 4-channel mouse array coil. The brains are fixed in 4% PFA solution before transferring to a Fomblin solution. After insertion of the containing tube in the coil and optimizing the magnet, a high-resolution 3D T2 weighted RARE anatomical scan and a high-resolution DTI scan at the same resolution as T2 were performed on each brain. The DTI scan was processed for fiber tracking analysis and the network connectivity between interested regions was performed. The significance of network connectivity lies in its ability to integrate microstructural effects, such as neurodegeneration of gray and white matter or toxicity associated with Ca^{2+}-mediated degenerative excitotoxicity. The volume derived from DTI scan revealed significant reductions of the olfactory bulb and superior colliculus. Moreover, tractography determined markedly decreased neuronal tract numbers between the olfactory bulb and the hippocampus for olfactory memory as well as between the superior colliculus and lateral geniculate nucleus for vision function in the aging GluN3A KO brain. The analysis of brain connections including the volume of specific structures and neuronal tracks provides insight into network aberrations during the progression of this sporadic AD/ADRD model.

Title: Alzheimer's disease triggers unusual structural plasticity in human dentate granule cells

Authors: *B. MÁRQUEZ-VALADEZ[1,2,3,4], A. RABANO[5,6], M. LLORENS-MARTÍN[1,2,3,4]; [1]Neurophatology, Ctr. de Biología Mol. “Severo Ochoa”, Madrid, Spain; [2]Spanish Res. Abstract: Alzheimer´s disease (AD), the most common form of dementia in industrialized countries, severely targets the hippocampal formation in humans and mouse models of this condition. The adult hippocampus hosts the continuous addition of new dentate granule cells (DGCs) in numerous mammalian species, including humans. Although the morphology and positioning of DGCs within the granule cell layer (GCL) match their developmental origin in rodents, a similar correlation has not been reported in humans to date. Our data reveal that DGCs located in inner portions of the human GCL show shorter and less complex dendrites than those found in outer portions of this layer, which are presumably generated developmentally. Moreover, in AD patients, DGCs show early morphological alterations that are further aggravated as the disease progresses. An aberrantly increased number of DGCs with several primary apical dendrites is the first morphological change detected in patients at Braak-Tau I/II stages. This alteration persists throughout AD progression and leads to generalized dendritic atrophy at late stages of the disease. Our data reveal the distinct vulnerability of DGCs located in the inner and outer portions of the GCL to AD and support the notion that the malfunction of the hippocampus underlies cognitive impairments in patients with AD.

Abstract: Amyloid-beta oligomers (AβOs) are thought to initiate a pathological cascade that leads to Alzheimer's disease in humans. We have previously shown (Beckman et al., 2019, PNAS) that one month of treatment of rhesus monkeys with synthetic AβOs leads to neuroinflammation and reductions in thin dendritic spines in dorsolateral prefrontal cortex. This phenotype resembles accelerated cortical aging, which may set the stage for vulnerability to developing Alzheimer's disease. The consequences of AβO treatment on brain function in this model are not known. We tested male and female rhesus monkeys on a battery of behavioral, cognitive, and affective tasks. Testing included spatiotemporal working memory (delayed response), visual recognition memory (delayed nonmatching-to-sample), 24-hour activity levels in the home environment, affective reactivity (human intruder test and object reactivity), and autonomic responses to affective videos. Individuals carrying out testing and scoring of behavioral data are blinded to treatment condition. Following completion of training, monkeys then received 9 weekly infusions into the lateral ventricle of AβOs derived from postmortem brains of humans with Alzheimer's disease (N = 5), or control material that was identical except for the immunoprecipitation of AβOs out of the infusate prior to infusion (N = 4). Monkeys experienced a decrease in locomotor activity during the infusion period relative to pre-infusion baseline. This decrease was attenuated in the AβO group, perhaps reflecting increased locomotor activity associated with the development of neuroinflammation. Retesting on all cognitive and affective tasks will occur after infusions are complete and will provide insight as to whether the AβO infusions adversely impact these domains. Following the behavioral assessments, the monkeys will be perfused and analyzed for cellular and synaptic reflections of neuropathology. These data will provide direct evidence on whether pathological sequelae of AβO administration in rhesus monkeys are accompanied by impairments in cognition and affect that are characteristic of individuals in the early stages of Alzheimer's disease, potentially validating this as a novel nonhuman primate model of early Alzheimer's pathogenesis.

Title: Complex effects of age, sex, and Alzheimer’s Disease on hippocampal spatial coding

Authors: *R. LONG[1], Y. FANG[3], G. J. AUGUSTINE[4], S.-C. YEN[2];
[1]N.1 Inst. of Hlth., [2]Engin. Design and Innovation Centre, Col. of Design and Engin., Natl. Univ. of Singapore, Singapore, Singapore; [3]Ageing Res. Inst. for Society and Education, Interdisciplinary Grad. Programme, [4]Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: Encoding of spatial memory in the human hippocampus is impaired during aging and in Alzheimer's disease (AD), with women being more susceptible to AD than men. However, the interactions between age, sex, and AD remain poorly understood. We compared spatial coding in wild-type (WT) mice and in an AD model mouse with three human AD-related APP mutations (APP-TKI; Nature Neurosci. 17: 661). *In vivo* two-photon calcium imaging was used to measure the activity of hippocampal CA1 neurons while the animals traversed a 220-cm treadmill. The effects of aging, AD, and sex on spatial coding were examined in both genotypes by comparing young (3–8 months) and old (17–24 months) animals of both sexes. Dimensionality reduction (Isomap) was used to represent neural population activity as manifolds and a linear mixed-effects model was used to test the significance of effects. Age affected the mean curvature of these manifolds ($d = 1.57$, $p < 0.01$). For old mice, both AD ($d = -1.38$, $p < 0.05$) and sex ($d = -1.89$, $p < 0.01$) significantly affected the mean curvature, with a significant interaction ($d = 3.13$, $p < 0.05$) between them. We also characterized manifold topology by using persistent homology, specifically focusing on the properties of 1-dimensional homologies (H1). For the rank of H1, which signified the number of 1-dimensional holes in the manifold, there was a significant age effect ($d = 1.38$, $p < 0.01$). For old mice, there was a non-significant AD effect ($d = -0.834$, $p = 0.076$), a significant sex effect ($d = -1.32$, $p < 0.01$), and a significant AD and sex interaction ($d = 1.78$, $p < 0.05$). Furthermore, age significantly affected the length of the longest H1 interval ($d = -1.49$, $p < 0.01$), which captured the continuity of the longest uninterrupted segment of the manifold. For old mice, both AD ($d = 1.77$, $p < 0.01$) and sex ($d = 2.29$, $p < 0.01$) had a significant effect, with significant negative interaction between AD and sex ($d = -4.05$, $p < 0.01$). In summary, old female APP-TKI mice had more severe spatial memory impairment than their male counterparts. Surprisingly, this trend was reversed in the WT mice, with the old male mice exhibiting greater spatial memory impairment than old female mice. Our overall findings suggest that sex differences play a major role in both aging-related and AD-related impairment of spatial memory coding.

Title: Hyperexcitability of interneurons is causally involved in early neuronal network dysfunction and memory impairment in APP/PS1 mice

Authors: *M. ABDOLLAHI NEJAT[1], S. HIJAZI[2], A. B. SMIT[1], R. E. VAN KESTEREN[1]; [1]Dept. of Mol. and Cell. Neurobiology, Ctr. for Neurogenomics and Cognitive Res., VU Univ. Amsterdam, Amsterdam, Netherlands; [2]Dept. of Pharmacol., Univ. of Oxford, Oxford, United Kingdom

Abstract: Imbalances in neuronal networks resulting from alterations in both the excitatory and inhibitory signaling pathways are thought to play a role in the pathogenesis of Alzheimer's disease (AD). Here, we contribute to the growing evidence of neuronal network dysfunction as an early symptom in AD by highlighting alterations in specific inhibitory interneurons in the hippocampus CA1 of APP/PS1 mice, a mouse model for amyloidosis. Specifically, we show that both hippocampal parvalbumin (PV) and somatostatin (SST) interneurons are hyperexcitable at an age of ~16 weeks, while pyramidal neuron excitability remains unaltered. The hyperexcitable state of these interneurons is concurrent with increased inhibitory transmission onto hippocampal pyramidal neurons and coincides with impairments in spatial learning and memory. Interestingly, hippocampal PV interneurons exhibit a biphasic response, becoming hypoexcitable at ~24 weeks of age, while SST interneurons remain hyperexcitable. Our previous work shows that early intervention aimed at preventing PV interneurons from becoming hyperexcitable not only restores alterations in PV interneuron excitability in the short-term, but also has long-term beneficial effects on memory and hippocampal network activity. We now show that also early intervention targeted at restoring SST interneuron activity results in long-lasting restoration of SST interneuron excitability. Interestingly, targeting SST interneurons also rescued PV interneuron function on the long term. These findings suggest that the imbalances in hippocampal neuronal networks observed in AD may involve the dysfunction of multiple inhibitory interneurons, and that early intervention targeted at restoring interneuron activity could have clinical implications in terms of preventing memory decline.

Title: Aberrant coding patterns in the prefrontal-hippocampal circuit during naturalistic risky decision-making in a mouse model of Alzheimer's disease

Authors: *E. KIM[1], S. PARK[3], B. P. SCHUESSLER[4,5], H. BOO[1], J. CHO[3], J. J. KIM[1,2]; [1]Psychology, [2]Program in Neurosci., Univ. of Washington, Seattle, WA; [3]Brain and Cognitive Sciences, Scranton Col., Ewha Womans Univ., Seoul, Korea, Republic of; [4]VA Northwest Geriatric Res. Educ. and Clin. Ctr., [5]VA Northwest Mental Illness Research, Education, and Clin. Ctr., VA Puget Sound Hlth. Care Syst., Seattle, WA

Abstract: The focus of basic research on Alzheimer's disease (AD) using animal models has predominantly centered on neuropathological markers and memory loss. However, there remains a significant gap in our understanding of how AD distinctly affects the neural circuit mechanisms underlying risky decision-making. This study aimed to investigate how the presence of amyloid pathology affects risky foraging decisions and prefrontal-hippocampal circuit activity in a mouse model of AD. To achieve this, five familial AD (5XFAD) and wild-type (WT) mice (4-9 mos old) were subjected to a naturalistic 'approach food-avoid predator' paradigm, adapted from Kim et al. (2016). Animals implanted with tetrode arrays in the medial prefrontal cortex (mPFC) and dorsal hippocampus (dHPC; targeting the CA1 subregion) ipsilaterally went through successive stages of nest habituation, baseline foraging, and predator testing in a T-shaped maze with two different pellets in each arm (grain-based vs. chocolate-flavored). Neural activities were recorded during the predator testing, which consisted of successive pre-predator, predator, and post-predator stages. During the predator trials, each time the animal approached the preferred pellet, a predator (a puppet eagle on wheels) surged forward via a linear actuator, while no predator was present on the non-preferred pellet side. In response to the predator, the WT mice switched their foraging strategy from preferred to non-preferred pellets. In contrast, the 5XFAD mice continued to choose their preferred pellets at a high rate, indicating an inability to adjust their foraging behavior flexibly in the face of threats. The WT mice showed threat distance-dependent stability of dHPC place cells between the pre-predator and predator sessions, while the 5XFAD mice displayed comparable levels of session-by-session spatial correlations across the place field locations. At the risky decision point, the proportion of synchronous dHPC-mPFC cell pairs decreased in 5XFAD mice compared to the WT group. Following predator encounters, 5XFAD mice exhibited decreased and shortened dHPC sharp-wave ripple activity compared to the WT mice. However, both WT and 5XFAD mice displayed comparable post-shock and contextual freezing in a contextual fear conditioning paradigm, indicating that unconditioned and conditioned fear levels remained intact in 5XFAD mice. These findings suggest that the impairments in risky decision-making in AD might stem from abnormal interregional neuronal interactions between the dHPC and mPFC.

Title: Monosynaptic Rabies Viral Tracing Reveals Subiculum Circuit Connectivity Alterations in Alzheimer's Disease

Authors: *Q. YE, G. GAST, E. G. WILFLEY, H. HUYNH, C. HAYS, X. XU;
UC Irvine, Irvine, CA

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease in the elderly and causes progressive memory and behavioral impairment. Examining the changes in neural circuitry using AD model mice is an emerging strategy for a better understanding of AD neural mechanisms toward discovering new therapeutic targets. Our recent work indicates the disruption of long-range and local neural circuit connections in the hippocampus using an AD mouse model. The subiculum is the major output structure of the hippocampus and is among the earliest AD-impacted brain regions. We hypothesize that age-progressive alterations also occur in the neural circuit organization of the subiculum in the 5xFAD mouse model. To comprehensively map cell-type-specific circuit inputs, we utilized the novel viral-genetic tool of monosynaptic rabies tracing. We quantitatively assessed and compared the circuit connectivity of subiculum excitatory neurons in age-matched C57BL6 control and 5xFAD model mice at young and middle ages (3-4 months vs 8-9 months) in both sexes. The major subiculum input brain regions mapped by rabies tracing include hippocampal subregions, medial septum and diagonal band (MS-DB), subiculum (SUB), post subiculum (post SUB), visual (VIS) cortex, auditory (AUD) cortex, entorhinal cortex (EC), thalamus, and temporal association cortex (TeA). Our results reveal significant alterations in local and long-range circuit connections to the subiculum in AD model mice. The overall brain-wide connectivity strengths of subiculum inputs in aged AD model mice are weaker than in wild type mice. There are significant age and sex differences in the connectivity strengths of multiple input regions, including the hippocampal CA1, CA2, MS-DB, thalamus, RSC, VIS, AUD, and TeA. Our work provides new insights into subiculum-directed neural circuit mechanisms during AD progression and supports neural circuit disruptions as a prominent feature of AD.

Title: Revealing hidden sensorimotor memories in mice with AD-relevant pathology

Authors: *A. SANTI, S. MOORE CORONA, A. WANG, J. LAWLOR BLONDEL, K. FOGELSON, K. KUCHIBHOTLA;
Johns Hopkins Univ., Baltimore, MD

Abstract: Memories must be accessible for them to be useful. Alzheimer's disease (AD) is a progressive form of dementia in which cognitive capacities slowly deteriorate due to underlying neurodegeneration. Interestingly, anecdotal observations have demonstrated that Alzheimer's patients can exhibit cognitive fluctuations during all stages of the disease. In particular, it is thought that contextual factors are critical for unlocking these hidden memories. To date, however, exploration of the neural basis of cognitive fluctuations has been hampered due to the lack of a behavioral approach in mouse models to dissociate memories from contextual performance. Our previous work demonstrated that interleaving 'reinforced' trials with trials without reinforcement ('probe' trials) in an auditory go/no-go discrimination task, allows us to distinguish between acquired sensorimotor memories and their contextual expression. Here, we used this approach, together with two-photon calcium imaging on behaving AD-relevant mice (APP/PS1+), to determine whether amyloid accumulation impacts underlying sensorimotor memories (measured using 'probe' trials) and/or contextual-performance (measured using 'reinforced' trials) in an age dependent manner. We found that, while contextual-performance was significantly impaired in 6-8mo APP/PS1+ mice compared to age-matched controls, sensorimotor memories were surprisingly intact. At later ages (12mo), however, APP/PS1+ mice began to show deficits in both domains suggesting a sequence where contextual performance degrades before the sensorimotor memories. Using two-photon imaging in the auditory cortex of 6-8mo APP/PS1+ mice, we found that the poor contextual performance was accompanied by network suppression, reduced stimulus selectivity, and aberrant behavioral encoding. Impairments were not due to peripheral hearing deficits (measured by auditory brainstem response) and were concentrated near Aβ plaques. Strikingly, these deficits were less apparent in probe trials, suggesting the sensorimotor memory trace remains intact. These effects were recapitulated with a reinforcement learning model in which deficits in contextual scaling and inhibition explain the observed effects. Taken together, these results suggest that Aβ deposition impacts the integration of behavioral signals that enable contextual performance before degrading the underlying sensorimotor memory, suggesting that modulating these circuits may hold promise to reveal hidden memories.

Title: Impaired long term potentiation of lateral entorhinal input to CA1 in 5xFAD mice

Authors: M. THANGAVEL, C. TIAN, I. REYES, *A. V. MASURKAR;
Dept. of Neurol., NYU Grossman Sch. of Med., New York, NY

Abstract: **Motivation/problem statement:** Alzheimer disease (AD) disrupts synaptic integrity and plasticity in CA1, with evidence primarily for CA3→CA1 inputs. How AD disrupts direct entorhinal cortex (EC) inputs to CA1 and their plasticity is understudied, despite its critical role in memory. Moreover, dysfunction of lateral EC (LEC) input is less clear, despite its relevance to early AD pathogenesis. Here we examined how amyloid impacts long-term potentiation (LTP) of LEC→CA1 input in a transgenic model of amyloidosis. **Methods:** Acute hippocampal slices were prepared from 5xFAD and WT mice (7-8 mo. old, M/F) in which LEC had been injected with an AAV expressing ChR2. Ex vivo recordings were achieved with blue LED light to excite LEC axons and an extracellular field electrode in *stratum lacunosum moleculare* (SLM) of distal CA1 to record field responses. Input-output curves were established using 25-100% LED power for field postsynaptic potentials (fPSP) and postsynaptic excitatory potentials (fEPSPs) with inhibition intact and blocked (GABAA: 2μm SR95531, GABAB: 1μm CGP55845), respectively. LTP of fPSPs and fEPSPs was elicited with LED stimulation after a 10” baseline using theta burst stimulation (TBS). Fluorescence immunohistochemistry (IHC) was performed in separate mice using antibodies to N-type calcium channels. **Results:** All results are based on n=3-8/sex/genotype. LEC fPSP input-output curves were similar in WT and 5xFAD mice across both sexes. In contrast, LEC fEPSP slope input-output curves were reduced only in female 5xFAD mice, by ~50% compared to WT. TBS induced a late-onset LTP of the LEC fPSP of similar amplitude in female WT and 5xFAD mice (30” onset, 60” peak ~28%). With inhibition blocked, LTP of the fEPSP was earlier in onset (5-10”) and reached a higher 60” peak (~35%) in WT female mice, whereas in 5xFAD female mice it remained late-onset and reached a lower 60” peak (~17%). IHC of N-type calcium channels showed reduced fluorescence in the SLM of female 5xFAD mice versus WT. **Conclusion:** In 5xFAD mice, the impact of amyloid on LEC→CA1 input is sex-dependent, with alterations in female mice suggestive of reduced LEC-driven excitation and inhibition that maintains net excitatory impact. This alteration impacts the LTP of LEC→CA1 excitatory input, in both its onset and overall amplitude. A reduction in N-type calcium channels in female 5xFAD mice may serve as a presynaptic mechanism for these findings.

Title: Frequency-specific and sex-specific effects of sensory stimulation in a female mouse model of Alzheimer's disease

Authors: *A. PRICHARD[1,2], T. FRANKLIN[1], M. GOODSON[1], V. SILLS[1], M. SERI[1], E. SNYDER[1], A. KHAN[1], V. BHAT[1], C. HE[3], A. SINGER[1];

Abstract: Beneficial and maladaptive neuroimmune responses play a key role in the progression of Alzheimer's disease. We have found that noninvasive audiovisual neurostimulation (flicker) has different neuroimmune effects depending on the frequency of light and sound stimulation, which could be useful to induce different neuroimmune responses in the context of Alzheimer's disease pathology. However, few studies have examined flicker's effects in healthy and transgenic female mouse models of amyloidoisis, despite the known sex-specific differences in Alzheimer's disease etiology and incidence. In male animals, flicker alters hippocampal microglia morphology, an indicator of microglia activity, in healthy and transgenic male mouse models of Alzheimer's disease. Audiovisual flicker at 40Hz also improves memory performance in male mouse models of Alzheimer's disease. We discovered that neuroimmune signaling, including NFkB and cytokines, plays a causal in flicker's effects on microglia morphology. Neuromodulators and neurotropic factors are also known to affect microglia function, however the role of these factors in flicker's effects remain unknown. Accordingly, we tested the hypothesis that flicker induces frequency-specific effects on behavior, microglia, and neuromodulators and neurotrophic factors that regulate microglia in female mice. We examined changes in microglia morphology as well as neuromodulators and neurotrophic factors in the hippocampus and prefrontal cortex following exposure to chronic (1hour/ day for 7 days) audiovisual flicker across frequency, sex, and the presence or absence of amyloid pathology. We found sex-specific and frequency-specific differences in microglia morphology compared to no stimulation, as well as behavioral differences based on flicker frequency in female mouse models of AD. These results provide evidence that flicker frequency-induced changes to neuropathology as well as memory performance are driven by frequency and are dependent on sex. We suggest that these results may guide the future optimization of flicker interventions for neurodegenerative disease in humans.

Title: Optogenetic 40 Hz stimulation of parvalbumin- and somatostatin-expressing interneurons synergistically generate gamma oscillations and induce behavioral changes in wild-type and Alzheimer's disease mice

Authors: *E. S. BRADY[1], P. HONMA[1], P. NAMBIAR[1], Y. QIU[1], S. SAILLET[1], J. J. PALOP[1,2];
[1]Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]Dept. of Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: Network hypersynchrony and alterations to neuronal oscillations begin to occur in the early stages of Alzheimer's disease, ultimately resulting in impaired cognition. Changes to gamma oscillations as a result of amyloid pathology have previously been identified, with research from our lab suggesting these alterations occur as a result of dysfunctional inhibitory neurotransmission. Both parvalbumin (PV)- and somatostatin (SST)-expressing interneurons are thought to contribute to the generation of gamma oscillations and there is evidence for both groups of interneurons being affected in mouse models of amyloidopathy. What is still to be elucidated is the relative contribution of PV- and SST-expressing interneurons to generating the gamma oscillation in awake *in vivo* recordings and the cell type-specific effects amyloid pathology has upon their function. Therefore, using wild-type and hAPP-J20 mice, we sought to answer these questions using a combination of *in vivo* electrophysiology in freely moving animals and optogenetics. Optogenetically exciting PV-expressing interneurons at 40 Hz reliably induced a 40 Hz gamma oscillation, whereas stimulating SST-expressing interneurons at the same frequency did not. Interestingly, simultaneous stimulation of both groups of interneurons using mice expressing channelrhodopsin in Lhx6+ cells resulted in a larger increase in gamma oscillation power than with PV alone, suggesting a synergistic relationship between these two groups of interneurons. We further explored the effects of Lhx6+ interneuron-induced gamma oscillations and found that this stimulation paradigm could bring about real-time changes in spontaneous behavior in the open-field, identified using a machine learning approach. Lastly, in hAPP-J20 mice we found that the ability of PV+ and Lhx6+ interneurons to generate 40 Hz gamma was impaired, resulting in a reduction in gamma oscillation power. Changes to the extracellular action potentials of both PV+ and Lhx6+ interneurons were identified as well as impairments in the coupling of these interneurons and their post-synaptic targets to the gamma oscillation. Taken together, these experiments highlight the synergistic relationship between PV- and SST-expressing interneurons in generating gamma oscillations and the susceptibility of this circuitry to Alzheimer's disease-associated pathology.

Title: Entorhinal-hippocampal desynchronization in a mouse model of Alzheimer's disease pathology

Authors: *L. M. VETERE[1], N. VAUGHAN[2], A. GALAS[1], O. LIOBIMOVA[3], Y. FENG[1], D. J. CAI[1], T. SHUMAN[1];

Abstract: Background: Alzheimer's disease (AD) is an age-related neurodegenerative disease characterized by progressive cognitive decline and memory loss. Impairments in spatial navigation and hippocampal function in AD are well established, but it is unclear whether these changes are driven primarily by local dysfunction, or by altered inputs, such as projections from medial entorhinal cortex (MEC). Methods: To understand how AD pathology alters entorhinal-hippocampal circuits, we used male and female 3xTg mice, which express mutations in APP, presenilin, and tau. We performed acute *in vivo* silicon probe recordings to simultaneously record local field potentials and single units from MEC and hippocampus. Head-fixed mice were trained to run on a virtual reality linear track and recordings were performed during active navigation. By recording in two age groups, we were able to compare neural activity before and after the onset of spatial memory impairments. Results: We find an early loss of theta synchrony between MEC and CA1 prior to cognitive decline in 6-month-old 3xTg mice compared to WT controls. This desynchronization suggests a loss of communication between these brain regions, even before the onset of spatial memory impairments. Conversely, we detect decreases in hippocampal theta and fast gamma power (amplitude) that progress with age in 3xTg mice and coincide with the onset of spatial memory impairments at 8-months-old. Given that hippocampal theta power is driven in part by MEC inputs, loss of hippocampal theta power may reflect further loss or dysfunction of MEC inputs. Decreased fast gamma power may indicate a combination of altered inputs and local hippocampal changes. Ongoing analysis will examine how physiological changes on the single cell level could mediate these differences. Conclusions and Future Directions: Our data highlight early desynchronization between MEC and hippocampus prior to memory impairments. This could serve as a potential early biomarker, which is notable as the importance of early detection and treatment for AD is gaining attention. We also find changes in hippocampal oscillations that progress with age and coincide with cognitive impairment. Overall, these data will inform future experiments where we manipulate these circuits to prevent or reverse memory impairments.

Title: Entorhinal cortex circuit dysfunction in mouse models of APOE4 and chemotherapy-induced cognitive impairment

Authors: *N. LUO[1], S. VICINI[2], G. REBECK[3];
[1]Neurosci., Georgetown Univ. Med. Ctr. Interdisciplinary Program In Neurosci., Washington, DC; [2]Dept Parmacology & Physiol., Georgetown Univ. Med. Ctr., Washington, DC; [3]Neurosci., Georgetown Univ. Sch. of Med., Washington, DC

Abstract: *APOE4* has broad effects, one of which is worsened cognitive outcomes in cancer survivors following chemotherapy treatment compared to *APOE3*. We used 1-2 month old female *APOE3* and *APOE4*-Targeted Replacement (TR) mice treated with and without doxorubicin (a breast cancer chemotherapeutic) to determine 1) the effects of *APOE* genotype on normal circuit function in the entorhinal cortex- a critical brain region responsible for information gating between the cortex and hippocampus - and 2) the *APOE* genotype effects on entorhinal circuit function in the presence of doxorubicin. Whole cell patch-clamp experiments were performed in layer II/III pyramidal cells in the entorhinal cortex and cells were filled with 0.5% biocytin to visualize morphology *post hoc* under a confocal microscope. Two types of excitatory cells were identified based on morphology: pyramidal and stellate. Chemotherapy was introduced via a single intraperitoneal injection of doxorubicin (10 mg/kg) or saline (control). Mice were euthanized one-week post-injection. We found that pyramidal cells in the entorhinal cortex of *APOE4*-TR mice (4 mice, n=23 cells) exhibit significantly decreased spontaneous inhibitory postsynaptic current frequencies, thereby contributing to an elevated excitatory-inhibitory balance compared to *APOE3*-TR mice (4 mice, n=22 cells). Doxorubicin-treated *APOE3*-TR mice (4 mice, n=28 cells) showed a significant increase in spontaneous excitatory and inhibitory postsynaptic current amplitude compared to controls (2 mice, n=13 cells), while doxorubicin-treated *APOE4*-TR mice (5 mice, n=18 cells) displayed no such synaptic changes compared to controls (4 mice, n=18 cells). These findings suggest that 1) *APOE4* brains have baseline deficits in entorhinal cortex circuit inhibition and 2) *APOE4* brains lack a robust response to chemotherapy, potentially increasing vulnerability to cognitive impairment. To investigate inhibitory-specific dysfunction in the entorhinal cortex, we bred *APOE* mice with TdTomato/Parvalbumin (PV)-Cre mice to look at passive and active properties of PV cells - the most abundant inhibitory cell type in the entorhinal cortex.

Title: Intrinsic neural timescales link structural and network abnormalities in Alzheimer's disease

Authors: *S. A. MURAI[1], T. MANO[2], J. N. SANES[3,4,5], T. WATANABE[1];
[1]Intl. Res. Ctr. for Neurointelligence (WPI-IRCN), Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Degenerative Neurolog. Dis., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]Dept. of Neurosci., [4]Dept. of Carney Inst. for Brain Sci., Brown Univ., Providence, RI; [5]Ctr. for Neurorestoration and Neurotechnology, Veterans Affairs Providence Healthcare Syst., Providence, RI

Abstract: Alzheimer's disease (AD) is associated with brain atrophy and atypical functional changes in the default mode network (DMN). However, much remains unknown regarding the brain region(s) whose local brain atrophy induces atypical network activity in the DMN. We measured intrinsic neural timescales (INT) to potentially identify one or more brain regions that trigger such DMN abnormalities and to bridge knowledge gaps between atypical structural and functional changes in the DMN in AD. INT, known as temporal receptive windows or temporal receptive fields, represents the time window for one brain region to integrate inputs from other regions. The DMN, which receives inputs from myriad brain areas, has a crucial role in cognitive capability in older adults (Ezaki et al., 2018) and typically exhibits longer INT compared to other sensory-related brain regions. Furthermore, a previous study that focused on autism spectrum disorder revealed that atypically shorter INT in the sensory cortex was a key mediating factor to account for a significant correlation between the atypical reduction in the grey matter volume (GMV) in the regions and autistic symptoms (Watanabe et al., 2021). These outcomes suggest that INT may link local neuroanatomical changes to atypical neural processes and lead to DMN impairment and cognitive symptoms of AD. Here, we compared INT, using resting-state functional MRI methods, between patients diagnosed with AD and age-/sex-/handedness-matched cognitively healthy individuals. We first performed an exploratory whole-brain analysis and found a shorter INT only in the left angular gyrus (AG) in the AD group compared to the cognitively normal group. We also found that the left AG exhibited AD-specific decreases in

GMV and that the diminished GMV induced the shorter INT in the left AG, which in turn caused shortened overall INT within the DMN. In addition, we found that the overall INT of the DMN was associated with the symptomatic severity of AD, especially for attention-related functions. Taken together, the left AG represents a crucial region whose structural atrophy and resultantly shorter INT leads to DMN impairment, which consequently results in AD symptoms. Given that INT length indicates the capacity of local information integration, these findings suggest that, in individuals with AD, the atrophy of the left AG disturbs the DMN's capability to integrate information from diverse neural inputs, which underlies a part of cognitive decline in AD. Our findings suggest the possibility that INT of the left AG could serve as a convenient biomarker for diagnostic and therapeutic use.

Title: Differential neural circuit vulnerability to β-amyloid and tau pathologies in Alzheimer's disease mice

Authors: M. D. CAPILLA-LÓPEZ[1,2], A. DEPRADA[1,2], *J. RODRIGUEZ-ALVAREZ[1,2], A. PARRA-DAMAS[1,2], C. A. SAURA[1,2];
[1]Inst. de Neurociències, Univ. Autònoma de Barcelona, Barcelona, Spain; [2]Ctr. de Investigación Biomédica en Red Enfermedades Neurodegenerativas (CIBERNED), Madrid, Spain

Abstract: Alzheimer's disease (AD) is characterized by memory loss and neuropsychiatric symptoms, but how amyloid-β (Aβ) and microtubule-associated protein tau (*MAPT*) cooperate to cause synaptic changes underlying memory and emotional disturbances in dementia is largely unknown. We employed pathological, behavioral, tissue clearing/expansion microscopy, and bulk and cell-specific transcriptomic approaches to evaluate sex and aging effects of amyloid-β (Aβ) and/or tau pathologies on memory- and emotional-related neural circuits in amyloid precursor protein (APP), Tau and double APP/Tau transgenic mice. Compared to single transgenic mice, Aβ pathology increased phosphorylated tau in the hippocampus of 9 month-old

APP/Tau mouse females, whereas tau had not effect on amyloid pathology, indicating that Aβ promotes tau pathology. Interestingly, APP/Tau mice develop learning and memory deficits associated with tau pathology in hippocampal excitatory neurons, whereas innate anxiety and impaired fear memory extinction were linked to Aβ accumulation in the basolateral amygdala (BLA). Tissue clearing/3D imaging in novel neuronal activity reporter AD mice (APP/Tau;*c-fos*$_{p}$-EGFP) revealed impaired activation of excitatory neurons coinciding with synaptic accumulation of tau and reduced synaptic proteins in the hippocampus. Importantly, transcriptional profiling reveals region-specific but also common transcriptional changes in response to Aβ/tau pathology in the hippocampus and BLA, including deregulation of 63 AD risk genes involved in synapse transmission and inflammation. These findings indicate that APP/Tau mice reproduce pathological, behavioral, synaptic, and transcriptional changes linked to known molecular determinants of AD development. The differential regional effects of Aβ and tau in emotional- and memory-related neural circuits provide evidence that both factors should be considered in future AD therapeutic strategies.

Title: Masupirdine (SUVN-502), a pure 5-HT$_6$ receptor antagonist: Rationale for evaluation in patients with agitation in dementia of Alzheimer's type

Authors: *P. JAYARAJAN, R. MEDAPATI, V. GRANDHI, R. ABRAHAM, R. BADANGE, K. BOJJA, S. MANCHINEELLA, A. SHINDE, R. NIROGI;
Suven Life Sci. Ltd., Hyderabad, India

Abstract: Agitation in Alzheimer’s disease (AD) is one of the disabling neuropsychiatric symptoms most commonly observed in AD. It affects the patients’ quality of life and results in considerable caregiver distress. Currently there are limited pharmacological agents for the management of agitation. The commonly used agents possess modest efficacy and carry several notable safety concerns like increased risk of mortality, sedation, falls, and worsening of cognitive skills. Thus, there is a need for novel, efficacious and safe agents. Serotonin-6 (5-HT$_6$) receptors are G-protein-coupled receptors with unique localization and specific distribution in the brain regions having a role in mood, and behaviour. In addition, clinically used psychotropic agents have strong affinity for 5-HT$_6$ receptors. Thus, modulation of 5-HT$_6$ receptors may have therapeutic utility for behavioural disorders. Masupirdine is a pure and potent 5-HT$_6$ receptor antagonist. In animal models for aggressive behaviour i.e., dominant-submissive assay (DSA) and resident-intruder task (RIT), masupirdine was evaluated at doses ranging from 1 to 10

mg/kg. Oral administration of masupirdine significantly ($p<0.05$) attenuated aggressive behaviors. In addition, masupirdine significantly modulated levels of dopamine and norepinephrine in brain at a dose of 10 mg/kg, *s.c.* The post hoc analysis of the Phase-2 study (NCT02580305) in patients with moderate AD suggested treatment with masupirdine at 50 mg and 100 mg significantly decreased the agitation/aggression score from Week 13 to Week 26 suggesting potential treatment effects of masupirdine on agitation/aggression symptoms. To explore the beneficial effects, masupirdine is currently being evaluated as a monotherapy in a global Phase-3 study for the potential treatment of agitation in participants with dementia of Alzheimer's type (NCT05397639).

Hosp. of Munich, Dept. of Nuclear Med., Munich, Germany; [5]Univ. Hosp. of Munich, Dept. of Psychiatry and Psychotherapy, Munich, Germany; [6]Aging Epidemiology (AGE) Res. Unit, London, United Kingdom

Abstract: Background. The locus coeruleus (LC), the main noradrenergic nucleus and primary source of noradrenaline (NA) in the forebrain is one of the earliest brain regions affected in Alzheimer's disease (AD). Patients with AD often experience olfactory deficits decades before the onset of cognitive impairments, highlighting the potential of early diagnosis for effective

treatment. Here, we seek to better understand the mechanisms underlying the vulnerability of the LC in the context of olfaction. **Methods.** We used female and male wild-type (WT, C57BL/6J) mice and transgenic APP^{NL-G-F} mice, aged between 1 and 12 months. **Results.** Our immunohistochemical findings reveal an age-dependent loss of LC-noradrenergic axons in the olfactory bulb (OB), starting as early as 2 months. Notably, at 3 months of age, LC axonal loss is exclusively observed in the OB. This loss coincides with olfactory dysfunction, as demonstrated by impaired performance in a buried food test. Reducing NA release in the OB by optogenetics recapitulates the olfactory phenotype. We observe altered electrophysiological properties of LC neurons in 6-month-old APP^{NL-G-F} mice compared to WT mice. Importantly, the integrity of mitral cells, the main output neurons in the OB, remains unaffected. Asking for the underlying mechanism of LC axon loss we hypothesized that microglia engulf damaged LC axons. To test this, we investigated the role of the translocator protein (TSPO) in LC vulnerability. The LC axon loss is reduced in APP^{NL-G-F} crossed with TSPO-KO mice and the olfactory performance remains unaltered compared to WT animals. This suggests that microglia, the main cell type expressing TSPO, are involved in the degradation process of LC axons. We also conducted positron emission tomography (PET) scans to assess early neuroinflammation and show elevated TSPO-PET signals in the OB region of patients with mild cognitive impairment, which did not further increase in AD patients. All patient groups show hyposmia and the post-mortem tissue analysis of a different cohort of prodromal AD patients reveals a decline of LC axons in the OB. **Discussion.** In summary, our study highlights the early-onset loss of LC-noradrenergic axons in the OB and its contribution to olfactory dysfunction in a mouse model of AD and in post-mortem brain tissue from prodromal AD patients. Additionally, we provide evidence suggesting the involvement of microglia in the LC-axon vulnerability. Our findings elucidate the early changes in the LC and offer insights into the potential mechanisms underlying olfactory deficits in AD, thereby providing a potential target for therapeutic strategies aiming at slowing or halting the disease progression.

Title: Consequences of locus coeruleus degeneration in a rat model of Alzheimer's disease

Authors: *A. E. MARRIOTT[1], M. A. KELBERMAN[1], A. KORUKONDA[1], J. P. SCHROEDER[2], K. E. MCCANN[1], D. WEINSHENKER[1];
[1]Dept. of Human Genet., [2]SOM: Core Labs, Emory Univ., Atlanta, GA

Abstract: Background: The noradrenergic locus coeruleus (LC) is exceptionally susceptible to insult during Alzheimer's disease (AD), beginning with the early accumulation of hyperphosphorylated tau and culminating in frank neuronal loss. Inducing LC damage with the selective neurotoxin N-(2-chloroethyl)-N-ethyl-2-bromobenzylamine hydrochloride (DSP-4) exacerbates AD-like neuropathology and cognitive impairment in amyloid-based murine models of AD, indicating a causal relationship between LC degeneration and disease progression. Unlike other rodent models, TgF344-AD rats display both amyloid and tau pathology and develop endogenous tau in the LC prior to other brain regions, as observed in human AD. By inducing LC-specific damage in TgF344-AD rats using DSP-4, this study will explore the impact of LC degeneration on AD- and noradrenergic-relevant behaviors.
Methods: At ~1 month of age, male and female TgF344-AD rats and wild-type littermates received 2 doses of DSP-4 (50 mg/kg) or saline spaced 1 week apart, followed by single monthly injections until ~5 months of age. Behavioral testing began ~1 week following the final injection to assess changes in social behavior, stress-induced repetitive behaviors, arousal, anxiety-like behavior, and learning and memory.
Results: The effects of DSP-4 were more pronounced than those of genotype. In general, DSP-4 treated animals showed blunted stress-induced repetitive behaviors and circadian locomotor activity. DSP-4 animals also displayed augmented contextual freezing in a fear conditioning paradigm.
Conclusions: We have shown that depletion of NE by DSP-4 has profound effects of stress-induced repetitive behaviors, locomotor activity, and contextual fear memory. The reduction in repetitive behaviors such as nestlet shredding and stick chewing, as well as diminished locomotor activity in NE-depleted rats is consistent with the important role of LC-NE transmission in arousal.
Typically, 7-8-month-old TgF344-AD rats do not display deficits in fear conditioning, a measure of associative learning. Because LC degeneration is correlated with cognitive deficits in human AD, we expected LC lesions would unmask this phenotype, causing DSP-4 treated animals to exhibit less contextual freezing. However, the opposite effect was observed.
The next step is to assess the effects of the DSP-4 on AD-like pathology and noradrenergic dysfunction in the TgF344-AD rats using immunohistochemistry and high-performance liquid chromatography. Based on previous experiments in other rodent models of AD, it is anticipated that neuroinflammation, Aβ, and aberrant tau will be exacerbated in DSP-4 treated TgF344-AD rats.

Title: Disrupted neuromodulatory regulation of cortical network dynamics in Alzheimer's Disease

Authors: *P. XU, C. BARNES, R. OREN, S. COOK, J. NWAINOKPOR, J. A. CARDIN; Yale Univ., New Haven, CT

Abstract: Disruption of major neuromodulatory centers, including the cholinergic neurons of the basal forebrain Nucleus Basalis (NB), is a hallmark of multiple neurodegenerative diseases such as Alzheimer's Disease (AD). Loss of coordinated cholinergic signaling likely contributes to perturbation of state-dependent neural activity and cognitive functions, including attention, arousal, and memory. Both cellular degeneration of the basal forebrain and the cognitive impacts of decreased cholinergic signaling are recapitulated at older ages in mouse models of AD, suggesting that early detection of neuromodulatory dysregulation could be a key biomarker of initial pathology. We recently developed an approach for dual-color mesoscopic imaging of neuromodulatory release and neural activity across the dorsal cortex of awake behaving mice. Because imaging can be performed through the skull and requires only short sessions, animals can be imaged across the lifetime in a moderate-throughput screen. Using this approach, we imaged cholinergic release and neural activity in animals from the APP/PS1 and AppNL-G-F/MAPT dKI mouse lines across ages. To express genetically encoded indicators for acetylcholine (ACh) and calcium, we injected AAVs carrying ACh3.0 and RCaMP1b into the transverse sinus of neonatal mice from both lines and wildtype controls. Behavioral states were continuously monitored using pupillometry, running speed, and facial motion. Regression analyses were used to examine the predictive relationship between ACh and calcium signaling in different cortical regions across behavioral states. In young adult mutants and controls, both ACh and calcium activity exhibited significant spatial and temporal heterogeneity, varying with behavioral state and cortical region. Correlation analyses revealed state-dependent differences in the spatial structure of cholinergic signaling and the coupling between ACh signaling and local cortical activity, which varied reliably across cortical areas and behavioral states. At later time points (>P240), we observed a progressive disruption of state-dependent cholinergic signaling in mutants from both lines. Mutant mice showed a loss of the correlational structure for both ACh and calcium signals across cortical areas, which became more pronounced with increasing age. Additionally, AD mutants in both groups exhibited a decoupling between cholinergic and local cortical activity. Together, our results suggest a progressive disruption of cholinergic signaling in AD mutants that culminates in a loss of state-dependent regulation of neuronal activity and a loss of spatiotemporal coordination of network activity.

Title: Dopaminergic neuron degeneration and loss of reward processing in an Alzheimer's disease rat model

Authors: *B. E. LINNEMAN[1], L. A. ADRIAN[2], T. J. SLOAND[2], M. NIEDRINGHAUS[2], E. A. WEST[2];

Abstract: Alzheimer's disease (AD) is typically characterized by memory loss and the accumulation of neuropathological markers, however neuropsychiatric symptoms of AD, such as apathy, are often overlooked. Degeneration of dopaminergic neurons in the ventral tegmental area (VTA) have been implicated in the loss of motivated behaviors in both an AD mouse model and human patients. Using a transgenic AD rat model expressing both behavioral phenotypes and histological markers consistent with the AD human population (TgF344-AD “AD rats”), we investigated motivated behavior to a natural reward. We conducted a conditioned place preference (CPP) in which one side was paired with Froot Loops as the palatable reward and the other side was paired with food chow (6 pairings each, 1 pairing/day) in AD and wild-type (WT) littermate control rats of both sexes at ages 2-3 months (WT, n=6, AD n=7) and 6-7 months (WT, n=12, AD n=12) of age. We found that 2-3-month rats formed a conditioned place preference to the chamber paired with the palatable reward, but this preference was absent in 6-7-month-old AD rats (Δpreference, AD=-0.04 +/- 0.07, WT= 0.29 +/- 0.08, $t=3.1$, $p<0.01$). In addition, we found a decrease in consummatory behavior of the palatable reward relative to the food chow in AD rats relative to WT rats at 6-7-months but not at 2-3 months (reward type x age x genotype interaction: $F=23.5$, $p<0.0001$) suggesting that age-related deficits in conditioned place preference in AD rats could be due to an age-dependent decrease in the motivational value of Froot Loops to AD rats. This loss of CPP could also indicate a contextual learning deficit, thus, we performed a conditioned place aversion assay in which we paired one side of the conditioned place chamber with raucous sounds and flashing lights and the other paired with no noise in AD (n=12) and WT (n=16) rats. We found that at 6-7 months of age, both AD and WT rats form a conditioned place avoidance (Δpreference, WT: -0.34 +/- 0.07, AD: -0.32 +/- 0.1, $t=0.1$, $p=0.91$). Together, these findings suggest that the inability of the AD rats to form a preference to the context predicting the palatable reward is likely not due to impairment in contextual learning at this age. Finally, in our 6-7-month-old AD rats, we also found a significant loss of Tyrosine Hydroxylase (TH+) cells in the VTA, potentially indicating that the inability to form a preference may be linked with a loss of dopamine. Together, these findings indicate an age-dependent decrease in motivation in AD rats for a palatable reward that is not due to deficits in contextual memory.

Title: Examining noradrenergic changes in the AppNL-G-F mouse model of Alzheimer's Disease

Authors: N. KILIC[1], H. KAUR[2], *C. COMBS[1];
[1]Univ. of North Dakota Sch. of Med., Grand Forks, ND; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Alzheimer's disease (AD)-associated neuronal death has been hypothesized to include degeneration of the norepinephrine (NE) producing locus coeruleus (LC) neurons as an initial region of loss responsible for propagating death to efferent projection areas. However, the mechanisms explaining this early and preferential dysfunction of the noradrenergic system remain unclear. To better understand LC changes during disease we compared littermate control six-month-old male and female C57BL/6 wild type mice to the *App*$^{NL-G-F}$ knock-in model of AD (n=6). Immunostaining for tyrosine hydroxylase, as the rate-limiting enzyme for norepinephrine synthesis, was used to quantify cell loss in the LC. As a relevant efferent output of the LC, we quantified norepinephrine levels in the hippocampus and compared this, via western blot, to levels of the catabolic enzymes, monoamine oxidase A (MAO-A), catechol O-methyltransferase (COMT), and monoamine oxidase B (MAO-B). Western blot analysis was also used to assess overall presynaptic and post-synaptic compartment integrity through quantifying levels of synaptophysin and PSD95, respectively. Finally, compensatory changes in noradrenergic receptor levels were also quantified by western blot. As expected, we observed a significant reduction in hippocampal NE levels in both male and female *App*$^{NL-G-F}$ mice. Surprisingly, this did not correlate with any change in TH immunoreactivity in the LC suggesting that cell death was not responsible for the observed decrease in NE. To investigate whether the decrease in NE levels might result from altered norepinephrine turnover, we assessed levels of COMT, MAO-A, and MOA-B and observed a selective increase in MAO-A levels in both sexes of *App*$^{NL-G-F}$ mice compared to wild type controls. As a possible consequence of the NE deficiency, we quantified a decrease in hippocampal protein levels of beta-2 adrenergic receptors (β2-AR) in male and female *App*$^{NL-G-F}$ mice compared to wild-type controls. There were no differences in synaptophysin or PSD95 in *App*$^{NL-G-F}$ compared to wild type mice in either sex suggesting no overall synaptic loss in the hippocampus. Our findings revealed a specific modulation of β2-AR

and MAO-A levels in the *App*$^{NL-G-F}$ mice that is not associated with robust cell death or synaptic loss. These data suggest a potential selective disruption in adrenergic signaling. Moreover, this change in NE neuron function may identify an early phenotype change during disease that precedes or contributes to eventual neuron and synaptic loss.

Title: Genetic and social influences on cognitive flexibility and fronto-insular circuits in a mouse model of Alzheimer's Disease

Authors: *H. WNUK[1], Y. ZUO[2], K. WANG[3];
[1]Univ. of Rochester, Rochester, NY; [2]UC Santa Cruz, Santa Cruz, CA; [3]Neurosci., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Social interaction is an important factor in the progression of Alzheimer's Disease (AD), a dementia that impairs an individual's cognitive functions. Recent research has implicated the fronto-insular cortical circuits in socioemotional processing and regulation of cognitive flexibility. However, how social interaction influences AD pathology in fronto-insular cortices and cognitive flexibility associated with these regions is unknown. Here, using the APP/PS1 mouse model of amyloidosis, we investigated how APP/PS1 mutations and social housing impact fronto-insular pathology and cognitive flexibility in the attentional set-shifting task (AST). Three-month-old adult APP/PS1 and wild-type (WT) mice were housed in group or isolation for one month and then tested in AST, followed by histological assays of AD-related biomarkers. Our data showed that these four groups of mice performed similarly well in simple sensory discrimination tasks to obtain food reward, suggesting intact sensorimotor and motivation functions in the early stage of this APP/PS1 model. In contrast, APP/PS1 mice exhibited significant deficits in shifting attention to relevant cues in a different sensory dimension, which is known to depend on fronto-insular function. Furthermore, APP/PS1 mice showed greater individual variations in cognitive performance compared to WT mice, and these variations were moderated by social housing and body weight loss due to food restriction before AST. Interestingly, group housed APP/PS1 mice with more weight loss exhibited greater cognitive impairment relative to APP/PS1 mice with less weight loss, or WT mice of comparable weight loss, whereas an opposite trend was observed in isolated mice. Additional histological analyses revealed increased amyloidosis and microglia coverage, as well as altered c-Fos gene

expression, in prelimbic and anterior insular cortices of socially isolated mice compared to group housed mice. Together, these results indicate that fronto-insular dependent cognitive flexibility function is particularly vulnerable to the detrimental effects of APP/PS1 mutations. Our studies further suggest that social interaction and bodily changes jointly moderate the severity of cognitive impairment in individual animals with genetic dispositions to AD, which may provide a model system to investigate the underlying neural mechanisms and test potential intervention strategies.

Title: BAC transgenic mouse model of human MS4A4E modifies amyloid pathology and transcriptome in 5xFAD mice

Authors: *A. J. DE LA ROCHA[1], X. GU[1], C. LEE[1], P. LANGFELDER[2], X. YANG[1,3]; [1]Ctr. for Neurobehavioral Genet., [2]Dept. of Human Genet., [3]Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: Genome Wide Association Studies (GWAS) have identified several AD risk loci in the Membrane-Spanning 4-Domains subfamily A (MS4A) gene cluster on chromosome 11. The MS4A genes are expressed in myeloid cells, including microglia, and are involved in immune response and regulation. One of the most significant traits associated with these MS4A variants is the level of soluble Triggering Receptor Expressed on Myeloid Cells 2 (sTREM2), a biomarker of AD, in the cerebrospinal fluid. However, it is unknown how these MS4A genes confer risk and how they are connected to sTREM2 processing and secretion. We generated a Bacterial Artificial Chromosome (BAC) transgenic mouse model to express the MS4A gene cluster (named BAC-MS4A mice). The BAC contains a human genomic locus, encompassing MS4A4A, MS4A6A, MS4A4E, and their surrounding proximal regulatory region. Notably, the mice carrying MS4A BAC only express human MS4A4E, a gene that has yet to be understood in the context of AD pathogenesis, but not MS4A4A or MS4A6A. We crossed BAC-MS4A mice with 5xFAD, an amyloid depositing mouse model of AD, and found an exacerbation of plaque pathology in male, but not female, 5xFAD/BAC-MS4A mice in both the cortex and hippocampus at 7 months old. The plaques in the cortex and hippocampus of 5xFAD/BAC-MS4A males were also more fibrillary than those of 5xFAD control mice. Moreover, RNA sequencing analysis of cortical tissue also revealed a sex-dependent increase in the number of

differentially expressed (DE) genes in male 5xFAD/BAC-MS4A compared to 5xFAD controls, including further upregulating the expression of several Disease-Associated Microglia (DAM) genes. Together, our results indicate that human-specific MS4A4E could be a modifier of amyloid AD. This human genetic mouse model could be used to decipher the role of the MS4A gene locus in AD pathogenesis, and the mechanism underlying the association between sTREM2 and the MS4A gene cluster.

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease with complex etiology. Predicting AD risk is critical for early diagnosis and disease intervention. AD is attributed to polygenic genetic components; multiple variants across the human genome thus jointly contribute to disease susceptibility. The polygenic nature of AD allows life-time risk prediction by evaluating polygenic risk scores (PRSs) accounting for the combined effects of disease-associated genetic variants. Meanwhile, many AD biomarkers have been developed to examine disease risk and progression, such as plasma amyloid beta, phosphorylated tau, and neurofilament light proteins. Given the complexity of AD etiology, nonlinear interactions among genetic variants and the crosstalk between genetic and non-genetic factors play critical roles in the modulation of disease risk, while traditional (generalized) linear models fail to consider such effects. Nonetheless, deep learning methods can capture nonlinearity within high-dimensional data, which may enable more accurate disease risk prediction and improve our understanding of AD etiology. Accordingly, we developed a neural network model to model the nonlinear polygenic risk and its interaction with protein biomarkers for predicting AD. Our comprehensive analyses demonstrate that the neural network model outperforms the traditional regression models for predicting AD risk. Moreover, we stratified the genetic risks by performing unsupervised clustering based on the polygenic risk and plasma protein biomarkers. We showed that the stratified disease risks correlate with critical disease-associated biological pathways. Therefore, our findings suggest that deep learning methods are effective in leveraging multi-omic profiles for predicting and stratifying AD risk.

Abstract: Variants within *ABCA7*, which encodes a member of the ABC lipid transporter superfamily, can be associated with increased risk of late onset Alzheimer's disease (LOAD). Knock out studies have implicated ABCA7 in microglial phagocytosis, clearance, and lipid metabolism. The human ABCA7 variant V1599M, encoded by SNP rs117187003, has been reported to have differential risk for developing LOAD in GWAS meta-analyses. We used CRISPR to generate mice with an *Abca7^{V1613M}* allele, which models the human V1599M variant, and crossed these mice with the 5xFAD mouse model of amyloidosis. Primary microglia from *Abca7^{V1613M}* homozygous pups, in the absence of amyloid beta (Aβ) pathology, had increased phagocytic capacity for beads and Aβ1-42 peptide compared to wild-type controls, indicating the involvement of ABCA7 in microglial phagocytosis. Furthermore, differential gene expression profiles were observed between wild-type and *Abca7^{V1613M}* mice after LPS challenge, which suggested impaired resolution of inflammation in *Abca7^{V1613M}* mice.We also investigated the effects of the *Abca7^{V1613M}* variant on lipid metabolism. Analysis of plasma lipids showed increased cholesterol and trending increases in HDLs, triglycerides, and vLDLs in homozygous *Abca7^{V1613M}* mice. Bulk lipidomics of cortical tissue revealed distinct changes in lipid composition in 5xFAD hemizygous/*Abca7^{V1613M}* homozygous mice compared to 5xFAD controls, including increased phospholipids. Regarding Aβ plaque pathology, 5xFAD/*Abca7^{V1613M}* mice had fewer plaques in the cortex and subiculum compared to 5xFAD mice, which was sustained from 4 to 12 months of age. 5xFAD/*Abca7^{V1613M}* mice also showed reduced Aβ-40 and -42 in both insoluble and soluble fractions of hippocampal and cortical tissue compared to 5xFAD controls. Western blot analysis revealed reduced full-length APP and C-terminal (C99/C83) fragments, but no effect on BACE-1, PSEN1, or ADAM-10 in 5xFAD/*Abca7^{V1613M}* mice compared to 5xFAD controls. 5xFAD/*Abca7^{V1613M}* mice also had reduced Aβ-associated inflammation, as indicated by bulk RNA-seq and WGCNA analysis, and reduced microgliosis and astrogliosis. There were age-associated changes in neuronal damage, with reduced LAMP1, plasma and brain NfL levels in 5xFAD/*Abca7^{V1613M}* mice compared to 5xFAD controls in both 4- and 12-month animals.Overall, the findings suggest that the *Abca7^{V1613M}* variant influences phagocytosis, response to LPS challenge, lipid metabolism, Aβ pathology, inflammation, and neuronal damage in the 5xFAD mouse model. The variant may confer a gain of function for ABCA7 and potentially contribute to a protective effect against AD-related pathology.

Title: From Transcription to Degeneration: Investigating Dysregulation of R-Loop Homeostasis in Neurodegenerative Disorders

Authors: *E. M. ARNOLD[1], J. L. BURFORD[1], D. J. MORTON[1], L. A. HIGGINSON[1], N. A. BARR[1], A. SETH[2];
[1]Mol. and Computat. Biol., [2]USC, Los Angeles, CA

Abstract: A substantial amount of effort has been devoted to investigating the dysregulation of protein homeostasis in neurodegenerative diseases. Despite this, our understanding of the underlying mechanisms responsible for initiating or perpetuating these phenotypes remains incomplete. Mounting evidence suggests that the dysregulation of transcriptional regulatory events, including the formation of regulatory DNA:RNA hybrids (R-loops), are key factors in the pathogenesis of neurodegenerative disease. R-loops are transient, mainly co-transcriptional, three-stranded structures that consist of an RNA:DNA hybrid and a single-stranded DNA strand that is displaced by the RNA strand. In addition to their role in genomic instability, R-loops are thought to contribute to gene expression by inducing changes in chromatin structure, thereby modulating lineage-specific promotor-enhancer interactions. Interestingly, mutations in key regulatory proteins required for R-loop resolution and homeostasis are associated with a variety of neurodegenerative diseases. Thus, dysregulation of R-loop homeostasis may serve as a potential unifying initiating event that underlies a spectrum of neurodegenerative disorders. The goal of this study is to identify associations between pathological R-loops, altered gene expression and neurodegenerative phenotypes. To examine R-loop homeostasis, we have begun to systematically and comparatively examining the formation and/or persistence of R-loops and their effect on gene expression by utilizing well-established Drosophila models of neurodegenerative disease (Alzheimer’s disease, Parkinson’s disease, and ALS). To begin to assess the formation of R-loops across distinct age-related neurodegenerative disorders in Drosophila, we employed S9.6 antibody-mediated slot blots utilizing fly brain tissue. Our preliminary findings indicate that we can detect R-loops in flies modeling neurodegenerative disease. Given that several recent studies that challenge the reported specificity of S9.6 antibody toward RNA:DNA hybrids, we will perform a modified CUT& RUN approach termed MapR in flies. MapR exploits the natural affinity of RNase H to detect RNA:DNA hybrids. The combination of these approaches will allow comprehensive understanding of the impact of

aberrant R-loop formation on gene expression in neurodegenerative disorders. Thus, this integrated approach will provide insights into the specific targets affected by R-loop-mediated pathological processes and underlying neurodegenerative diseases.

Abstract: Alzheimer’s Disease (AD) is the most common form of neurodegeneration, currently affecting over 6 million Americans. Previous research suggests that circular RNAs (circRNAs) are heavily implicated in neuronal gene regulation; however, their precise role in AD pathogenesis has yet to be established. In this study, we examined circRNA of two AD-causing genes, presenilin 1 and 2 (PSEN1 and PSEN2), for the presence of pathogenic variants. cDNA from individuals with familial AD (FAD) was PCR amplified using divergent primers to target back-spliced regions specific to circRNAs, and the purified PCR product was subsequently Sanger sequenced. Four variants, I143T, S212Y, V272A in PSEN1, and N141I in PSEN2, were identified in circRNAs. The presence of pathogenic variation in circRNAs marks a crucial first step in determining their role in AD pathogenesis. To our knowledge, this research is the first of its kind to identify pathogenic variants in circRNAs of AD risk genes.

Title: The RELN-COLBOS mouse model of resilience to Alzheimer's disease

Authors: *C. MARINO[1], S. AREVALO-ALQUICHIRE[1], H. GORDON[1], P. PEREZ-CORREDOR[1], D. SEPULVEDA-FALLA[2], Y. T. QUIROZ[3], J. F. ARBOLEDA-VELASQUEZ[1]; [1]Dept. of Ophthalmology, Harvard Med. Sch., Boston, MA; [2]Inst. für Neuropathologie, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany; [3]Massachusetts Gen. Hosp., Boston, MA

Abstract: We recently characterized the second patient with extreme protection against autosomal dominant Alzheimer's disease (ADAD) caused by the Presenilin-1 (PSEN1) E280A mutation. This male individual did not develop mild cognitive impairment until his 70s, more than two decades after the expected age at onset for his family. We discovered that his resilience against ADAD was facilitated by the presence of a rare mutation in the RELN gene, the H3447R (termed RELN-COLBOS mutation). The gain of function of RELN-COLBOS, along with our previously discovered loss of function of ApoE3 Christchurch variant, allowed us to hypothesize the presence of a converging mechanism of protection against ADAD characterized by the reduced interaction of ApoE and the increased interaction of RELN with heparan sulfate proteoglycans (HSPGs). Here, we characterized the function of RELN-COLBOS mutation by generating a novel knock-in transgenic mouse model, using neuronal density analysis, immunohistochemistry, western blotting, and behavioral studies. Our data confirmed that the RELN-COLBOS mutation is sexually dimorphic and operates via increased phosphorylated disabled-1 protein (pDAB1) levels, and reduced tau hyperphosphorylation. The RELN-COLBOS mutation also improved motor functions in a crossed mouse model to a transgenic tau model, thus validating its protective effect and suggesting therapeutic potential against dementia.

Title: Increased ER-to-mitochondria calcium signaling due to presenilin loss results in lysosomal enlargement and alkalization

Authors: K. C. RYAN, Z. ASHKAVAND, J. T. LABOY, *K. R. NORMAN;
Regenerative and Cancer Cell Biol., Albany Med. Col., Albany, NY

Abstract: Compromised lysosome function is implicated in the pathology of many neurodegenerative diseases. Alzheimer’s disease (AD) models show defective clearance of lysosomal contents, but the cause is unclear. Familial Alzheimer’s disease (FAD) is caused primarily by mutations in the presenilin encoding genes, but the underlying mechanism remains obscure. We previously reported that loss of the conserved *C. elegans* presenilin orthologue SEL-12 results in increased mitochondrial calcium, which promotes mitochondrial dysfunction and neurodegeneration. Here, we find that the lysosomes in *sel-12* null mutants are significantly enlarged and more alkaline due to increased ER-to-mitochondrial calcium signaling. We further show that lysosome dysfunction is independent of SEL-12 protease function. Additionally, these defects and their dependence on mitochondrial calcium are recapitulated in human FAD cells, demonstrating a conserved role for mitochondrial calcium in presenilin-mediated lysosome dysfunction. We also find that *sel-12* mutants have increased contact surface area between the ER, mitochondria, and lysosomes, suggesting *sel-12* has an additional role in modulating organelle contacts and organelle communication. Overall, we have demonstrated that SEL-12 maintains lysosome acidity and lysosome health by controlling ER-to-mitochondrial calcium signaling.

Title: Total PLCG2 ablation impairs microglial responses and confers diverse transcriptional alterations in a murine model of Alzheimer's disease

Authors: *E. J. MESSENGER[1], A. P.-Y. TSAI[4], P. B.-C. LIN[5], G. XU[1], A. N. ANSARI[1], A. OBLAK[6], B. T. LAMB[6], G. E. LANDRETH[2], S. J. BISSEL[3];

Abstract: Many of the genes associated with altered risk for Alzheimer's disease (AD) are predominantly expressed in microglia and affect innate immune responses. Among these genes is phospholipase C gamma 2 (PLCG2), a critical mediator of transmembrane signaling that acts downstream of many immune receptors on microglia, including TREM2. PLCG2 is robustly induced by amyloid pathology in AD and recent transcriptomic studies suggest a vital role for PLCG2 in the immune response to AD pathology, learning, and metabolism. Reduction in PLCG2 activity is associated with exacerbated AD pathology, but the mechanisms underlying these effects remain unclear. Therefore, we explored the impact of *Plcg2* ablation or haploinsufficiency on amyloid pathology and microglial response in the amyloidogenic 5xFAD murine model of AD and compared this to 5xFAD mice deficient in *Trem2* to establish contributions of upstream signaling. While *Plcg2* haploinsufficiency increased X34+ and 6E10+ amyloid plaque pathology, loss of *Plcg2* in 5xFAD mice results in similar plaque burden as wildtype and *Trem2*-deficient mice. Additionally, *Plcg2* deficiency significantly impaired microglial interactions with plaques and showed reduced immunoreactivity of microglia activation marker CD68 when compared to *Plcg2*$^{+/-}$ mice. Transcriptomic analysis revealed several biological processes altered by loss of *Plcg2*, including pathways associated with the microglial response, metabolism, synapses, and cell signaling. Weighted gene correlation network analysis (WGCNA) produced many significant modules of co-expressed genes such as those associated with immunity, metabolism, mitochondrial respiration, and synaptic connectivity. Importantly, one module was differentially expressed between each genotype and contained many immune-related genes, including disease-associated microglia (DAM) genes. These findings suggest PLCG2 depletion impairs the ability of microglia to effectively transduce surface receptor signals in response to amyloid plaques, leading to a stunted immune response. Overall, this study highlights the importance of PLCG2 in the innate immune response to amyloid pathology and reveals several novel pathways which may be regulated by PLCG2.

Title: Tip60 HAT-specific activators as an epigenetics-based therapeutic strategy for Alzheimer's Disease

Authors: *A. ZAYA[1], A. BHATNAGAR[1], S. KORTAGERE[2], F. ELEFANT[1];
[1]Biol., Drexel Univ., Philadelphia, PA; [2]Drexel Univ. Col. of Med., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Reduced histone acetylation in the brain caused by disruption of histone acetylation homeostasis is an early event in Alzheimer's Disease (AD) etiology that causes cognitive impairment prior to amyloid beta plaque formation. While genetics plays a role in the development of AD, over 90% of patients hospitalized for AD are diagnosed with sporadic AD, highlighting the importance of epigenetic dysregulation in disease progression. Numerous small molecules, including epigenetic modulators, are currently in clinical trials for AD. These epigenetics-based treatments aim to restore histone acetylation homeostasis by inhibiting histone deacetylases (HDACs), which remove acetyl marks from histones causing chromatin to condense, leading to a reduction in gene expression. While promising, many HDAC inhibiting treatments are not specific to one HDAC, causing side effects likely due to global hyperacetylation. Our work focuses on Tip60 histone acetyltransferase (HAT), which generates pattern-specific acetyl marks onto histones to decondense chromatin, leading to enhanced transcription. We have shown that genetically increasing Tip60 HAT levels functionally rescues both cognitive deficits and expression of critical neuroplasticity genes repressed in a well-characterized *Drosophila* amyloid precursor protein (APP) model of AD by restoring histone acetylation homeostasis. Since our findings support a neuroprotective role for Tip60 HAT in AD, we propose an epigenetics-based therapeutic strategy using small molecules that selectively activate Tip60 HAT to restore histone acetylation homeostasis. We developed small molecule compounds using a structure-based approach with a general HAT activator, then further optimized the compounds using a pharmacophore function-based approach. Using an *in vitro* HAT assay, we identified three of the compounds as robust and specific Tip60 HAT activators. Future work will elucidate the efficacy of these compounds in functional assays to assess locomotion and learning & memory in the *Drosophila* AD model and assess expression profiles of neuroplasticity genes responsible for cognitive function using real-time quantitative polymerase chain reaction (RT-qPCR). Our therapeutic strategy of designing a specific Tip60

HAT activator that restores histone acetylation homeostasis is a promising AD treatment that could address cognitive impairment that precedes other disease characteristics observed at later stages.

Title: Functional contribution of Scully and its interacting molecules to dementia

Authors: *C. CHEPKOSGEI[1], M. SOLIS[2], P. SABANDAL[2], K.-A. HAN[2];
[2]Biol., [1]The Univ. of Texas at El Paso, El Paso, TX

Abstract: Alzheimer’s disease and related dementias (ADRD) are neurodegenerative diseases characterized by progressive deterioration of cognitive functions. Many genetic and non-genetic (e.g., age, sleep homeostasis and social stress) risk factors are associated with ADRD. However, how these risk factors interact for ADRD remains unclear. Through an unbiased genetic screen for novel ADRD genes, we identified Scully (Scu) as a genetic risk factor interacting with social stress for dementia. Scu is a multifunctional mitochondrial enzyme and is known to bind beta amyloid peptides. The heterozygous *Scu* flies (*Scu/+*) exhibited accelerated loss of memory and inhibitory control. To identify the cellular pathway by which Scu mutation causes dementia, we investigated the molecules known to interact with Scu (SIMs for Scu interacting molecules) physically or genetically. We generated the flies transheterozygous for Scu and individual SIMs (56 out of total 59 SIMs) and assessed their inhibitory control capacities at the ages of 4 days, 2 weeks, and 4 weeks. At 4-days old, all *Scu/SIM* double heterozygous lines showed normal inhibitory control. At 2 and 4 weeks old, however, 9 double heterozygous lines exhibited dysfunctional inhibitory control. This suggests that the positive hit SIMs function in the Scu signaling pathway for dementia. We are currently investigating the cellular and neural mechanisms by which SIMs interact with Scu for dysfunctional inhibitory control. The findings of our study will narrow the knowledge gap on the cellular pathways leading to ADRD.

Title: The role of integrin in aging-related loss of inhibitory control

Authors: *A. P. BALLESTEROS SANCHEZ, D. MURILLO, P. SABANDAL, K.-A. HAN; Univ. of Texas at El Paso, El Paso, TX

Abstract: Progressive cognitive decline including impairments in inhibitory control and memory are key clinical manifestations of Alzheimer's disease and related dementias (ADRD). Although, substantial progress has been made about our understanding of ADRD pathophysiology (i.e., β-amyloid aggregation and hyperphosphorylated tau accumulation) the underlying mechanisms remain incomplete. We hypothesize that the interaction of genetic and non-genetic risk factors is important for ADRD. To test the hypothesis, we conducted an unbiased functional genetic screen to discover novel ADRD genes interacting with non-genetic factors (i.e., aging and social stress)in Drosophila. One of the ADRD genes we identified is inflated (if), which codes for one of the alpha integrin subunits. The overarching goal of this study is to identify how if causes dementia in an aging-dependent manner. Alpha integrin is a cell adhesion molecule and is involved in many developmental processes like cell migration. Yet, its role in aging and dementia is unknown. To address this knowledge gap, we examined the inhibitory control capacity of theheterozygous if (if/+) mutants across different ages (4 days, 2 weeks and 4 weeks old) using aGo/No-Go test. We found that the 4 days old if/+ displayed robust movement suppression similar to the wild-type Canton-S (CS). At 2 weeks and 4 weeks old, however, the if/+ exhibitedsignificantly augmented levels dysfunctional inhibitory control compared to CS. We also found that the hypomorphic if mutants have altered structural integrity of the mushroom body lobes, which are important for inhibitory control as well as learning and memory. We are currently testing the notion that if in the mushroom body neurons plays an important role in the aging-dependent loss of inhibitory control and the progress in this study will be presented. The findings of our study will provide novel insights on the role of alpha integrin in aging and ADRD.

Title: The role of DNA damage-induced epigenetic alterations in age-related cognitive decline and Alzheimer's disease

Authors: *S. BARTMAN, L. GASPAR, H. TOBIAS-WALLINGFORD, D. ZAMOR, G. COPPOTELLI, J. M. ROSS;
George and Anne Ryan Inst. for Neuroscience; Col. of Pharm., Univ. of Rhode Island, Kingston, RI

Abstract: Recent decades have witnessed a dramatic increase in human longevity, which has contributed to higher prevalence of age-related diseases including brain aging disorders, such as Alzheimer's disease (AD). The aging process is accompanied by an accumulation of damage to macromolecules, organelles, and cells, which ultimately leads to organ/tissue dysfunction and death. Although the precise cause of the aging process is unknown, epigenetic alterations and deregulation of gene expression have been implicated in playing a role. Using the innovative ICE (inducible changes to the epigenome) mouse model together with the well-characterized APP/PSEN1 (APP/PS1) mouse, we are directly testing, for the first time, whether epigenetic alterations induced by DNA damage, can affect the onset and progression of AD pathology in "DICE" (dementia from inducible changes to the epigenome) mice. A battery of behavioral testing is ongoing to compare possible cognitive changes in DICE mice with APP/PS1/CRE, ICE, and CRE controls. Preliminary results thus far indicate that male and female DICE mice move significantly more and with faster speed than controls, when assessing spontaneous locomotion in the open field behavioral assay. Using the startle reflex behavioral assay to evaluate brainstem functioning, both male and female DICE mice demonstrated a larger motor response following various auditory stimuli, as compared to controls. Ongoing studies aim to characterize and quantify Aβ; plaque formation as well as gliosis and microglial expression in brains from DICE mice as compared to APP/PS1/CRE controls using immunohistochemistry, western blot, ELISA, and qPCR. These findings will provide valuable insights into the etiology of Alzheimer's disease, especially as it pertains to the role of epigenetics.

Title: The dementia gene Scully and its role in the mitochondria

Authors: *M. SOLIS, C. CHEPKOSGEI, P. R. B. SABANDAL, K.-A. HAN;
Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Dementia has complex etiology that involves both genetic and non-genetic risk factors. How these risk factors interact for dementia remains poorly understood. To address this gap in knowledge, we conducted an unbiased genetic screen to identify novel dementia genes that interact with non-genetic risk factors (i.e., aging and social context) in *Drosophila melanogaster*. We identified *Scully* as a new genetic factor for dementia. *Scully* is the homolog of human 17-β-hydroxysteroid dehydrogenase 10, which is a multifunctional mitochondrial enzyme. We found that flies with the heterozygous mutation in *Scully* (*Scu/+*) exhibited deficits in inhibitory control and short-term memory in an aging-dependent manner. To determine the underlying mechanism, we focused on the potential role of *Scu* in mitochondria. We found no gross difference in mitochondria content in the aged *Scu* mutant and control brains. We are currently examining mitochondria dynamics, bioenergetics, and oxidative stress. Our study will provide novel insight on how genetic and non-genetic risk factors interact for dementia.

[3]Neurosci., Genentech, South San Francisco, CA; [4]Denali Therapeut., South San Francisco, CA

Abstract: Alzheimer's disease (AD) is characterized by amyloid plaques, neurofibrillary tangles, and synaptic and neuronal loss. Recently, a rare autosomal dominant coding mutation, T835M, was discovered in the Un-coordinated 5c (*Unc5c*) netrin receptor gene that segregated with late-onset AD (LOAD). T835M alters a conserved amino acid in the hinge region of the Unc5c death domain, suggesting the mutation may increase apoptosis. Indeed, in primary hippocampal neurons, overexpression of Unc5c T835M increased cell death in response to neurotoxic stimuli including beta-amyloid (Aβ). These results suggest a mechanism by which Unc5c T835M may confer increased risk of LOAD, however the effects of this mutation in an AD animal model have not yet been explored. We hypothesize that the T835M mutation predisposes to LOAD by exacerbating neuronal death via increased sensitivity to Aβ-induced neurotoxicity and UNC5C death domain activation. Toward this end, we generated a mouse knock-in (KI) model of Unc5c T835M and crossed it with the NLGF mouse model of amyloid pathology and neuron loss. Our preliminary results show that homozygous KI mice have significantly reduced hippocampal volume, increased ventricular volume, dendritic disorganization (CA1 region) and reduced Unc5c protein level by 12-18 months of age. Further, we show that the neuronal cell death is observed in the KI mice by 12 months of age by TUNEL analysis and activated Caspase 3/7 activity assay. Additionally, KI mice also show morphological changes in the astrocytes with increased number of branched processes and reduced GFAP levels. Proteomics analysis of KI and wildtype hippocampal samples corroborate the biochemical and histological results which showed upregulation of oxidative stress and downregulation of chaperone proteins at 18 months. We are further investigating mechanisms of cell death and distal phenotypes in NLGF KI; Unc5c T835M KI mice by biochemical, cellular, and unbiased proteomics approaches. We expect our results to provide valuable insight into the molecular mechanism of UNC5C T835M mutation-mediated Aβ-associated cell death, and thereby identify novel therapeutic targets to prevent neuron loss in AD.

Title: Scully interacts with ecdysone in inhibitory control deficit

Authors: *P. SABANDAL, M. SOLIS, C. CHEPKOSGEI, K.-A. HAN;
Univ. of Texas, El Paso, El Paso, TX

Abstract: Scully (Scu) is linked to Alzheimer's disease (AD) because it binds to Aβ peptides and is overexpressed in the postmortem brains of AD patients. However, there is no study demonstrating that Scu contributes to AD in vivo. To narrow this knowledge gap, we investigated the role of Scu in dementia by measuring inhibitory control and memory in *Drosophila*. We found that the Scu-deficient flies exhibit aging-associated inhibitory control deficit and memory loss. We also identified the mushroom body as the major neural site for Scu's role in the aging-associated cognitive decline. Scu is the multifunctional mitochondrial enzyme HSD17β10 and is known to be involved in neurosteroid homeostasis in mammals and tRNA processing in *Drosophila*. We examined which Scu's function is important for its role in dementia. We found no genetic interaction of Scu with t-RNA processing molecules but found strong interaction with ecdysone, a major steroid hormone in *Drosophila*, metabolic enzymes. Specifically, the Scu mutant's phenotype in inhibitory control was aggravated by lessening ecdysone biosynthesis and reduced by decreasing ecdysone breakdown. Our findings will advance the knowledge of how Scu contributes to AD pathogenesis.

Title: Teasing apart a bi-level neuronal function for Tip60 HAT at the chromatin and RNA level.

Authors: *C. THOMAS, A. BHATNAGAR, F. ELEFANT;
Drexel Univ., Philadelphia, PA

Abstract: The histone acetyltransferase (HAT) Tip60 is an essential epigenetic mediator of neuronal transcriptional regulation and is implicated in Alzheimer's disease (AD). Tip60 contains a catalytic HAT domain that promotes histone acetylation mediated chromatin control and a chromodomain (CD) that interacts with methylated histone lysine residues. Recently, our

lab reported a novel RNA binding function for Tip60 that is localized within its CD and underlies neuronal RNA alternative splicing (AS) regulation in the brain. AS of RNA is a process that enables brain cells to generate different functional variants of the same protein to promote the protein diversity required for dynamic brain function in making new memories. Recent reports highlight defects in RNA splicing of genes in the brains of AD patients, thus making splicing disruptions a widespread hallmark of AD. Unfortunately, causes for these splicing disruptions in the brain are currently unknown. To further elucidate Tip60's RNA binding/splicing function, we carried out high resolution homology modeling and molecular visualization of Tip60's chromodomain (CD). Our results strongly predict the RNA binding loop within Tip60's CD is critical for direct Tip60-RNA interaction. To tease apart Tip60's RNA versus histone binding function in neural gene control and cognition, we mutated highly conserved amino acids (a.a) in Tip60's CD strongly predicted to specifically interact with either histones ($Tip60^{mutHis}$) or RNA ($Tip60^{mutRNA}$) and generated transgenic flies carrying these inducible mutant Tip60 constructs. These transgenic $Tip60^{mutRNA}$ and $Tip60^{mutHis}$ fly models will serve as powerful tools to tease apart neural functions dependent upon histone vs. RNA binding or both. We will induce expression of mutant Tip60 in the fly brain and carry out functional assays to assess cognitive ability using both larval (single odor paradigm) and adult (olfactory shock learning) learning and memory assays as well assess brain morphology using immunohistochemistry with well characterized markers. We will also assess gene expression using RNA-Seq, Tip60 splicing activity using rMATs on RNA-Seq data, and chromatin and RNA binding using ChIP and RIP, respectively. We anticipate that RNA versus histone binding functions are required for specific functional outputs and some neuronal processes will be more dependent on a given Tip60 binding function than others. Our results will elucidate a new bi-level regulatory role for Tip60 in chromatin and RNA that has potential to transform how researchers view Tip60 HAT mediated neural gene control in the context of cognition and AD.

Title: Reduced euchromatin and increased facultative heterochromatin in advanced Alzheimer's disease in human postmortem brain tissue

Authors: *A. UCEDA-HERAS, C. CAVADA, M. GARCÍA-CABEZAS;
Anatomy, Histology and Neurosci., Univ. Autonoma de Madrid, Madrid, Spain

Abstract: Gene expression in the human cerebral cortex seems to be increased in mild cognitive impairment and early Alzheimer´s disease (AD) stages. In contrast, in advanced AD stages there is marked gene expression decrease in cortical areas. This apparent paradox could be mediated by a time-course of epigenetic modifications in the nuclei of cortical neurons in parallel to AD progression. To address this question, we quantified the expression of two posttranslational histone modifications, H3K27-trimethylated histone (H3K27me3), which marks facultative heterochromatin, and H3K4-mono/di/trimethylated histone (H3K4me1/2/3), which marks euchromatin, in postmortem human brain tissue of neurotypical subjects and early (Braak II) and advanced (Braak V) AD cases. We used immunohistochemistry to label H3K27me3 and H3K4me1/2/3 in human temporal lobe intact tissue because it allows the quantification of histone modifications by layer and cortical type; thus, we parcellated the human temporal neocortex in mesocortical (agranular, dysgranular) and isocortical (eulaminate I, eulaminate II, eulaminate III, and koniocortex) types and measured the immunostaining of H3K27me3 and H3K4me1/2/3 across layers III, IV, and V of all neocortical types. We found that the expression of H3K27me3 increased in Braak II AD stage; this increase was statistically significant in isocortical areas that are not involved by AD pathology at this stage ($p<0.05$). In Braak V AD stage, H3K27me3 expression increased in a subpopulation of pyramidal layer III neurons in mesocortical and eulaminate I and II types; all these types are severely affected by AD pathology at this stage. We also found that the expression of H3K4met1/2/3 was higher in layers III, IV, and V of eulaminate III and koniocortical types in Braak II AD stage ($p<0.01$); in contrast, in Braak V AD stage, H3K4met1/2/3 expression decreased across all cortical layers and types ($p<0.01$). We conclude that histone marks related to euchromatin increase in cortical neurons in early AD stages and decrease in advanced AD stages; in parallel to these changes, histone marks that are related to facultative heterochromatin increase in advanced AD stages in a subpopulation of layer III pyramidal neurons, specifically, in mesocortical and eulaminate I and II types. Our findings highlight the need for postmortem human brain studies using intact tissue to characterize the progression of epigenetic modifications by cortical type and layer in parallel to AD stages.

Title: Potential relevance of SNPs in linkage disequlibrium with APOE variants identified by genome wide sequencing

Authors: *S. D. EDLAND[1], C. NASAMRAN[2], K. FISCH[2];
[1]Neurosci., [2]Ctr. for Computat. Biol. & Bioinformatics, UCSD, La Jolla, CA

Abstract: It is an open question whether cis acting transcription factors in linkage disequilibrium with the known Alzheimer's disease risk variant missense mutations on the apolipoprotein E (*APOE*) gene are relevant to disease expression. To investigate this, we performed haplotype analysis of genome wide sequencing (GWS) data from 456 subjects (220 Alzheimer cases and 236 normal controls) from the Alzheimer's Disease Neuroimaging Initiative (ADNI) cohort. SNPs in the region of chromosome 19 spanning from *TOMM40* to the multiple enhancer region *ME.2* immediately distal to *APOC1* were assessed for association with the *E2* and *E4* variants rs7412 and rs429358 on *APOE*. Identified variants were queried against expression quantitative trait loci databases, including RegulomeDB, SNP2TFBS, MEME, and BRAINEAC. We identified a haplotype block including the *E2* rs7412 variant SNP associated with Alzheimer's disease. Twelve of 12 SNPs defining this haplotype are flagged by the Regulome database as potential gene expression regulatory loci, including a SNP in the ME.1 multiple-enhancer region shown to affect APOE expression levels in astrocytes (rs483082), and including a SNP within a putative RNA polymerase II subunit Rpb1 binding region (SNP rs1065853). SNP rs483082 is a common variant strongly associated with Alzheimer's disease within the ADNI sample (minor allele OR=0.43, p=6.0e-9). SNP rs1065853 is in near perfect disequilibrium with *APOE E2* (R-squared 0.97 versus rs7412) and is more strongly associated with Alzheimer's disease than is *APOE E2* rs7412 within the ADNI sample (odds ratio=0.25, p=6.7e-5 versus odds ratio=0.27, p=2.5e-4). A number of polymorphisms in linkage disequilibrium with *APOE* risk alleles affect transcription factor binding sites and regulatory regions. It is plausible that these potentially functional polymorphisms contribute to disease risk beyond the risk conferred by the *E2* and *E4* missense mutations on *APOE*.

Title: Investigating the Relevance of Genetic Variation at Post-Translational Modification Sites in the Polygenic Risk Model for Alzheimer's disease-associated Phenotypes

Authors: *S. PACO[1], F. PEREIRA[2], S. ANDREWS[3], L. T. GRINBERG[4], M. NASLAVSKY[5];

Abstract: Alzheimer's disease (AD) is projected to become three times more prevalent by 2050, contributing to the escalating global burden of dementia. Recent advancements in biotechnology have sparked significant interest in early detection, prevention, and capitalizing on genetic characteristics for patient stratification. A Genome-wide association studies (GWAS) research have identified more than 80 loci associated with AD explaining 53-70% of heritability. Polygenic risk score (PRS) aggregates the effect of multiple genetic variants to provide an estimate of genetic liability for a trait. However, the clinical implementation of PRS necessitates refinements, such as the incorporation of genetic loci with functional annotation spanning post-translational modifications (PTMs), chromatin data, and variants associated with quantitative expression traits. This study aims to investigate the impact of genetic variation on potential PTMs target sites to improve risk prediction in AD. In this work the PRS were constructed using the largest AD GWAS to date (n= 63,926) as the base dataset, the Alzheimer's Disease Neuroimaging Initiative (ADNI) (n= 808) as the target dataset, and PRSice. Using PLINK, we performed a comprehensive filtering process and quality control assessment, keeping 4.8 and 6.3 million variants in the base and target files respectively, 760 samples remained. PRSice implements a clumping and threshold model - r2 :0.1, window size: 250 kb, over p-value thresholds ranging from 1 to 10−8. The optimal theshold was 1.4 e-08.. Logistic regression was used to evaluate the predictive performance of the AD-PRS (PRSz thereshold-0.55) yielding a sensitivity and specificity of 0.9 and 0.18, respectively, and the accuracy of the prediction was found to be 0.65. As this initial phase of the study primarily focused on GWAS array genotyping variants with reasonable precision, we hypothesize that PTM annotations (accessible only in sequencing datasets) are likely to enhance the correctness by upweighting coding variants in a PRS. In conclusion, these preliminary results establish a pipeline for further investigations, emphasizing the significance and potential of incorporating additional analyses and relevant information to improve the precision and reliability of PRS in AD risk prediction. We will focus on innovative approaches for filtering genetic variants and incorporating additional biological functional information of PTMs.

Title: Identifying human-relevant genetic interactors of APOE using genetically diverse mouse strains

Authors: *K. ELK[1], K. D. ONOS[1], A. UYAR[2], K. KEEZER[1], R. KASPER[1], O. MAROLA[1], D. GARCEAU[1], R. PANDEY[1], G. W. CARTER[1], G. HOWELL[1], M. SASNER[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Jackson Lab., Farmington, CT

Abstract: *APOE$^{\varepsilon 4}$* is the greatest genetic risk factor for late-onset Alzheimer's Disease (AD), and recent work has introduced human *APOE* variants in classical laboratory mouse strains, typically the C57BL/6J (B6J). While this has led to advances in our understanding of *APOE* biology, it is known that risk encoded by *APOE$^{\varepsilon 4}$* can differ dependent on other genetic factors present. We have previously shown that AD mouse models on genetically diverse wild-derived mouse strains demonstrate robust differences in immune response to amyloid and neurodegeneration, better representing the phenotypic spectrum of AD than previous models. Therefore, we seek to use these models to identify human-relevant genetic interactors of *APOE* within disparate genetic contexts and in the presence/absence of amyloid. Mice were developed by backcrossing *B6J.APOE$^{\varepsilon 4}$* to the respective wild strain (PWK/PhJ, WSB/EiJ) for 5 generations and then were crossed with congenic APP/PS1 carriers of each respective strain. This led to characterization of cohorts of 4- and 8-month males and females homozygous for *APOE$^{\varepsilon 4}$*, with and without hemizygous *APP/PS1*. Transcriptional profiling of brain hemispheres was performed, followed by neuropathological assessments via immunofluorescence (IF) and plasma measurement of key biomarkers such as Neurofilament Light (NfL). Data were assessed for strain-, genotype-, and age-specific variation. Differential expression (DE) analysis of transcriptomic data indicated that *APOE$^{\varepsilon 4}$* homozygosity was the greatest source of variation, independent of amyloid, in 4- and 8-month PWK animals. In addition, neurodegeneration in multiple cortical regions was identified via IF in 8-month (but not 4-month) PWK *APOE$^{\varepsilon 4}$* homozygotes, a finding which was again independent of *APP/PS1* genotype. Preliminary IF results also show a significant increase in the prevalence of disease-associated microglia (DAMs) in APP/PS1 brains as expected, but DAM response to amyloid is significantly attenuated by *APOE$^{\varepsilon 4}$* homozygosity in PWK animals. *APOE$^{\varepsilon 4}$* increased the incidence and severity of cerebral amyloid angiopathy (CAA) in transgenic mice regardless of background. Further neuropathological assessments are ongoing and will be correlated with DE results. Overall, we use neuropathology and transcriptomics to identify potential interactors of *APOE* by utilizing natural genetic variation, describe varying effects of AD's most potent genetic risk factor dependent on genetic context and promote the incorporation of genetically diverse mouse strains in the study of complex neurodegenerative disorders such as AD.

Title: Identification of entorhinal cortex neuron subpopulation markers

Authors: *A. MORELLO, H. KAHVECIOGLU, C. DIMOVASILI, J.-P. ROUSSARIE; Boston Univ. Grad. Program In Anat. & Neurobio., Boston, MA

Abstract: The entorhinal cortex (EC) is the first brain region to be selectively affected by neurofibrillary tangles (NFT) in preclinical stages of Alzheimer's disease (AD). Precisely, NFT start accumulating in the layer II of the transentorhinal cortex. Because the EC is a very heterogeneous region in terms of connectivity, cytoarchitecture, and function, a prerequisite to understand how gene expression determines vulnerability is the generation of a precise molecular atlas of the region. Our previous work provides evidence of conservation of EC layer II cell-types between mouse and humans (Roussarie et al., Neuron, 2020). However, gaining insight into EC layer II neuron subtypes and the degree to which these are conserved in a species closer to humans is necessary. Therefore, guided by our previously generated mouse atlas of the EC, we aim to create a comprehensive atlas of the EC in macaque. Using in situ hybridization, we studied whether previously identified neuronal subpopulations distributed along the dorsal-ventral axis of mouse EC layer II were conserved in macaque. We identified conserved neuronal subpopulations markers in macaque EC, and observed distinct distributions of neuronal subpopulation markers along the medial-lateral axis. Furthermore, we investigated whether these markers were conserved with sex and age. Overall, this atlas will set the basis for the characterization of the different neuronal subpopulations and subregions of the EC, significantly advancing our understanding on how cellular identity might play a role in AD vulnerability.

Title: Phenotypic characterization of a novel Bin1^{K358R} mouse model of Alzheimer's disease

Authors: *A. GOMEZ ARBOLEDAS, L. FERNANDEZ GARCIA-AGUDO, S. KAWAUCHI, C. DA CUNHA, G. MILINKEVICIUTE, K. TRAN, A. TENNER, F. LAFERLA, G. MACGREGOR, K. GREEN;
Univ. of California, Irvine, Irvine, CA

Abstract: Background: Bridging integrator 1 (BIN1) has been identified as a genetic loci directly associated to the risk of developing late-onset Alzheimer's Disease (AD). Several SNPs in the BIN1 gene have been identified by Genome-Wide Association Studies (GWAS), including the rare BIN1 coding variant rs138047593 (K358R). Different BIN1 isoforms are involved in a wide range of functions, including endocytosis or membrane remodeling, among others. However, the role of BIN1 during AD pathogenesis is still controversial as it's been shown to be involved in amyloid- β production by targeting BACE1, but it has also been described its potential contribution to the spreading of Tau aggregates by modulating the endocytic pathway. Here, in an effort to understand the impact in brain biology of different LOAD risk variants as well as with the objective of developing more accurate and valuable mouse models for Alzheimer's Disease, the UCI MODEL-AD group has developed a novel mouse model with the $BIN1^{K358R}$ variant. **Method**: By using CRISP/Cas9, we have generated $BIN1^{K358R}$ mice that carry a coding mutation corresponding to the rs138047593 SNP found in human BIN1. We then crossed the BIN1 mice with the 5xFAD mouse model of AD and aged them to 4 and 12 months of age. Mice were prefursed, and brains were harvested and further processed for bulk RNAseq, MSD and IHC analysis. Confocal images were further analyzed by Imaris sorftware in order to quantify amyloid plaques and glial cells. **Results**: At 4 months, 5xFAD;$BIN1^{K358R}$ showed a significant reduction in amyloid plaques as well as a significant reduction in microglial cell density compared to 5xFAD mice. However, at later stages of the disease (12 months of age), we observed a significant increase on amyloid pathology in the 5xFAD;$BIN1^{K358R}$ mice, but no changes in the microglial response towards these plaques were further detected. Interestingly, at 12 months of age, we observed an impaired astrocytic and oligodendrocytic response towards these amyloid plaques in the 5xFAD;$BIN1^{K358R}$ when compared to 5xFAD mice. Finally, reduced levels of plasma and brain NfL were also detected at 12 months of age in 5xFAD mice carrying the $BIN1^{K358R}$ variant. **Conclusion:** Our results indicate that the $BIN1^{K358R}$ variant has a profound effect on Aβ deposition in the 5xFAD mouse model of AD. Moreover, the BIN1 variant resulted in an impaired astrocytic and oligodendrocytic response towards these amyloid plaques, which in turn correlates with reduced levels of NfL.

Title: Discovery Of New Alzheimer's Disease Therapeutic Targets: Knowledge Graph Approach

Authors: *S. KEEGAN[1], G. CARY[1], R. TRIPATHY[2], J. WILEY[3], H. WANG[2], T.-A. .[4], Y. LI[2], G. W. CARTER[1];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Jackson Lab., Farmington, CT; [3]Sage Bionetworks, Seattle, WA; [4]Emory University, Sage Bionetworks, The Jackson Laboratory, Stanford University,, Bar Harbor, ME

Abstract: Background: Alzheimer's disease (AD) therapeutics have largely been unsuccessful in alleviating disease burden, potentially due to a narrow focus on limited disease mechanisms. The TREAT-AD Consortium is identifying novel molecular targets for AD from underexplored areas of disease linked pathology. Method: We created 19 knowledge graphs (KGs) representing distinct endophenotypes of AD, each with annotated protein-protein interactions connecting genes. The gene nodes were characterized by multi-omic data and Gene Ontology (GO) annotations, and the edges were scored for confidence. A weighted Key Driver Analysis (wKDA) predicted causal nodes within each KG. A Graph Neural Network (GNN) using the KGs as a base network predicted how key drivers affect clinical phenotypes. Result: KGs included key AD processes such as immune response, mitochondrial metabolism, and oxidative stress. The overlap in causal genes for endolysosome and lipid metabolism identified CLTC and DAB2 as common driver proteins, particularly in their regulation of clathrin-coated endocytic vesicles and clathrin-coated vesicle membranes. These and other key connections are proposed as targets for further therapeutic studies. Conclusion: Alzheimer's Disease biology were subdivided into networks which represent molecular processes consistently altered in AD cases. Genes from these networks were prioritized to identify candidate therapeutic targets that are well situated to affect the network biology. TREAT-AD will next validate these targets in cell models and generate experimental resources to support further target development.

Title: Expression and Regulation of EZH2: Implications in Brain Aging and AD

Authors: *K. DENNEY[1], Y. LEI[2], Q. DU[2], X.-Y. LU[2];
[1]Neurosci. and Regenerative Med., Augusta Univ., Augusta, GA; [2]Neurosci. and Regenerative Med., Med. Col. of Georgia At Augusta Univ., Augusta, GA

Abstract: Epigenetic regulation plays an important role in aging and AD pathology. Enhancer of zeste homolog 2 (EZH2) is the catalytic subunit of polycomb repressive complex 2 (PRC2), which catalyzes histone and DNA methylation. Dysregulation of histone modifications and DNA methylation has been implicated in the aging process and the development of AD. The goal of this study was to investigate age- and AD-related changes in EZH2 expression in mice. Immunostaining of EZH2 was performed on brain sections from C57BL/6J mice of various ages, including 5 months, 10 months, and 20 months, and 5xFAD mice of 3 months and 9 months of age. We demonstrated that total levels of EZH2 protein expression decreased in the hippocampus and prefrontal cortex of aged C57BL/6J mice and 5xFAD mice. Additional experiments involving western blot analysis and electron microscopy are currently in progress to quantify and localize EZH2 within different cellular compartments in the brains of both wild-type mice and 5xFAD mice of various ages. On-going experiments are focused on assessing the impact of AAV-mediated EZH2 overexpression in the aged brain on cognitive performance. Furthermore, primary neuronal culture was established to investigate the mechanisms underlying the regulation of EZH2 protein expression by oxidative insults. These studies will provide insights into the potential mechanisms underlying EZH2 dysregulation in aging and AD, particularly in relation to epigenetic contributions to cognitive impairment.

Abstract: Mutations in the amyloid precursor protein (APP) gene can cause early onset familial Alzheimer's disease (FAD) and/or cerebral amyloid angiopathy (CAA). In this study we analyzed pathological aspects of the novel *de novo* APP Y681H *Aros* mutation, identified by whole genome sequencing in a Swedish subject who presented with a large cerebral hemorrhage at the age of 55 and died at the age of 66. The brain from the *Aros* mutation carrier showed prominent amyloid-β (Aβ) plaque deposition in the cortex and abundant CAA. Because the mutation is located next to the BACE1 β'-cleavage site on APP and in proximity of neprilysin (NEP) and insulin degrading enzyme (IDE) Aβ cleavage sites, we analyzed how the *Aros* mutation affects APP processing, Aβ degradation and Aβ aggregation propensities *in vitro*. Besides wild type (WT) APP and Aβ, we included the *Leuven* (*APP* E682K) FAD mutant for comparison. HEK293 cells were transfected with vectors containing WT or *Aros APP* sequences, and levels of Aβ1-40 and Aβx-40 were measured in the cell supernatants with Aβ-specific ELISAs (n=3). Size exclusion chromatography was performed on synthetic Aβ peptides to isolate monomers. Serial dilutions of Aβ1-42 WT, *Aros* and *Leuven* monomers were incubated in triplicates at 37°C for 18 h in the presence of 20μM ThT to monitor their aggregation in a time-dependent manner. *In vitro* digestion of Aβ monomers was performed by incubation with recombinant NEP and IDE for 2 h at 37°C (n=3). The digested products were visualized by western blot and their band intensities quantified with Image Lab software. A significant increase of both Aβ1-40 levels and the ratio of Aβ1-40/Aβx-40 was measured in the supernatant of *APP Aros* transfected cells compared to *APP* WT. ThT aggregation assay data showed no changes in Aβ1-42 *Aros* aggregation kinetics compared to WT, while Aβ1-42 *Leuven* aggregated faster. Aβ1-42 *Aros* was digested to a lesser extent by NEP and IDE *in vitro* compared to Aβ1-42 WT and *Leuven*. Taken together, the *APP Aros* mutation, causing AD with CAA, appears to influence APP processing and increase Aβ production. Whereas no changes in aggregation propensities were seen for Aβ1-42 *Aros*, the variants appear to be less degradable, which, together with the altered APP processing, could lead to increased levels of Aβ in the brain. In ongoing experiments, we are assessing the deposit composition, structural features, and toxic properties of the *Aros* Aβ mutant.

Abstract: Background: The Model Organism Development for Evaluation of Late Onset Alzheimer's Disease (MODEL-AD) Preclinical Testing Core (PTC) established a rigorous drug testing strategy for unbiased assessments of therapeutic agents. To validate this pipeline for therapeutic testing, the chimeric murinized antibody aducanumab (chAdu), was synthesized, qualified, and selected for evaluation in aged 5XFAD mice. To elucidate the pharmacodynamic (PD) impact on metabolic networks, functional connectomic modeling was performed. **Methods:** chAdu was synthesized by transfection and expression in TunaCHO™ cells and qualified by Size-Exclusion Chromatography and LC/MS/MS. To determine the safe and effective dosing strategy, PK studied were conducted in 9 mos 5XFAD mice of both sexes dosed with chAdu from 0.1 to 30 mg/kg, and blood sampled at 0, 1, 3, 7, 10, 14, 21, 24, and 27 days post administration. Based on PK/PD model simulations to predict dosing level and intervals, 9 mos male and female 5XFAD mice were dosed weekly at 0.1, 1.56, and 30 mg/kg. To assess brain metabolic network PD, mice were imaged at baseline and conclusion of chronic treatment via 18-FDG PET/CT. Images were segmented using the Paxinos-Franklin atlas and analyzed for network connectivity by z-score transformation, pairwise covariance analysis, and regional modularization via multi-resolution-consensus clustering (MRCC) of all 27 brain regions, where whole brain and module level statistics were conducted between sexes and across doses. **Results:** Analysis of synthesized chAdu showed high purity and stability with freeze/thaw cycles. PK/PD modeling revealed $T_{1/2}$ of ~2.5 days and informed the PD dose regimen (0.1-30 mg/kg Q1W, IP). 12-week treatment with chAdu resulted in dose- and sex-dependent dependent reversal of glycolytic loss in key brain regions. Whole brain covariance analysis of regional 18F-FDG PET uptake thresholded at the $p<0.05$ level, revealed a dose and sex dependent changes in network degree (nodal connections), density (network connections), positive and negative connection strength (nodal strength), and clustering coefficient (number of sub-networks). Brain network MRCC modules composition and distribution showed dose and sex dependency, indicating that chAdu altered brain network connectivity consistent with whole network analysis. **Conclusions:** These data indicate that chAdu was selective and stable, and resulted in sex and dose dependent relevant metabolic network changes consistent with neuromodulation, and thus demonstrate the value of metabolic connectomic modeling for evaluating drug efficacy.

Abstract: Introduction. Alzheimer's disease (AD) is the most common cause of dementia, and it is histopathologically characterized by extracellular amyloid plaques composed of the Amyloid-β peptide (Aβ) and intracellular neurofibrillary tangles constituted by the hyperphosphorylated tau protein. Alzheimer's disease is classified into sporadic late-onset (LOAD) disease representing more than 99% of the cases, and familiar AD (FAD) or early-onset familial disease (EOAD), which represents 1% of the cases. FAD is caused by the autosomal dominant mutations in the AβPP, PS1, and PS2. Fibroblasts from FAD patients, with a mutation in PS1, have shown increased expression of the macroautophagy markers and alterations in signaling pathways related to cellular stress, autophagy, lysosomes, and tau phosphorylation (Lopez-Toledo et. al., 2022), additionally, a dysfunction in autophagy, and, chaperone-mediated autophagy (CMA) is related with neurodegenerative disorders, that is why, our study has the aim to evaluate the macroautophagy and CMA in FAD fibroblast. **Methods.** Skin Fibroblasts from FAD patients and non-affected individuals were obtained from the Coriell Institute (New Jersey) repository and cultured in Earl MEM salts medium with 15% non-inactivated FBS. The macroautophagy and CMA markers in these cells were characterized by Western blot, moreover, autophagy was induced by starvation and chloroquine addition to evaluate the autophagic activity and autophagic flux with Cyto-ID essay and PremoTM Autophagy Tandem Sensor respectively. **Results.** Autophagy Assays showed differences in the autophagy activity in the cells of FAD patients vs cells from healthy controls pointing to an increase in autophagy in FAD fibroblasts with very low autophagy flux. Western blotting of CMA markers showed downregulation in these markers. **Conclusion.** Autophagy activity and CMA markers showed dysregulation in the fibroblasts of FAD patients vs the cells of healthy individuals. These findings in peripheral cells could have the potential for early diagnosis, detection of new biomarkers, and drug testing.

Title: Linking cognitive and pathological resilience using brain-wide immunohistochemistry in the AD-BXD panel

Authors: *B. GURDON[1], N. HADAD[1], S. YATES[2], T. MURDY[1], M. PUCHADES[3], J. G. BJAALIE[3], K. O'CONNELL[1], C. C. KACZOROWSKI[4];
[1]The Jackson Lab., Bar Harbor, ME; [3]Inst. of Basic Med. Sci., [2]Univ. of Oslo, Oslo, Norway; [4]Neurol., The Univ. of Michigan, Ann Arbor, MI

Abstract: The relationship between regional cell composition, brain pathology, and memory impairment in Alzheimer's disease (AD) remains incompletely understood. The specific brain regions and tracts (and their interactions) that explain the heterogeneity of cognitive decline with AD are not clear. By integrating brain-wide immunohistochemistry and cognitive outcomes we can achieve unbiased detection of regions of interest (ROIs) and identify cellular correlates of cognitive resilience for causal testing. Immunohistochemistry (IHC) was completed to evaluate neurodegeneration (NeuN), gliosis (Iba1 & GFAP), amyloid beta (Aβ) pathology (AB1-42), and cell bodies (Thionine) in adult (6 months (m)) and middle-aged (14m) mice of the AD-BXD genetic reference panel (n=228). Using the QUINT workflow, hemibrain slices were systematically segmented and registered to the Allen Brain Atlas to gain a global perspective of percent cell and pathology coverage. IHC traits were correlated with contextual fear conditioning outcomes to identify regions whose stain composition is associated with memory performance. Contrary to our prior work using ELISA-based Aβ measurement, we find that Aβ quantified via IHC at the presymptomatic time point (6m) is strongly correlated with differences in short- and long-term memory in 14m female 5XFAD carriers. Furthermore, the degree of astrogliosis at 6m in cortical, striatal, and thalamic regions acts as a predictor of cognitive outcomes at 14m. While age-related decreases in NeuN load were not observed, wide variation in neurodegeneration levels could be attributed to strain differences, and 14m NeuN load was positively correlated with 14m long-term memory among this female 5XFAD population. Highlighting the importance of genetic background on AD progression, we were able to categorize strains as resilient or susceptible to pathological and cognitive decline and evaluate the overlap of these traits. Strains that exhibit the unique identity of being pathologically susceptible but cognitively resilient offer a novel opportunity to investigate the underlying mechanisms of protection from cognitive decline with AD. In conclusion, by integrating brain-wide IHC and behavioral data, we were able to identify regional and cellular correlates that may predict downstream cognitive outcomes. Detection of these biomarkers may prove a valuable resource to disseminate the

insidious prodromal stages of AD in which biochemical changes precede apparent clinical symptoms.

Abstract: The role of Frequenin 1/Neuronal calcium sensor 1 in inhibitory control
Aldo Pizana, Kimberly Loya, Paul Rafael Sabandal and Kyung-An Han
Inhibitory control is a cognitive process which enables organisms to suppress inappropriate thoughts and actions, allowing them to properly execute goal-driven behaviors. The mechanism underlying inhibitory control is not fully understood. To address this gap in knowledge, we conducted a screen to identify genes that interact with the dopamine system for inhibitory control using a Go/No-Go test in *Drosophila*. One of the genes we discovered is *Frequenin 1* (*Frq1*). Specifically, the heterozygous mutant *Frq1* (*Frq1/+*) or dopamine transporter mutant *fumin* (*fmn/+*) exhibited robust movement inhibition in Go/No-Go test while the double heterozygous *Frq1/+; fmn/+* mutant showed dysfunctional inhibition. Frq1 codes for a calcium-binding protein and is a homolog of the mammalian neuronal calcium sensor 1 (NCS-1). Frq1 is known to regulate synaptic transmission and plasticity during development, but our study is the first to reveal the role frq1 in adult brain function. The goal of this study is to identify how the Frq1-dopamine interaction leads to loss of inhibitory control. We found that the Frq1 mutant brains have less tyrosine hydroxylase (the rate-limiting enzyme for dopamine biosynthesis) compared to controls. We are currently investigating how Frq1 mutation affects dopamine neurons and their postsynaptic mushroom body neurons. Our finding will advance our understanding on the

role of Frq1 in inhibitory control.
Key words: Neuronal calcium sensor 1, inhibitory control, dopamine

Title: Investigating retrotransposon-derived circular DNA as a driver of neuroinflammation in Alzheimer's disease and related tauopathies

Authors: *M. E. LAMBERT;
Cell Systems and Anat., Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX

Abstract: Transposable elements, or “jumping genes,” have the ability to mobilize within the genome. Retrotransposons, the largest class of transposable elements, are thought to have derived from ancient retroviral infections that involved insertion of viral genomes into the germline and thus became fixed within the human genome. While transposable elements comprise of 45% of the human genome, the vast majority are transcriptionally silenced due to their localization within heterochromatin and post-transcriptionally silenced by cellular defense mechanisms involved in the innate immune response. In Alzheimer’s disease and related tauopathies, pathogenic forms of tau protein destabilize the nucleoskeleton, causing heterochromatin to decondense. Opening of the heterochromatin causes previously silenced genes, such as retrotransposons, to be aberrantly transcribed. Retrotransposon activation involves transcription of host retrotransposon DNA and reverse transcription into a new DNA copy. Such DNA copies can exist in an episomal state or be inserted into the genome. Episomal DNA is detected by the cell and activates the innate immune response, driving intracellular inflammation and subsequent cell death. Previous work from our lab and others report that tau transgenic mice and Drosophila have increased retrotransposon DNA copy number. In preliminary studies, we find increased retrotransposon DNA copy number in human patients with Progressive Supranuclear Palsy, a primary tauopathy. While these studies suggest retrotransposon transcripts have been reverse-transcribed, we do not currently know whether this copy number increase can be attributed to genome insertion or extrachromosomal activity. We are utilizing frontal cortex brain lysate from human patients with tauopathy to investigate circular DNA as a potential source of increased retrotransposon DNA copy number and a driver of intracellular inflammation.

Title: Molecular profiles of precision midlife combinatorial therapy in hAPP hAPOE risk model of AD

Authors: *H. VAN ROSSUM[1,2], G. TORRANDELL[2,1], E. REYES-REYES[2,1], Y. SHANG[2,1], R. D. BRINTON[2,1];
[2]Ctr. for Innovation in Brain Sci., [1]Univ. of Arizona, Tucson, AZ

Abstract: Determinants of late-onset Alzheimer's disease (LOAD) are multifactorial. While age, sex and APOE4 genotype remain the leading non-modifiable risk factors, other modifiable conditions including hypercholesterolemia, type-two diabetes (T2D), and increased peripheral inflammation contribute to disease progression. Preliminary bioinformatic analysis of Alzheimer's Disease Coordinating Center (NACC) data indicated that patients using a combination of lipid lowering, T2D, and anti-inflammatory therapies exhibited greatest resilience to cognitive decline based on mini-mental state exam (MMSE) score. Determining the molecular impact of combination therapy is important in the context of a midlife risk-reduction intervention for LOAD. For this study we assessed known LOAD risk factors (age, sex, and APOE4 genotype) in a transgenic mouse model with hAPOE alleles (JAX 27894 APOE3/3 KI and JAX #29018 APOE4/4 KI) bred to homozygous B6(SJL)-Apptmq.qAduci/J animals (JAX #030898, hAbeta-loxP-KI). hAPP hAPOE3/3 and hAPP hAPOE4/4 mice were exposed to midlife combinatorial therapy intervention at 15 month (human equivalent 49 years-old). Both male and female mice were orally treated with combination drug formulations or control via chow across a 30 or 90-day intervention period (human equivalent 51 years-old or 56 years-old, respectively). Animals were single housed and monitored weekly to determine accurate dosing. To assess the molecular mechanisms of midlife combinatorial therapeutic intervention in the context of AD risk, we conducted analyses of both plasma and the brain. Sex, APOE genotype, and combination-specific differences were identified in plasma levels of total cholesterol, HDL, LDL, and glucose. We found combination-specific differences in inflammatory profiles using 1) multi-color flow cytometry to measure lymphocytes (CD3, CD4, CD8b, CD69), monocytes (Ly-6C, CD43), and neutrophils (CD62L, CXCR4) in peripheral blood and meninges and 2) ELISA assays to quantify protein levels of β-Amyloid (Aβ) 40-42, and proinflammatory cytokine levels including TNF-α, IL-6, and IL-1β in plasma and cortex. Understanding the therapeutic potential of FDA-approved combinatorial precision intervention strategies warrants further investigation in LOAD. Strategies targeting both non-modifiable and modifiable risk factors demonstrate

promise toward the National Alzheimer's Project Act mission to prevent or effectively treat Alzheimer's disease and related dementias by 2025.

Title: Modulation of ApoE by the mevalonate pathway and inflammation

Authors: *J. MILSTEIN, J. A. KULAS, S. HOSSEINIBARKOOIE, T. WEIGEL, H. A. FERRIS;
Univ. of Virginia, Charlottesville, VA

Abstract: Alzheimer's Disease (AD) is a neurodegenerative disease characterized by the aggregation of amyloid-β plaques and neurofibrillary tau tangles, and is often associated with neuroinflammation. The strongest genetic risk factor for developing AD is the ε4 allele of Apolipoprotein E (ApoE). ApoE is an integral component of HDL-like lipoparticles that are secreted by astrocytes under homeostatic conditions, and are also secreted by microglia in response to neuroinflammation like that observed during AD disease progression. These particles carry lipids and proteins, particularly cholesterol, and bind to LDL receptor related protein 1 (LRP1), leading to endocytosis of the particle and its contents. Previous work from our lab has shown astrocyte cholesterol synthesis through the mevalonate pathway is required for development of AD pathology in an AD mouse model. The mevalonate pathway is responsible for controlling two vital cellular processes, cholesterol production and protein prenylation. However, the roles that both the mevalonate pathway and inflammation play in regulating ApoE and whether they act in conjunction or separately in doing so is not well-understood. Here, we use pharmacological treatments of mouse mixed glial primary cultures to address these questions. We find that the mevalonate pathway has different effects on ApoE depending on which part of the pathway is being targeted pharmacologically. Specifically, inhibiting the protein prenylation arm of the pathway with either simvastatin or the prenylation inhibitor FGTI-2734 reduces secretion of ApoE, whereas inhibiting the cholesterol synthesis arm of the pathway with zaragozic acid reduces the size of the ApoE lipoparticles being secreted from the cells. In addition, we observe that treating our cultures with an established inflammatory cytokine cocktail inhibits ApoE secretion independently of protein prenylation. Interestingly, we find that

inhibiting protein prenylation reduces cellular levels of LRP1 and that treating cells with an LRP1 antagonist induces inflammatory activation of microglia, the latter result confirming previous reports. Overall, our data suggest that inflammation and protein prenylation regulate ApoE secretion through different mechanisms, and that cholesterol synthesis controls the generation of mature, large ApoE lipoparticles. Additionally, our data suggest involvement of LRP1 modulation by protein prenylation and inflammation in their effects on ApoE.

Title: Longevity treatments affect Alzheimer's neuropathology in aged male EFAD mice

Authors: *A. CHRISTENSEN, A. ZAIDI, C. J. PIKE;
Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: Aging is the greatest risk factor for Alzheimer’s disease (AD). The primary genetic risk factor for AD is the e4 allele of apolipoprotein E (*APOE4*). Interestingly, *APOE* genotype also regulates aging and longevity, with *APOE4* associated with decreased longevity in both humans and rodents. Several pathways impaired by normal aging and *APOE4* are implicated in AD pathogenesis, suggesting that interventions known to improve health- and lifespan by targeting age-related pathways may also function as effective therapeutic strategies for AD, especially in the context of *APOE4*. To investigate this topic, we studied the independent and combined efficacies of two longevity interventions in EFAD mice, a rodent model of AD with knock-in of human *APOE3* or *APOE4* and overexpression of familial AD transgenes. The first intervention was Fasting Mimicking Diet (FMD), a version of caloric restriction that reduces caloric intake for 4 consecutive days once every 14 days while maintaining the intake of micronutrients. The second intervention was 17α-estradiol (17αE2), a naturally occurring weak estrogen and stereoisomer of the primary estrogen 17β-estradiol, that has been shown to increase lifespan as well as beneficially regulate inflammatory and metabolic pathways. Sixteen-month-old male *APOE3* and *APOE4* EFAD mice were randomized into one of four treatment groups: (1) vehicle + *ad libitum* diet; (2) vehicle + FMD; (3) 17αE2 + *ad libitum* diet; or (4) 17αE2 + FMD. After nine weeks of treatment, outcomes on a range of systemic and neural were determined. Systemically, *APOE4* mice generally showed higher levels of age-related measures, which tended to be improved by 17αE2 and to a lesser extent by FMD. In brain, both 17αE2 and

FMD reduced AD-related measures (e.g., amyloid accumulation), but there was no additive benefit with combined treatment. These data show that both FMD and 17αE2 improved metabolic and neuropathological outcomes in aged EFAD mice, findings that support continued investigation of longevity-promoting interventions for improvement in late stages of AD.

Title: Comparison of risk-modifying, Alzheimer's disease-associated APOE isoforms in lipid-bound state provides insight into structural differences

Authors: *R. TUCKEY[1], R. A. GREER[2], H. DEAN[3], E. D. ROBERSON[4], Y. SONG[2]; [1]Neurol., UAB Neurosci. Grad. Programs, Birmingham, AL; [2]Biomed. Engin., Univ. of Alabama at Birmingham, Birmingham, AL; [3]Biomed. Engin., [4]Neurol., Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Genetic variants in *APOE*, encoding the lipid carrier protein apolipoprotein E, are strongly associated with altering risk of developing Alzheimer's disease (AD), the leading cause of dementia worldwide. The common variants *APOE2* and *APOE4*, are associated with decreased and increased risk of developing AD, respectively, relative to the most common *APOE* variant, *APOE3*. The rare *APOE* variants *APOE3-R136S* (Christchurch), *APOE3-V236E* (Jacksonville), and *APOE4-R251G* have been found to protect against AD. Previously, we examined how these variants altered APOE structure in its lipid-free state. These models are limited as APOE is mostly in a lipid-bound state *in vivo*. Our current study uses molecular dynamics (MD) simulations to examine how common and rare variants in *APOE* alter its interaction with lipids while also comparing lipid-free and lipid-bound structures. Our starting APOE structure, provided by Prakashchand *et al.*, was generated from coarse-grained MD simulations of a mutant APOE structure (PDBID: 2L7B) in the presence of DPPC lipid molecules. We then took the lipid-bound APOE mutant and converted it to APOE3. Subsequent simulations were used to generate a representative structure of APOE3 before mutating it to the other APOE isoforms. These were made using APOE3 as it can be converted to all other variants via a single amino acid substitution using PyMOL, except for APOE4-R251G which was made using APOE4. MD simulations for each APOE variant were performed in triplicate beginning with separate starting APOE3 molecules. The last 300 ns of equilibrated simulations for each simulated system were used for analysis. Simulations of the APOE-lipid complex allowed for

analysis of each isoform in relation to their lipid interactions, conformational stability, secondary structure occupancy, dynamic cross-correlated motion, and solvent accessible surface area. Findings from this study identify features that distinguish rare isoforms from common isoforms and show effects of lipidation on each APOE isoform. Comparison of isoforms by their lipid interactions, conformational stability, secondary structure occupancy, dynamic cross-correlated motion, and solvent accessible surface area highlight the impact variants have on APOE-lipid interactions. Alterations in structure and lipid binding ability of rare isoforms could potentially change downstream function, thereby contributing to their protection against developing AD. This work was supported by the NIH R01AG068395 and Alzheimer's Drug Discovery Foundation.

Title: Exploring the influence of APOE polymorphisms on neuronal and hepatic mitochondrial bioenergetics and dynamics

Authors: *C. LYSAKER, C. JOHNSON, V. CSIKOS DRUMMOND, E. FRANCZAK, X. CAO, R. KEMNA, C. S. MCCOIN, J. P. THYFAULT, P. C. GEIGER, J. K. MORRIS, H. M. WILKINS;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Background: Emerging evidence has shown that liver dysfunction is closely associated with Alzheimer's disease (AD) risk, suggesting the liver is a novel target for the study of AD. Variation in the apolipoprotein E (*APOE*) gene not only influences the risk of AD, but other diseases as well. While APOE is secreted by both the liver and brain, it does not readily cross the blood brain barrier (BBB) resulting in two distinct pools of APOE. Additionally, APOE has roles in physiological and metabolic processes such as lipid transport, as well as amyloid beta clearance from the brain, but its direct effect on mitochondrial function is not well characterized. We look to investigate the role of different APOE isoforms on mitochondrial function, and further elucidate how these genetic variations impact liver and brain health.

Despite what is known regarding APOE, the full extent of its impacts on liver and brain health in relation to mitochondrial function is not well understood. **Methods:** In this preliminary study, we used male and female APOE targeted replacement mice on a C57BL/6N background (Taconic Biosciences), homozygous for either *ε3* or *ε4* alleles and aged to 16 weeks on a standard chow diet. Both liver and brain tissue were collected upon euthanasia with measures of mitochondrial function assessed using Seahorse XF analysis and Oroboros O2k respirometry. Proteomics analysis was conducted on isolated mitochondria from both tissues and confirmed using western blot analysis. **Results:** We found that male and female APOE4 mice have reduced carbohydrate driven mitochondrial respiration in the liver, but not the brain when compared to their APOE3 counterparts. Additionally, male APOE4 mice showed reduced state 3S and uncoupled lipid driven respiration in the liver when compared to APOE3 male mice. Pathway analysis revealed that APOE4 mice had enriched expression of proteins associated with sirtuin signaling, EIF2 signaling, and reduced oxidative phosphorylation in the liver. In the brain, the mevalonate pathway and NAD signaling were increased in APOE4 mice when compared to APOE3 mice. Additionally, DRP1 and MFN2, proteins associated with mitochondrial fission and fusion, showed differential expression by both genotype and tissue when compared in the liver and brain. **Conclusions:** Our data show early APOE genotype-dependent changes to mitochondrial bioenergetics occurring in both the liver and brain as well as suggested alterations in mitochondrial dynamics. Further studies are ongoing to investigate mechanistic changes that underlie these differences in metabolism, and their implication of the liver and brain function.

Title: Overexpression of heat shock protein 27 modulates hippocampal apolipoprotein E and reduces aggregation of transactive response DNA binding protein 43

Authors: *M. ABEER, A. GAUFF, J. SHERAD, I. BROOKS, M. GITCHO;
Delaware State Univ., Dover, DE

Abstract: Aggregation of transactive response DNA binding protein 43 (TDP-43) is the primary pathological feature of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD).

Recently, in up to 50% of Alzheimer's disease (AD) cases, TDP-43 pathology was discovered and this pathology has been referred to as limbic-predominant age-related TDP43 encephalopathy (LATE). Several studies reported that TDP-43 binds to heat shock protein family B (small) member 1 (HSPB1 or HSP27) but no functional evaluation of this interaction has been explored. Inducing expression of HSP27 has been shown to be protective of many other disease conditions and has been shown to reduce aggregation of amyloid in AD. In general, the goal is to utilize both primary neuronal cultures and mice that are selectively expressing pathogenic TDP-43, HSP27, and apolipoprotein E (APOE) in the brain to characterize the effect of HSP27 overexpression on TDP-43 and APOE. This will give us a better model to understand TDP-43 proteinopathies. In the present study, we hypothesize that increased expression of HSP27 may reduce TDP-43 aggregation and alter mitochondrial morphology. A new transgenic mouse model was developed to selectively drive human HSP27 and pathological TDP-43 with a defective nuclear localization signal (ΔNLS) in the hippocampus and neocortex using the Ca^{2+}/calmodulin protein kinase (Camk2a) tetracycline-inducible system. The following genotypes have been evaluated for immunohistochemistry, biochemistry (solubility fractionation), and Western blot: wild-type, Camk2a/ΔNLS, Camk2a/HSP27 and Camk2a/HSP27/TDP43ΔNLS at 4 months of age. Preliminary *in vitro* results show that cells overexpressing HSP27 reduce aggregation and protein levels of TDP43. However, mice overexpressing HSP27 in a TDP43ΔNLS background in the hippocampus and cortex do not show any reduction in the soluble fraction. Interestingly, increased expression of HSP27 in the hippocampus of Camk2a/HSP27 mice showed a significant reduction of endogenous APOE expression. Immunohistochemical and bioenergetic experiments are currently being carried out to evaluate the brain and mitochondrial morphology upon HSP27 overexpression. Overall, our initial data suggests that modifying HSP27 expression modulates endogenous APOE levels.

Abstract: Dementia and more specifically Alzheimer's Disease (AD) currently pose a global health crisis with more than 3 million cases of AD in the US alone. Inheritance of the ε4 allele of apolipoprotein E (ApoE) is the strongest genetic risk factor associated with the sporadic form of AD, whereas the rare ApoE ε2 allele has the opposite effect. ApoE4 differs from ApoE3 by a single amino acid, an arginine instead of cysteine at position 112. This small change presumably alters the conformation of the protein, altering its activity in many biological pathways resulting in both gain and loss of function activities that increase the risk for AD. We and others have previously shown that purified recombinant ApoE4 has a lower thermal stability than that of ApoE3 and that this change in thermal stability is indictive of a change in structure that is likely important for ApoE's function. To explore if this feature extends to ApoE protein in a cellular context we deployed a Cellular Thermal Shift Assay (CETSA), which measures the thermal stability (ie. melting point) of proteins in complex and native cell states rather than using purified protein. We found that ApoE4 denatures at a lower temperature than ApoE3 in brain extract from both human cases and mouse models.

To further study this phenomenon we have developed a system that uses a HiBiT-LgBiT (Promega) split luciferase. This system consists of a small, 11 amino acid peptide tag, HiBiT, and its complementary partner LargeBiT. These proteins bind with high affinity and perform with excellent sensitivity and linear dynamic range. We have transfected HEK cells with plasmids encoding for HiBiT tagged ApoE of multiple isoforms and found that the different melting points between ApoE 2, 3 and 4 were maintained in this system. We then went on to use this cell culture model to investigate the effect of rare variants of ApoE that have been implicated in disease including R136S, R145C, L28P, V236E, and R251G. We have found that some of these single amino acid changes have significant effects on the thermal stability of ApoE indicating that these changes in structure are likely having a functional impact.

We then went on to further understand the structure and function relationship of ApoE mutants. This work shows that thermal stability in this assay is a good surrogate for protein structural changes that have real world implications in terms of relative risk for generating AD and that investigating ApoE structure and function is crucial to our understanding of this important risk factor.

Title: Ameliorating effects of GSK2606414 in ApoE4 accelerated endoplasmic reticulum stress and cognitive impairments, a mice study

Authors: *X. LONG[1], Y. YANG[1], L. DU[2], X. XIE[1];
[1]Henan Univ., Kaifeng, China; [2]Qingdao Univ., Qingdao, China

Abstract: Alzheimer's disease (AD) is a neurodegenerative condition that results in dementia among a population of over 50 million elderly individuals. Apolipoprotein E4 (ApoE4) allele is a robust genetic risk factor for AD, conferring a higher risk compared to the more common ApoE3 allele. AD is characterized by the decline in memory that is induced by neuronal endoplasmic reticulum (ER) stress and unfolded protein responses (UPR), which are further enhanced by PERK activation. GSK2606414 is a PERK inhibitor that was initially identified as a UPR modulator with anticancer and antiproliferative properties. The neuropharmacological effects of GSK2606414 have not been extensively studied on any ApoE-related AD animal model. This study aims to investigate the effects of GSK2606414 on PERK inhibition in APOE4 knock-in mice. We compared the AD progression between ApoE3 and ApoE4 knock-in mice, including beta-amyloid pathology, long-term spatial learning, and cognitive functions. GSK2606414 suppressed protein expressions in the PERK-eIF2α pathway and exhibited improvements in cognitive performance. The study also addressed the alleviating effects of GSK2606414 on AD-related ER stress and memory decline. These findings indicate the pharmacological effects of GSK2606414 on ApoE4-associated AD pathology and suggest future directions for ApoE-targeted treatments.

Title: The isoform-dependent effects of apolipoprotein E on the deposition of Aβ

Authors: *M. TANAKA[1], A. KOKAWA[2], H. UCHIGAMI[3], T. HASHIMOTO[4], T. IWATSUBO[5];
[1]神経病理学科, 東京大学, 東京, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]the Univ. of

Tokyo, Tokyo, Japan; [4]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [5]Univ. Tokyo, Tokyo, Japan

Abstract: The *APOE ε4* allele is a strong genetic risk factor for the development of Alzheimer's disease (AD). To investigate the role of apoE in the pathogenesis of AD, we crossed APP transgenic (tg) mice with human *APOE3* knock-in (KI) mice, and found that APP tg/*APOE3* KI mice exhibited significantly lower Aβ deposits compared to APP tg mice, suggesting that human apoE3 may suppress the deposition of Aβ. To test this hypothesis, we performed an *in vivo* seeding experiment that allows the induction of Aβ deposition in the brain by a single inoculation of Aβ seeds. Hippocampal inoculation of TBS-soluble fraction from brains of Aβ-laden APP tg mice induced deposition of Aβalong the molecular layer of the dentate gyrus in the hippocampus of APP tg mice. Notably, both APP tg/*APOE3* KI and APP tg/*APOE4* KI mice exhibited significantly less Aβ deposition than APP tg mice. In addition, seed-induced Aβ deposition was significantly higher in APP tg/*APOE4* KI mice than in APP tg/*APOE3* KI mice. These data suggest that apoE affects Aβ deposition in an isoform-dependent manner.To further elucidate the role of apoE on the deposition of Aβ, we performed an *in vivo* seeding experiment in apoE-deficient APP tg (APP tg / APOE KO) mice. We found that no seed-induced Aβ deposition was observed in the hippocampus of APP tg/APOE KO mice. Adeno-associated virus-mediated astrocyte overexpression of human apoE3 resulted in the induction of Aβ deposits in the hippocampus of APP tg/APOE KO mice. These data suggest that apoE is an essential factor for seed-dependent Aβ deposition. Taken together, our findings implicate that apoE modulates Aβ deposition in an isoform-dependent manner by facilitating the seeding activity of Aβ seeds in the brain.

Title: Deciphering ApoE Christchurch protein-protein interactions in the brain

Authors: ***P. A. PEREZ**[1], C. MARINO[1], C. ORTIZ[2], S. WANG[3], Y. T. QUIROZ[4], J. ARBOLEDA-VELASQUEZ[1];

[1]Schepens Eye Res. Inst., Boston, MA; [2]MIT, Boston, MA; [3]MIT, Cambridge, MA; [4]Massachusetts Gen. Hosp., Boston, MA

Abstract: Our group previously identified an individual who despite carrying the *PSEN1* E280A mutation leading to early-onset dementia, only developed cognitive impairment three decades after the family's expected age of onset. We found that she was homozygous for a rare mutation in *APOE,* called Christchurch (R136S, APOE3Ch), and that this mutation appears to have protected her against tau pathology. While a mechanism of protection has been proposed based on the protein interactions between the mutated region of ApoE and Heparan sulfate proteoglycan (HSPG), a comprehensive understanding of other ApoECh protein-protein interactions in the brain is still unknown. To address this, we performed affinity purification experiments using His-tagged ApoE3 and ApoE4 (wildtype and Christchurch) proteins produced in HEK cells. Our goal was to bait potential interacting partners from adult mice brain protein lysates (n=3). We identified the interactors via mass spectrometry and quantified the number of proteins bound to ApoE wild type (ApoEwt) and ApoECh. Additionally, we performed an analysis based on the abundance of the proteins using the Ingenuity Pathway Analysis software (IPA). Our results revealed a lower number of proteins interacting with ApoE4wt compared to ApoE3wt. ApoE4Ch showed a trend towards an increase in the number of interactors compared to ApoE4wt (P=0.08). Notably, Mapt protein (Tau) was one of the upstream regulators in the IPA analysis, exhibiting a stronger bound to ApoE3Ch and ApoE4Ch compared to the wild type counterparts. To validate this finding, we performed a pull-down assay using recombinant human Tau-441 protein 2N4R with the His-tagged ApoE proteins used previously, confirming a higher affinity of human Tau protein to ApoE3Ch and ApoE4Ch compared to the wild type proteins. In this study, we identified the different ApoECh interacting partners and validated Tau as an interacting partner that is affected by the presence of Christchurch mutation.

Title: Apoe Isoforms Differentially Modulate Tau Propagation in Regions Associated with Early Alzheimer's Disease in a Novel Mouse Model

Authors: *H. A. ARAIN, T. NURIEL;
Taub Institute; Columbia Univ. Med. Ctr., New York, NY

Abstract: Possession of the APOE4 allele is the strongest risk factor for developing the sporadic form of Alzheimer's disease (AD). Extensive research in the field has largely focused on the roles APOE has on modulating amyloid-beta (abeta) pathogenesis. Recently, studies have shifted to elucidating the role APOE plays in tau pathology. However, it remains unclear if differential APOE isoform expression can modulate pathological tau propagation in regions associated with early tau accumulation in AD. To investigate the role APOE plays in the propagation of tau in AD-vulnerable brain regions, we created a novel APOE-expressing mouse model that mimics tau pathology observed early on in AD. To facilitate the expression of tau mainly in the entorhinal cortex, mice expressing human MAPT harboring the P301L mutation, under control the neuropsin-tTa promoter, were crossed to humanized homozygous APOE3/3 or APOE4/4 target-replacement mice. Both male and female mice were analyzed at middle and old age (15-17 and 25-27 months, respectively) by Morris Water Maze and structural MRI. Mice were subsequently euthanized, and neuropathological analysis was performed for overt tau pathology. MRI and histological analysis of the middle-aged and old entorhinal cortex and hippocampus demonstrates differential tau propagation and atrophy that is affected by APOE genotype. Interestingly, our results point mainly to decreased tau spread in APOE4-expressing mice. Upon analysis of the middle-aged mice, separated by sex, we have discerned a significant decrease in tau propagation to the hippocampus (CA1, CA3; $p<0.01$) and lateral entorhinal cortex ($p<0.01$) in female mice containing the APOE4/4 allele compared to female APOE3/3 mice. This effect in tau spread was attenuated in both male APOE3/3 and APOE4/4 mice. Here we report for the first time the generation of a novel APOE-tau mouse model that recapitulates the region-specific tau pathogenesis observed in early AD, independent of abeta pathology. Our results offer novel insights into APOE's role in modulating the propagation of tau along anatomically connected, vulnerable AD brain regions.

Title: In vitro Model of Alzheimer’s Disease based on Neurons and Astrocytes Generated from Patient iPSCs using Transcription Factor-Based Rapid Differentiation Technology

Authors: *R. TANAKA[1], T. SAMESHIMA[1], R. YAMOTO[1], T. TANAKA[2], M. SEO[2], T. HOSOYA[1];
[1]Ricoh Company, Ltd., Kawasaki-shi, Kanagawa, Japan; [2]Elixirgen Scientific Inc., Baltimore, MD

Abstract: Alzheimer's disease (AD) is the most common form of dementia. Since no animal models fully recapitulate the AD phenotype and drug responses, human iPS cell-derived cells are a highly valuable tool in the investigation of the AD pathology. The major pathological phenotypes of AD are extracellular accumulation of amyloid plaques and intracellular neurofibrillary tangles of phosphorylated Tau. Accumulation of Aβ and/or phosphorylated Tau has been observed in neurons generated from patient iPSCs. In this study, we asked whether the pathological phenotypes can be observed in patient iPSC-derived neurons and astrocytes generated by the transcription factor-based technology for rapid differentiation (Quick-Neuron™). iPSC-derived neurons generated from a sporadic Alzheimer's disease patient with a genetic polymorphism in the APOE4 gene (AD neurons) were cultured for one to eight weeks, with neuros from a healthy donor as control. After six weeks of culture, the AD neurons exhibited significantly higher accumulation of Aβ40 and Aβ42 in the culture media compared to the control neurons. Tau accumulation and Tau phosphorylation were also significantly higher in the AD neurons after four weeks culture. β-secretase inhibitors that inhibit Aβ production significantly reduced the accumulation of Aβ40 and Aβ42 in the AD neurons. These results imply that the patient-derived Quick-Neuron™ exhibit the pathological phenotypes of Alzheimer's disease within four to six weeks of culture. Because astrocytes play a central role in APOE4 mediated cholesterol transport to neurons, we are also investigating the phenotypes of astrocytes generated from the patient iPSC using the rapid differentiation technology (Quick-Glia™). Contribution of the neurons and astrocytes generated from AD patients using the rapid differentiation technology will be discussed in the context of the disease mechanism investigation and phenotypic drug screening.

Title: Retinal Phenotyping of the APOE4 Knock-In Mouse Model of Alzheimer's Disease under Hyperglycemia

Authors: *G. D. HARTMAN, S. D. ABHYANKAR, Q. LUO, T. W. CORSON, A. L. OBLAK, B. T. LAMB, A. D. BHATWADEKAR;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Alzheimer's Disease (AD) is a neurodegenerative disease characterized by cognitive decline. There is an unmet need to identify new biomarkers to aid with diagnosis. Retinal phenotypes are promising biomarkers for AD, as AD patients have several ocular abnormalities. Late-onset AD (LOAD) accounts for 95% of AD cases, with the apolipoprotein ε4 allele (*APOE4*) being the strongest genetic risk factor. Those with diabetes and the *APOE4* allele may have worsened retinal function and accelerated development of diabetic retinopathy (DR). Although the *APOE4*-knock-in (*APOE4*-KI) mouse model is available, the retinal phenotype is unknown. We assessed the retinal structure and neural function of LOAD-risk mice (*APOE4*-KI) compared to LOAD-neutral mice (*APOE3*-KI) and whether a diabetogenic Western diet (WD) accelerates the development of the phenotype. During a 6-month period, male and female mice carrying the *APOE4* and *APOE3* genetic variants were subjected to either Western diet (WD) or control diet (CD). Body weight and fasting blood glucose levels were monitored. Retina structure was evaluated using fundus examination and optical coherence tomography. Vascular architecture was visualized with fluorescein angiography. Neural function of the retinas was assessed using an electroretinogram (ERG). Both *APOE3*- and *APOE4*-KI mice on WD exhibited increased body weight and fasting glucose compared to CD. Retinal thickness was increased in *APOE4*-KI WD compared to *APOE4*-KI CD. Arterial tortuosity was increased with *APOE4*-KI on WD compared to APOE3-KI on WD. *APOE4*-KI mice exhibited reduced a-wave and b-wave amplitudes compared to *APOE3*-KI mice. WD further exacerbated these reductions. LOAD-risk mice exhibit heightened vascular dysfunction compared to LOAD-neutral mice. The introduction of a high-fat WD further aggravated a range of ocular irregularities, implying that the combination of *APOE4* and diabetes might expedite retinal dysfunction. The reduced ERG response observed in LOAD-risk mice signifies compromised neural activity in photoreceptors, on-bipolar cells, and Müller cells. These discoveries shed light on the mechanisms behind retinal dysfunction in a mouse model with a heightened risk of LOAD combined with diabetes and identifies potential novel biomarkers for AD.

Title: Effects of Adiponectin Signaling on lipid homeostasis in astrocytes

Authors: *J. M. NOUGAISSE, Y. LEI, X.-Y. LU;
Neurosci. & Regenerative Med., Augusta Univ., Augusta, GA

Abstract: Disruptions in lipid homeostasis have been implicated in various neurological disorders and neurodegenerative diseases, including Alzheimer's disease (AD). However, the specific contributions of lipid dyshomeostasis to the pathology of AD and the underlying mechanisms require further investigation. Among the apolipoproteins involved in brain cholesterol transport, ApoE plays a significant role as a major component of high-density lipoprotein (HDL)-like particles secreted by astrocytes. The ApoE4 isoform is the most prevalent genetic risk factor for late-onset AD. ApoE in the brain is primarily expressed by astrocytes and microglia. Astrocytes expressing ApoE4 exhibit increased intracellular accumulation, as indicated by a higher number of lipid droplets, compared to astrocytes expressing ApoE2 and ApoE3. Adiponectin, an adipokine known to enhance HDL biogenesis and secretion in peripheral tissues, can cross the blood-brain barrier. We hypothesized that adiponectin is involved in regulating cholesterol synthesis and secretion in astrocytes. To test this hypothesis, we treated astrocytes expressing ApoE2, ApoE3, and ApoE4 with adiponectin and analyzed intracellular and extracellular lipid levels. Our findings suggest that adiponectin signaling contributes to astrocyte lipid homeostasis. Future studies will explore the underlying mechanisms that mediate the effects of adiponectin in vitro and in vivo.

Title: Assessing the pathogenic role of Alzheimer’s disease genetic risk factor ApoE4 in 3D cortical organoids

Authors: *K. K. MEYER-ACOSTA, A. ARUK, A. MUNIZ PEREZ, Y. RAFATI, J. HSIEH;
Neuroscience, Developmental, and Regenerative Biol., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Alzheimer's disease (AD) is substantially heritable with genetic risk factors significantly contributing to AD risk. The leading genetic risk factor for AD, Apolipoprotein E4 (APOE4), is associated with a 3-12 fold increased risk for AD. AD develops decades prior to cognitive decline, and studying the earliest pathogenic mechanisms that precede end-stage AD pathology is technically challenging. Human induced pluripotent stem cell (iPSC) technology provides a tool to study genetic effects on human disease-relevant phenotypes, in a variety of cell-types. There is considerable evidence that GABAergic neurons, the primary inhibitory neuronal subtype in the brain, are disproportionately susceptible with APOE4 genotype in vivo, and in vitro; In a study using iPSC derived cultured neurons, APOE4/4 results in loss or degeneration of GABAergic neurons. Patient-specific iPSC-derived cortical organoids can provide a snapshot of early APOE4 mediated pathogenic mechanisms that precede end stage pathology and later AD-related pathology. To study the cell-type specific effects of APOE4, we have generated two types of iPSC-derived cortical organoids, human cortical organoids (hCO) enriched in excitatory neurons, and human subpallial organoids (hSO) enriched in inhibitory neurons. We have preliminary data suggesting the APOE4 allele alters APOE expression, growth, and related cellular phenotypes compared to organoids carrying the non-risk allele, APOE3. These preliminary findings support the notion that APOE4 may influence neuronal subtypes differentially leading to increased AD-risk.

Title: Preliminary behavioral studies suggest phenotypic differences between humanized ApoE4 knock&-in and humanized ApoE3 knock&-in rats

Authors: N. RIVEIRA, D. OKWUBODU, ***J. TARANATH**, L. LEE COLGIN;
Univ. of Texas at Austin, Austin, TX

Abstract: Apolipoprotein-E4 (ApoE4) is the highest genetic risk factor for late-onset Alzheimer's disease in humans. We performed behavioral assays with humanized-ApoE4 knock-in (hApoE4-KI) rats and humanized-ApoE3 knock-in (hApoE3-KI) rats as controls. In pilot behavioral studies, hApoE4-KI (n=5) and hApoE3-KI (n=6) rats ran on a one-dimensional circular track, performed an object-place-association (OPA) memory task (as previously described in *Zheng et al. 2016*), and were tested for anxiety in an open field arena. The rats ran on the circular track for three 10-minute sessions with 10-minute inter-session rest periods across

4 days. Putative head scanning events were identified with an algorithm used previously in *Monaco et al. 2014*. We observed preliminary evidence of increased head scanning event durations per session in hApoE4-KI rats compared to hApoE3-KI rats. Also, the head scanning event rate (head scanning events per total session pause times) was higher in hApoE4-KI rats compared to hApoE3-KI rats. During the OPA task, two identical objects were placed at adjacent corners of an open-field arena during an initial familiarization session. During a subsequent novel stimulus session, one of the two identical objects was placed in a different location (NL condition) or was replaced with a different object either in the same location (NO condition), or in a different location (NO + NL condition). In preliminary data, we observed that hApoE4-KI rats spent less time near the new object and locations in the NO and NL sessions compared to hApoE3-KI rats, potentially indicating decreased novelty recognition. Further, both groups showed similar exploratory behaviors in open-field arenas. Overall, these results suggest disturbances in exploratory behaviors of hApoE4-KI rats that may inform future studies of Alzheimer's disease.

Title: Apolipoprotein E genotype effects on attention, everyday memory and brain activity

Authors: A. C. STUART, C. DEMIRBATIR, ***S. L. KING**;
Univ. of Sussex, Brighton, United Kingdom

Abstract: Carrying the APOE4 variant of the Apolipoprotein E gene increases the risk of late-onset Alzheimer's disease, faster age-related cognitive decline, and drives dysfunction in multiple cellular pathways. How APOE4 deficits in cognition develop across the lifespan are unknown, and in early life APOE4 may be cognitively beneficial. Separate cohorts of APOE3 and APOE4 targeted replacement mice (APOE-TR, female and male) were repeat-tested in either a five choice serial reaction time task (5CSRTT) or a new rapid everyday memory task across the lifespan. A third experiment measured activation of cFos in three and twelve month-old mice. The experiments sought to map the impact of APOE genotype on profiles of cognition and brain activation across their life span. APOE-TR mice demonstrated a complex set of genotype, age, and sex-dependent effects across all three experiments. We used a modified 5CSRTT task, where

mice have continuous access to the testing chamber and testing occurs 24 hours a day. We found response accuracy (correct / (correct + incorrect trials)) varied with stimulus duration (a measure of attention) but not sex, genotype or age. Some aspects of performance improved with age (likely due to repeat training), however, this also did not vary with genotype. To measure everyday memory we developed a new appetitive adapted Barnes maze to test rapid learning in a delayed match to place paradigm. We saw some differences between sex and genotype, though these varied across age and measure, with no obvious pattern. cFos immunoreactivity was measure in cohorts of three and twelve month old mice in response to a novel context. Three month APOE4-TR mice showed a larger ensemble of cFos+ neurons in CA1 compared with APOE3-TR mice. This response was modified by sex but not associated with dendritic structural differences in cFos+/cFos- neurons. The genotype difference was no longer significant at 12 months.Together our results suggest that there is very little difference in the cognitive profile of APOE3 and APOE4-TR mice in the context of repeat testing across the lifespan. However, we saw a state of hippocampal hyperactivity in APOE4-TR mice early in life. We hypothesise that repeat testing might provide an enrichment-induced protection from the predicted APOE4-driven neurocognitive decline. Future testing in age-matched naïve mice or combining genotype with an environmental insult (e.g. early life stress or inflammation) might reveal age-related APOE4 deficits in performance.

Title: Rescue of ApoE4 related lysosomal autophagic failure by targeted small molecules: A multifaceted drug-discovery approach

Authors: *S. GRIFFIN[1], M. BALASUBRAMANIAM[2];
[2]Geriatrics, [1]Univ. of Arkansas for Med. Sci., Little Rock, AR

Abstract: Introduction: Inheritance of the ε4 variant of the Apolipoprotein gene (*APOE*ε4) is the most impactful factor, genetic or otherwise, in the development of Alzheimer's disease (AD). We found a novel mechanistic explanation in the ability of this allele's protein product, ApoE4, to enter the nucleus, bind to the Coordinated Lysosomal Expression and Activity and Regulation DNA motif (CLEAR) and in this way repress transcription of three mRNAs essential to lysosomal autophagy (*SQSTM1*, *LAMP2*, and *MAP1LC3B*) in brain tissue from Alzheimer patient carriers of *APOEε4,4*, but not *APOE*ε3,3, thus prompting us to: *i*) identify and ii) directly target the ApoE4-CLEAR DNA-binding site with small molecules that we show restored

lysosomal autophagic clearance in cell and animal models of AD carrying human *APOEε4*. **Methods:** ApoE4 protein was assessed via multi-scale computational modeling for the presence of a stable druggable pocket. ApoE4-specific lead molecules were predicted using High-throughput Virtual Screening of a small-molecule library. Autophagic gene expression was assessed: *i*) in a glioblastoma cell line (T98G) expressing either ApoE3 or ApoE4; *ii*) in mouse primary astrocytes derived from an ApoE4 Targeted-Replacement mouse strain; and *iii*) in *C. elegans* models with pan-neuronal expression of human amyloid β-peptide (Aβ) accompanied by global expression of either human ApoE3 or ApoE4 protein. **Results:** Computational modeling predicted a novel druggable site in the ApoE4 protein that comprises its CLEAR DNA-binding region. High-throughput Virtual Screening predicted small molecules with high affinity for this binding site in the ApoE4 protein. Experimental characterization of the five top molecules identified a novel lead candidate that blocked interactions between ApoE4 and CLEAR DNA motifs in multiple *in vitro* model systems, restoring the expression of three TFEB-regulated mRNA transcripts (*SQSTM1, LAMP2,* and *MAP1LC3B*) in these models. Treatment with our predicted lead molecules also inhibited Aβ accumulation in a *C. elegans* line expressing ApoE4. **Conclusion:** Our identification of both the CLEAR DNA-interacting ligand-binding pocket in ApoE4 and small molecules that binds exclusively to this druggable pocket holds promise of restoring lysosomal autophagy in individuals who inherit one or both *APOEε*4 alleles. We have thus implicated a drug as a preventative agent to delay or prevent AD in the 50-65% of the AD population that carries at least one *APOEε*4 allele.

Title: Endothelial cell APOE3 is an important regulator of neural function

Authors: *F. M. MAROTTOLI, H. ZHANG, E. FLORES-BARRERA, E. ARTUR DE LA VILLARMOIS, K. TSENG, L. M. TAI;
Anat. and Cell Biol., Univ. of Illinois At Chicago, Chicago, IL

Abstract: Human *APOE* is intricately involved in numerous aspects of neural function. Indeed, studies on aging and neurodegenerative disease have demonstrated greater cognitive decline during aging, poorer outcomes following stroke and traumatic brain injury, and higher risk of developing Alzheimer's disease with *APOE4* when compared to *APOE3*. *APOE* modulates

various functions throughout the body and increasing evidence emphasizes the impact of *APOE* on neurovascular function. Further, deficits in permeability, vessel coverage and cerebral blood flow are lower with *APOE3* compared to *APOE4* in aging and neurodegeneration in both humans and mouse models. It is, therefore, necessary to identify neurovascular functions modulated by *APOE3* to elucidate its impact on neurological functions. Brain endothelial cells are the highly specialized foundation of the neurovasculature and are responsible for its unique properties compared to other vascular systems. Currently, the role of endothelial cell *APOE3* in neurovascular function remains unresolved, and much of what is known about *APOE* and its role in the neurovasculature focuses on apolipoprotein produced by non-endothelial cells. However, we recently found that brain endothelial cell *APOE3* plays a protective role in neurovascular cell function *in vitro*. In the present study, we sought to advance these findings *in vivo* by testing whether the loss of endothelial cell *APOE3* is sufficient to impact brain vascular and neural function. We achieved this by evaluating brain function in a mouse model of humanized *APOE* at 9 months of age in which we induced the endothelial-specific knockdown of *APOE3*. In doing so, we found that the loss of endothelial cell *APOE3* results in disrupted neurovascular, neuronal, and behavioral function. Specifically, mice lacking endothelial cell *APOE3* have higher neurovascular permeability and lower vessel coverage, deficits in spatial memory and fear memory extinction, and disruption of cortical excitatory-inhibitory balance. Our data collectively demonstrate that endothelial cell *APOE3* serves an important purpose in the regulation of neural function in both physiological aging and neurodegeneration.

Discovery Inst., Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [8]Genet. and Aging Res. Unit, [7]Harvard Med. Sch., Charlestown, MA

Abstract: Therapeutics discovery and development for Alzheimer's disease (AD) has been an area of intense research to alleviate memory loss and the underlying pathogenic processes. Treatment progress has been slow with failed clinical drug development programs that have followed conventional non-clinical disease model assessments. More recent drug discovery approaches have broadened to utilize in silico computational strategies for drug candidate selection which has opened the door to repurposing and repositioning drugs for AD. Computational network analysis of gene expression signatures of patients stratified by the APOE4 risk allele of AD led to the discovery of the FDA-approved drug bumetanide as a top candidate agent that reverses APOE4 transcriptomic brain signatures and improves memory deficits in APOE4 animal models of AD. Bumetanide is a loop diuretic which acts at the kidney NKCC2 transporter for the treatment of hypertension and edema associated with cardiovascular, liver, and renal disease. Analyses of electronic health records (EHR) of large health systems revealed that patients exposed to bumetanide have lower incidences of AD by 35-70%. In the brain, bumetanide has been proposed to antagonize the NKCC1 transporter to decrease intracellular chloride ion levels which promotes GABAergic receptor mediated hyperpolarization to ameliorate disease conditions of GABAergic-mediated depolarization. NKCC1 is expressed in neurons and glia cells (oligodendrocytes, microglia, and astrocytes) in brain. In consideration of bumetanide as a repurposed drug for AD, this review evaluates its pharmaceutical properties with respect to its estimated brain levels across doses that can improve neurologic disease deficits of animal models to assess NKCC1 or non-NKCC1 mechanisms (other mechanisms). These data indicate that bumetanide efficacy may occur at brain drug levels that are below those required for inhibition of the NKCC1 transporter, which implicates non-NKCC1 mechanisms for improvement of brain dysfunctions and memory deficits. Furthermore, clinical bumetanide doses that may be efficacious to improve neurological deficits are reviewed. In summary, the efficacy of bumetanide to improve memory deficits in the APOE4 model of AD and its potential to reduce the incidence of AD in those at risk provide compelling support for clinical investigation of bumetanide as a repurposed therapeutic agent to improve AD deficits.

Title: Meta-analysis of NIH Alzheimer's disease-related dementias (ADRD) programs responsive to the national plan to address Alzheimer's disease (AD)

Authors: *A. MCCARTNEY, A. SHUKLA, X. YIN, S. DODSON, E. BRYANT, R. CORRIVEAU;
NIH/ NINDS, Bethesda, MD

Abstract: AD/ADRD diseases currently impact more than 6 million people in the United States. Rare forms of AD/ADRD are caused directly and unambiguously by genetic mutations. However, most AD/ADRD burden is complex in etiology and thought to result from an interplay among multiple incompletely understood genetic, biological, lifestyle, environmental and psychosocial risk factors. Moreover, these risk factors interact with other health factors to impact AD/ADRD outcomes. For example, while the most common dementia diagnosis is AD, research over the past decade revealed that most people with a diagnosis of AD have multiple brain pathologies, other comorbidities, and many people diagnosed with clinical AD do not have AD pathology at all. This new knowledge highlights the importance of better understanding dementia syndromes, and the relationships among them, to increase chances of developing effective interventions. The National Institute of Neurological Disorders and Stroke (NINDS) partners with the National Institute on Aging (NIA), the overall lead for NIH's response to the National Plan to address AD. NINDS leads ADRD including frontotemporal dementia (FTD), Lewy body dementias (LBD), vascular contributions to cognitive impairment and dementia (VCID) and multiple etiology dementias (MED). This project aims to evaluate NIH and the ADRD field's responsiveness to ADRD research milestones from triennial NINDS ADRD Summits by mapping NIH-funded research activities to ADRD milestones. The approach used text-based analysis/mining of grant titles, abstracts, and specific aims to map awards and activities to specific ADRD milestones. Mapping was followed by expert vetting and concurrence, including for funding opportunity announcements. The study includes new or competitively renewed NIH ADRD awards out of total $3.2 Billion toward NIH funded ADRD research from fiscal years 2017-2022. Findings will help NIH to better understand the state of the field, identify research gaps and opportunities for future efforts, and enable public communication of research activities with an accurate, accessible, compact, and updatable data visualizations. Results indicate the approach is feasible, and importantly the field and NIH have largely been responsive to the ADRD milestones in the National Plan to Address AD. The analysis points to several cross-cutting ADRD research areas that may benefit from increased attention going forward, including health equity, the multiple etiology hypothesis of common dementias, emerging risk factors for common dementias (e.g. COVID-19, traumatic brain injury, and TDP-43 proteinopathy), and clinical trials.

Title: Manipulation of the diet-microbiota-brain axis in Alzheimer's disease.

Authors: D. LEE[1], V. M. LEE[2], ***S. HUR**[3];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. Pennsylvania Sch. Med., Univ. Pennsylvania Sch. Med., Philadelphia, PA; [3]Neurosci. department, Genentech Inc., South San Francisco, CA

Abstract: Several studies investigating the pathogenesis of Alzheimer's disease have identified various interdependent constituents contributing to the exacerbation of the disease, including Aβ plaque formation, tau protein hyperphosphorylation, neurofibrillary tangle accumulation, glial inflammation, and the eventual loss of proper neural plasticity. Recently, using various models and human patients, another key factor has been established as an influential determinant in brain homeostasis: the gut-brain axis. The implications of a rapidly aging population and the absence of a definitive cure for Alzheimer's disease have prompted a search for non-pharmaceutical tools, of which gut-modulatory therapies targeting the gut-brain axis have shown promise. Yet multiple recent studies examining changes in human gut flora in response to various probiotics and environmental factors are limited and difficult to generalize; whether the state of the gut microbiota in Alzheimer's disease is a cause of the disease, a result of the disease, or both through numerous feedback loops in the gut-brain axis, remains unclear. However, preliminary findings of longitudinal studies conducted over the past decades have highlighted dietary interventions, especially Mediterranean diets, as preventative measures for Alzheimer's disease by reversing neuroinflammation, modifying the intestinal and blood-brain barrier (BBB), and addressing gut dysbiosis. Conversely, the consumption of Western diets intensifies the progression of Alzheimer's disease through genetic alterations, impaired barrier function, and chronic inflammation. This review aims to support the growing body of experimental and clinical data highlighting specific probiotic strains and particular dietary components in preventing Alzheimer's disease via the gut-brain axis.

Abstract: American nursing homes are in crisis (National Academies, 2022). At least 95% of residents have neurological or psychiatric disorders related to dementia (49%) (2023 Alzheimer's Disease Facts/Figures), mental illness excluding the dementias (25%) (Rahman and Anjum, 2013) or mild cognitive impairment (21%) (Chen et al., 2023). This does not count those with the behavioral complicators of stroke, traumatic brain injury and developmental disabilities. Each disorder is a risk factor for challenging behaviors under normal circumstances and especially during crises. Challenging behaviors due to psychiatric and neurological disorders are a major source of resident suffering and staff burnout. It is clear that: 1) Each disorder has a different pathophysiology that requires specialized pharmacotherapy related to, e.g., the "behavioral and psychological symptoms of the dementias" and the "neurobehavioral complications" of brain injury.2) Each disorder also responds to person-centered behavioral controls. And 3) There is excessive use of pharmacological restraints for challenging behaviors and the need for more non-pharmacological behavioral management techniques. In fact, non-pharmacological controls are more effective for dementia challenging behaviors than pharmacological controls (Watt et al., 2019). This assumes appropriate training in behavioral management techniques and sufficient staffing. However, during the COVID-19 pandemic facilities with reduced staffing and higher minority populations increased the use of pharmacological restraints (Yan et al., 2022). Hence, we developed a "Compassionate Crisis Care" behavioral management program to reduce staff burnout, reduce pharmacological restraints, and produce freely available YouTube training videos for challenging behaviors during pandemics and disasters. Our first posted video is focused on certified nursing assistants (CNAs): They are the primary professional caregivers in nursing homes. The video is designed to both train and empower them. Google: EVMS Compassionate Crisis Care. Our second video is focused on Virginia Medical Reserve Corps volunteers. Subsequent videos will focus on, e.g., the National Guard. The videos are produced in collaboration with the Richmond PBS Station, VPM Media Corporation, which is nationally recognized for its documentaries, and the internationally recognized Standardized Patient program at Eastern Virginia Medical School whereby actors model patients and providers. All videos include challenging behaviors due to Alzheimer's disease and traumatic brain injury and are under the supervision of a Statewide Steering Committee of experts.

Title: Patients with mild alzheimer's disease and chronic musculoskeletal pain show symptom improvement following online yoga

Authors: S. ALLENDE[1,2], L. MAHONEY[1], J. FRANCISCO[1], B. JO[2], A. K. LAU[1], ***P. J. BAYLEY**[1,2];
[1]VA Palo Alto Hlth. Care Syst., Palo Alto, CA; [2]Psychiatry and Behavioral Sci., Stanford Univ., Palo Alto, CA

Abstract: Chronic musculoskeletal pain conditions are common in patients with Alzheimer's disease (AD), and there is growing awareness that chronic pain has a major impact on cognitive function in dementia. Clinical practice guidelines are generally silent on multidisciplinary integrated care for these comorbid conditions, increasing the potential for inadequate treatment. Yoga has shown promise in treating cognitive impairment and chronic pain in AD patients, but these effects have not been demonstrated in individuals with comorbid pain and AD. We assessed the feasibility of a remotely delivered online yoga intervention for AD patients and explored the relationship between clinical outcomes. Participants were patients with mild AD (*n*=15, 57-95 years old; 77% female, mean (±SD) Mini-Mental State Exam=22.5 (±2.3)) and comorbid chronic musculoskeletal pain, and their caregivers (*n*=15, 50-75 years old; 71% Female). Patient-caregiver dyads received 12 weekly 75 min synchronous online yoga sessions, with homework on 5 non-class days. Results showed that pain severity as measured by the Brief Pain Inventory (BPI) improved from baseline (mean BPI (±SD)=4.21 (±1.9) to end-of-treatment (EOT) (mean BPI=3.29 (±1.83) ($p < .05$, Cohen's d=0.59). Mood, as measured by the Beck Depression Inventory-II (BDI) also improved from baseline (mean BDI (±SD)=18.40 (±9.96) to EOT (mean BDI =9.15 (±7.94)) ($p<.005$, Cohen's d=1.14). Changes in cognitive function were assessed using the Cambridge Neuropsychological Test Automated Battery (CANTAB) but did not reach statistical significance (all p's >.05). However, a trend in the direction of improved cognition following treatment was observed in tests of episodic memory (paired associate learning) (mean errors baseline=28.0 vs. EOT=18.5, $p>.05$, Cohen's d=0.45) and sustained attention (false alarms baseline = 12.5 vs. EOT=2.88, $p>.05$, Cohen's d=0.56), but not in a test of spatial working memory (mean errors baseline=18.5, EOT=21.0, $p>.05$, Cohen's d=0.2). The study met its main feasibility benchmarks of adherence to treatment (≥65% treatment sessions attended), treatment satisfaction (≥2 on treatment satisfaction indicating neutral satisfaction), recruitment rate (ability to recruit 15 dyads), retention rate (≥65% participants at EOT), and missing data rate (≤15%). In conclusion these results suggest that online yoga may be effective for treating chronic pain in patients with AD, and that such treatment can also benefit other comorbid symptoms including cognition and mood. The results also provide a rationale for a future larger randomized clinical trial.

Title: Determination of sex hormones and their relationship with cytokine and cognitive function in women during the transition to menopause

Authors: *D. A. MORALES-MARTÍNEZ[1], A. OLEA-PÉREZ[1], I. S. ROMERO-FLORES[2], E. VERA-AGUILAR[1], A. MONSALVO-SALGADO[3], C. ESTRADA-GARCÍA[3], A. VIELMA-VALDEZ[4], R. CHAVIRA[4], J. GARCIA-MENA[2], S. G. AGUILAR-NAVARRO[3], C. PEREZ-CRUZ[1];

Abstract: Recent studies indicate that older women are mostly affected by Alzheimer's Disease (AD); however, factors associated with sex-related vulnerability remain unknown. It has been hypothesized that changes in sex hormones production during the transition to menopause may be involved [1,2] On the other hand, estradiol (E2) and progesterone (P) regulate cytokine milieu [3,4] and AD patients show low-grade inflammation even decades before the onset of dementia [5,6]. Thus, we hypothesized that E2/P ratio regulates the proinflammatory status and cognitive function during the transition to menopause. We conducted a transversal clinical study in cognitively healthy Mexican women (30 - 65 years of age). Neuropsychological tests were followed by clinical and neurological evaluations, and MMSE was done to rule out cognitive impairment. Systemic levels of E2, Progesterone, Interleukin (IL)-1b, IL-6, and IL-10 were determined by Enzyme-linked ImmunoSorbent Assay on serum and plasm samples. Data were normalized by age, years of schooling, and the presence of the Apolipoprotein epsilon gene polymorphism (APOE). We observed that E2/P ratio was associated with proinflammatory status and alterations in specific cognitive functions according to age. These data support the proposal that alterations in sex-hormones concentrations during the transition to menopause may be involved in females' higher vulnerability to developing AD. However, we also highlight the role of E2/P ratio as an essential modulator of cytokine release that may impact cognitive function. Therefore, the optimal regulation of cytokine levels during the transition to menopause may counteract the hormonal deficit in women during the transition to menopause. Title: Clinical and biomarker evaluation of sensory-evoked steady state gamma oscillation in Alzheimer’s Disease patients

Authors: *M. HAJOS[1,2], A. BOASSO[1], E. HEMPEL[1], C. SESHAGIRI[1], A. CIMENSER[1], M. SHPOKAYTE[1], B. VAUGHAN[1], R. KERN[1], Z. MALCHANO[1];
[1]Cognito Therapeut., Cambridge, MA; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Developing safe and disease modifying therapies for Alzheimer’s disease (AD) is still challenging, in spite of recent advancements in the understanding of AD pathophysiology. Modulation of functional network abnormalities may provide new strategies for disease-modifying treatments in AD. Cognito Therapeutics is developing a novel treatment option, based on recent experimental findings demonstrating that sensory-evoked 40Hz steady-state oscillation alleviates AD pathology in AD-related transgenic mice (Adaikkan & Tsai, 2020). A phase I/II clinical trial (Overture, NCT03556280) was designed to evaluate the feasibility, safety, and efficacy of Cognito Therapeutics Proprietary Gamma Sensory Stimulation System in participants with clinical presentation of AD. In the 6-month, randomized, sham-controlled trial, participants were randomized 2:1 (active:sham) to receive daily, one-hour treatment using Cognito’s Sensory Stimulation System that elicits 40Hz steady-state oscillations through audio-visual stimulation or sham stimulation. 135 participants were screened, 74 were randomized and 53 completed (20 sham arm, 33 active arm) the study. The safety of daily use of the Gamma Sensory Stimulation System was confirmed. MRI data was used to confirm the absence of ARIA and to evaluate the effects of treatment on brain structure. High adherence to daily therapy was established based on device-recorded usage. Clinical assessments included a broad range of efficacy outcome measures since no previous trials evaluated clinical benefits of this treatment. Prespecified

primary outcome measures, including MADCOMS, ADAS-Cog14 and CDR-SB showed similar decline from baseline in both sham and active arms without significant separation. Key secondary measure ADCS-ADL scores showed a reduced decline in active arm participants compared to sham arm participants. Similarly, MMSE scores showed a significantly greater decline in sham than in active arm participants. Quantitative MRI analysis revealed significantly less whole brain, and occipital lobe volume loss, along with a significantly attenuated reduction in occipital cortical thickness in the active arm compared to sham. Significant correlations between volumetric changes and outcomes in cognition and function were also demonstrated. These clinical benefits were achieved without reduction in amyloid plaque load assessed by amyloid PET scan. Our results demonstrate that daily treatment with Cognito's Proprietary Gamma Sensory Stimulation System that elicits 40Hz steady-state oscillations was safe and well-tolerated and demonstrated potential clinical benefits in AD.

Title: Patients in the prodromal stage of Alzheimer's disease show weaker response to gamma entrainment

Abstract: Recently, a therapeutic technique based on “Gamma ENtrainment Using Sensory stimuli” (GENUS) has been proposed for Alzheimer’s disease (AD), following promising outcomes in mouse models. During GENUS, subjects are presented with periodic sensory stimulation at 40 Hz. Even though GENUS effectively reduced amyloid load in mice, studies in humans have not been conclusive. We recruited 7 prodromal, biomarker-proven AD patients (43 % female, mean age 71.29 ± 6.65, MMSE 27 ± 3.06) and 17 age-matched, cognitively normal (CN) controls (64.71 % female, mean age 70.65 ± 7.27, MMSE 29.53 ± 0.72), and subjected them to 3 different visual GENUS stimulation conditions while their EEG was recorded using a 128-channel set-up. Conditions were (1) regular 40 Hz stimulation, (2) idem with an attention task, and (3) random 30-50 Hz stimulation, with stimulation in each condition lasting 5 minutes. Stimulation was displayed using an 8 × 8 white LED matrix. For the attention condition, participants were instructed to count the number of times a red LED flashed, located in the middle of the matrix. EEG data was cut into 30 s segments with 50 % overlap, the frequency spectrum for each electrode extracted, and the results averaged. As expected, the regular 40 Hz stimulation conditions elicited a clear peak at 40 Hz while the irregular stimulation did not elicit any discernible response in its range. Next, the signal-to-noise ratio (SNR) was computed as the ratio of the spectral amplitude at 40 Hz and the average of the surrounding amplitudes (38-42 Hz), excluding 40 Hz. Comparing AD and CN groups’ SNRs, the cluster-based permutation test showed a statistically significant difference ($p < 0.01$) between AD and CN for both 40 Hz conditions, with CNs exhibiting higher SNRs. The group difference in SNR was mostly pronounced occipitally, spreading occipito-parietally in the condition with attention task. These results suggest that GENUS elicits a stronger response in CNs compared to prodromal AD patients. Furthermore, the addition of an attention task propagates the entrainment further in the brain, past the occipital region.

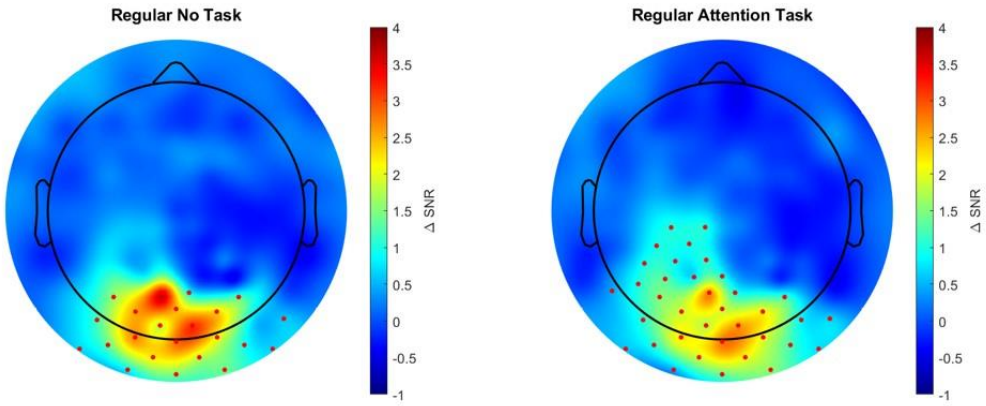

Figure 1: Spatial distribution of the group difference in SNR for two regular conditions.

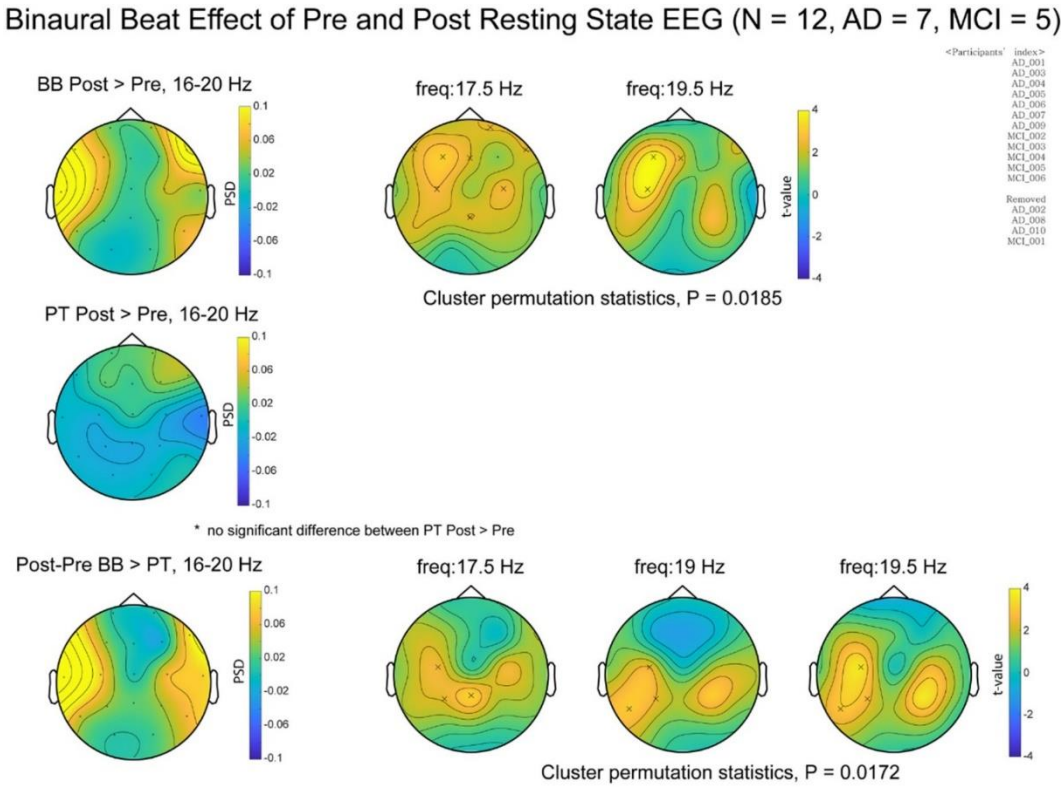
Title: The effect of beta binaural beat stimulation on resting-state brain activity in patients with mild cognitive impairment or Alzheimer's Disease

Authors: *C. LEUNG, J.-H. KIM, J. HAPPE, J. KOVAR, Y. S. LEE;
The Univ. of Texas at Dallas, Richardson, TX

Abstract: There is a growing interest in using non-invasive brain stimulation for Alzheimer's disease (AD). Here, we used another non-invasive method, called binaural beat stimulation that is thought to entrain specific neural systems through sound. Binaural beats refer to illusory tones when two slightly mismatched frequencies are dichotically presented. Although binaural beat has been shown to improve cognition and psychological states in healthy and clinical populations, the effectiveness of binaural beat stimulation in AD and/or mild cognitive impairment (MCI) remains to be determined. In this pilot resting-state EEG (electroencephalogram) study, we measured the change of resting-state brain power between binaural beat stimulation in people diagnosed with MCI and AD. We used 18 Hz (beta) binaural beat to explore its clinical efficacy in cognitive and language intervention for these patients. Twelve patients (7 AD, 5 MCI) underwent two resting-state EEG experiments on different days (roughly a week apart), one for the binaural beat condition and another for the pure tone (control) condition. The order was counterbalanced across participants. In both conditions, participants were asked to close their eyes for a pre-resting-state EEG recording, followed by 10-minute auditory stimulation (e.g., binaural beat played with slow, non-rhythmic music), and a post-resting-state EEG recording. Results revealed a significant increase in beta power (16-20 Hz) in the bilateral frontotemporal cortex after the beta binaural beat stimulation, compared with the pure tone stimulation (see figure). Together, this finding lays the foundation for future studies in investigating the clinical efficacy of beta binaural beat stimulation in MCI and AD populations in improving their language functioning, an area that is unexplored.



Note: BB = binaural beat; PT = pure tone; PSD = power-spectrum density.

Title: Long-term effects of gamma frequency sensory stimulation after 30 months in patients with mild probable Alzheimer's disease

Authors: *D. CHAN[1,2], B. JACKSON[1], G. DE WECK[1], M. COLBURN[1], N. MILMAN[4], V. FERNANDEZ[1], E. KITCHENER[5], E. N. BROWN[6,3], E. S. BOYDEN[1,7], L.-H. TSAI[1];

Technol., CAMBRIDGE, MA; [7]HHMI, Cambridge, MA

Abstract: BACKGROUND: Non-invasive gamma frequency light and sound stimulation at 40Hz was shown to reduce Alzheimer's disease (AD) pathology and improve performance during behavioral testing in mouse models of AD. Sensory stimulation inducing 40Hz entrainment reduced amyloid burden and hyperphosphorylated tau and prevented brain atrophy in different models of AD. Based on these studies, we hypothesized that induced gamma neural activity with light and sound can be used as a disease-modifying therapeutic for AD.
METHOD: We conducted a placebo-controlled, randomized control trial in subjects with probable mild AD to use our light and sound device at home for one hour daily (NCT 04042922). In the open-label extension phase, we report results after 30 months of daily 40Hz synchronized light and sound in late-onset AD (n=3) and early-onset AD (n=2) patients. Longitudinal electroencephalogram (EEG) was used to evaluate for safety and neural activity when using the 40Hz stimulation. Phone questionnaires were used to assess safety. Magnetic resonance imaging (MRI) was used to evaluate brain structure and actigraphy was used to record sleep. Cognitive evaluations included the mini mental state exam (MMSE), Montreal cognitive assessment (MoCA), Alzheimer's disease cooperative study cognitive behavior (ADAS-Cog) test and the Clinical Dementia Rating scale (CDR).
RESULT: Chronic 40Hz light and sound stimulation was safe and well-tolerated after 30 months of daily usage. EEG data show that our novel light and sound device continue to safely and effectively induced 40Hz neural activity. After 30 months of daily stimulation, 40Hz stimulation slowed brain atrophy as compared to historical age-matched controls. There was improvement of intradaily stability in 3 out of the 5 participants. Performance on cognitive testing scores improved in late-onset AD patients but not as much in early-onset AD patients.
CONCLUSION: Gamma frequency light and sound stimulation can be used safely daily for 30 months and slows AD-related degeneration. Induced neural activity using sensory stimulation at 40Hz shows promise as a novel disease modifying therapeutic for Alzheimer's dementia.

Title: Transplanted human pluripotent stem cell-derived GABAergic neuronal precursors develop electrophysiological properties of MGE pallial-type interneurons in host mouse brains

Authors: ***C. CHEN**[1], L. FUENTEALBA[2], Y. QIU[1], K. SHEN[1], D. CHERKOWSKY[2], Y. MAURY[2], M. BERSHTEYN[2], C. R. NICHOLAS[2], J. PALOP[1];

Abstract: During brain development, precursors of non-fast and fast-spiking GABAergic cortical interneurons are generated in the medial ganglionic eminence (MGE) and, following transplantation, retain a remarkable capacity for migration and integration in adult host brains, where they fully mature into functional inhibitory interneurons and have been shown to ameliorate multiple rodent models of neurological disorders. Thus, transplantation of human MGE-type interneuron precursors represents a novel cell therapy strategy for neurological disorders linked to impaired inhibitory function, including epilepsy, autism, schizophrenia and Alzheimer’s disease. Neurona Therapeutics has developed a clinical cell therapy candidate, NRTX-1001, comprising human pluripotent stem cell (hPSC)-derived post-mitotic GABAergic interneurons of a specific MGE pallial-type lineage. NRTX-1001 was cleared for clinical research by the FDA and is currently being evaluated in an ongoing Phase I/II trial for drug-resistant focal epilepsy. Here, we describe preclinical electrophysiological characterization of research-grade hPSC-derived interneurons in culture and in the mouse cortex for up to 18 months post-transplant. We demonstrate the progressive functional maturation of the grafted human cells and protracted acquisition of two divergent firing properties and waveforms, including fast-spiking and non-fast spiking MGE pallial-type interneurons. Our data highlight the remarkable capacity for transplanted human interneuron precursors to mature and functionally integrate into adult circuits and support further preclinical and clinical development of human GABAergic interneuron cell therapy for neurological disorders characterized by deficient inhibitory function.

Title: Virtual music therapy for autobiographical memory and neuropsychiatric symptoms in mild cognitive impairments and Alzheimer's disease

Authors: *K. KANG[1], S. BAKHSHI[1], D. J. LI[1], K. DEVLIN[1], B. WINSTON[2], F. S. BARRETT[2], P. B. ROSENBERG[2], A. PANTELYAT[1];

Abstract: Music therapy has shown promise for improving cognitive functioning, quality of life, and neuropsychiatric symptoms in individuals with dementia. We are investigating the potential brain network impact and effectiveness of individualized virtual MT (VMT) sessions for autobiographical memory and neuropsychiatric symptoms in individuals with mild cognitive impairment and mild dementia due to Alzheimer's disease.
Participants and caregivers attended 16 VMT sessions (two 30-minute sessions per week) with certified music therapists. Neuropsychiatric symptom assessments and MRI scans were conducted pre and post VMT sessions. For functional MRI, participants listened to 3 autobiographically salient songs, 3 digitally scrambled autobiographically salient songs, and 3 non-preferred songs. The 9 stimuli (1 minute each) were played in pseudorandomized order. After the scan, participants listened to brief excerpts from each song they heard in the scanner and rated how they felt about each excerpt. Participants (2 males, age (Mean±SD=73.50±6.36), MoCA (20±0.00)) showed decreased anxiety (STAI Scores: Pre=41.00±0.00, Post=38.50±10.61) and depressive symptoms (GDS score: Pre=4.50±2.12, Post=2.50±2.12) with increased nostalgia (Pre=25.50±6.36, Post=29.50±6.36) after VMT. Participants also reported increases in quality-of-life scores (Pre=39.50±7.78, Post=40.00±7.07) (Figure1). Initial group statistical comparisons and MRI analyses are planned after the 5th participant completes the study.
Understanding the neural network impact and neuropsychiatric symptom changes of tailored VMT may inform future interventions and improve the overall well-being of patients with these conditions.

Title: Musical approaches to getting in sync: Using music therapy to re-establish interpersonal behavioral and neural synchrony for persons with dementia and their caregivers.

Authors: *J. R. S. CULLIGAN[1], N. TASNIM[1], P. WINTER[4], T. UPTHEGROVE[1], L. SANDS[2], B. KNAPP[1], D. F. ENGLISH[5], J. C. BASSO[3];

Abstract: The impact of dementia on the well-being of and connection between caregiver-carepartner pairs is profound. Pharmacological interventions deployed to address symptoms associated with this illness are often ineffective, with negative side effects. The failure rate of translating animal model research to develop these interventions is significant. Moreover, challenges supporting persons with dementia (PWD) to engage in this imperative research is high. For persons in long-term partnerships, the progression of this disease can negatively alter established interpersonal relationships with feelings of estrangement, distress, and confusion. Despite cognitive changes PWD experience, there is evidence that music memory is not only preserved, but it is surprisingly robust. Anecdotally, music brings PWD "back" with caregivers expressing connection when making music with their PWD. Hypothesizing caregiver-PWD pairs would show an increase in interpersonal behavioral and neural synchrony through passive and active music engagement, our team engaged three 55+, age-matched caregiver-PWD pairs in 12-weeks of music therapy sessions led by a trained music therapist (1 session per week, ~1 hour each). During sessions, we collected 8-channel electroencephalography (EEG) data (Cognionics, San Diego, CA) from the PWD, caregiver, and music therapist, aligning the signals such that the hyperscanning approach could be applied. Additionally, 360 degree video and audio was recorded so later motion-capture could be analyzed. Laban Movement Analysis was utilized to detect non-verbal communication between participants, analyzed in 20-second epochs. Behaviorally, initial findings in one caregiver-PWD pair from session 1 to 12, indicate an increase in the number of times PWD initiates nonverbal communication by attending their gaze and head movements toward not just their own partner, but to other group members. Additionally, there was an increase in gaze and head movement communication during the music portions of the session compared to the non-music (transition) portions of the session. Inter-brain synchrony was determined by calculating coherence across the same EEG channels across the caregiver, PWD, and music therapist. inter-brain synchrony occurred primarily in the theta (4-8 Hz) and alpha (8-12 Hz) frequency bands, especially in frontal brain regions. Future analyses will assess the relationships between behavioral and neural synchrony. Collectively, these findings suggest that music therapy interventions may help support interpersonal synchrony at the level of the brain and behavior and critically help caregivers reconnect with their PWD.

Title: Phosphodiesterase-5 inhibitor use is associated with a 68-72% relative decrease in the rate of Alzheimer's disease and related dementias: a cohort study supporting the need for a phase 3 clinical trial

Authors: *D. S. HENRY, R. G. PELLEGRINO;
Baptist Hlth. Ctr. for Clin. Res., Little Rock, AR

Abstract: Background: Preclinical studies have provided support for the use of phosphodiesterase-5 inhibitors (PDE5i) to decrease the risk of Alzheimer's disease (AD), but two recent retrospective cohort studies evaluating the association of PDE5i use with AD and Alzheimer's disease and related dementias (ADRD) reported opposing conclusions. We recently performed an unmatched case-control study using the electronic medical record database of a large healthcare system which demonstrated reduced odds of PDE5i use among patients with AD or ADRD versus patients with no ADRD in three patient populations with PDE5i indications: erectile dysfunction (ED), benign prostatic hyperplasia (BPH), and pulmonary hypertension (pHTN). Due to limitations in the data analysis platform, we were unable to establish a temporal relationship between exposure and outcome in our previous study.
Methods: We conducted a retrospective cohort study using the electronic medical record database from a large healthcare system to evaluate whether previous PDE5i use is associated with a decreased rate of AD and ADRD among patients with ED, BPH, and/or pHTN over six years of follow-up.
Results: We observed a 68-72% relative hazard reduction for AD and ADRD associated with a history of PDE5i use among populations with ED (n[$PDE5i^+$]=6068, n[$PDE5i^-$]=3698), BPH (n[$PDE5i^+$]=3540, n[$PDE5i^-$] =15479), and pHTN (n[$PDE5i^+$]=407, n[$PDE5i^-$]=3347). Survival free from ADRD was higher for patients with than for patients without a history of PDE5i use among 50-60- and 60-70-year-old patients with ED and among 50-60-, 60-70-, and 70-80-year-old patients with BPH. As pHTN is the only chronic PDE5i indication for women, we stratified by sex and observed higher survival free from ADRD among female patients with than those without a history of PDE5i use.
Conclusions: History of phosphodiesterase-5 inhibitor use (sildenafil [Viagra], tadalafil [Cialis], and vardenafil [Levitra]) was associated with a 68-72% relative hazard reduction for Alzheimer's disease and related dementias among patient populations with erectile dysfunction, benign prostatic hyperplasia, and pulmonary hypertension. Lower rates of Alzheimer's disease and related dementias were observed among both male and female patients and across a wide range of ages. These findings support the need for a phase 3 clinical trial evaluating the use of phosphodiesterase-5 inhibitors in the prevention and treatment of Alzheimer's disease and related dementias.

Title: Blinded response data from the phase 3 NM101 trial of anti-inflammatory bezisterim (NE3107) in patients with mild to moderate Alzheimer's disease

Authors: C. L. READING, *J. PALUMBO, N. OSMAN, C. AHLEM;
BioVie, Carson City, NV

Abstract: Clinical diagnosis of Alzheimer's disease (AD) and related dementias in community-based medicine is still largely based on clinical presentation and exclusion of acute vascular factors. The majority of new dementia patients lack biomarkers that qualify them for treatment with recently approved anti-amyloid antibody therapies, creating a large unmet need for safe and effective AD therapies that can be broadly used in the community-based setting. Bezisterim (NE3107) is an orally bioavailable, blood-brain barrier-permeable anti-inflammatory agent with a new mechanism of action believed to inhibit extracellular signal-regulated kinase (ERK) activation, specifically in inflammation signaling pathways, without impacting homeostatic ERK functions. We collected baseline amyloid beta (Aβ), metabolic, inflammatory, and morphometric data from a phase 3, placebo-controlled, 7-month study of bezisterim in 400 patients with mild to moderate probable AD (Study NM101 [NCT04669028]). Baseline characteristics indicated differences in disease severity, as well as metabolic and inflammatory parameters between Aβ-positive and -negative subjects, which could largely be attributed to the subjects' age; Aβ-positive subjects were older with more advanced disease. Overall, the baseline metabolic, inflammatory, and morphometric data for the 2 populations were not fundamentally different. Analysis of blinded data indicated significant improvements from baseline in the Clinical Dementia Rating (CDR) global score (−0.170, $p<0.0001$), CDR Scale Sum of Boxes (−0.861, $p<0.001$), 12-item cognitive subscale of the AD Assessment Scale (−2.75, $p<0.0001$), AD Cooperative Study (ADCS)-Clinical Global Impression of Change (−0.650, $p<0.0001$), ADCS-Activities of Daily Living (+2.750, $p<0.0001$), Mini-Mental State Examination (+2.331, $p<0.0001$), AD Composite Score (−0.126, $p<0.0001$), Mild AD Composite Score (−1.860, $p<0.0001$), Moderate AD Composite Score (−0.672, $p<0.028$), fructosamine (−3.877, $p<0.004$), and C-reactive protein (−1.347, $p<0.036$) in response to bezisterim treatment and its anti-inflammatory activity, which were similar in Aβ-positive and -negative populations. These data suggest that the pathophysiology of dementia and cognitive impairment in probable AD are driven by inflammatory factors that are present in both Aβ-positive and -negative populations. Additionally, the study findings suggest that the current diagnostic criteria for AD based on Aβ status may be too stringent and may inadvertently prevent development of therapies for patients with probable AD.

Title: Resveratrol differentially affects MMP release from neurons and glia; implications for therapeutic efficacy

Authors: *M. AMONTREE[1], M. NELSON[1], L. STEFANSSON[2], D. T. S. PAK[3], K. MAGUIRE-ZEISS[5,2], R. S. TURNER[4], K. CONANT[2];
[1]Georgetown Univ. Med. Ctr. Interdisciplinary Program In Neurosci., Washington, DC; [2]Neurosci., [3]Dept. of Pharmacol. and Physiol., [4]Neurol., Georgetown Univ. Med. Ctr., Washington, DC; [5]Biol. Dept., Georgetown Univ., Washington, DC

Abstract: Resveratrol, a naturally occurring polyphenol that activates sirtuin 1 (SIRT1), has been shown to reduce overall levels of matrix metalloproteases-2 and -9 (MMP-2 and MMP-9) in cerebrospinal fluid (CSF) samples from patients with Alzheimer's dementia (AD). Depending on the site of release, however, MMP-9 has the potential to improve or impair cognition. In particular, its release from microglia or pericytes proximal to the blood brain barrier can damage the basement membrane, while neuronal activity dependent release of this protease from glutamatergic neurons can instead promote dendritic spine expansion and long-term potentiation of synaptic plasticity. In the present study, we test the hypothesis that resveratrol reduces MMP levels in CSF samples from patients with APOE4, an allele associated with increased glial inflammation. We also examine the possibility that resveratrol reduces inflammation-associated MMP release from cultured glia, but spares neuronal activity dependent release from cultured cortical neurons. We observe that resveratrol decreases overall levels of active MMP-9 in CSF samples from patients with APOE4/APOE3 > APOE3/APOE3. Reservatrol also reduces CSF levels of tissue inhibitor of metalloproteinases-1 (TIMP-1), a glial derived protein, in an APOE4 allele dependent manner (APOE4/APOE4 > APOE3/APOE4 > APOE3/APOE3). Consistent with these results, we observe that resveratrol reduces basal and lipopolysaccharide (LPS)-stimulated MMP release from cultured microglia and astrocytes. In contrast, however, resveratrol does not inhibit NMDA stimulated release of MMP-9 from cortical neurons. Overall, this data is consistent with the possibility that while resveratrol reduces potentially maladaptive MMP release, adaptive MMP release is spared. In addition, this data suggests that further studies may be warranted to determine if resveratrol's effects on glial MMP-9 release could support clinical trials to determine whether if it would be a useful adjunct to AD and/or anti-amyloid therapy related damage to the blood brain barrier.

Title: Amylovis-201, a potential compound for the treatment of Alzheimer's disease, is a potent sigma-1 protein agonist with anti-amyloidogenic activity

Authors: L. GARCIA PUPO[1], L. CROUZIER[2], J. MEUNIER[2], A. MORILLEAU[2], B. DELPRAT[2], A. BENCOMO MARTINEZ[1], M. SABLON CARRAZANA[1], R. MENENDEZ SOTO DEL VALLE[1], E. ORTA SALAZAR[3], S. DIAZ CINTRA[3], ***T. MAURICE**[2], C. RODRIGUEZ TANTY[1];

Abstract: Aggregation of amyloid-ß (Aß) peptides is associated with neurodegeneration in Alzheimer's disease (AD). We identified novel naphthalene derivatives, including Amylovis-201, able to form thermodynamically stable complexes with Aß1-42 fibrils, according in silico studies. Amylovis-201 showed a high potency to: inhibit $Aß_{1-42}$ aggregation in human microglia, decrease Aß burden in 3xTg-AD mouse brain and attenuate cognitive deficits in mice [Rivera-Marrero et al., Bioorg Med Chem 2020]. The drug has a naphthalene group chemical scaffold monosubstituted by an amidoalkyl chain with a terminal thiocarbamate group. The structure of the molecule allows hydrogen bonds and hydrophobic interactions, which seems suitable for effective binding to the sigma-1 receptor (S1R) chaperone. It resembles the current agonists developed as neuroprotective drugs in AD. We investigated a putative action of Amylovis-201 at S1R. S1R agonist activity is defined by ligand ability to dissociate the ER stress chaperone BiP from S1R in S1R-overexpressing cells. The prototype agonist PRE-084 (Ki 44 nM) dissociated BiP from S1R with an IC_{50} of 426 nM and its effect was blocked by the antagonist NE-100. Amylovis-201 showed an IC_{50} of 362 nM, thus a strong S1R agonist activity. *In vivo*, the drug was tested in the dizocilpine-induced amnesia in mice and in the hyperlocomotor response of *Wfs1ab*^{KO} zebrafish, two S1R responses [Maurice et al., Brain Res 1994; Crouzier et al., Science Transl Med 2022]. Amylovis-201 attenuated dizocilpine-induced deficits, in the spontaneous alternation and passive avoidance tests, at 0.03-1 mg/kg, and blocked the increase in motor response of *Wfs1ab*^{KO} zebrafish at 3 µM. Both effects were blocked by NE-100. Finally, the drug also prevented the learning and memory deficits in mice intracerebroventricularly injected with oligomerized Aß25-35 peptide, a pharmacological model of Alzheimer's disease previously used to demonstrate the efficacy of S1R agonists and modulators [Meunier et al., Br J Pharmacol

2006; Maurice et al., Pharmacol Res 2019]. These data showed that Amylovis-201 shows a potent S1R agonist activity that is likely related to the drug ability to interfere with Aß aggregation and toxicity.

Title: Analyzation of tRNA modification 5-methylcytosine (m^5C) and NOP2/Sun RNA Methyltransferase 2 (NSUN2) leads to new insights in pathological aging and Alzheimer’s Disease.

Authors: ***M. JOERG**[1], L. WALZ[1], M. LANDER[1], K. ENDRES[2], M. HELM[1], K. FRIEDLAND[3];
[1]Johannes Gutenberg Univ., Mainz, Germany; [2]Univ. Med. Ctr. Mainz, Univ. Med. Ctr. Mainz, Mainz, Germany; [3]Johannes Gutenberg-University, Mainz, Germany

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disease, characterized by gradual cognitive decline and later dementia. About 15% of the over-65s and over 50% of the over-80s are affected by AD worldwide. Despite intensive basic research, the pathogenesis of AD is only partially understood, and no high-efficacy treatment options are available. New approaches focus on the ribonuclease angiogenin (ANG) and RNA modifications in pathological aging and AD development. Especially tRNA modifications play a crucial role in RNA function and stability, but their role in pathological aging and AD remains unknown. To incorporate RNA modifications, specific proteins are required. This group of proteins is collectively known as RNA-modifying proteins (RMPs) and is further subdivided into three distinct groups: “writers”, “readers”, and “erasers”. "Writers" chemically label RNA; “erasers” remove them again; and “readers” selectively recognize and bind to certain specific chemical RNA modifications leading to producing a cellular response. Therefore, we used an Liquid Chromatography with tandem coupled mass spectrometry (LC-MS/MS) based approach in different aging and AD cell, animal, and human postmortem brain tissue models to determine whether specific tRNA modifications contribute to mitochondrial defects following the dynamic changes in modification patterns along the pathological process of aging and AD. The tRNA modification 5-methylcytosine (m^5C) located in the anticodon and variable loop region at positions 34/38/48/49/50 plays a crucial role in the stress-induced ANG-mediated tRNA cleavage. First results of LC-MS/MS and Western Blotting revealed various changes in tRNA

modifications in pathological aging and AD, especially for m^5C and the writer NOP2/Sun RNA Methyltransferase 2 (NSUN2) in an age- and sex-specific manner. Our group also determined an age-, sex- and AD-dependent dysregulation of ANG expression. These results suggest that ANG and tRNA modifications act as critical factors in the further development of AD or other neurodegenerative diseases. This line of research could be a new road to defining early biomarkers for AD and represent an important step toward developing new therapeutic strategies to improve the symptoms of AD patients.

Title: SUVN-I7016031: A novel M1-receptor positive allosteric modulator (M1-PAM) for the treatment of cognitive deficits associated with Alzheimer's disease

Authors: *R. MEDAPATI, V. R. GRANDHI, R. ABRAHAM, R. SUBRAMANIAN, V. R. C. PALACHARLA, R. K. BADANGE, K. BOJJA, T. NARASIMHULA, R. NIROGI;
SUVEN LIFE SCIENCES, HYDERABAD, India

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder due to the accumulation of β-amyloid peptide, neurofibrillary tangles and disruption of several neurotransmitters. AD is associated with cognitive impairments and behavioural disturbances. One approach to improve cognitive function in mild to moderate AD patients is by enhancing the cholinergic transmission using acetylcholinesterase inhibitors, but this approach has limited efficacy and dose limiting adverse effects. New drugs that target specific receptor subtypes of the cholinergic system may have advantages. Modulation of M1 muscarinic receptors is one option for developing new treatment for AD. M1 muscarinic receptors are G-protein coupled receptors and are highly expressed in central nervous system which plays a major role in cognition, attention and sensory processing. Developing and targeting selective M1 subtype ligands has been unsuccessful due to highly conservative orthosteric binding sites. The ligands which positively modulate the M1 allosteric sites may be a good therapeutic approach. SUVN-I7016031 is a novel, selective M1 positive allosteric modulator (M1-PAM). Reporter gene assay was used to assess its effect on the allosteric site of the M1 receptors. It was evaluated for its binding ability at the orthosteric site across all muscarinic receptors. The pharmacokinetic properties of SUVN-I7016031 were evaluated in rodent and non-rodent species. The effect on the modulation of soluble amyloid precursor protein-α (sAPP-α) was also evaluated in rat cortex. SUVN-I7016031 effects on cognitive deficits were evaluated using various animal models of cognition. The cholinergic side effects were also evaluated. SUVN-I7016031 is a selective M1-

PAM with no agonistic activity and has good selectivity over other muscarinic receptor subtypes M2 to M5. It has good oral bioavailability and brain penetration. It produced significant increase in cortical levels of sAPP-α in rats. SUVN-I7016031 reversed the time-induced as well as scopolamine-induced amnesia in object recognition task in rats. In social recognition task, rats treated with SUVN-I7016031 remembered the conspecific familiar juvenile and spent more time investigating the novel juvenile. SUVN-I7016031 reversed the scopolamine-induced cognitive deficits in contextual fear conditioning task. It also enhanced cerebral blood flow and no side effects were observed that are associated with direct mechanism of cholinergic stimulation. SUVN-I7016031 may be a future promising therapeutic intervention in alleviating cognitive deficits associated with AD.

Title: Allopregnanolone as a Regenerative Therapeutic for Alzheimer’s Disease:Rationale & Design of a phase 2 proof-of-concept clinical trial using hippocampal volume as a surrogate endpoint.

Authors: *G. D. HERNANDEZ[1], C. M. LOPEZ[1], A. RAIKES[2], D. MATTHEWS[4], R. D. BRINTON[3];
[1]Univ. of Arizona / CIBS, Tucson, AZ; [3]Ctr. for Innov in Brain Sci., [2]Univ. of Arizona, Tucson, AZ; [4]ADMdx, Northbrook, IL

Abstract: Hippocampal volume is a well-established imaging biomarker of neurodegeneration and hippocampal atrophy is predictive of cognitive decline in Alzheimer’s disease. Thus, we propose its use as a surrogate endpoint to test the efficacy of allopregnanolone as a regenerative therapeutic for mild AD. The study design to be carried out is a phase 2 multi-center, double-blind, parallel-group, randomized-controlled clinical trial. Approximately 20 sites will recruit 200 participants with mild AD, 100 participants per treatment arm. Eligible participants are male or female, age 55 to 80 years old, diagnosed with probable AD, with a MMSE score between 20-26 and APOE ε4 genotype carriers (3/4 and 4/4). Participants will be randomized to 4 mg Allo (administered intravenously over 30 minutes, once per week) or matching placebo, 1:1 allocation, for a 12-month period. After 12 months, all participants in the placebo group will be

crossed-over to receive Allo for the remainder of the study (6 month open-label phase). Brain imaging to evaluate the primary endpoint will be conducted at baseline, 6 and 12 months. A critical component of this trial is that all imaging sites participating in the trial are capable of performing both basic and advanced MRI sequences required in the protocol. The primary endpoint is mean rate of change in hippocampal volume at 12 months. Secondary Endpoints include mean rate of change in cognitive outcomes (CANTAB-PAL, ADAS-Cog11), functional outcomes (ADCS-iADL) and safety outcomes at 12 months. Exploratory endpoints include other imaging outcomes (regional brain volumes, white matter fiber tract diffusion measures as determined by DTI, average intrinsic connectivity as determined by resting state fMRI, and cerebral region cerebral blood flow); blood-based biomarkers of target engagement; other cognitive and functional outcomes (CDR-SB score, ADAS-Cog14 score, MMSE score, NPI-Q score, EuroQol 5-Dimension / 5-Level (EQ-5D-5L) health-related quality of life scale scores, QoL-AD score, Zarit Burden Interview Questionnaire score at 12 and 18 months. Additionally, change from baseline to 6, 12 and 18 months in open-label treatment participants switching from placebo to Allo at 12 months in the above endpoints. Outcomes from this study will validate previous findings indicating that allopregnanolone may exert both regenerative and neuroprotective effects on structure and connectivity in the Alzheimer's brain.

Title: A novel small molecule inhibitor mitigates toxic amyloid oligomers and behavioral abnormalities in an Alzheimer's disease mouse model

Authors: *E. SHAO[1], M. KOKES[1], S. ARYA[1], J. SCHWARZ[1], K. BURK[1], X. LIU[2], S. GAIKWAD[3], R. KAYED[3], M. T. BOWERS[2], A. SINGH[1], V. MATHUR[1], K. PLANEY[1]; [1]Acelot.Inc, South San Francisco, CA; [2]Dept. of Chem. and Biochem., Univ. of California, Santa

Barbara, CA; [3]Departments of Neurol. & Neurosci. & Cell Biol. & Anat., Univ. of Texas Med. Br., Galveston, TX

Abstract: Background: Alzheimer's disease (AD) is characterized by the accumulation of insoluble aggregates of the amyloid beta 1-42 (Aβ42) fragment of amyloid precursor protein (APP) and hyperphosphorylated tau protein, leading to synaptic and neuronal loss and inflammation in the central nervous system. The contribution of specific tau and amyloid beta species to cognitive decline in AD is still debated. However, evidence suggests that small oligomers, rather than higher-order aggregates, are primarily responsible for the toxic effect leading to neuronal death. While individual targeting of Aβ42 and tau is currently under investigation, the potential benefits of combination therapy have been underexplored. **Objectives**: the objectives of this study are to assess the in vitro potency and mechanism of action of Acelot's novel small molecule, ACE258, to determine its pharmacokinetic properties and target engagement in vivo, and to evaluate its efficacy in the 3xTg mouse model of AD. **Methods:** by employing our joint pharmacophore space (JPS) machine learning platform, we have identified novel small molecules that bind to both Aβ42 and tau oligomers. We demonstrate in vitro mechanism of action using the Thioflavin T assay, ion mobility-mass spectrometry (IM-MS), and oligomer toxicity assay. Furthermore, we evaluate the drug efficacy in vivo using a 3xTg mouse model of AD, which exhibits both Aβ and tau pathologies. **Results:** our findings indicate that ACE258 effectively reduces the fibrilization of Aβ42 in the Thioflavin T assay. IM-MS reveals that the Aβ42 peptide forms dimers to dodecamers in vitro. Coincubation with ACE258 or incubation post-oligomerization reduces toxic dodecamer oligomer species and increases Aβ42 monomers in solution. Moreover, ACE258 rescues tau oligomer-dependent toxicity in rat primary neuronal cells, highlighting its cell permeability and potent activity in neuronal models. Additionally, ACE258 mitigates tau oligomer-dependent electrophysiological abnormalities in mouse hippocampal brain slices. Oral administration of ACE258 in mice demonstrates good tolerability and brain penetration for up to 24 hours. Lastly, ACE258 ameliorates certain behavioral abnormalities in the 3xTg mouse model of AD. **Conclusion:** ACE258 is a clinical candidate drug with favorable pharmacokinetic properties and brain permeability. It functions as a poly-disaggregator that targets toxic forms of both Aβ42 and tau, inhibits fibrilization and toxic amyloid oligomers in vitro, reduces oligomer-dependent neuronal toxicity, partially restores oligomer-associated nerve conduction, and rescues behavioral abnormalities in 3xTg AD mice.

Title: Novel LXR-PPAR agonist improves behavior deficits and synaptic plasticity in a model of Alzheimer's disease.

Authors: *R. H. AMIN[1], I. STEINKE[2], F. S. WIBOWO[3], S. YOO[3], V. SUPPIRAMANIAM[4], M. SINGH[3], R. ARNOLD[3];
[1]Drug Discovery and Develop., Auburn Univ., AUBURN, AL; [2]Dept. of Drug Discovery and Devlopment, [3]Drug Discovery and Develop., Auburn Univ., Auburn, AL; [4]Kennesaw State Univ., Marietta, GA

Abstract: The increased incidence of Alzheimer's disease (AD) and its associated mortality rate represent an unmet medical need and a critical need for novel molecular therapeutics. Recent work focusing on patients with the apoE4 alleles has highlighted the association of brain cholesterol dysregulation with elevated pathological burden, and neurodegeneration. These studies have highlighted the importance of the nuclear receptor Liver X receptor (LXR) for developing AD therapies. However, LXR agonists have been observed to induce hepatotoxicity and neutropenia in humans and thus have failed in clinical trials for atherosclerosis. Our newest dual agonist, AU403, was developed computationally as a novel Liver X Receptor-β (LXRβ) with partial PPARδ/α activity. Our library of compounds (>100) was created in silico and is based upon selective amino acid interactions in the ligand-binding domains of both LXRβ and PPARδ/α with negligible PPARγ activity. Thus, our design serves as a dual LXRβ/ PPARδ/α agonist. This strategy seeks to avoid the unwanted side effects of traditional LXRα and PPARγ agonists, including liver toxicity, neutropenia, edema, and heart failure. **Methods:** Our lead compound, AU403 was designed computationally using Schrodinger software and molecular dynamics to model enzymatic activity against known PPAR agonists, using crystal structures of PPAR (γ, α, δ). Further AU403, drug design was optimized by modeling ADME properties using both QikProp and GastroPlus to enhance distribution to the CNS. Improved working declarative memory was observed in 12-month 3xTgAD mice, using Y-maze and Novel object recognition studies after 3 months of AU403 treatment (5mg/kg / daily). Improvement on synaptic plasticity was measured by long-term potentiation studies. **Results:** Our *in silico* design was formulated on Based on these evaluations our lead compound AU403 displays avoidance of Trp443 and Leu439, which are deep in the LXRα-AF2 ligand binding pocket. Furthermore, we observed significant improvement in working declarative memory and long-term potentiation in 12-month old 3xTgAD mice treated with our lead compound AU403. Mechanistically we observed enhanced microglia interaction with dendritic spine density. **Conclusion**: We have observed that AU403 can serve as a highly novel potential therapeutic agent for AD.

Abstract: Alzheimer’s disease (AD) and osteoporosis often coexist in the elderly population. Observational studies suggest the association between these two diseases in which i) lower bone mineral density (BMD) is associated with a higher risk of developing AD, and ii) AD patients have reduced BMD and increased incidence of falls and hip fractures compared to healthy people. However, the pathophysiologic link between AD and skeletal health has been poorly defined and the mechanisms underlying AD-associated reduction of BMD are unknown. We examined the skeletal phenotype of 5xFAD mice, an AD model with accelerated neuron-specific amyloid-beta accumulation causing full-blown AD phenotype by the age of 8 months. Micro-computed tomography indicated significantly lower trabecular and cortical bone parameters in 8-month-old male, but not female, 5xFAD mice than sex-matched wild-type littermates. Dynamic histomorphometry revealed reduced bone formation and increased bone resorption in 5xFAD males, in which quantitative reverse transcription-polymerase chain reaction (qRT-PCR) showed elevated the skeletal resorption stimulation factor, receptor activator of nuclear factor kappa-B ligand (RANKL) gene expression and a tendency for reduced expression of several osteoblast/osteocyte-specific genes, including bone sialoprotein (*Ibsp*), dentin matrix protein-1 (*Dmp1*), sclerostin (*Sost*), and the wingless-related integration site (Wnt)/beta-catenin targets AXIS inhibition protein 2 (*Axin2*) and transcription factor-7 (*Tcf7*). 5xFAD males also had reduced body fat percentage with unaltered lean mass, as determined by dual-energy X-ray absorptiometry (DXA) and showed elevated the circadian rhythm-regulating gene, uncoupling protein 1 (*Ucp1*) mRNA levels in brown fat, indicating high sympathetic nervous system activity. Moreover, male 5xFAD bones showed abnormal expression levels of multiple circadian rhythm-regulating genes, including brain and muscle arnt-like protein-1 (*Bmal1*) and RAR-related orphan receptor A (*Rora*). Together, our findings indicate that AD promotes osteopenia by affecting both bone formation and bone resorption via mechanisms likely involving increased sympathetic tone and a disrupted circadian rhythm. Our study provides novel insights into the link between AD pathophysiology and osteoporosis, which may help develop strategies to treat osteoporosis in AD patients.

Title: Molecular dynamics and experimental validation identify the CPE/NF-a1 binding site on HTR1E responsible for b-arrestin activation and subsequent neuroprotection

Authors: X. YANG[1], J.-Y. LEE[2], S.-K. KIM[3], S. VINAY[1], *Y. LOH[1,2,3], W. A. GODDARD, III[3];
[1]NICHD, NIH, Bethesda, MD; [2]Therapeut. and Biotech. Div., Korea Res. Inst. of Chem. Technol., Daejeon, Korea, Republic of; [3]Materials and Process Simulation Ctr., Caltech, Pasadena, CA

Abstract: Carboxypeptidase E (CPE), also known as neurotrophic factor (NF-α1), is both a prohormone processing enzyme involved in the biosynthesis of neuropeptides and peptide hormones and a neurotrophic factor that has neuroprotective activity. To uncover the underlying mechanism of CPE in neuroprotection, we had previously identified an interaction between the serotonin receptor, HTR1E, and the central part of CPE, which protect human neurons against oxidative/neuroexcitotoxic stress via β-arrestin/extracellular signal-regulated kinase (ERK) signaling. We had also predicted various amino acids in CPE that are involved in the interaction with HTR1E, forming three salt bridges between the two molecules. In this study, by mutating a series of sites in the central part of CPE that are predicted to be important for CPE/HTR1E interaction, we found a single mutation of CPE K302A (M1), along with other two combination of mutations, CPE K302A+D306A+D275A (M11), CPE D259A+E260A+W319A (M15), decreased binding to HTR1E. The CPE site K302 is the most important one among 16 CPE mutants we tested, which is consistent with molecular dynamic simulation analysis. *In silico* analysis also revealed these 3 mutants might dramatically reduce activation of β-arrestin due to decreases in binding, consistent with decreased pERK1/2 level found in cells treated with these mutants. Unlike the other CPE mutants, we also found that CPE K302A is the only one that attenuates CPE's ability to protect cells from H_2O_2-induced cytotoxicity. In summary, the results confirm experimentally, validating the previously predicted CPE binding site to 5-HTR1E that is responsible for β-arrestin activation and subsequent neuroprotection. This provides the target for

experiments and *in silico* computational screening to identify small molecules to replace the CPE/ NF-α1 protein as novel drugs to protect human neurons against oxidative/neuroexcitotoxic stress via β-arrestin/ERK signaling.

Title: Effects of interventional genetic knockdown of the serotonin transporter on L-DOPA-induced behaviors in a rat model of Parkinson's disease

Authors: *G. MCMANUS[1], A. CENTNER[1], N. LIPARI[1], C. BUDROW[1], S. VENKATESH[1], C. BISHOP[1], F. P. MANFREDSSON[2];
[1]Binghamton Univ., Binghamton, NY; [2]Barrow Neurolog. Inst., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Parkinson's disease (PD) is a neurodegenerative disease typified by the loss of dopamine (DA) neurons in the substantia nigra pars compacta (SNpc) that results in motor symptoms including resting tremor, rigidity, akinesia, and postural instability. Dopamine replacement therapy with L-3,4-dihydroxyphenylalanine (L-DOPA) has remained the gold-standard treatment for the motor symptoms of PD, however, chronic use leads to the development of treatment-induced side effects known as L-DOPA-induced dyskinesia (LID). The mechanisms underlying LID are multifaceted, but accumulating research has strongly implicated aberrant neuroplasticity in raphe-striatal serotonin (5-HT) circuits. This compensatory neuroplasticity may be beneficial in earlier stages of PD but becomes maladaptive and precipitates LID with continued dopamine (DA) denervation in later stages. Given that the 5-HT transporter (SERT) has an affinity for DA uptake and is upregulated in the brain of dyskinetic patients and in animal models of LID, it has emerged as an intriguing target for anti-dyskinetic adjuncts. Therefore, we employed a genetic knockdown of SERT (SERT-KD) to investigate its role in LID expression. 6-hydroxydopamine-lesioned Sprague-Dawley rats were administered sub-chronic L-DOPA daily for 2 weeks to establish LID. Following the last day of L-DOPA treatment, animals underwent a second surgery where they received either a recombinant adeno-associated virus 9 (AAV9) short-hairpin RNA driven SERT-KD (SERT-shRNA) or control scrambled shRNA AAV9-GFP (SCR-shRNA). Animals were allowed 4 weeks for optimal transfection after which they received another 2 weeks of daily sub-chronic L-DOPA treatment to track changes in LID expression. We hypothesized that this genetic intervention would reduce

LID expression by attenuating the dysregulated DA efflux from 5-HT cells, a primary presynaptic mechanism thought to underlie LID. Behavioral data showed a marked reduction in LID across the second treatment period in animals who received the SERT-KD viral condition compared to SCR-shRNA controls. This suggests a reorganization of pro-dyskinetic circuitry following SERT-KD knockdown that further supports SERT as an important mechanism in the development and expression of LID and provides a promising avenue for developing novel therapies to optimize PD treatment.

Title: Effect of Practice Schedule on Motor Learning of Reactive Balance Responses in Persons with Parkinson's Disease and Age-matched Control

Authors: *R. Y. AKINLOSOTU[1], K. P. WESTLAKE[2];
[1]Physical Rehabil. Sci., Univ. of Maryland, school of Med., Baltimore, MD; [2]Dept. of Physical Therapy & Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Objective: Persons with Parkinson's disease (PwPD) have set-shifting impairments that may limit motor learning of protective responses to prevent falls. Practice schedules (blocked and random practice), a widely used motor learning principle in sports, may enhance or limit the acquisition and retention of protective stepping responses to balance challenges. This study compares the acquisition & retention of protective stepping stability via blocked versus random practice schedules in PwPD & age-matched controls. **Methods:** Twenty PwPD & 20 age-matched controls (HC) will experience a slip & trip-like perturbations to induce stepping responses via random & blocked practice schedules. Blocked practice is repeating a task (e.g., slip) several times before the next, while random practice is randomly practicing two tasks (slip & trips). Each subject will wear a safety harness with an integrated load cell to prevent falls. Our primary outcome, the margin of stability (MoS) at 1st the protective step before, 10 minutes, & 2 days after practice, will be analyzed using two ANOVA (Group vs. Trial). **Results:** To date, we have assessed 2 & 4 healthy controls in the random (HC_RAND) & blocked (HC_BLOC) practice group, respectively & 2 PwPD each in the blocked (PD_BLOC) & random (PD_RAND) practice group. With baseline MoS normalized to 0, the mean of the normalized change score

was reported. The HC_BLOC improved their MoS from the pretest to posttest slip (0.086) at the acquisition phase, & from the pretest to retention slip test (0.067). Although HC_RAND MoS decreased from the pretest to posttest slip (by -0.011), they improved their MoS from the pretest to posttest slip (-0.02). Among PwPD, while the MoS for PD_BLOC improved from pretest to posttest (0.164) & from pretest to retention test (0.118), PD_RAND's MoS declined from pretest to posttest (-0.0275), & from pretest to retention (-0.0213). The MoS change score was higher for persons with lower MoS at baseline than those with higher MoS at baseline. **Significance of Impact:** The findings will provide knowledge that may foster the development of robust balance rehabilitation protocols to improve postural responses in PwPD & reduce fall-related delayed & ineffective stepping responses in PD.

Title: Functional changes of nigral dopamine neurons in a neuromelanin-producing rat model of Parkinson's disease

Authors: *A. LEDONNE[1,2,3], S. L. D'ADDARIO[2,3], M. MASSARO CENERE[2,3], F. COSSA[1,2,3], M. VILA[3,4,5], N. B. MERCURI[1,2,3];

Network, Chevy Chase, MD; [4]Vall d'Hebron Res. Inst. (VHIR)-Center for Networked Biomed. Res. on Neurodegenerative Dis. (CIBERNED), Autonomous Univ. of Barcelona (UAB), Barcelona, Spain; [5]Catalan Inst. for Res. and Advanced Studies (ICREA), Barcelona, Spain

Abstract: Neuromelanin (NM) is a dark brown intracellular pigment that accumulates in human substantia nigra pars compacta (SNpc) dopamine (DA) neurons with age, conferring the nigral dark look that inspired area's nomenclature. NM buildup has long been associated with Parkinson's disease (PD), in light of the evidence that NM-containing neurons particularly degenerate during PD progression and Lewy bodies (LBs) mainly form in close proximity with NM. To date, the functional impact of the progressive NM accumulation on nigral DA neurons activity is completely unknown, with limitations in preclinical investigations mainly due to lack of overt NM production in rodents, oppositely to humans. In this study, we induced in vivo intranigral NM production in rats, by injections of an adeno-associated viral vector (AAV) carrying human tyrosinase (hTyr), the enzyme responsible for the peripheral melanin formation. We found that AAV-hTyr-injected rats, few weeks after AAVs injection, exhibit hTyr expression

associated with NM production in SNpc DA neurons, as proved by hTyr immunolabeling and NM detection by the Masson-Fontana staining procedure. To determine the functional consequences of NM expression on SNpc DA neurons activity, we performed ex vivo patch-clamp recordings of nigral DA neurons in midbrain slices of AAV-hTyr-injected rats and controls rats, injected with an AAV-empty vector. We found that NM accumulation produces overt functional changes of nigral DA neurons, by modifying passive membrane properties and the spontaneous firing activity, by switching the firing pattern toward increased activity/bursting mode. In parallel, we observed modifications in some intrinsic currents that physiologically control spontaneous pacemaker firing activity of nigral DA neurons. In conclusion, here we display the first evidence on a functional impact of NM accumulation on nigral DA neurons activity. As firing rate and modality critically affect DA release in the striatal projection areas, the observed functional alterations might correlate with changes in DA levels in the projection areas. Future investigations might disclose if the observed functional modifications are compensatory adaptations of nigral DA neurons, attempting to counteract initial neurodegeneration, or represent early pathological features preceding nigral DA neurons loss.

Title: Glutamate co-transmission by serotonin neurons of the dorsal raphe nucleus contributes to L-Dopa dyskinesia expression

Authors: *L. SAIDI, V. RIOUX, M.-J. WALLMAN, S. POZZI, M. LÉVESQUE, C. PROULX, M. PARENT;
Cervo - Univ. Laval, Quebec, QC, Canada

Abstract: OBJECTIVE: Parkinson’s disease is characterized by the progressive loss of midbrain dopamine neurons that innervate the striatum. The dopamine precursor L-3,4-dihydroxyphenylalanine (L-Dopa) is the most effective pharmacotherapy but its chronic use is hampered by side effects such as abnormal involuntary movements (AIMs), also termed L-Dopa-induced dyskinesia (LID). Previous studies have shown the crucial role of serotonin (5-HT) neurons in the conversion of exogenous L-Dopa into dopamine, and in LID expression. Here, we specifically addressed the functional role of glutamate co-transmission by 5-HT neurons of the dorsal raphe nucleus (DRN) in the regulation of motor behavior and in LID expression.

METHODS: In 6-hydroxydopamine-intoxicated mice, a chemogenetic approach was first used to alter the neuronal activity of DRN 5-HT neurons while administering L-Dopa in order to specifically address the role of these neurons on LID expression. Using the same mouse model of Parkinson's disease, we then used CRIPSR-Cas9 technology and virus injections to knock-out or overexpress the atypical vesicular glutamate transporter 3 (VGluT3) in 5-HT neurons of the DRN. These mice were then treated with L-Dopa to induce AIMs. **RESULTS**: Compared to control conditions, more severe AIMs were observed when 5-HT neurons of the DRN were acutely activated by hM3Dq-DREADD. Our CRIPSR-Cas9 manipulations led to exacerbated AIMs in dopamine-lesioned VGluT3-conditional knock-out mice that were treated with a non-dyskinetic dose of L-Dopa (1mg/kg), compared to controls and to transgenic mice overexpressing VGluT3. At higher doses of L-Dopa (3, 6, 12 mg/kg), mice overexpressing VGluT3 showed more severe orofacial AIMs. **CONCLUSIONS**: Glutamate that is co-released by 5-HT neurons of the DRN is involved in the expression of LID.

Title: Effects of interventional genetic expression of dopamine D2 receptors on dorsal raphe neurons on L-DOPA-induced dyskinesia in a hemiparkinsonian rat model

Authors: *A. CENTNER[1], N. LIPARI[1], F. MANFREDSSON[3], C. R. BISHOP[2]; [2]Binghamton Univ., [1]Binghamton Univ., Binghamton, NY; [3]Barrow Neurolog. Inst., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Levodopa (L-DOPA) continues to be the standard treatment for Parkinson's Disease despite the eventual development of abnormal involuntary movements (AIMs) known as L-DOPA-induced dyskinesia (LID). Serotonergic cells originating in the dorsal raphe nucleus (DRN) have been implicated in the *development* and *maintenance* of LID in both preclinical and clinical literature. Serotonin (5-HT) neurons terminating in the striatum are believed to take up L-DOPA, convert it to dopamine (DA), and release it like its native neurotransmitter 5-HT. Although this gain-of-function may be beneficial in early stages of PD, the unregulated release of DA via 5-HT terminals ultimately results in debilitating motor fluctuations that are poorly managed with current treatments. Serotonin transporter (SERT) blockers and 5-HT_{1A} agonists can reduce dyskinetic behaviors, however several compounds are shown to disrupt L-DOPA's motor efficacy, implicating a paucity of knowledge on the mechanisms through which 5-HT

compensation acts to convey L-DOPA's effects. Previous work from our group has shown that *prophylactic* expression of DA D2 autoreceptors (D2AR) can prevent the development of LID in hemiparkinsonian rats. The present work sought to *interventionally* reduce established LID, a more powerful and clinically relevant approach. To do so, tryptophan-hydroxylase-2 (TPH2)-Cre+ male and female Long Evans rats received a unilateral 6-hydroxydopamine (6-OHDA) medial forebrain bundle lesion to induce hemiparkinsonism. Following recovery, animals were split into equally lesioned groups and received daily L-DOPA (6 mg/kg; subcutaneous) or vehicle injections for 14 days to establish stable LID. AIMs were assessed on days 1, 7 and 14. After this 14-day treatment period, animals underwent a second survival surgery to infuse either Cre-dependent AAV-FLEX-D2AR or AAV-FLEX-GFP (control) into the DRN. To provide optimal transfection, animals were allowed 4 weeks of recovery, after which they were treated with their respective chronic treatments for 14 days and AIMs observed on days 1, 7, and 14 to assess their dyskinesia levels post-intervention. We assessed animals' motor performance with the forepaw adjusting steps (FAS) test pre- and post-intervention to assure L-DOPA's efficacy was not hindered. Overall, this project will determine whether autoregulation of DA release via 5-HT cells is sufficient to reduce or reverse L-DOPA-induced complications without affecting L-DOPA's benefits while further implicating 5-HT neuroplasticity in L-DOPA's effects in the parkinsonian brain.

Abstract: Prediction of engraftment success guides selection of iPSC-derived dopaminergic neurons inpreclinical models Authors: Genevieve Beauvais*, PhD, Jim Mossman*, PhD, Jason Stein, Chandnee Chandrasekaran, PhD,Ha Tran, Louisa Zebrowski, Andres Bratt-Leal, PhD, Roy Williams, PhD, Xiaokui Zhang, PhD* First co-authors. The motor symptoms of Parkinson's disease (PD) are aresult of dopamine deficiency in the brain due to progressive degeneration ofdopaminergic neurons in the substantia nigra pars compacta and theirprojections in the putamen. Restoringthe levels of dopamine by transplanting functional dopaminergic progenitorneurons (DANPCs) into the central nervous system would potentially provide anefficient therapeutic approach to treat these symptoms. The technology nowexists for ex vivo

generation of patient-specific dopaminergic neurons byde-differentiating patient-derived somatic cells into induced pluripotent stemcells (iPSCs) followed by differentiating the iPSCs to dopaminergicneurons. Towards development of anautologous neuron replacement therapy, Aspen Neuroscience has established abattery of robust quality control assays to examine the purity, identity andefficacy of manufactured DANPCs. Among these, large reference data sets havebeen generated for developing predictive genomic analyses to evaluate genomicintegrity of DANPCs, as well as their potential ability to successfully engraftafter intracranial transplantation and be efficacious in vivo. Using a data setof nearly 800 human DANPC-derived transplants within the striatal regions ofimmunocompromised Rowett athymic nude rats, encompassing approximately 100independent differentiations of iPSCs from 12 patients with unique geneticbackgrounds across both sexes, we tested the ability of the transcriptome dataof DANPCs to predict engraftment outcomes such as graft survival and size. We found that bulk RNASeq analysis correlatedwith graft characteristics such as: (a) human nuclei counts, and (b) area withpositive human cytoplasm staining. These findings could allow successfulranking of various DANPC lots generated from the same donor for drug productconsistency, expected ability to engraft and in vivo efficacy, and couldultimately inform the selection of particular drug product lots for clinicalapplication.

Title: Subthalamic and pallidal local field potential activity associated with cognitive performance in patients with Parkinson's disease

Authors: *J. L. CHAN, K. A. JOHNSON, L. E. KENNEY, D. BOWERS, J. D. HILLIARD, K. D. FOOTE, C. DE HEMPTINNE;
Univ. of Florida, Gainesville, FL

Abstract: Although Parkinson’s disease (PD) is a neurodegenerative disorder most readily characterized by motor symptoms, concurrent cognitive impairment is common, debilitating, and difficult to treat. Loss of dopaminergic neurons in the substantia nigra and associated dysfunction of cortico-basal ganglia-thalamocortical circuits are thought to underlie motor and cognitive symptoms. Lesion, functional imaging, and neurophysiological studies, along with cognitive impairment in PD, have implicated the subthalamic nucleus (STN) and globus pallidus interna (GPi) in normal cognitive control. However, the mechanisms by which the STN and GPi contribute to cognitive function and dysfunction remain poorly understood. In this study, the

relationship between STN and GPi local field potential (LFP) activity and cognitive performance was investigated by using intraoperative LFP recordings in PD patients undergoing DBS implantation surgery and their presurgical neuropsychological assessments, including measures in the domains of attention, executive function, delayed verbal memory, language, and visuospatial function. Sixty seconds of LFPs at rest in the off-medication state were recorded in monopolar configuration from 15 PD patients (3 females, mean age 64.5 years) with STN DBS and 38 PD patients (10 females, mean age 68.3 years) with GPi DBS. The power spectral density (PSD) was computed for each DBS lead contact using the Welch periodogram method with a 1 s Hanning window and 0.5 s overlap, and mean normalized power in the delta (1-4 Hz), theta (4-8 Hz), alpha (8-13 Hz), beta (13-30 Hz), and low gamma (30-70 Hz) frequency bands was calculated across all contacts for each patient. A significant correlation was found between both STN and GPi theta power and attentional tests. Specifically, higher resting theta power was associated with worse performance on the digit span test and Trails Making Test Part A. LFP power was not associated with performance in tests of delayed verbal memory, language, or visuospatial function. These results suggest that the STN and GPi may play a role in attentional impairment in PD and that theta activity may be an electrophysiological biomarker of cognitive impairment. Cognitive impairment in PD preferentially affects attention and identifying abnormal oscillatory activity in cortico-basal ganglia-thalamocortical circuits may guide the development of neuromodulatory therapies.

Title: Changes in diurnal brain activity of rats with impaired dopamineric system: Implications to biomarker discovery for the Parkinson's disease.

Authors: T.-Y. YEN[1], **J. YANG**[1], Y.-H. KUO[1], Y.-C. CHANG[1], *H. CHEN[2];
[1]BioPro Scientific, Hsinchu, Taiwan; [2]Natl. Tsing Hua Univ., HsinChu, Taiwan

Abstract: Parkinson's Disease (PD) is one of the most common neurodegenerative diseases, affecting millions of individuals worldwide. Methodologies allowing us to detect this disease at an earlier stage and monitor its progression have been intensively investigated. High-voltage-spindle (HVSs) are spontaneous episodes of brain oscillation (5-13 Hz) which are detected in various brain areas of rodents. Increases in the frequency and power of HVSs have been reported in rats with impaired dopaminergic neurons. It has thus been proposed that increases in HVS

may be considered as an indicator of the disruption of the dopaminergic system in rodents. By utilizing a wireless neural recording system (NeuLive model F, BioProScientific), we have recorded the brain activities from multiple brain areas, continuously for 24 hours, of rats before and after their dopaminergic system is compromised, either irreversibly by 6-OH-dopamine-injection or reversibly by reserpine-injection. Our results indicate that during the course of damaging the dopaminergic system, the occurrence of HVSs in rat brain undergoes a shift in the diurnal cycle. The same set of recording data are also analyzed for the changes of other brain oscillations, including those in the regimes of high-beta and gamma, during the diurnal cycle before and after the dopaminergic system is compromised. This study introduces a novel approach to identify disease biomarkers. Traditionally, biomarkers manifest as biochemicals, behaviors, or brain signals that appear, disappear, increase, or decrease as the disease progresses. However, our findings suggest that a biomarker, such as HVS, can undergo a shift in its diurnal cycle without altering its overall level as the disease advances. These results offer valuable insights for further research and the potential discovery of non-invasive biomarkers for Parkinson's Disease.

Title: The Effects of Chemogenetic Inhibition of Serotonin-Projecting Pathways on L-DOPA-Induced Dyskinesia and Sensorimotor Gating in a Bilateral Rat Model of Parkinson's Disease

Authors: ***N. LIPARI**[1], A. CENTNER[2], F. P. MANFREDSSON[3], K.-Y. TSENG[4], C. R. BISHOP[5];
[1]Psychology, State Univ. of New York, Binghamton, Vestal, NY; [2]Psychology, State Univ. of New York, Binghamton, Binghamton, NY; [3]Barrow Neurolog. Inst., Barrow Neurolog. Inst., Phoenix, AZ; [4]Univ. of Illinois At Chicago - Col. of Med., Univ. of Illinois At Chicago - Col. of Med., Chicago, IL; [5]Binghamton Univ., Binghamton Univ., Binghamton, NY

Abstract: Parkinson’s Disease (PD) is most commonly characterized by severe dopamine (DA) depletion within the substantia nigra (SN) leading to a myriad of motor and non-motor symptoms. The gold standard pharmacotherapy for motor symptoms Levodopa (L-DOPA), leads

to motor fluctuations like L-DOPA-induced dyskinesia (LID), and in many patients, though less understood, affective and cognitive fluctuations. One source of these fluctuations could be the raphe nuclei, wherein serotonin (5-HT) neurons possess the machinery necessary to convert and release DA from exogenous L-DOPA. In DA-depleted brain regions these 5-HT neurons can act as surrogates to the DA system and aberrant neuroplasticity which has been linked to LID may also contribute to non-motor fluctuations. In support, recent work from our lab established a positive relationship between LID and dysfunction in sensorimotor gating in parkinsonian rats treated with chronic L-DOPA implicating an underlying 5-HT mechanism. Therefore, it was hypothesized that normalizing 5-HT forebrain input would reduce the co-expression of LID and prepulse inhibition (PPI). To do so, we expressed 5-HT projection specific inhibitory designer receptor exclusively activated by designer drugs (DREADDs) using Cre-specific AAV-hM4di in tryptophan hydroxylase 2 (TPH2)-Cre, bilaterally 6-OHDA-lesioned rats. Thereafter we used of the designer drug Compound 21 (C21, 0, 3 or 6 mg/kg) to selectively inhibit 5-HT raphe-projections during L-DOPA treatment to modulate sensorimotor gating assayed by PPI and LID quantified by the abnormal involuntary movements (AIMs) test. Our results displayed that 6-OHDA bilaterally lesioned animals show significant baseline motor deficits in stepping on the forepaw adjusting steps (FAS) test compared to shams. In addition, lesion animals chronically treated with L-DOPA showed stable LID development which was significantly reduced after acute co-treatment with C21 at both doses compared to vehicle. Importantly, C21 did not significantly interfere with L-DOPA's motor efficacy once again measured using the FAS test. Our PPI data further validated previous work from our lab showing chronic L-DOPA treatment in lesioned rats produces significantly impaired sensorimotor gating compared to all other groups. Contrary to our LID effects, C21 acute co-administration with L-DOPA intensified the sensorimotor gating deficits seen in lesioned L-DOPA animals compared to C21 vehicle. Overall, this study highlighted that motor and non-motor symptoms are differentially modulated by L-DOPA and 5-HT informing novel avenues for future treatment of this heterogeneous disease.

Title: The cGMP-PKG pathway signaling in striatal projection neurons for modulation of motor behavior in Parkinson's disease

Authors: *T. YABUMOTO, B. KOCHOIAN, S. COLETTA, C. BURE, S. M. PAPA;
Emory Natl. Primate Res. Center, Emory Univ., Atlanta, GA

Abstract: BACKGROUND: A primary mechanism that underlies the decline of L-DOPA efficacy over the course of chronic therapy of Parkinson's disease (PD) is related to maladaptive plasticity in striatal projection neurons (SPNs). This results in altered responses to dopaminergic stimuli involving both direct and indirect SPNs (d/ i-SPNs). Dopamine responses in SPNs are mediated primarily by cAMP/Protein Kinase A and cGMP/Protein Kinase G (PKG) signaling cascades. To understand the impact of cGMP/PKG signaling on parkinsonian motor behavior, we tested the effects of PKG overexpression selectively in SPN subtypes. METHODS: We used transgenic rat lines (Cre/D1 or A2A receptors). Rats received unilateral 6-OHDA lesion of the medial forebrain bundle and apomorphine rotational test to confirm lesion extent. rAAV-Syn-Flex-PKG-GFP or scramble control virus was injected in the dorsolateral striatum in parkinsonian and intact rats. We compared the impact of increased PKG expression in either d- or i-SPNs on motor performance. We also evaluated the evolution of dyskinesia-like behaviors between groups receiving chronic L-DOPA treatment. Parkinsonian motor deficits and behavioral responses to L-DOPA were assessed before (baseline) and after virus injection using standard tests and scales. RESULTS: Elevated PKG activity in i-SPNs and d-SPNs differentially impacted motor behavior in intact and parkinsonian rats. Our results indicate that cGMP/PKG signaling plays a role in SPN responses to DA in the context of chronic PD. DISSCUSSION: Results of this study may contribute to understanding the pathophysiology of maladaptive plasticity in striatal neurons, and thereby developing new pharmacological strategies targeting SPN-specific signaling mechanisms for the therapy of PD.

Title: Sars-cov-2 infiltration of dopamine neurons suggests potential linkage to parkinson's disease

Authors: *H. CROY[1], D. THEOBALD[2], A. OMAIR[2], S. M. AKULA[2], S. SRIRAMULA[2], J. EELLS[3];
[1]Anat. and Cell Biol., [2]East Carolina Univ., Greenville, NC; [3]East Carolina Univ. Sch. of Med., Greenville, NC

Abstract: COVID 19 has triggered a variety of neurological ailments of which the world is just beginning to deal with. COVID-19, caused by severe acute respiratory syndrome coronavirus 2

(SARS-CoV-2), can produce a variety of neurological symptoms such as, but not bound to, neuroinflammation, chemokine/ cytokine storms, and cognitive disorientation. These SARS-CoV-2 symptoms could exacerbate multiple neurological diseases including Parkinson's Disease (PD).PD is caused by the progressive degradation of dopamine nerve cells located in the substantia nigra pars compacta (SNpc). The SN is the region of the brain responsible for motor control and production of dopamine, in conjunction with the ventral tegmental area (VTA). A decrease in dopamine secretion is directly correlated to tremors, muscle rigidity, and impaired coordination – all hallmark PD symptoms. A link between SARS-CoV-2 and PD has been suggested, however, data is limited. One potential mechanism for SARS-CoV-2 infection damaging dopamine neurons is direct infiltration of SARS-CoV-2 into dopamine neurons located within the SNpc. To test the vulnerability of dopamine neurons to infection in vivo, the transgenic K18-hACE2 mouse model was used. The K18-hACE2 mice were infected with SARS-CoV-2 developed severe disease and were euthanized around 6 days post infection. Immunohistochemical techniques were performed on paraffin embedded brain sections and labeled for three separate fluorescent targets: [1] neural nuclei (DAPI), [2] dopamine neurons (tyrosine hydroxylase -TH), [3] SARS-CoV-2 infection (SARS spike protein). Following the immunofluorescence, slide imaging throughout the SNpc and VTA from rostral to caudal was obtained with a Keyence fluorescent microscope. Cell quantification was performed manually by transitioning between the overlay view and either the TH+ or SARS+ view of each section. Cell counts resulted in an overall SARS+TH+ infection rate of 73.3%. Interestingly, the infection rate was lower in the SN averaging 66.5% than in the VTA, averaging 79.1%. These data demonstrate that dopamine neurons are vulnerable to SARS-CoV-2 infection. Currently, the mechanism of SARS-CoV-2 infection of dopamine neurons is not known. Additionally, whether SARS-CoV-2 infects dopamine neurons in mild disease has not been determined. Future studies are underway to address this question and determine the virus's persistence in dopamine neurons along with the relevance of these potentially destructive capabilities for PD patients.

Abstract: 5'-Nucleotidase domain-containing protein 2 (NT5DC2) has been revealed by Genome Wide Association Studies (GWAS) as a gene implicated in neuropsychiatric disorders related to the abnormality of dopamine (DA) activity in the brain. However, it remains unknown about its physiological function, although NT5DC2 is assumed to be a member of the family of haloacid dehalogenase-type phosphatases based on only its amino acid sequence. We recently reported that tyrosine hydroxylase (TH) binds to NT5DC2 and that the down-regulation of NT5DC2 increases DOPA synthesis by increasing the level of TH phosphorylated. This result indicates that NT5DC2 could decrease in phosphorylation of TH. Therefore, we speculate that NT5DC2 has a crucial role in catecholamine biosynthesis, because TH which catalyzes the conversion of tyrosine to DOPA is the rate limiting enzyme in the biosynthesis of catecholamines and its activity is regulated by the phosphorylation of TH molecule. In this study, we examined whether the decrease in phosphorylation of TH by NT5DC2 was due to potentiation of dephosphorylation or inhibition of kinase activity. The overexpression of NT5DC2 using expression vector decreased DOPA synthesis in PC 12D cells. The decreased DOPA synthesis should be attributed to the decreased catalytic activity of TH controlled by its phosphorylation, because western blot analysis revealed that the incubation of cell lysate from PC12D cells overexpressing NT5DC2 at 37 C decreased TH phosphorylation. Next, we phosphorylated the purified TH with a kinase and then reacted the phosphorylation form of TH to purified NT5DC2. Western blot analysis revealed that purified NT5DC2 binds to the phosphorylation form of TH more than the non-phosphorylation form and that purified NT5DC2 promoted dephosphorylation of the phosphorylation form. Collectively, our results indicate that NT5DC2 decreases the DOPA synthesis by decreasing the phosphorylation of TH. We propose that NT5DC2 might regulate the phosphorylation of TH by promoting dephosphorylation like a phosphatase.

Title: Distinct patterns of structural brain change progression in Parkinson's disease subtypes

Authors: *S. CRISOMIA[1], A. BOWER[2], J. CHUNG[1], R. G. BURCIU[1];
[1]Dept. of Kinesiology and Applied Physiol., Univ. of Delaware, Newark, DE; [2]Dept. of

Kinesiology and Applied Physiol., Interdisciplnary Neurosci. Grad. Program - Univ. of Delaware, Newark, DE

Abstract: Parkinson's disease (PD) is a heterogeneous neurodegenerative disease with two main motor phenotypes: tremor dominant (TD) and postural instability and gait dominant (PIGD). These phenotypes are typically distinguished based on the ratio of tremor and postural instability sub-scores on the Movement Disorder Society-Sponsored Revision of the Unified Parkinson's Disease Rating Scale (MDS-UPDRS-III). Previous studies have reported that in comparison to TD patients, PIGD patients have a faster disease progression and are more likely to develop additional non-motor symptoms. However, few studies have sought to incorporate neuroimaging to examine the differences in the rates of brain change progression between TD and PIGD sub-types. One promising progression imaging marker in PD is free water (FW). FW is a measure that assesses the presence of increased extracellular fluid in brain tissue, which is an indicator of neural degeneration and inflammation. In PD, FW imaging repeatedly demonstrated a longitudinal increase in FW in the posterior substantia nigra compared to controls that predicts changes in clinically significant measures (Burciu et al 2017, Ofori et al 2015). Our study sought to expand upon previous findings by investigating the variations in FW across multiple nuclei in the basal ganglia and cerebellar circuits between TD and PIGD patients enrolled in the Parkinson's Progression Marker Initiative (PPMI; https://www.ppmi-info.org). The cohort consisted of 18 TD and 14 PIGD patients with a similar distribution of age, sex, motor severity, and cognitive status that underwent diffusion tensor imaging at baseline and 2 years later. At baseline, TD patients had higher FW than PIGD in the subthalamic nucleus. At two years, PIGD patients showed a greater percentage increase in FW in the caudate, putamen, globus pallidus, and lobule VI of the cerebellum when compared to TD. In summary, PIGD patients showed a faster progression of structural brain changes both within and beyond the basal ganglia which may contribute to a more accelerated progression of motor symptoms as observed in the literature. These results further validate the use of FW as a marker of disease progression in PD and may allow for a better understanding of the differential disease course in PD subtypes.

Title: High resolution histological definition in the rhesus monkey brain of fiber trajectories (ChAT, TH, and 5HT) accessing the anterior cingulum bundle

Authors: K. S. ROCKLAND[1], ***A. DUQUE**[2];
[1]Dept. of Anat. and Neurobio., Chobanian & Avedisian Sch. of Medicine, Boston Univ., Boston, MA; [2]MacBrain Resource Ctr. - Neurosci., Yale Univ. Sch. Med., New Haven, CT

Abstract: Neuromodulatory axons positive for choline acetyltransferase (ChAT), serotonin (5HT), or tyrosine hydroxylase (TH) are present in the cingulum bundle and are reported to access it by multiple routes. In order to further chart their trajectories, we visualized these at high resolution in histological sections of rhesus monkey brains reacted in spaced sequential series (1.0mm section-to-section, within the several series) by immunocytochemistry with DAB as chromogen (MacBrain Resource Center: https://macbraingallery.yale.edu/collection6/). A region of interest was delineated between the frontal pole anterior to the corpus callosum (CC) and the anterior commissure. In this material, the lateral cholinergic tract (LCT), consistent with previous reports in monkey or human brains (postmortem histology or in vivo imaging), was localized in the external capsule, but could be further differentiated as lying medial, closely adjacent to the putamen. The medial cholinergic tract (MCT) ascended in a dorsal-ventral orientation, parallel to layer 6 of the medial frontal cortex. The LCT, with anterior progression shifted medially and ventrally, and appeared to join with the MCT in a characteristic V-shaped juncture at the ventromedial edge of the anterior-most caudate nucleus or, in some brains, just anterior to this. Bundles of fibers positive for 5HT or TH followed a lateral and medial trajectory similar to that of the LCT, including the V-shaped juncture with a more medial tract. Cholinergic signal was most distinct in young brains (1 year or less), as was the V-shaped juncture (e.g., sections 17-19 in Brain 61). Fiber density was greater for TH- than ChAT-positive bundles. Scattered fibers positive for ChAT, 5HT, or TH perforated through the CC in a predominant dorsal-ventral orientation. These were especially evident near the midline at anterior levels, where they traversed between the induseum griseum, cingulum bundle, and underlying septum. In addition, there were compact bundles of fibers with an anterior-posterior orientation, evident in all three markers, that were organized in narrow striae medio-laterally oriented from the edge of the lateral ventricle; for example, see sections 18-21 in Brain 79 and section 16 in Brain 84 for all three substances, and sections 20-21 in Brain 61 for ChAT and TH. We suggest the differential fiber trajectories may be relevant for interpretation of tractography studies, and for assessing stage and progression of neurodegenerative and other disease conditions.

Title: Differences in VTA-SN Anticipatory Brain Responses and Positive Emotions in Parkinson's Disease.

Authors: *S. A. MABRY[1], E. RILEY[1], E. DE ROSA[1], M. GONZALEZ[1], A. K. ANDERSON[2]; [1]Cornell Univ., Ithaca, NY; [2]Dept. of Psychology, Univ. Toronto, Syracuse, NY

Abstract: Resilience, in the context of the human experience, describes being met with significant pressure but bouncing back from the stress without dysfunction or psychopathology. Experiencing positive emotions, even in stressful situations, is associated with successful adaptation and is a critical component of resilience. This study aims to compare positive emotions during stress between people living with Parkinson's disease (PD), a neurodegenerative that leads to motor and emotional changes, and healthy individuals, using a reward-effort anticipatory task. Preliminary functional MRI (fMRI) data indicates behavioral and Blood Oxygen Level-Dependent (BOLD) signal differences in the dopamine-producing Ventral Tegmental Area (VTA) and Substantia Nigra (SN) areas across groups. We hypothesize that brain activity during anticipation of trial events will differ between PD and healthy control populations and [predict behavior]. In this study, 20 participants (10 PD, 10 age-sex-education-matched healthy individuals) earn money based on their performance in a task. The maximum potential earnings are $5. Each trial consists of three phases. First, participants view a multiplier (0, 1, 10, or 100) which creates anticipation for how many points and, thus, how much money can be earned during the trial. Second, participants exert effort by pressing a button as many times as possible within three seconds to earn points. Third, participants observe the number of button presses, points, and money earned for that trial for seven seconds. Forty-eight trials are performed to determine the total points earned during the task. Behavioral data show participants with PD earn fewer points on the task than their age-sex match control (8563 vs 6400 average), press the button less often for higher reward multipliers (100,10) than healthy individuals, and may have less BOLD activation. Dopamine brain networks help people create predictions about their environment. Differences in the VTA/SN BOLD signal during reward anticipation may indicate that the SN has an understudied role in emotional processing. This role in reward, emotional processing, and resilience may explain the comorbidity between PD, depression, and compulsive disorders and the understudied progressively worsening emotional symptoms experienced by PD patients.

Title: Mtorc1-s6k1-darpp32 signaling regulates homer1a expression and locomotive behavior in healthy and 6ohda lesioned mice.

Authors: *L. H. GLADULICH, R. LIN, C. S. C. REDDY, P. F. WORLEY;
Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: *Homer1a* (H1a) plays an important role in synaptic plasticity, yet mechanisms that control its expression remain largely unknown. Previous work from our lab demonstrated that *Rheb*^{S16H} mutant mice, with hyperactive mTORC1, do not induce *H1a* expression in response to multiple stimuli. Additionally, we demonstrated that mTORC1-S6K1 activates DARPP32 by phosphorylation at the same site as PKA. These results suggest a link between mTORC1-S6K1-DARPP32 activity and *H1a* expression, and a role for mTORC1-DARPP32 in plasticity and behavior. To examine the role of mTORC1-S6K1-DARPP32 signaling, we generated a novel mouse model that expresses DARPP32(R29A). DARPP32(R29A) can be phosphorylated at T34 site by the canonical PKA, but not by S6K1. *DARPP32*$^{R29A/R29A}$ mice, as well as their littermate wild-type (WT) controls and *DARPP32*-KO were administered 3-5mg/kg amphetamine and their striatum was dissected after 15, 30, or 60 minutes. Tissues were analyzed by western blotting and immuno-fluorescent staining. *H1a* expression was measured via qPCR. Locomotive activation was analyzed via open field infrared recording. Additionally, cohorts of the same genotypes received unilateral injections of 6OHDA to the substantia nigra, followed by a two-week recovery time and amphetamine challenge. In response to amphetamine, we observed altered dynamic phosphorylation of ERK, mGluR5, DARPP32, S6K and S6 comparing *DARPP32*$^{R29A/R29A}$ mice with WT. Additionally, we observed a marked reduction of *H1a* expression in *DARPP32*$^{R29A/R29A}$ compared to WT and *DARPP32*-KO mice. Changes in *H1a* mRNA expression correlated with reduced localization of DARPP32 and phosphorylated histone H3 in the nucleus, suggesting their role in *H1a* expression. *DARPP32*$^{R29A/R29A}$ mice also showed diminished locomotive response to amphetamine. Lastly, 6OHDA treatment resulted in unilateral dopamine hypersensitivity in WT and *DARPP32*-KO mice that was reduced in *DARPP32*$^{R29A/R29A}$. These findings suggest mTORC1-S6K1-DARPP32 phosphorylation contributes importantly to the transcriptional induction of *H1a*. While PKA-DARPP32 appears critical for acute responses, mTORC1-S6K1-DARPP32 appears important for sustained responses and long-term adaptations.

Inst., Phoenix, AZ

Abstract: Parkinson's disease (PD) results from the loss of dopamine (DA) producing neurons within the substantia nigra pars compacta (SNc) leading to debilitating motor impairments such as tremor, rigidity, and akinesia. DA replacement therapy via levodopa (L-DOPA), though effective, chronically can often result in the development of levodopa-induced-dyskinesia (LID), characterized by excessive hyperkinetic choreic and dystonic movements. While a myriad of mechanisms are implicated in LID, neuroplasticity within serotonin (5-HT) neurons from the dorsal raphe nucleus (DRN) appear to influence LID onset, persistence, and severity. Indeed, 5-HT cells can take up L-DOPA, convert it into DA, and release DA in an impulse-dependent manner. However, 5-HT neurons lack autoregulatory elements necessary for steady DA release and uptake, which may drive LID. While prior work has established a link between the 5-HT system and LID, a causal relationship remains elusive. Thus, the current set of experiments examined the contribution of the 5-HT system in LID progression and severity by implementing an inhibitory chemogenetic technique using designer receptors exclusively activated by designer drugs (DREADDs). In experiments 1 and 2, we virally transfected 5-HT neurons of the DRN of hemi-parkinsonian TPH2-CRE transgenic rats with inhibitory DREADDs (AAV9-hM4Di-mCherry or control AAV9-GFP) followed by chronic L-DOPA treatment. To assess the influence of DRN 5-HT inhibition on established LID, we administered the DREADD ligand C21 (0, 3 or 6 mg/kg, s.c.) in a within-subjects design in experiment 1. In experiment 2, we administered C21 (0, 0.1, 1.0 mM) directly into the DA-lesioned striatum of DRN-DREADD-transfected TPH2-CRE transgenic rats via reverse *in vivo* microdialysis to determine if local 5-HT terminal inhibition altered established LID. Results revealed C21-induced suppression of LID whether given systemically (experiment 1) or intrastriatally (experiment 2). These findings were only seen in AAV-hM4Di-expressing TPH2-CRE rats, indicating a key component of raphe-striatal functioning underlying the expression of LID.

Title: Dynamic cell type-specific transcriptional profiles of striatal cells across theDynamic cell type-specific transcriptional profiles of striatal cells across the development of L-DOPA-induced dyskinesiadevelopment of L-DOPA-induced dyskinesia

Authors: *H. DE OLIVEIRA AMARAL[1], D. FIGGE[2], D. G. STANDAERT[3], K. L. JAUNARAJS[2];
[1]Univ. of Alabama at Birmingham Chapter, Birmingham, AL; [3]Dept. of Neurol., [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: L-DOPA-induced dyskinesia (LID) is a debilitating, motor side effect of L-DOPA treatment ofL-DOPA-induced dyskinesia (LID) is a debilitating, motor side effect of L-DOPA treatment of Parkinson disease (PD), precipitated by a shrinking of the therapeutic window as PD progresses and sensitization to L-DOPA develops, a phenomenon known as “priming”. A comprehensive idea of the mechanism(s) underlying L-DOPA development and stable expression have been elusive due to the heterogeneous nature of the striatum, consisting of several subpopulations of medium spiny output neurons (MSNs) and interneurons, as well as supporting cells, all of which differentially respond to L-DOPA treatment. As such the goal of the current project, was to establish a transcriptional profile of LID development and expression in each population of striatal cells, utilizing single nucleus RNA-sequencing (snRNA-seq). Mice were rendered hemiparkinsonian and treated with vehicle for 10 d or L- DOPA for 1, 5, or 10 d, corresponding with Control or Acute, Subchronic, and Chronic L- DOPA exposure, respectively. One h after the last treatment, striata was harvested from all mice and pooled into 2 separate samples/group and nuclei were isolated and purified with flow cytometry for snRNA-seq. Subsequent transcriptomic analyses revealed 28 clusters of cells, including MSNs, interneurons and glia. Subclustering of dopamine D1 receptor expressing MSNs (D1-MSNs) in both patch and matrix was particularly altered by acute experience with L-DOPA, with different subtypes being affected differentially by repeated exposure. In dopamine-depleted striata, acute L-DOPA caused a large proportion of patch and matrix D1R-MSNs to become transcriptionally active, expressing immediate early genes (IEGs) such as Fos, FosB, and Arc. Gene ontology analyses suggested that acute L-DOPA induced gene modules involved in glutamatergic synaptic function in both patch and matrix activated D1-MSNs. More chronic exposure led to enhanced transcription of genes involved in physical cellular remodeling. In addition, oligodendroglia, astrocytes, and microglia population ratios were enhanced upon L-DOPA exposure and DEG analyses revealed acute cellular activation of nearly all glial cells. These data collectively reveal a coordinated response of a majority of striatal cell subtypes to acute L-DOPA exposure that is dynamically impacted by repeated treatment and lend credence to the existence of an “engrammatic” striatal D1-MSN subpopulation that directly encodes the dyskinetic response to repeated L- DOPA treatment.

Title: Double dissociation of dopamine and subthalamic nucleus manipulations on effortful cost/benefit decision making

Authors: *G. PAGNIER[1], W. F. ASAAD[2], M. J. FRANK[1];
[1]Neurosci., [2]Neurosurg., Brown Univ., Providence, RI

Abstract: Deep brain stimulation (DBS) and dopaminergic therapy (DA) are common interventions for Parkinson's disease. Both treatments typically improve patient outcomes, and both can have adverse side effects on decision making (e.g., impulsivity). Nevertheless, they are thought to act via different mechanisms within basal ganglia circuits. Here, we developed and formally evaluated their dissociable predictions within a single cost/benefit effort-based decision-making task. In the same patients, we manipulated DA medication status and subthalamic nucleus (STN) DBS status within and across sessions. Using a series of descriptive and computational modeling analyses of participant choices and their dynamics, we confirm a double dissociation: DA medication asymmetrically altered participants' sensitivities to benefits vs. effort costs of alternative choices, whereas STN DBS lowered the decision threshold of such choices without affecting cost/benefit sensitivity. To our knowledge, this is the first study to show, using a common modeling framework, a double dissociation of DA and DBS within the same participants. We compare these findings to preliminary behavioral results from an analogous effort task administered to pallidal DBS patients. As such, this work offers a comprehensive account for how different mechanisms impact decision making, and how impulsive behavior (present in DA-treated PD patients and DBS patients) may emerge from separate physiological mechanisms.

Title: The influence of dopamine on afferent inhibition and corticospinal excitability

Authors: *F. C. ADAMS, S. FOGLIA, K. RAMDEO, C. V. TURCO, M. TARNOPOLSKY, A. J. NELSON;
McMaster Univ., Hamilton, ON, Canada

Abstract: Afferent inhibition is a phenomenon where the afferent volley evoked by nerve stimulation can alter the motor output assessed by transcranial magnetic stimulation (TMS) which can provide noninvasive assessments of the excitability of the sensorimotor system. This phenomenon can be elicited at two phases known as short-latency afferent inhibition (SAI) and long-latency afferent inhibition (LAI). Currently, the neural mechanisms contributing to the function of these neural circuits are unclear although they are altered in special populations including Parkinson's and Alzheimer's disease. This study aimed to determine if SAI, LAI and muscle representation in M1 are modulated by dopaminergic receptor activity. In this placebo-controlled and double-anonymous study, Apo Levocarb (100mg levodopa/25mg carbidopa) and placebo were administered in two separate sessions to 32 right-handed males (mean age 24.38 ± 3.2 years). Measures of SAI, LAI and motor corticospinal maps were obtained before, at the peak plasma concentration and at the half-life following ingestion of the medication. SAI and LAI were evoked by stimulation of the median nerve and recorded from the first dorsal interosseous muscle. SAI was obtained with two interstimulus intervals (ISI) using the latency of the N20 potential: N20+2 ms and N20+4 ms. LAI was obtained using an ISI of 200 ms. Motor corticospinal maps were acquired by delivering 80 suprathreshold TMS pulses over a 6 x 6 cm grid centered over the FDI motor hotspot of the left M1. Saliva samples were obtained and a polygene score was created using the following genes: COMT, DRD2, DRD1, ANKK1, DAT1. Preliminary results indicate that SAI is modulated by dopaminergic medication. Further results are pending the completed gene analyses.

Title: The impact of fragile X mental retardation protein loss on nigrostriatal system vulnerability in early Parkinson's disease

Authors: *S.-L. RUMPF[1], P. GAO[1], W. CHEN[1], J. HERMS[2,3,4], T. KÖGLSPERGER[1,5];
[2]Dept. of Translational Brain Res., [1]DZNE, München, Germany; [3]Ctr. for Neuropathology and Prion Research, LMU Munich, Munich, Germany; [4]Munich Cluster for Systems Neurol. (SyNergy), Munich, Germany; [5]Dept. of Neurol., LMU Univ. Hosp., Munich, Germany

Abstract: ***Background***. In Parkinson's disease (PD), classical motor symptoms arise due to the progressive loss of dopaminergic (DA) neurons in the substantia nigra pars compacta (SNc). The neuropathological hallmark is alpha-synuclein (α-Syn) positive inclusion bodies termed Lewy bodies (LBs), which progressively arise throughout the peripheral and central nervous system and are thought to be associated with the eventual demise of DA neurons. At the early disease stage, when Lewy body pathology (LBP) is restricted to the brainstem and olfactory bulb, is termed incidental Lewy body disease (iLBD) and can be considered to be a preclinical phase of PD. Critically, up to 20% of SNc DA neurons are already lost at this stage, despite the absence of LBP. Therefore, we aim to understand the causes of neuronal dysfunction and cell death in this early disease period. Previously we have shown that during this phase, Fragile X mental retardation protein (FMRP), an RNA-binding protein which acts as a translational repressor, is already lost from the SNc. Here, investigated molecular components of the nigrostriatal pathway in FMRP-KO mice. ***Method***. We employed female wild-type (WT, C57BL/6J) and homozygous FMRP-KO mice aged 3 months. We used immunohistochemistry (IHC) and Western blot techniques to analyse the abundance of the Dopamine Transporter (DaT), Tyrosine Hydroxylase (TH), and Dopamine receptors 1 and 2 (DRD1 and DRD2). In addition, we applied patch-clamp recording from SNc DA neurons to examine the effect of FMRP on the electrophysiological properties of these cells. ***Results***. Through quantifying IHC staining on mouse midbrain slices from either genotype, we found an increase in DaT and a decrease in TH, DRD1 and 2 in the striatum of FMRP-KO mice. Conversely, DaT, TH and DRD2 was decreased in the SNc, suggesting a region-specific effect of FMRP on midbrain integrity. Western blot data confirmed our results from IHC. Patch-clamp recordings showed no difference in basic measurements of electrical excitability (AP frequency and shape). ***Conclusion***. In summary, our study indicates a compromised nigrostriatal pathway in the absence of FMRP, further implicating FMRP in the pathophysiology of PD.

Title: Topography of regional cerebral cholinergic vesicular transporter correlates of visual contrast sensitivity in Parkinson's disease: A [^{18}F]-FEOBV PET study

Authors: *P. KANEL[1], T. BROWN[1], S. ROYTMAN[1], K. A. FREY[1], P. J. H. SCOTT[1], R. A. KOEPPE[1], R. L. ALBIN[2], N. I. BOHNEN[1];

Abstract: Impairments in contrast sensitivity are well documented in Parkinson's disease (PD) and have been associated with retinal dopaminergic depletion. Contrast sensitivity impairment in PD may also be predictive of cognitive decline and associated with decreased attention and visuospatial skills. The Rabin contrast sensitivity test assesses visual acuity and letter contrast sensitivity by representing different levels of contrasts in 8 lines. Here, we investigate whether contrast sensitivity is associated with cholinergic deficits in specific brain regions in individuals with PD. 113 PD subjects (88 males, 25 females; age: 66.64±6.14; disease duration: 6.15±4.68; HY: 2.42±0.53) underwent vesicular acetylcholine transporter (VAChT) [^{18}F]-fluoroethoxybenzovesamicol (FEOBV) PET and MR imaging. Rabin contrast sensitivity scores were based on incorrect answers to determine normative log contrast sensitivity values. We performed SPM whole brain voxel-based regression analysis to find clusters of spatially contiguous voxels that are statistically significant. SPM correlational analysis between Rabin scores and regional VAChT binding showed significant (FDR-adjusted $p<0.05$) reduction in the bilateral temporal poles (BA 22), insula, cingulum (posterior > anterior), right hippocampus, right lateral geniculate nucleus, right proximal optic radiation, precentral cortical, and only limited effects in the caudate nuclei and posterior visual cortical areas. Impaired contrast sensitivity was associated with cholinergic vulnerability in predominant paralimbic (BA 22, insula) and limbic (hippocampus, cingulum) regions with only limited effects in typical visual processing regions. These findings suggest that cerebral cognitive, rather than primary visual processing areas, underlie contrast sensitivity test performance. Therefore, contrast sensitivity testing may be used more as a test for cognitive performance than visual sensory assessment.

Title: Brain-heart coupling reflects the reduced motor symptoms under dopaminergic therapy in Parkinson’s disease.

Authors: *D. CANDIA-RIVERA, M. VIDAILHET, M. CHAVEZ, F. DE VICO FALLANI; Paris Brain Institute: Inst. du Cerveau, Paris, France

Abstract: Parkinson's disease (PD) is often known for its classical motor symptoms, but non-motor symptoms including autonomic dysfunctions can be much more debilitating. Autonomic dysfunctions are highly comorbid in PD and can lead to a faster motor and cognitive decline, and increased mortality risk. Noteworthy, the mechanisms behind these autonomic dysfunctions are not well understood, and it is difficult to predict the development of cardiovascular, urinary, or thermoregulatory abnormalities in these patients. During the early stages of PD, disruptions in the connectivity of multiple brain regions are observed as well. This has prompted the study of PD as a network-level phenomenon, rather than a pathology affecting specific brain regions. Our hypothesis is that by examining the relationship between brain connectivity and heartbeat dynamics, we can gain insight into the large-scale network disruptions in PD. Our results show that the coupling between brain alpha connectivity and heartbeat dynamics in PD patients is reduced, as compared to healthy participants. Furthermore, we show that PD patients under dopamine medication recover part of the brain-heart coupling, in proportion with the reduced motor symptoms, suggesting a dopaminergic-dependent physiological network. Although further research may be needed to understand the role of brain-heart communication in neurodegenerative diseases, our proposal offers a promising approach to developing new diagnostic methods for the early stages of the disease, as well as for evaluating the effectiveness of treatments.

Title: Astrocyte calcium activity improves motor function in Parkinson's disease.

Authors: *W. R. EVANS, S. S. BASKAR, A. C. COSTA, A. ARIGBE, Z. LI, R. HUDA;
Div. of Life Sci., Rutgers Univ., New Brunswick, NJ

Abstract: The dorsal striatum is an integrative nucleus innervated by sensorimotor projections from the cortex and thalamus and is reliant on dopaminergic (DA) neuromodulation for proper functioning. Loss of DA projections into the striatum is the major cause of motor dysfunction in Parkinson's disease (PD). Though much has been learned about how diverse subtypes of striatal neurons and interneurons modulate movement, we know comparatively less about astrocyte contributions to the function of striatal circuits. In lieu of electrical excitability, astrocytes have spatiotemporally rich and robust calcium dynamics that are modulated under multiple forms of local neuronal activity. In turn, these transient increases in astrocyte calcium levels are implicated in local circuit dynamics and synaptic plasticity. Here, we studied the role of astrocyte calcium signaling in the dorsal striatum in both control and dopamine lesioned animals utilizing the 6-hydroxydopamine (6-OHDA) model of PD. We characterized the role of astrocytes in the dorsal striatal circuit by recording fiber photometry signals from mice virally expressing the membrane-tagged calcium indicator GCaMP6f-lck under an astrocyte specific gfaABC$_1$D promoter. We recorded voluntary and forced locomotion conditions in freely moving and head-fixed animals. We forced animals to locomote under two forms of DA reduction (6-OHDA and flupenthixol administration). Astrocytes in the dorsal striatum exhibit robust increases in calcium during locomotion across behavioral paradigms. Acute pharmacological dopamine receptor antagonism and chronic dopamine lesioning with 6-OHDA reduced movement-related calcium activity. To understand the behavioral effects of direct astrocyte activation, we unilaterally injected an astrocyte specific viral vector expressing either Gi-DREADD or mCherry control into the dorsal striatum and infused 6-OHDA (or vehicle) into the medial forebrain bundle (MFB). Chemogenetic activation of astrocytes in 6-OHDA lesioned animals increased open field locomotion compared to control conditions. Taken together, our data suggest that astrocytes are important endogenous neuromodulators of movement-related dorsal striatal circuits, and represent a potential therapeutic target for the motor symptoms of PD.

Title: A unique kinematic signature of tremor in Parkinson's disease using quantitative digitography

Authors: *A. GALA[1], K. B. WILKINS[1], M. N. PETRUCCI[2], Y. KEHNEMOUYI[1], A. VELISAR[4,1], M. TRAGER[5,1], H. BRONTE-STEWART[1,3];

Abstract: *Background:* Parkinson's disease (PD) is the fastest growing neurological disease in the world. Current methods of clinical care are inefficient, requiring an in-person evaluation of motor symptoms. Quantitative Digitography (QDG) is a remote-monitoring technology that provides objective measures of all cardinal motor symptoms from a 30-second repetitive alternating finger-tapping (RAFT) task. Emergent tremor during RAFT is an involuntary movement that can overtake voluntary tapping and may contaminate measurement of motor symptoms such as bradykinesia, rigidity and freezing behavior. In this study, we developed an algorithm that reliably distinguished tremor strikes from voluntary strikes and demonstrated a unique signature of tremor during RAFT.
Methods: Ninety-six people with PD (52 males) and 42 healthy controls (20 males) participated in the study. An experienced movement disorders specialist (HBS) identified periods of tremor during RAFT from videos of trials performed by 31 tremor dominant (TD) and five akinetic rigid individuals (rater blinded to phenotype). Visually identified tremor and non-tremor strikes were used to create a labelled dataset. An XGBoost classifier was developed to identify tremor during RAFT using temporal and amplitude measures of tapping as features. The classifier's output was compared to the movement disorders specialist's (HBS) visual ratings and the time spent with tremor per trial was compared to MDS-UPDRS III tremor scores.
Results: The XGBoost classifier had 98% sensitivity, an 84.2% precision rate, a 2.7% false positive rate and a 0.981 area under the precision-recall curve. Feature importance analysis revealed that temporal and amplitude features of tapping were important for identifying tremor. The classified tremor strikes had a significantly different distribution for all temporal and amplitude metrics compared to that of non-tremor strikes. The classifier's output was consistent with the rater's visual identification for all tremor trials and four out of five trials with no tremor. The percent duration of classifier-identified tremor per trial was significantly correlated with MDS-UPDRS III tremor scores in TD participants ($P < 0.01$). QDG measures of bradykinesia, rigidity and freezing behavior from only voluntary strikes also correlated with corresponding MDS-UPDRS III items.
Conclusions: Emergent tremor during RAFT had a unique signature comprising both temporal and amplitude metrics, could be reliably measured, and was correlated with MDS-UPDRS tremor scores. Isolating tremor from voluntary tapping enabled more precise quantification of bradykinesia, rigidity, and freezing behavior.

Title: Subthalamic Aperiodic Activities in Parkinson's Disease: Associations with Freezing of Gait

Authors: *C. CUI, K. WILKINS, Y.-J. GUO, R. CROCKETT, H. BRONTE-STEWART; Stanford Univ., Palo Alto, CA

Abstract: Objective: Aperiodic 1/f activity has been shown to be a physiological component of neural signals that is independent of oscillatory activity, suggesting its significance beyond mere noise. A decrease in aperiodic activity (i.e., flatter 1/f) in subthalamic nucleus (STN) local field potentials (LFP) was observed in parkinsonian compared to control rats. Additionally, lower aperiodic activity was correlated with poorer clinical motor scores in patients with Parkinson's disease (PD). However, the association between the aperiodic component and specific PD symptoms remains unexplored. The goal of this study is to investigate the association between aperiodic activity and freezing of gait (FOG), one of the most debilitating motor symptoms of PD. Methods: Seventeen PD patients (six non-freezers and eleven freezers) implanted with an investigational neurostimulator (Activa © PC + S, Medtronic PLC) were included in this study. Patients walked through the "turning and barrier course" (TBC), which we developed to elicit FOG. Patients were off medication and off stimulation. We obtained the power spectral density from STN LFPs during the TBC and extracted the aperiodic offset and exponent using the FoooF algorithm. Gait kinematics were simultaneously recorded using IMU sensors (APDM Inc.) placed on both shanks and the percentage of time spent freezing during trials was computed. Results: Preliminary data showed a significant group by STN interaction effect on the aperiodic components. Post-hoc pairwise comparisons revealed that non-freezers exhibited higher aperiodic offset and exponent in their less affected STN compared to freezers, while no difference was observed between the two groups for the more affected STN. Conclusions: Our findings suggest that PD patients who freeze may have pathologically lower aperiodic exponent across both hemispheres. We plan to further investigate this association with quantitative measures of gait impairments and explore the changes in aperiodic activity over disease progression.

Title: Beta Burst Driven Closed Loop Deep Brain Stimulation for Freezing of Gait in Parkinson's Disease

Authors: *K. WILKINS[1], E. LAMBERT[1], J. MELBOURNE[1], M. PETRUCCI[1], A. GALA[1], P. AKELLA[1], L. PARISI[1], S. ADITHAM[1], G. ORTHLIEB[1], J. A. HERRON[2], H. BRONTE-STEWART[1];
[1]Stanford Univ., Palo Alto, CA; [2]Univ. of Washington, Seattle, WA

Abstract: Background: Freezing of gait (FOG) is a debilitating symptom of Parkinson's disease (PD) that is often refractory to medication. Pathological prolonged beta bursts within the subthalamic nucleus (STN) are associated with both worse impairment and freezing behavior in PD. Both high and low frequency deep brain stimulation (DBS) improve FOG and attenuated burst durations. Therefore, the goal of the current study was to investigate the feasibility, safety, and tolerability of beta burst driven closed-loop deep brain stimulation at high and low frequencies for FOG in PD. Methods: Eight individuals with Parkinson's disease were implanted with the investigational Summit RC+S DBS system with leads placed bilaterally in the STN. A PC-in-the-loop architecture was used to adjust stimulation amplitude in real-time based on the observed beta burst durations in the STN. Patients performed either a harnessed stepping-in-place (SIP) task or a free walking turning and barrier course (TBC) OFF stimulation, on closed-loop, open-loop, or a randomized intermittent open-loop DBS. DBS conditions were performed either at high frequency (i.e., 140 Hz) or low frequency (i.e., 60 Hz). Overall motor impairment was measured as well as quantitative gait metrics across each condition. Results: Beta burst driven closed-loop DBS was successfully implemented and deemed safe and tolerable in all eight participants. Both overall motor impairment and gait metrics were improved from OFF to closed-loop DBS, which showed similar efficacy as open-loop. High-frequency DBS offered better overall symptom control compared to low-frequency DBS across all stimulation conditions. Conclusion: Beta burst driven closed-loop DBS was feasible, safe, and tolerable in individuals with PD. Less overall symptom control was observed with low frequency DBS without significant improvements in gait compared to high frequency DBS, suggesting limited generalizability of a low-frequency DBS approach.

Title: Know your limit, rest within it: investigating the effectiveness of neural adaptive deep brain stimulation for rest tremor.

Authors: *P. AKELLA[1], R. CROCKETT[1], K. WILKINS[1], J. A. HERRON[2], H. BRONTE-STEWART[1];
[1]Stanford Univ., Palo Alto, CA; [2]Univ. of Washington, Seattle, WA

Abstract: *Background:* The Parkinsonian state is characterized by increased subthalamic nucleus (STN) neuronal oscillatory power and prolonged burst durations in the beta range (13-30 Hz). Emergence of rest tremor is associated with attenuation of STN beta activity. Neural adaptive DBS (NaDBS), driven by increased beta band power or prolonged beta burst duration is effective for treating Parkinsonian symptoms. However, it has been shown that the emergence of rest tremor during NaDBS attenuated beta band activity and caused NaDBS to decrease stimulation intensity to zero, resulting in return of Parkinsonian symptoms including tremor. We hypothesize that the use of a non-zero lower therapeutic limit (I min) for NaDBS would prevent rest tremor re-emergence. *Methods:* Four participants implanted with an investigative STN DBS system (Medtronic Summit RC+S) completed a repetitive wrist flexion-extension (rWFE) task under three stimulation conditions: 1) OFF stimulation; 2) ON NaDBS; or 3) ON open-loop DBS (olDBS), where stimulation intensity was controlled such that the total electrical energy delivered was approximately equal to that of NaDBS. The NaDBS algorithm modulated stimulation intensity within a therapeutic window (I min to I max) based on the duration of beta bursts. I min was set such that the participant received multisymptomatic benefit, including tremor, and I max was set at the maximum tolerable stimulation intensity no greater than 125% of clinical stimulation. Kinematics were recorded using IMU sensors and STN local field potentials were recorded during rest periods in the WFE task. Participant specific frequency bands for tremor were identified using the power spectral density of the gyroscopic data across an entire rest period while OFF stimulation. Tremor power was then calculated in 1 second bins using IMU gyroscopic data. Beta band power was calculated in 500ms bands in the neural timeseries between stimulation changes. Change in beta power and tremor power were compared between OFF, olDBS, and NaDBS conditions. *Results:* UPDRS-III tremor subscores decreased in the olDBS and NaDBS conditions compared to OFF DBS. On average, lower rest tremor power was observed during the olDBS and NaDBS conditions compared to OFF DBS. There was no substantial re-emergence of tremor in the NaDBS condition, even when stimulation intensity was declining. *Conclusion:* The presence of a non-zero minimum DBS intensity during NaDBS may reduce the likelihood of rest tremor re-emergence in PD. Determining safe and therapeutic DBS intensity limits in NaDBS should avoid adverse effects from over stimulation and re-emergence of symptoms from under stimulation.

Title: Closed loop deep brain stimulation using real-time kinematic inputs for gait impairment and freezing of gait in Parkinson's disease

Authors: *L. PARISI[1], P. AKELLA[1], E. LAMBERT[1], J. MELBOURNE[1], A. GALA[1], C. CUI[1], Y. KEHNEMOUYI[2], J. O'DAY[2], K. WILKINS[1], M. PETRUCCI[2], S. ADITHAM[1], G. ORTHLIEB[1], J. A. HERRON[3], H. BRONTE-STEWART[1];
[2]Bioengineering, [1]Stanford Univ., Palo Alto, CA; [3]Univ. of Washington, Seattle, WA

Abstract: Parkinson’s disease (PD) is a debilitating neurodegenerative disorder characterized by the cardinal symptoms of rigidity, bradykinesia, and tremor. Gait impairment (GI) and freezing of gait (GI&FOG) increase the risk of falling and negatively impact activities of daily living leading to reduced independence and quality of life. Deep brain stimulation (DBS) is an effective treatment for GI&FOG. However, standard clinical DBS uses an open loop configuration, in which stimulation settings are at a constant amplitude and frequency regardless of symptom prominence. Adaptative DBS (aDBS) can adjust stimulation parameters using real-time kinematic (K) biomarkers and may better manage symptoms by providing on-demand therapy. In this study, we used a novel KaDBS algorithm that adjusts stimulation intensity or frequency (140 Hz to 60 Hz) in response to real-time freezing behaviors, which the algorithm detects through two inertial measurement units (IMUs) placed on the patient’s shanks. The primary aim was to determine the safety and tolerability of KaDBS, and the secondary aim was to investigate changes in gait metrics in comparison to: 1) OFF DBS therapy; 2) open loop DBS (clinical settings); 3) KaDBS; and 4) intermittently adjusted DBS. Six PD participants implanted with the investigative Medtronic Summit™ RC+S system performed a harnessed stepping-in-place (SIP) task and a free walking task in a turning and barrier course (TBC) under each stimulation condition. Tolerability was assessed using aDBS custom feedback questionnaires and kinematic data from the IMUs was used to assess arrhythmicity, asymmetry, stride time, and swing angular range. Participants commonly reported no adverse effects related to stimulation changes during testing. All gait parameters improved during KaDBS compared to OFF therapy and were comparable or better than open loop and intermittent DBS. This novel KaDBS system was safe and tolerable by participants with PD and improved GI&FOG.

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) or the globus pallidus (GP) is an effective treatment for the motor symptoms of Parkinson's disease. However, patient needs from stimulation vary throughout the day based on medication and activity levels. Continuous DBS (cDBS) cannot meet the dynamic needs of patients, creating a tradeoff between side effect prevalence and symptom reduction. Patients and their neurologists select the balance between symptoms and side effects during clinic visits rather than in a naturalistic setting. Conversely, adaptive DBS (aDBS) can change stimulation parameters to respond quickly to patients' needs. However tuning aDBS settings requires specialized training and significant clinician time. Here we propose a pipeline for rapidly reducing the aDBS parameter space and demonstrate it in a cohort of 6 participants receiving dual target STN+GP DBS using the Medtronic Summit RC+S^{TM} implantable pulse generator. All study activities were approved by the FDA and Duke IRB and all participants provided informed consent.
We first determined that the amplitudes of beta (13-30 Hz) oscillations in the STN were linearly correlated to the degree of bradykinesia by measuring the speed of hand grasps. Five of six participants showed positive correlations for at least one STN and severity of bradykinesia in the contralateral hand. We then randomly varied DBS amplitude on the timescale used for aDBS to examine the range and repeatability of beta amplitudes during aDBS. These data were then used to determine initial parameters of proportional plus integral (PI) aDBS controllers. PI parameters were further refined with short experiments in clinic. In clinic there was no significant difference between unified Parkinson's Disease rating scale scores under cDBS and PI aDBS (median [inner quartile range] 20.2 [12.6 22.2] for PI aDBS; 23.2 [14, 23.9] for cDBS; $p = 0.28$ Wilcoxon signed rank). Three participants streamed data from their homes for a total of 234 hours. The participants blindly selected cDBS or PI aDBS each time streaming was started. We observed no change in tremor or dyskinesia scores while the average stimulation power was reduced with aDBS (Wilcoxon ranked sum, $p > 0.05$ for each participant's tremor and dyskinesia scores) as measured by Apple's movement disorders API. Together these data indicate that PI aDBS can

dynamically respond to changing symptom states and potentially reduce stimulation side effects in naturalistic settings. Devices were donated by Medtronic PLC.

Title: Deep reinforcement learning for adaptive Deep Brain Stimulation

Authors: *Q. GAO[1], S. L. SCHMIDT[1], A. H. CHOWDHURY[1], G. FENG[1], K. T. MITCHELL[1], J. J. PETERS[1], K. GENTY[1], W. M. GRILL[1], D. A. TURNER[2], M. PAJIC[1];

Abstract: Deep brain stimulation (DBS) is a surgical treatment which delivers electrical pulses to the basal ganglia to treat motor symptoms caused by Parkinson’s disease (PD). Currently available devices deliver continuous stimulation (cDBS) at a fixed amplitude, do not adapt treatment dynamically for activity, and may cause challenging side-effects (e.g., dyskinesia). Adaptive DBS (aDBS), where stimulation parameters are modulated dynamically, has been shown effective for reducing side-effects, but existing methods rely heavily on on-site parameter tuning which requires lengthy trial and error adjustments. In this work, we introduce an offline reinforcement learning (RL) framework, allowing the use of past clinical data to train an RL control policy to adjust the stimulation amplitude in real time. The goal is to reduce energy use while maintaining the same level of treatment efficacy as cDBS, but without the need of online parameter tuning. Moreover, clinical protocols require demonstrating the safety and performance of such RL controllers prior to deployment in patients. Thus, we also introduce an offline policy evaluation (OPE) method to estimate the performance of RL control policies using historical data.

We evaluated our combined OPE-RL framework in 5 participants using the Medtronic Summit RC+S^{TM} during visits to the clinic (> 120 min per participant). Control efficacy was evaluated by severity of bradykinesia and tremor as well as participant ratings. All study activities were approved by the FDA and Duke IRB and all participants provided informed consent. The results from clinical experiments show that our RL-based controller maintains the same level of efficacy as cDBS (Wilcoxon ranked sum, $p > 0.05$ for each participant's tremor and dyskinesia scores and ratings), but with significantly reduced mean amplitude squared power (percentage reduction as proportion of cDBS; 52.2 [45.8, 58.7], 20.4 [15.9, 24.9], 12.0 [10.8, 13.3], 36.9 [34.0, 39.7], 76.9 [67.9, 85.8]; median [IQR] for each participant respectively). Further, the OPE method can accurately estimate and rank the expected returns of RL controllers, which is effective for ensuring the safety of clinical testing before deployment, as well as selecting the most promising RL controller candidate to be deployed.

Title: In vitro, ex vivo and clinical data from patients demonstrate that the purely thermodynamic anti-prionic mode of action for the treatment of neurodegenerative diseases is promising

Authors: *D. WILLBOLD;
Forschungszentrum Jülich, Jülich, Germany

Abstract: Neurodegenerative protein-misfolding diseases, like Alzheimer's (AD) and Parkinson's disease (PD), are driven by prion-like self-replicating and propagating protein assemblies of amyloid β (Aβ), α-synuclein, and many more. The conformation these proteins have in the aggregated state is thermodynamically more stable than their physiological monomer conformation, which is often intrinsically disordered. Therefore, we have developed all-D-enantiomeric peptide ligands that bind the monomeric protein of interest with high affinity, thereby stabilizing the physiological intrinsically disordered monomer structure. These ligands are eliminating already existing aggregates by disassembling them into harmless monomers. This purely thermodynamic driven mode of action (MoA) is truly "anti-prionic", because it is

eliminating already existing oligomers and fibrils, thus disrupting prion-like replication and propagation of toxic protein aggregates.
Methods: atomic force microscopy (AFM), dynamic light scattering (DLS), size exclusion chromatography (SEC), surface plasmon resonance spectroscopy (SPR), nuclear magnetic resonance spectroscopy (NMR), and a clinical studiy: 20 AD patients in early disease stages were recruited to participate in a single center, randomized, placebo-controlled, double-blind study. Patients received once daily oral doses of 300 mg PRI-002 or placebo for 28 days.
Results: The all-D-enantiomeric ligand for α-synuclein, SVD-1a, disassembled preformed α-synuclein fibrils (PFF) as shown by AFM, DLS and SEC analysis. SPR and NMR demonstrated picomolar affinity of SVD-1a to α-synuclein monomers, while keeping them in their physiological IDP conformation. The all-D-enantiomeric ligand for Aβ, RD2, demonstrated ex vivo target engagement and disassembled Aβ oligomers obtained from brain tissue of former AD patients. A clinical phase Ib, double-bind, placebo-controlled study with 20 mild cognitively impaired (MCI) due to AD and mild AD patients treated once daily orally with RD2 or placebo for 4 weeks with an additional 4 weeks follow up period yielded good safety and tolerability. Also, as demonstrated and published before with four different animal models in four different laboratories, patients treated with RD2 improved their short term memory abilities significantly, as shown with the Word List assay of the CERAD battery of neurocognitive testing. A phase II study with 270 patients and 12 to 24 months treatment is scheduled. I will also acknowledge the many contributors of both developments that are too many to be included here in the abstract.

Title: Optimization of Numeric Attributes for Machine Learning Distinction of an Assortment of Deep Brain Stimulation Parameter Configurations

Authors: *R. LEMOYNE[1], T. J. MASTROIANNI[2];
[1]Independent, Running Springs, CA; [2]Cognition Engin., Cognition Engin., Pittsburgh, PA

Abstract: Deep brain stimulation enables an approach for resolving movement disorder symptoms, such as for Parkinson’s disease. The response to deep brain stimulation can be objectively quantified through conformal wearables comprised of inertial sensors in the context of the subject’s tremor. This inertial sensor signal data can then be consolidated to numeric attributes for distinction through machine learning of the respective deep brain stimulation parameter configurations. The amalgamation of machine learning with conformal wearable

inertial sensors enables the opportunity to produce automated diagnostics with regards to deep brain stimulation and the considerable number of available parameter configurations. Further refinement of the machine learning process can emphasize the optimization of the numeric attributes derived from the inertial sensor signal data acquired from the conformal wearables that quantify the tremor response based on the deep brain stimulation parameter configurations. The research objective is to optimize the associated numeric attributes, in order to better improve the process of achieving machine learning classification for the assortment of deep brain stimulation parameter configurations.

Title: The behavior of the periodic and aperiodic components of LFP differ in both temporal variation and spatial distribution during the period of dissipation of the microlesion effect after deep brain stimulation electrode implantation in Parkinson's disease

Authors: *T. NAOKI[1], T. EMURA[1], Y. KIMOTO[1], T. MATSUHASHI[1], T. YAMAMOTO[3], K. HOSOMI[1], S. OSHINO[1], H. KHOO[1], Y. FUJITA[1], R. FUKUMA[2], T. YANAGISAWA[2], H. KISHIMA[1];

Abstract: BackgroundB power of the subthalamic nucleus (STN) local field potential (LFP) is used as a biomarker for adaptive deep brain stimulation (DBS) therapy because it correlates with and fluctuation of the motor symptoms of Parkinson's disease (PD). However, β power is not a perfect biomarker and often does not correlate with motor symptoms. We explored the issue of β power as a biomarker by recording LFP during the 6-month period after DBS electrode implantation when the microlesion effect was wearing off.**Method**LFP was measured for 6 months in PD patients with DBS electrodes implanted in the bilateral STN and connected to a pulse generator implanted in the body. The DBS electrodes have contact numbers 0, 1, 2, and 3 in order from the ventral side. Measurements were taken at any time during outpatient visits or hospitalization, and data were later retrieved and analyzed. LFPs were transformed into power spectrum density using Fourier transform, and further divided into periodic and aperiodic components. The LFP measurement period was analyzed by dividing 6 months into 5 periods. Differences by recording period and by recording contact were statistically analyzed, respectively. Analysis was performed with the Steel-Dwass test of nonparametric multiple

comparisons, and statistical significance set at p<0.001.**Results**The subjects were 13 patients with PD, mean age at electrode implantation was 62.2 years, and the time from onset to electrode implantation was 14.5 years. The electrode contact with the highest effect on improving motor symptoms was 1 (n = 13) or 2 (n = 13). STN LFP was measured for approximately 30 seconds at a time, averaging 437 measurements per person over a 6-month. Total power increased consistently until 6 months postoperatively, as did aperiodic component. On the other hand, the periodic component increased irregularly over a six-month period. The aperiodic component tended to have a larger amplitude at the ventral contact, while the periodic component tended to have a larger amplitude at the middle contact. In particular, the periodic component of the β band tended to become progressively stronger in contact 1 and 2 during the period when the microlesion effect disappeared.**Conclusion**During the period when the microlesion effect was disappearing, the periodic and aperiodic component behaved differently and should be considered separately as biomarkers. The position where the periodic component of the β band was stronger coincided with the effective site of stimulation, which may suggest that the periodic component of the β band can be a better biomarker.

Title: Closed-loop stimulation over one year wasn't worse than conventional deep brain stimulation in advanced Parkinson's Disease patients.

Authors: *T. EMURA, N. TANI, K. HOSOMI, T. MATSUHASHI, Y. KIMOTO, M. HIRATA, H. KISHIMA;
Osaka Univ., Suita city, Japan

Abstract: It is known that the local field potential (LFP) beta band (approximately 13-30Hz) changes in correlation with fluctuation in motor symptoms of Parkinson's disease (W.-J. Neumann et al., 2017). A new deep brain stimulation (DBS) device approved in Japan in 2020 is capable of adjusting stimulation through a closed-loop system based on changes in LFP (adaptive DBS; aDBS). In addition to reducing battery consumption, aDBS is expected to reduce the duration of off-state and dyskinesia. The use of aDBS was approved for clinical use in Japan before any other country, and its safety has not yet been proven. We report our findings after introducing aDBS to our patients.We switched from conventional continuous DBS (cDBS) to aDBS in 11 Parkinson's disease patients who had undergone DBS electrode implantation and had passed more than 6 months since the surgery. PDQ39 and UPDRS were evaluated just before the

switch from cDBS to aDBS, and 6 month and 1year after the switch. UPDRS Part3 was evaluated in 4 states of stimulation on/off and medication on/off.Seven patients were male and four were female. In the nine newly implanted DBS devices cases, an average of 7.3 months had passed since electrode implantation, and in the 2 cases of battery replacement, 64 and 135 months had passed since the electrode implantation. We used PerceptTM PC of Medtronic for IPG. In 7 cases, the stimulation was effectively automatically adjusted on one side of the hemisphere. One person was not substantially automatically adjusted by the stimulation. The remaining 3 patients returned to cDBS due to side effects such as disabling dyskinesia, so aDBS was not used. For the 7 patients who continued to use aDBS, UPDRS was 58.6 points (SD 12.5) when using cDBS, 51.9 points (19.1) 6 months after using aDBS, and 59.1 points (19.6) 1 year after using aDBS. PDQ-39 was 40.8 points (21.2), 42.1 points (22.7), and 45.5 points (28.6) on average respectively. UPDRS Part 4, which is related to motor complications, was 6.0 points (2.3), 6.2 points (2.7), and 7.6 points (3.3).The fact that UPDRS improved the most after 6 months of switch to aDBS is reasonable, as this is the time when the adjustment of many parameters of stimulation is optimized. On the other hand, the original purpose of aDBS, i.e., improvement of motor complications such as dyskinesia, was not achieved. We will continue to collect and follow-up aDBS cases to clarify the usefulness of aDBS in the long term.

Title: Autoradiography validation of two novel PET radiotracers [^{3}H]M503-1619 and [^{3}H]HY-2-15 for imaging a-synuclein in PD and MSA.

Authors: *D. SATURNINO GUARINO[1], W. CHIA[1], G. TIAN[1], H. KIM[1], V. LEE[1], K. C. LUK[2], R. H. MACH[3];
[2]Univ. of Pennsylvania, [1]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Pennsylvania, Univ. of Pennsylvania Neurosci. Grad. Group, Philadelphia, PA

Abstract: Objective: The accumulation of aggregated α-synuclein is a pathological hallmark of Parkinson´s disease (PD) and other synucleinopathies, such as dementia with Lewy bodies and multiple system atrophy (MSA). The ability to image α-synuclein deposition in the brain would be key for the diagnosis of synucleinopathies, to monitor the disease progression over time, and to facilitate the development of novel treatments. Here within, we report the in vitro characterization of two potential radioligands for the detection of α-synuclein respectively in

Parkinson's disease and multiple system atrophy. **Methods:** For [^{3}H]M503-1619 and [^{3}H]HY-2-15 *in vitro* real-time autoradiography, fresh frozen brain sections derived from PD, PDD, MSA, AD, CBD, PSP and control cases were pre-incubated with PBS + 0.1% BSA buffer, pH 7.5 for 15 min under constant gentle shaking. Sections were then incubated for 90 min using the same buffer containing 5 nM of [^{3}H]M503-1619 and [^{3}H] HY-215 in two separate set of experiments. Non-specific binding was determined via co-incubation with 1 µM of M503-1619 and HY-2-15. Following incubation, slides were washed 2 x 5 min in ice-cold (4ºC) PBS + 20% EtOH and 1 x 1min in ice-cold dH2O, and then dried with a hot plate. Images were obtained by using the BeaQuant, a new generation of gas detector for real time autoradiography. Furthermore, immunohistochemistry studies were performed in order to investigate the nature of the autoradiographic signal. **Results:** *in vitro* real-time autoradiography experiments combined with immunohistochemistry studies revealed binding of [^{3}H]M503-1619 to α-synuclein deposits in PD brain but not in MSA; conversely [^{3}H] HY-2-15 autoradiography showed the opposite pattern. Both radiotracers were partially blocked after incubating the slides with 1µM unlabeled M503-1619 and HY-2-15, demonstrating a good selectivity of the signal. However, specific binding of both radioligands was also observed in tissue from AD, PSP, CBD cases indicating binding to tau pathology, that was confirmed by the immunostaining with ptau antibody. **Conclusions:** [^{3}H]M503-1619 demonstrates high affinity and selectivity to α-synuclein deposits found in PD brain, while [^{3}H] HY-2-15 showed the same binding pattern but in MSA pathology. These findings suggest that α-synuclein in PD and MSA has a unique conformation that is selectively recognized by the two tracers and that M503-1619 and HY-2-15 are promising candidates as imaging agents for PD and MSA.

Title: High-intensity interval training improves executive performance in early-stage Parkinson's disease patients: a preliminary intervention study

Authors: *H. SHIN[1], R. KIM[2], K. BYUN[1];
[1]Div. of Sport Sci., Incheon Natl. Univ., Incheon, Korea, Republic of; [2]Inha Univ. of Col. of Med., Inha Univ. Hosp., Incheon, Korea, Republic of

Abstract: Exercise has been reported to be effective in improving motor symptoms in patients with Parkinson's disease (PD). However, the effects of exercise intervention on non-motor symptoms such as cognitive function are not yet well known. This preliminary study explored the effects of 6 months of moderate-intensity continuous training (MICT) and high-intensity interval training (HIIT) on the non-motor symptoms of early-stage PD patients. Thirty-three early-stage PD participants (15 males; mean age: 66 years, SD 7.8) who had been diagnosed with PD within the previous 5 years, were randomly assigned to the MICT group (n = 11), the HIIT group (n = 11), or the usual care group (UC; n = 11). Participants assigned to the MICT and the HIIT groups participated in three exercise sessions (60-80 min/session) each week for 6 months. Participants in the MICT group exercised continuously with a load equivalent to 60% of the VO_{2peak} of each individual. Participants in the HIIT group repeatedly alternated between short bouts of high-intensity cycling exercise (100 rpm, 30-50 s/bout) at 60% of their maximum aerobic power and 60 s of rest. The UC group members were directed to maintain their normal, daily physical activity levels. Before and after the exercise interventions, peak oxygen consumption and executive performance (determined based on response time (RT)/error rate (ER) for color-word matching Stroop tasks) were evaluated. VO_{2peak} of the participants in both the MICT and HIIT groups significantly increased after the 6-month exercise interventions. There was significant interaction between group (MICT, HIIT, UC) and time (Pre, Post) for Stroop RT during the incongruent task, which requires cognitive control and the involvement of related neural resources. Post-hoc results revealed that RT during the incongruent condition was significantly shortened only in the HIIT group after the 6-month intervention. Based on these results, we concluded that a long-term HIIT intervention improves the executive performance of participants in the early stage of Parkinson’s disease.

Title: Predicting impulsivity in people with parkinson’s disease: a descriptive analysis of cohort demographics and medication usage

Authors: *S. CHEN[1], J. JAMES[1], D. BAUM[1], D. WEINTRAUB[2], E. SUH[3], V. VAN DEERLIN[3], A. CHEN-PLOTKIN[1], T. TROPEA[1];
[1]Neurol., [2]Psychiatry, [3]Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Parkinson’s disease (PD) is the second most common neurodegenerative disease worldwide, affecting up to 3% of people over the age of 65. Common treatments for PD target

dopamine, a brain neurotransmitter, and include levodopa and dopamine agonists (DA). However, DA treatment increases the risk of developing an impulse control disorder (ICD), characterized by the inability to control impulses despite self-harm. Recent work has demonstrated that a model consisting of clinical variables, DA and levodopa use, and 3 genetic markers can predict ICD risk in PD patients. How ICD risk affects different domains of human impulsivity, including response inhibition, decisional impulsivity, delayed gratification, risk-taking, and impulsive personality traits, is unknown. We first sought to characterize DA, levodopa or other PD medication exposure in people with PD who receive care at the UPenn PD clinic and are enrolled in the whole-clinic biobanking effort called the molecular integration in neurological diagnosis (MIND) initiative. At enrollment, all MIND participants self-report ICD symptoms. Next, we extracted participants' medical records to identify those who have a billing code of ICD, impulsiveness, sexual impulsiveness, or impulse disorder. We utilized descriptive statistics to summarize self-report of ICD, medication usage at time of clinical visit, and the demographics of 1475 PD individuals. Participants had an average age of 68 years old (SD = 9), 1343 (91% of total cohort) were White, 950 (64%) were male, and 525 (36%) were female. We find that only a small percentage of participants (4.36%) had an ICD diagnosis in their medical records. This differs from the self-reported frequency of 17.46% for ICD symptoms in the MIND cohort. Future research following this project involves recruiting individuals for clinical impulsivity testing to evaluate differences between high and low ICD-risk groups. The overall goal is to further validate the predictive model to enable future translation into a precision medicine treatment approach for PD patients.

Title: The efficacy of low-intensity pulsed ultrasound treatment in the movement disorder in Parkinson's disease: a double-blind, randomized controlled trial

Authors: *C. ZHONG[1], N. GUO[1], C. HU[2], R. NI[2], X. ZHANG[2], Z. MENG[1], T. LIU[2], S. DING[2], W. DING[3], Y. ZHAO[2], L. CAO[2], J. WU[1], Y. ZHENG[1];
[1]Dept. of Ultrasound in Med., [2]Dept. of Neurol., [3]Dept. of Neurosurg., Shanghai Sixth People's Hosp. Affiliated to Shanghai Jiao Tong Univ. of Med., Shanghai, China

Abstract: Background Parkinson's disease (PD) is a neurodegenerative illness marked by the loss of dopaminergic neurons, causing motor symptoms. Low-intensity pulsed ultrasound (LIPUS) has been shown to improve behavioral functions in PD animal models. It is a new type of neuromodulation approach that combines noninvasiveness with high spatial precision. **Objective** To investigate the efficacy of LIPUS in the treatment of movement disorders in patients with PD. **Methods and analysis** This trial is a single-site, prospective, double-blind, randomized controlled trial. 48 participants with clinically confirmed PD at Shanghai Sixth People's Hospital were randomly allocated to one of two groups: LIPUS group or sham group in a ratio of 1:1. The LIPUS group received pulsed therapeutic US (Shanghai, China) through the temporal bone window with a frequency of 600 kHz, an intensity of 1.0 W/cm2, a duty cycle of 75% (15 ms on, 5 ms off), and a duration of 30 minutes per day for four months. The sham group provided subjects with an identical experience, but without ultrasonic waves. All of the participants continue to use pharmacological therapy as a fundamental treatment. Changes in movement disorder were compared between the LIPUS group and the sham group using the Unified Parkinson's Disease Rating Scale (UPDRS) motor score (part III) from baseline to 4 months. Additional examinations include rating scales like the Mini-Mental State Examination (MMSE), the Beck Depression Inventory (BDI) and the Beck Anxiety Inventory (BAI), as well as high-density electroencephalography (hdEEG) and functional magnetic resonance imaging (fMRI). **Results** As of June 2023, 48 subjects were enrolled; 26 have completed the study, 1 has been lost to follow-up, and 21 are receiving ultrasound treatment. The median age was 63 years old (range, 42-79 years), with 66.7% men and 33.3% women. The UPDRS III scores decreased substantially in the LIPUS group after four months of low-intensity ultrasound therapy ($df = 16$, $p=0.0022<0.05$), whereas no significant change was observed in the sham group ($df = 8$, $p > 0.05$). In addition, the BDI ($p < 0.001$) and BAI ($p = 0.004 < 0.05$) scores exhibited a similar trend with a statistically significant effect in the LIPUS group, whereas the BDI and BAI scores in the sham group decreased marginally without statistical significance. No adverse events have thus far been reported. **Conclusions** We demonstrate that LIPUS can safely, noninvasively, and effectively alleviate motor symptoms in patients with PD and improve cognitive performance, indicating the considerable potential of LIPUS as a novel neuromodulation technique for the treatment of PD.

Abstract: Deep Brain Stimulation (DBS) is an established therapy for Parkinson's Disease (PD). Accurate surgical implantation and optimal postoperative programming require repeated testing with patient interaction, leading to discomfort and anxiety (Lee et al., 2018). Challenges remain, with up to 34% of surgeries requiring revision surgery for lead placement correction (Rolston et al., 2016). Our study aimed to determine if DBS local evoked potentials (DLEP) can guide targeting and postoperative programming. DLEPs are a recently introduced biomarker characterized by stimulation-induced oscillatory activity measured from the stimulating lead. DLEPs persist under anesthesia whereas "beta" oscillations and micro-electrode recordings (MER) require awake subjects (Schmidt et al., 2020). DLEPs could address current pitfalls by enabling asleep functional mapping, guiding postoperative programming, and minimizing patient effort. To determine the feasibility of DLEP-based functional mapping during awake surgery, we recorded intraoperative local field potentials from 18 PD subjects (STN=5, globus pallidus internus/GPi=13). We also explored the stability of DLEP features under general anesthesia (STN=3). We evaluated DLEPs evoked using low-frequency stimulation (11Hz, 0.5-3mA), and bursts of high-frequency stimulation (130Hz, 0.5-3mA). We developed a post-processing artifact-suppression pipeline to recover DLEP activity from a clinical amplifier (Neuro Omega). We also recorded spontaneous local field potential activity for peak beta power analysis (within 13-30Hz). Lead location information was recovered from imaging-based lead reconstruction. We demonstrate that our post-processing pipeline consistently extracted DLEPs during stimulation despite large stimulation-induced artifacts. Analysis of evoked responses revealed that DLEP root mean square (RMS) envelope amplitudes are highest when the stimulating contact is nearest to the sensorimotor target of the STN or GPi. We show how stimulation parameters (amplitude and frequency) modulate DLEP morphology (oscillatory frequency and amplitude), with stimuli of larger amplitudes and frequencies eliciting responses with higher amplitudes and oscillatory frequencies. The same behavior was observed in recordings from subjects who were awake as well as those who were under anesthesia. In conclusion, DLEPs have the potential to provide a data-driven approach to guide and validate electrode placement and programming within the

optimal DBS target (sensorimotor STN/GPi), and to improve the experience of patients undergoing DBS surgery.

Title: The Cleveland Clinic Virtual Home Environment platform successfully provokes freezing of gait using cognitive, emotional and physical triggers on and off therapy

Authors: *M. MILLER KOOP[1], A. ROSENFELDT[4], K. SCELINA[1], L. SCELINA[1], A. S. BAZYK[4], E. KUVLIEV, Jr.[1], J. REYES TORRES[1], C. WALTZ[5], V. BERKI[1], K. HASTILOW[1], J. LIAO[1], K. B. BAKER[2], J. L. ALBERTS[3];
[2]Dept. of Neurosci., [3]Cleveland Clin., [1]Cleveland Clin., Cleveland, OH; [5]Biomed. Engin., [4]Cleveland Clin. Fndn., Cleveland, OH

Abstract: Freezing of gait (FOG) is a debilitating symptom of PD as it can lead to falls and injuries, yet effective treatment remains elusive. Deep brain stimulation (DBS) utilizing patient-specific stimulation parameters may effectively eliminate FOG episodes; however, characterizing the therapeutic effects is challenging as there is no reliable method to provoke FOG in a clinical setting. The Cleveland Clinic Virtual Home Environment (CC-VHE) utilizes an omnidirectional treadmill (Virtualizer) coupled with an immersive VR system (VIVE) that includes motion trackers to quantify gait metrics and a safety harness to prevent falling. THE CC-VHE includes three continuous walking modules that include specific triggers known to provoke FOG (1) physical, (2) cognitive or (3) emotional stress (anxiety). Four PD patients who had previously undergone surgical implantation of the Percept DBS system (> 6 months) were tested on the CC-VHE in the off antiparkinsonians medication and OFF DBS off_med-OFF_DBS) and in the on_med-OFF_DBS conditions. Medications were withheld for >12 hours and DBS was turned off at least 1 hour prior to testing. FOG episodes were identified visually in real-time and confirmed later offline with video footage by a neurologically trained physical therapist (AR). The time points of the beginning and end of FOG episodes were recorded in each video utilizing custom Matlab software. The number of FOG episodes (count) and freeze duration (s) were quantified for each trial, and Wilcoxon signed-rank tests were utilized to determine differences in outcome measures between therapy states. Three out of the four patients were able to complete all three CC-VHE modules. Across all trials, patients experienced a total

of 77 FOG episodes with a duration of 449 s. The number and duration of FOG episodes were significantly less in the on_meds-OFF_DBS compared to the off_meds-OFF_DBS condition, 49%; $p<0.05$, 54%; $p<0.05$, respectively. Patients experienced the most FOG episodes during the cognitive and physical modules, 31 for both. The CC-VHE provides a reliable, safe approach to characterizing FOG in a clinical setting as it successfully provokes numerous FOG episodes in PD patients. Although medication was able to improve FOG behavior, they were not able to resolve it completely. Future work utilizing the CC-VHE will determine if patient-specific DBS parameters can be used to eliminate FOG in PD.

Title: Occupationally-based exercise compare well with gold standard aerobic exercises for patients with Parkinson’s Disease: A meta-synthesis

Authors: *S. AHMAD, J. K. LONGHURST, D. STILES, E. BORN, J. SHEFFLER, K. VOGEL;
St. Louis Univ., Saint Louis, MO

Abstract: Title: Occupationally-based exercise compare well with gold standard aerobic exercises for patients with Parkinson’s Disease: A meta-synthesis Research Question: What results in the best outcomes in Parkinson’s Disease, endurance exercise or occupation-based exercise? Methods: The subjects of the study were taken from a published Meta-analysis comparing aerobic exercise and non-aerobic exercise for Parkinson’s Disease that compared UPDRS total motor and total scores (Ahmad et. al, 2023). The meta-synthesis compared all of the activities against each other, to find any comparative advantages one may have over another. Multiple independent samples t-tests were used to compare the average unweighted effect sizes of the aerobic vs non-aerobic groups, along with comparisons of each exercise category vs. aerobic groups. A one-way ANOVA was used to compare all non-aerobic exercise groups. Placement of aerobic and non-aerobic groups was based upon the literature and Metabolic Equivalent (MET). Results: It was found that there were no significant differences between aerobic and non-aerobic exercises as a whole and their impact on PD. The aquatic group did have a slight positive difference, meaning that this option of exercise may be best for slowing the progression of motor symptoms for PD patients; more research is neededImplications: Non-aerobic eexercises may be just as effective in slowing the progression of motor symptoms in PD patients. This is important

for therapists to help their clients choose an exercise program that is significant to the patient and will encourage long term engagement.

Title: Causal evidence for the role of cognitive control networks in motor performance in Parkinson’s Disease: a combined fMRI-TMS approach

Authors: *R. PANDA[1], E. S. PROCTOR[2], Y. LI[2], Q. NGUYEN[1], R. L. ALBIN[3], M. VESIA[4], T. G. LEE[5];
[1]Psychology - Cognition and Cognitive Neurosci., [2]Psychology, Univ. of Michigan, Ann Arbor, MI; [3]Univ. of Michigan Dept. of Neurol., [4]Kinesiology, [5]Psychology, Univ. of Michigan, Ann Arbor, Ann Arbor, MI

Abstract: An accumulating body of work suggests that motor deficits in people with Parkinson’s (PwP) are driven by changes in frontal cortical processing more typically associated with executive functions such as attentional control. These changes affect the Attentional-Motor Interface (AMI), formed by interactions between attentional systems and basal ganglia circuits. Attentional systems can compensate for motor dysfunction due to dopaminergic degeneration until disease progression degrades cognitive AMI nodes, such as the dorsolateral prefrontal cortex (DLPFC), and unmasks latent motor deficits. However, the evidence from human research linking AMI disruption and motor deficits in PwP is correlational. That is, individuals with cognitive impairments often also display gait and balance deficits. In this study we perform robust causal tests of the AMI hypothesis using fMRI and a non-invasive brain stimulation technique called transcranial magnetic stimulation (TMS).
Participants initially underwent a neuroimaging session with functional magnetic resonance imaging (fMRI). Motor performance was assessed using a precision force-tracking task (FTT) while in the scanner. Participants used a grip-force dynamometer to match the movement of a cursor to the movement of a target. In half of the force-tracking blocks, participants were required to simultaneously perform a cognitively demanding 2-back working memory task to tax attentional systems. After the initial session, participants underwent three combined fMRI-TMS

sessions on separate days. Different TMS protocols were used to either focally suppress or enhance neuronal excitability in brain regions of interest. To this end, in two of the sessions participants received either continuous theta burst stimulation (cTBS) or intermittent theta burst stimulation (iTBS) over right DLPFC to transiently disrupt or upregulate activity in cognitive control networks. In the third session, participants received stimulation to a control site outside of the AMI. Immediately following stimulation, participants' motor performance was assessed inside the scanner. These sessions were counterbalanced across participants.
Dual-tasking performance resulted in increased activity in working memory and attentional networks to support motor performance. Preliminary results suggest that right DLPFC stimulation affects both tracking performance and network-level activity in the AMI relative to control stimulation. These initial results provide causal evidence for the role of the AMI in supporting motor performance in PwP.

Title: Prediction of 3-year Parkinson's disease progression with Graph Based Ensemble Algorithm

Authors: J. LIAN[1], X. LUO[2], ***C. ZHANG**[3];
[1]Hongkong Univ., Hongkong, China; [2]Microsoft, Shanghai, China; [3]Shanghai Jiao Tong Univ., Shanghai, China

Abstract: To benefit (Parkinson's disease) PD patients' disease management and treatment, we proposed a new graph-based algorithm to predict individual patients' progression from the aspects of Hoehn & Yahr (HY), Unified Parkinson's Disease Rating Scale (MDS-UPDRS) I, II, III, total score, axial score, tremor score, akinetic rigid score, Montreal Cognitive Assessment (MoCA) and Epworth sleepiness scale (ESS) on PPMI dataset.
This study analyzed a cohort consisting of 339 (PD) patients and 127 healthy controls (HC) who met specific criteria, including the availability of 3-year follow-up data, baseline genetic information, and T1 brain Magnetic resonance imaging (MRI) scans. We calculated the mean and standard deviation of label changes in the HC group and compared them to changes observed in PD patients. By establishing a reference interval based on the HC group's change values, PD patients' label scores were categorized as "no-change" if they fell within the interval or as "Better" or "Worse" if they exhibited fewer or more changes than the interval, respectively. Consequently, ten distinct three-class classification tasks were developed to predict PD progression over a 3-year period. As for graph modeling, each participant was considered a node,

with their baseline information, including tabular exams, MRI segment volumes, genetic data, and medication information as node features. Edge features were selected based on the predictive performance. An ensemble algorithm was applied for the final prediction to achieve optimal predictions utilizing the above graph models as weak classifiers.
Using our proposed algorithm, we achieved outperforming results in predicting 3-year progression for various assessments in PD individuals compared with other machine learning models. Specifically, the Micro-Average AUC values for HY, MDS-UPDRS I, MDS-UPDRS II, MDS-UPDRS III, MDS-UPDRS Total, Axial score, Tremor, Akinetic Rigid score, MoCA, and ESS were found to be 0.842, 0.681, 0.737, 0.810, 0.798, 0.775, 0.723, 0.814, 0.758, and 0.720, respectively. These results indicate that our model exhibited a high level of accuracy in prediction. Furthermore, our graph structure analysis suggested the substantial contribution of MRI and gene features to accurately predicting MDS-UPDRS II, MDS-UPDRS III, Tremor, Akinetic Rigid, MoCA, and ESS assessments.
Our proposed graph-based ensemble algorithm demonstrated impressive performance in predicting the progression of PD while also providing valuable insights through important feature analysis. Notably, objective features such as MRI and PRS (Polygenic risk scores) were helpful in predicting PD progression.

Title: Accuracy of Medtronic Percept’s in-device battery estimate derived from clinical data following device exchanges

Authors: *E. L. HARGREAVES[1], D. L. CAPUTO[2], D. DOLCE[1], R. J. DIPAOLA[2], S. F. DANISH[1];
[1]Neurosurg., [2]Neurol., Jersey Shore Univ. Med. Ctr. (JSUMC), Neptune, NJ

Abstract: In June of 2020 Medtronic received FDA approval for its Percept PC B35200 that was released with a new built in device longevity estimate. Previously we reported findings from 35 device exchanges transitioning from the older Activa PC to the newer Percept PC. Results indicated that Percepts predicted a greater longevity of the current device over the actual previous device life of its Activa predecessor. One of the follow up questions was to determine the accuracy of the Percept estimates, which we pursue here. We retrospectively examined data from the same 35 device exchanges (09/15/2020-05/18/2022) for accuracy of the Percept estimate across session intervals in which the contact configuration and programmed parameters remained constant. Theoretically, the estimates across such an interval, should be less by the duration of the interval. The individuals were originally implanted bilaterally targeting the

subthalamic nucleus for Parkinson's. Individuals and/or sessions that did not exhibit constant programming intervals were excluded. A total of 62 interval sessions were examined, averaging 5.17 intervals/individual. The average duration of all 62 intervals was 94.39 days (1.74 sem), while the average duration of the intervals with constant programming was no different at 93.04 days (2.94 sem). A total of 13 individuals were found to have 27 intervals that met the criteria of constancy. Of the constant intervals 18/27 were deemed accurate within 30 days of actual interval (mean: 3.18 days difference; 0.68 sem) with the estimate undershooting the actual difference 13/18 times. Conversely, 9/27 of the constant intervals were inaccurate (mean: 245.17days difference; 227.87 sem; range 61-996 days) with the estimate dramatically overshooting the actual interval in all 9 instances. Of the 13 individuals, 6 exhibited consistently accurate estimates, while another 6 exhibited mixed accuracy, leaving only 1 exhibiting consistent inaccurate estimates. The 9 inaccuracies could not be accounted for by duration of estimate, number of exchanges, bipolar contact configuration, interleaving, fractionation, or duration of interval. The Medtronic Percept battery longevity estimate is accurate in a 2:1 ratio of qualifying intervals. None of the six factors examined was able to explain the 9 inaccurate estimates and the inaccuracies grossly overshot the estimate by an average of 8 months.

Title: A randomized, placebo-controlled, double-blind, multiple ascending dose (MAD) study to evaluate the safety, tolerability, pharmacokinetics and pharmacodynamics of NX210c peptide in healthy elderly volunteers

Authors: D. DUMAS[1], J. LE DOUCE[2], S. MARIE[2], H. HIJMA[1], C. LACROIX[2], A. WEBER[2], S. LEMARCHANT[2], P. KREMER[1], V. BOURDÈS[2], A. I. JANUS[2], ***Y. GODFRIN**[2]; [1]The Ctr. for Human Drug Res. (CHDR), Leiden, Netherlands; [2]AXOLTIS Pharma, Lyon, France

Abstract: Background: Blood-brain barrier (BBB) dysfunction is central to aging and to the occurrence and/or progression of various neurodegenerative diseases, contributing to cognitive decline. NX210c is a synthesized 12-amino acid peptide derived from the subcommissural organ-spondin, a large brain-specific glycoprotein that contributes to neurogenesis during embryogenesis. NX210c increases BBB integrity, reduces neuroinflammation, and promotes synaptic transmission and neuroprotection (Delétage *et al*. 2021, Le Douce *et al*. 2021, Lemarchant *et al*. 2022). Therefore, NX210c is being developed as a new promising drug candidate for neurodegenerative diseases. A single ascending dose phase 1a study showed a good

safety profile and preliminary signals of effects (Bourdès *et al*. 2022) encouraging for the presented MAD study. **Objectives:** The primary objective is to assess safety and tolerability of MAD of intravenously administered NX210c (at 5 mg/kg and 10 mg/kg) in healthy elderly volunteers (HEVs). Blood pharmacokinetics (PK) is the secondary objective. Exploratory objectives aim at assessing the effects of NX210c on BBB integrity using DCE-MRI (which measures BBB permeability) and blood and cerebrospinal fluid (CSF) biomarkers, cerebral blood flow (ASL-MRI), cerebral activity (EEG, Neurocart), and neuroinflammation (blood and CSF biomarkers). **Methods:** It is a randomized, double-blind, placebo-controlled, MAD study in HEVs run in a single center in the Netherlands. Two cohorts of 15 HEVs were planned to be randomized successively (4:1 ratio), with two sentinels in each cohort. Subjects received treatment 3x/week for 4 weeks with a follow-up visit 2 weeks after last dosing. **Results:** A total of 29 subjects was randomized in 2 cohorts (cohort 5 mg/kg: 12 males, 3 females, median age 70 years-old (yo, 59-83yo, 40% >70yo); cohort 10 mg/kg: 6 males, 8 females, median age 68yo (56-91yo, 43% >70yo)). Preliminary results showed overall 51 TEAEs in 15 subjects, all of mild severity, and no serious adverse events. The most common TEAE concerned nervous system disorders (51%, headache, somnolence). NX210c half-life was 18 min on average, no accumulation was observed and mean C_{max} was 2485 and 6835 ng/mL for the cohorts at 5 and 10 mg/kg, respectively. Detailed safety, PK, and pharmacodynamic results from both cohorts will be presented further. **Conclusions:** NX210c demonstrated a good safety profile following multiple doses in healthy elderly volunteers in both doses tested. These preliminary results are very promising for further clinical development in patients suffering from neurodegenerative diseases.

Title: Unraveling neural correlates of attention dysfunction in iRBD Patients based on a transfer learning-based explainable machine learning

Authors: *H. KIM[1], P. SEO[1], J.-S. SUNWOO[2], K.-Y. JUNG[3], K. KIM[1];
[1]Biomed. Engin., Yonsei Univ., Wonju, Korea, Republic of; [2]Dept. of Neurol., Kangbuk Samsung Hosp., Seoul, Korea, Republic of; [3]Dept. of Neurol., Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Introduction: Idiopathic rapid eye movement sleep behavior disorder (iRBD) is a precursor to neurodegenerative diseases such as dementia with Lewy bodies and Parkinson's disease. iRBD patients often exhibit cognitive deficits, especially attention dysfunction [1]. Our study examines abnormal cortical activities in iRBD patients using a transfer learning technique and a 3D convolutional neural network (CNN) classifier on single-trial EEG during a visuospatial attention task. **Methods**: We obtained 60-channel EEGs from 49 drug-naive iRBD patients and an equal number of controls during Posner's cueing task. Cortical source activity was reconstructed using weighted minimum norm estimation. Single-trial cortical activities were averaged within 50 ms timeframes, up to 800 ms. Mollweide projection displayed cortical activities on a 2D image. Input data for classification comprised 120x120x16 three-dimensional volumes (2D space x time). We proposed a transfer learning-based method to train a CNN classifier using a limited dataset and identify crucial input nodes associated with attention dysfunction in individual iRBD patients [2]. We compared this with a traditional subject-dependent approach. Leave-one-out cross-validation assessed classification performance. Layer-wise relevance propagation generated heatmaps highlighting the significance of spatiotemporal features for each iRBD patient. **Results**: The transfer learning technique achieved training accuracy of 100 ± 0.00% for both pretrained and fine-tuned classifiers, and test data evaluation accuracy of 99.81 ± 0.32%. The subject-dependent method achieved training accuracy of 99.77 ± 0.11% and test data evaluation accuracy of 65.2 ± 7.54%. Both classifiers identified the same critical input nodes for all iRBD patients. Fine-tuned classifiers identified differentiated features as crucial for each patient. **Discussion**: The subject-dependent classifier recognizes shared spatiotemporal characteristics essential for predicting the iRBD patient group, while the fine-tuned classifier identifies unique characteristics vital for predicting individual patients. These insights may inform targeted intervention strategies for cognitive impairment in iRBD patients.

Title: Individualized targeting of subthalamic nucleus deep brain stimulation for gait disturbances in Parkinson disease

Authors: J. R. ZAK[1], K. L. CHOU[2,3], P. G. PATIL[2,3,4], ***K. A. MALAGA**[1];
[1]Biomed. Engin., Bucknell Univ., Lewisburg, PA; [2]Neurol., [3]Neurosurg., [4]Biomed. Engin., Univ. of Michigan, Ann Arbor, MI

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) is effective in alleviating the motor symptoms of Parkinson disease (PD). However, a generalized targeting approach may lead to suboptimal outcomes for patients with diverse symptoms. Volume of tissue activation (VTA) modeling can be used to compute the spatial extent of stimulation relative to specific neural structures to assess clinical outcomes. Improved outcomes for gait disturbances may be obtained by stimulating regions within or around the STN. In this study, 40 PD patients who underwent bilateral STN DBS were analyzed retrospectively. The therapeutic VTA for 72 implants was calculated to quantify STN and non-STN activation in different regions. Stepwise regression was used to evaluate associations between stimulation location and improvement in gait-related outcomes (items 3.10-3.12 of the MDS-Unified Parkinson's Disease Rating Scale). Implants grouped by stimulation location were then compared in terms of symptom improvement using Kruskal-Wallis tests. Electrode position (relative to the center of the STN) was also examined for comparison. Results revealed significant positive associations between anterior STN activation and gait symptoms ($p = 0.03$ for the gait item; $p = 0.01$ for the total gait score). Significant differences in freezing of gait (FoG) ($p = 0.03$) and total gait improvement ($p = 0.02$) were also found when comparing majority anterior and majority posterior STN activation. Lastly, a significant positive association between anterior external activation and FoG ($p = 0.02$) was found for non-STN activation. In contrast, no significant relationships between electrode position and gait symptoms were found. Given these findings, anterior STN DBS may be preferable for patients whose primary symptoms include gait disturbances. Overall, this study demonstrates the utility of VTA modeling and highlights the importance of individualized targeting based on patient-specific symptoms.

Title: Linking Mitochondrial Localization of Oligomeric Alpha-Synuclein to TOM40 Loss and Mitochondrial Dysfunction in Parkinson's Disease

Authors: *V. VASQUEZ[1,2], J. MITRA[1], M. KODAVATI[1], J. RAO[3], M. HEGDE[1,4]; [1]Neurosurg., Houston Methodist Res. Inst., Houston, TX; [2]Neurosci., Inst. de Investigaciones Científicas y Servicios de Alta Tecnología (INDICASAT AIP), Panama, Panama; [3]KL Deemed Univ., Vaddeswaram, India; [4]Med. Col., Weill Cornell, New York, NY

Abstract: Mitochondrial dysfunction, resulting from the altered function of translocases of the outer mitochondrial membrane (TOM) complex, has been associated with alpha-synuclein (α-Syn) pathology in Parkinson's disease (PD). However, the specific mechanism by which α-Syn accumulation drives the depletion of TOM40, a key component of the TOM complex, is not well-understood. In this study, we demonstrate that the loss of TOM40 in PD patients' brains involves protein degradation triggered by the mitochondrial localization of α-Syn. Experiments using α-Syn mutants with and without mitochondrial targeting sequences (MTS) in neuron cultures confirm this. Furthermore, we observed that factors such as 6-hydroxy dopamine and oxidative stress, which promote α-Syn oligomerization, significantly expedite TOM40 depletion in PD patient-derived cells carrying the SNCA gene triplication. Our data show that α-Syn interacts with both TOM40 and TOM20 in the outer mitochondrial membrane but leads to the depletion of only TOM40 via the ubiquitin proteasomal system (UPS) pathway. Detailed investigations, including Seahorse metabolic analysis, electron microscopy, mtDNA sequencing, and damage assessment, revealed that the mutant α-Syn-induced TOM40 loss results in compromised mitochondrial function characterized by reduced membrane potential, increased mtDNA damage, mutations, and morphological alterations. These findings provide critical insights into the relationship between
α-Syn accumulation, TOM40 degradation, and mitochondrial dysfunction, offering potential avenues for targeted interventions to mitigate mitochondrial defects in PD.

Title: Determining Parkinson's Disease-causing variants in Parkin using a pooled FACS-based screen

Authors: *A. J. GILSRUD, J. A. THAYER, D. P. NARENDRA;
NINDS, NIH, Bethesda, MD

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease after Alzheimer's Disease. The characteristic motor symptoms in PD are due to degeneration of dopamine neurons within a region of the midbrain called the substantia nigra pars compacta. Approximately 500,000 Americans are diagnosed with PD. 5-10% of Parkinson's disease cases are caused by genetic mutations, with loss of function mutations in PRKN (coding for the protein Parkin) being the most common cause of autosomal recessive Parkinson's disease. The pathogenicity of many PRKN missense variants, however, remains unknown. We recently found that approximately 1% of individuals carry a rare PRKN missense variant of unknown significance, complicating genetic counselling (Zhu et al. 2022). To resolve this uncertainty, we generated a pooled cDNA library of all rare Parkin missense variants in publicly available databases as well as alanine substitutions of critical Parkin residues (599 variants in total). The Parkin variants in the library were additionally tagged with YFP. Finally, we developed a novel FACS based screening approach to resolve the functional status of each variant, using two single-cell reporters of Parkin function we sorted cells into pools and utilized a next-generation sequencing approach to differentiate benign mutations from loss of function mutations. From our initial screens five novel loss of function mutations have been identified. Using pooled mutagenesis, we are constructing smaller libraries of the 599 variants to obtain full coverage from the FACS-based screens. The structural relationship of variants identified by subsequent screens will be assessed by mapping them onto the solved structures of Parkin in its auto-inhibited and active states. We anticipate the results of this study will help resolve the functional consequence of PRKN variants in the population and additionally reveal novel structural requirements for Parkin activity.

Abstract: Astrocyte Ca2+ signals are important for neuronal function. We have shown that astrocytes in live dorsolateral striatum (DLS) slices exhibit robust spontaneous Ca2+ influx events in their mitochondria, suggesting that astrocyte mitochondria actively participate in neuronal function. Based on this rationale, we hypothesize that the specific disruption of mitochondrial function in astrocytes within pre-specified brain regions would manifest as neuronal dysfunction in that brain region, while also accelerating neurodegeneration. To damage astrocytic mitochondria in pre-specified brain regions, we created an AAV expressing the restriction enzyme PstI (Mito-PstI) under the astrocyte GCaMP6f promoter and a Mito7 signal sequence. In principle, this AAV, Mito-Pst1, can direct AAV-expressed Pst1 specifically to astrocytic mitochondria. We rationalized that since mice possess Pst1 restriction sites in their mitochondrial DNA (mtDNA), flanking genes involved in the mitochondrial oxidative phosphorylation cascade, the AAV-mediated expression of Pst1 only in astrocytic mitochondria would significantly damage mtDNA in astrocytes. We also created a control AAV expressing GFP targeted to astrocytic mitochondria (called Mito-GFP). Mito-PstI and Mito-GFP were co-injected into the dorsolateral striatum (DLS) of mice, a brain region relevant to Parkinson's disease. Compared with control mice injected with only Mito-GFP, in mice injected with Mito-PstI, we observed a significant depletion in mtDNA content and a specific deletion of the PstI-flanked mtDNA sequence. Mito-PstI demonstrated a significant increase in the number of mitochondria, a decrease in mitochondrial size, and altered mitochondrial network structure in DLS astrocytes. Mito-PstI also caused significant changes in inflammatory profiles within the DLS and increased astrocytic GFAP and microglial IBA1. Functionally, the kinetics of spontaneous mitochondrial Ca2+ influx signals in Mito-PstI expressing astrocytes was significantly altered. We also found that exposure of Mito-Pst1 expressing DLS astrocytes to the mitochondrial decoupler FCCP caused a substantial increase in the production of reactive oxygen species in DLS astrocytes as well as a delay in the loss of TMRM fluorescence as a measure of loss of mitochondrial membrane potential. Together, these data show that we have successfully developed an AAV-based tool to specifically damage mtDNA in astrocytes in predetermined brain regions. In the future, we will use this tool to study the acceleration of neurodegeneration in the context of Parkinson's disease.

Title: Repair of ATP synthase stoichiometry rescues neurite outgrowth defects in DJ-1 lacking mesDA neurons

Authors: *R. CHEN[1], P. LICZNERSKI[1], C. MARTINEZ-ACEVES[1], W. CARTER[1], M. GRAHAM[1], W. MANDEMAKERS[2], V. BONIFATI[2], E. A. JONAS[1];

Abstract: Mitochondrial dysfunction is a hallmark of the development of PD. Fibroblast studies can provide a way to detect pathological alterations present in brain. In comparing the mitochondrial properties (morphology and bioenergetics) of fibroblasts containing mutant DJ-1 to those of aged-matched healthy controls or to patient cells lacking DJ-1, we observed that average mitochondrial electron density in fibroblasts that lack DJ-1 completely is greater than that of the healthy controls or of cells containing mutant DJ-1, suggesting that there is a different metabolic condition present in cells completely lacking DJ-1. Both sets of PD patient fibroblast mitochondria carry dramatically low numbers of cristae; in addition, we also noticed that fibroblasts containing mutant or lacking DJ-1 have much lower overall protein synthesis rate than the control group. Protein synthesis rates in these cells were normalized by overexpression of the ATP synthase β subunit, which enhances mitochondrial inner membrane coupling. We used DJ-1-/- neurons as a model for the patient neurons lacking DJ-1. We measured protein synthesis rate for ATP synthase β subunit by puromycin proximity ligation assay (PLA). During four weeks of growth, the DJ-1-/- neurons had a lower rate of β subunit protein production than the WT neurons, especially at the 3rd week, when neurite growth is most exuberant. The low level of ATP synthase β-subunit protein could also result from low β-subunit mRNA, therefore we speculated that the mechanism of decreased growth and branching of DJ-1 deficient neurons is likely related to a lack of DJ-1 trafficking of mRNAs to distal neurites. As we expected, our data showed that the ATP synthase β-subunit mRNA levels are strikingly low in DJ-1-/- neuronal processes.To confirm our hypothesis, we introduced exogenous ATP synthase β-subunit in DJ-1-/- cortical neurons or TH+ neurons. We found that the defects of the total protein synthesis rate in these neurons were completely recovered, and the defects of TH + neuronal outgrowth were significantly improved. These observations suggest a connection between ATP synthase complex stoichiometry, protein synthesis rate and PD.

Title: Nox4 plays an essential role in mediated neuroinflammatory cytokines in the hippocampal astrocytes of Parkinson's disease

Authors: C. KIM[1], *S. YI[2];

Abstract: Oxidative stress and mitochondrial dysfunction have been believed to play an important role in the pathogenesis of aging and neurodegenerative diseases, including Parkinson's disease (PD). The excess of reactive oxygen species (ROS) increases with age and causes a redox imbalance, which contributes to the neurotoxicity of PD. Accumulating evidence suggests that NADPH oxidase (NOX)-derived ROS, especially NOX4, belong to the NOX family and is one of the major isoforms expressed in the central nervous system (CNS), associated with the progression of PD. We have previously shown that NOX4 activation regulates ferroptosis via astrocytic mitochondrial dysfunction at the Alzheimer's disease. At present, there are limited data to understand the molecular mechanism of whether NOX4 regulates the pathogenesis of PD. This study was designed to evaluate if NOX4 is involved in PD by MPTP-induced PD mouse model compared to human PD patients. We could detect that the hippocampus was dominantly associated with elevated levels of NOX4 and α-synuclein during PD and the neuroinflammatory cytokines, myeloperoxidase (MPO) and osteopontin (OPN), were upregulated particularly in astrocytes. Intriguingly, NOX4 suggested a direct intercorrelation with MPO and OPN in the hippocampus. Upregulation of MPO and OPN induces mitochondrial dysfunction by suppressing five protein complexes in the mitochondrial electron transport system (ETC) and increases the level of 4-HNE leading to ferroptosis in human astrocytes. Overall, our findings indicate that the elevation of NOX4 cooperated with the MPO and OPN inflammatory cytokines through mitochondrial aberration in hippocampal astrocytes during PD.

Title: Usp13 role in parkin stability and function in parkinson's disease

Authors: *M. KWATRA[1], J. PARK[2], Y. LEE[2], H. KO[1];
[1]Neuroregeneration and Stem cell Programs, Inst. for Cell Engin., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Pharmacol., Sungkwunkwan Univ., Suwon, Korea, Republic of

Abstract: PINK1 along with parkin is known to play a key role in mitophagy control. However, dysfunction of PINK1/parkin-dependent mitophagy is attributed to pathogenesis of Parkinson's Disease (PD). Parkin is a cytosolic E3 ubiquitin ligase that mediates mono/poly-ubiquitination of itself and of several diverse target proteins (AIMP2 and PARIS). Parkin gets mutated in autosomal recessive and sporadic early-onset PD. Mitochondria damage mediates activation of parkin-dependent mitophagy pathway. Nevertheless, substantial evidence also justifies that along with ubiquitination, deubiquitination process is also important in regulation of protein stability and signaling in mitophagy. This process is catalyzed by a large group of deubiquitinating enzymes (DUBs) known as ubiquitin-specific proteases (USPs). USPs have three major regulatory mechanisms: post-translational modifications, allosteric interactions, and subcellular localization. Furthermore, it is yet to be investigated whether USP13 regulates the stability and function of parkin. Under oxidative stress conditions, it has been reported that parkin protein levels are reduced, even though its mRNA levels are upregulated. However, it is not known what mechanism causes a discrepancy between the mRNA and protein levels of parkin in response to oxidative stress. Our experiment results showed the USP13 interaction with parkin under basal conditions using tandem affinity purification (TAP) coupled with mass spectrometry in SH-SY5Y cells expressing TAP-tagged parkin. Further, we found USP13 responsible for regulating the stability and function of parkin under basal condition as a deubiquitinase of parkin that confirmed through some experiments **(i)** downregulation of USP13 and Parkin mRNA and protein expression under oxidative stress conditions in SHSY-5Y cells **(ii)** USP13 deubiquitinates the ubiquitinated Parkin under basal conditions of hemagglutinin (HA)-Ub overexpression in HEK-293 cells **(iii)** USP13 regulates basal parkin stability via ubiquitin-proteasome pathway in SHSY-5Y cells **(iv)** USP13 depletion leads to parkin downregulation and its substrates accumulation studied in SHSY-5Y cells. Also, when oxidative stress is induced by 6-hydroxydopamine, USP13 regulates parkin through the ubiquitin-proteasome pathway and parkin functions downstream of USP13 in the regulation of cell viability. Further, clinical relevance was established when USP13 and Parkin protein expression levels were found reduced in PD brains. Our results clearly indicate that maintenance of USP13-parkin pathway could be critical for mitochondrial function and cellular defense in PD pathological conditions.

Title: Mitochondrial CISD1 is a downstream target that mediates PINK1 and Parkin loss-of-function phenotypes

Authors: *A. METHNER[1], S. BITAR[2], L. ZHANG[2], G. ARENA[3];
[1]Johannes Gutenberg Univ. Mainz, Mainz, Germany; [2]Johannes Gutenberg Univ., Mainz, Germany; [3]Univ. of Luxembourg, Luxembourg, Luxembourg

Abstract: Parkinson's disease (PD) is caused by progressive degeneration of dopaminergic neurons in the substantia nigra of the midbrain. Mutations of the kinase PINK1 and the ubiquitin ligase Parkin, proteins involved in mitochondrial quality control, cause familial PD. The homodimeric mitochondrial iron-sulfur-binding protein CISD1 is a major target of Parkin-mediated ubiquitination and loss of CISD1 is associated with mitochondrial dysfunction, an altered redox state, and iron accumulation, which are also all hallmarks of PD. To ask if CISD1 is an important player in PD, we studied its role in Pink1 and Parkin mutant flies, dopaminergic neurons from patients suffering from PINK1 mutation, and fibroblasts without CISD1 or with a CISD1 mutant lacking its iron/sulfur cluster. Loss of Cisd, the Drosophila orthologue of CISD1, rescued the detrimental effects of Pink1 loss of function on lifespan, wing posture, climbing ability and mitochondrial ultrastructure. Gene reduction of Cisd also rescued Parkin-mediated defects in climbing ability and lifespan. Pink1 mutant flies and patient-derived dopaminergic neurons had a higher propensity to form CISD1 dimers. This corresponds to the iron-depleted state of CISD1 and a CISD1 mutant incapable of binding the iron-sulfur cluster results in mitochondrial fragmentation and increased levels of reactive oxygen species.Our results from both flies and humans suggest that the mitochondrial iron-sulfur cluster protein Cisd is downstream of the cascade initiated by Pink1 and Prkn loss of function. This sheds light on the pathophysiology of familiar and possibly also sporadic Parkinson's disease and implicates CISD1 as a therapeutic target protein.

Title: Ubiquitin-proteasome system and autophagy-lysosomal pathway affect each other during two neurotoxin-mediated differential cell death events in dopaminergic MN9D cells

Authors: *J. PARK[1], H. JANG[1], H. RHIM[2], K. CHUNG[1];
[1]Dept. of Systems Biol., Yonsei Univ., Seoul, Korea, Republic of; [2]Ctr. for Neurosci., Brain Sci. Institute, Korea Inst. Sci. Tech. (KIST), Seoul, Korea, Republic of

Abstract: The accumulation of misfolded or damaged proteins is a key pathogenic mechanism in many neurodegenerative disorders, including Parkinson's disease (PD). Thus, elucidating the precise operation and regulation of two intracellular proteolysis system such as ubiquitin-proteasome system (UPS) and autophagy-lysosomal pathway (ALP) is very important. Although many studies have suggested a close link between the UPS and ALP in resting cells, their interplay and tight regulation have rarely been studied during neuronal cell death. In this study, we explored whether and how the UPS and ALP affect each other in two neurotoxin-based cell death models of PD. Previously studies showed that dysregulated autophagy contributes to caspase-dependent neuronal apoptosis in dopaminergic MN9D cells by 6-hydroxydopamine (6-OHDA), whereas autophagic malfunction caused by 1-methyl-4-phenylpyridinium (MPP^+) treatment was due to impaired autophagic degradation associated with lysosomal deficits. In this study, monitoring intracellular UPS and ALP activity using their specific reporter plasmids revealed that treatment of MPP^+ or 6-OHDA decreased proteasome activity in MN9D cells. In addition, when the cells were co-treated with each toxin plus the ALP inhibitor ammonium chloride, the inhibition of ALP relieved the 6-OHDA-induced reduction of proteasome activity, whereas MPP^+-induced proteasomal inhibition was substantially potentiated. Moreover, when the cells were co-treated with each toxin plus the proteasome inhibitor MG132, 6-OHDA-induced excessive autophagic flux was considerably promoted, whereas the MPP^+-induced impaired autophagy activity was alleviated via autophagy induction. Taken together, these findings suggest a dynamic interplay between the UPS and ALP operating in MN9D cells, which affect each other under two distinct toxin-mediated cell death pathways. This novel perspective can be developed as a potentially effective strategy for PD treatment.

Title: Assessment of GPNMB as a lysosomal dysfunction biomarker in a chronic CBE-treated mouse model.

Authors: *F. D. TINGLEY, III[1], M. G. SCHMITT[2], B. A. JENKINS[3], R. RAGHUNATHAN[5], H. WANG[4];

Abstract: Some neuronopathic diseases can be described as lysosome dysfunction or lysosomal storage disorders (LSD) causing the accumulation of lipid glycoproteins tied with lysosomal degradation. One example is Gaucher's Disease (nGD)-- specifically type 2 and 3. It is characterized by a GBA1 gene mutation that encodes for a lysosomal hydrolase named acid B-glucosidase (GCase). This same gene has been associated with an increased Parkinson's Disease risk (PD) in humans. Mutations in the GBA1 gene and the lack of GCase activity result in the accumulation of glucosylceramide (GlcCer) —a glycolipid found within lysosomes and macrophages. In an effort to study nGD, two transgenic mouse models have been investigated ($Gba^{flox/flox}$ and K14-lnl/lnl); however, these strains are not ideal given their short lifespans, severity of disease, and cost. An alternative to transgenic mice, is the use of the chemical, conduritol B-epoxide (CBE) as an irreversible inhibitor of GCase activity. Chronic administration of this drug has been used to represent GD in mouse studies. Literature reports (mice) show the use of CBE inhibits GCase activity, increases GlcCer levels in brain, and changes GPNMB levels in CSF. Given this information, we sought to repeat these findings using chronic CBE (21 days) treatment (N=6, 50, 100 mpk) in female C57Bl6 mice (9 wks.) and measure multiple readouts for LSD induction. Some results following chronic CBE included the following: 1) GCase activity is significantly decreased at doses of 50 and 100 mpk in both mouse frontal cortex and hippocampus (34-66%) compared to controls; 2) brain levels of GPNMB significantly increase following 100 mpk CBE treatment in mid-cortex and hippocampus (50-97%); and 3) similar to brain GPNMB increases, levels of RNA expression in mouse cortex increased dramatically compared to controls (3 - 100 fold). Taken together, these data and others both corroborate and support previous literature reports detailing GPNMB as a marker of lysosomal dysfunction--warranting further evaluation as a biomarker in neurological diseases such as nGD and PD.

Title: Molecular Signaling Pathway in Manganese-Induced Apoptosis

Authors: *K. PRABHAKARAN[1], N. K. GUNASEKARAN[2], A. SERGEON[1], G. T. RAMESH[1], J. C. HALL[3];
[1]Biol., [2]Material Sci., [3]Chem., NORFOLK STATE UNIVERSITY, Norfolk, VA

Abstract: Exposure to high levels of manganese (Mn) has been shown to cause a Parkinson's-like syndrome known as manganism. Although much is known concerning the essentiality and toxicity of manganese, the mechanism for the neurodegenerative damage specific to select brain regions is not clearly understood. Hypoxia-inducible factor-1 α (HIF-1 α) is a transcriptive factor that regulates genes involved in metabolism, angiogenesis, proliferation, and apoptosis. HIF-1 α can respond to hypoxic and a variety of non-hypoxic stimuli that can initiate Reactive Oxygen Species (ROS) production, which then can activate the HIF-1 α cascade. In this study, an immortalized dopaminergic cell line was used to characterize the cell death signaling cascade activated by Mn. Mn-treated cells exhibited concentration-dependent apoptosis that was caspase-dependent and induced a dose-dependent increase of HIF-1 alpha expression, paralleling the cell death response. Mn induced a rapid surge of intracellular reactive oxygen species (ROS) generation, followed by p38 mitogen-activated protein kinase (MAPK) activation that leads to nuclear accumulation of hypoxia-inducible factor-1alpha (HIF-1alpha). Activation of p38 MAPK and HIF-1alpha accumulation were attenuated by N-acetyl-L-cysteine, GSH (antioxidants), 1400W (specific iNOS inhibitor), or a selective p38 MAPK inhibitor (SB203580), showing that oxidative stress and p38 MAPK act as upstream signals in the induction of HIF-1 alpha. Finally, RNAi knockdown of HIF-1 alpha protected the cells from Mn-induced mitochondrial dysfunction and cell death. These results indicate that Mn activated the HIF-1alpha-mediated signaling pathway, which served as an initiator of Mn-induced apoptosis in neuronal cells.

Title: Striatal arginase 2 supports functioning of mitochondria

Authors: *M. PODGAJNA[1], A. OWCZAREK[1], A. DALKA[1], A. KACZYNSKA[1], K. SKOWRONSKA[2], M. ZIELINSKA[2], M. WEGRZYNOWICZ[1];
[1]Lab. of Mol. Basis of Neurodegeneration, [2]Dept. of Neurotoxicology, Mossakowski Med. Res. Inst. Polish Acad. of Sci., Warsaw, Poland

Abstract: Arginase converts arginine (Arg) to ornithine (Orn). Arg2 appears to be the only arginase isoform in resting brain, although its distribution is limited to only few subpopulations of brain cells. Striatum is strongly enriched with Arg2, but the role and exact localization of this protein is unknown. Here, we aimed at determining detailed Arg2 localization and establishing the importance of Arg2 for Arg homeostasis and cellular pathways in striatum. We used in our experiments 3-months-old control WT C57Bl/6J mice and genetic model of Arg2 loss (Arg2 KO mice; Arg2tm1Weo/J), both males and females. We used western blot for measurements of protein levels and immunohistochemistry for analysis of protein localization. We have confirmed that Arg2 has been is the only arginase isoform expressed in the striatum under physiological conditions. As expected it localized in the mitochondria, was absent in microglia and astrocytes, but was specific for medium spiny neurons (MSNs),- where it was found primarily in cell bodies. To analyze Arg-related metabolic pathways controlled by Arg2 in striatum, we compared C57 and Arg2 KO mice for their amino acid profiles (HPLC, n=10-13), polyamine levels (MS) and nitrates and nitrites content (NOx as a cellular measure of nitric oxide (NO)) and α-ketoglutarate levels (n=6). We have found that loss of Arg2 resulted in a significant accumulation of Arg ($p > 0.004$) in the striatum, but didn't affect any other measured parameter. Then we performed proteomic study (n=5) which indicated that loss of Arg2 results in changes in the expression of several mitochondrial proteins, including some components of respiratory chain. Summarizing, Arg2 in the striatum is restricted to MSNs, suggesting its specific role for these neuron functioning. Arg2 controls Arg levels, but its absence does not affect ornithine (Orn) content, what may suggest activation of compensatory mechanisms to maintain Orn bioavailability. Importantly we show that Arg2 doesn't affect NOx content, what negates the hypothesis that Arg2 is a negative regulator of NO synthesis by competing with NOS for their common substrate, Arg (at least in resting brain, where NOS activity is low). The results of the proteomic analysis suggest that Arg2 may support proper functioning of striatal mitochondria and impairment of this enzyme, that was observed in Huntington's disease model (Bichell et al., 2017), may contribute to the development of the disease.

Title: Mechanisms of synaptic death in lysosomal storage diseases

Authors: *D. ZELADA, N. SALDIVIA, A. KONJETI, R. REBIAI, M. I. GIVOGRI, K.-Y. TSENG, S. ALFORD, E. R. BONGARZONE;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Lysosomal storage diseases (LSDs) are characterized by decreased activity of lysosomal enzymes leading to the accumulation of undegraded material. Many LSDs course with cognitive, learning limitations and neuronal dysfunction. Amongst LSDs, Krabbe disease (KD) is a fatal LSD caused by mutations of Galactosylceramidase (GALC), triggering the accumulation of the sphingolipid psychosine, with subsequent demyelination and neurodegeneration of central and peripheral nervous system. Three classes of KD are known (infantile, juvenile or adult), being the infantile form the most frequent and severe. Importantly, the effects of GALC deficiency observed in the infantile form of KD can be recapitulated in the Twitcher (Twi), a KD mouse model that exhibits null GALC activity and consequently psychosine accumulation. Although demyelination is deemed as the primary cause of neuropathology in KD, recent findings have shown that neuron-restricted GALC deletion is sufficient to induce motor, neuro-axonal, and behavioral impairments. Thus, the mechanism of neuronal disease in KD is not clear, but we hypothesize that psychosine accumulation exerts detrimental effects directly in neuronal function and structure. To test this idea, we analyzed synaptic function by employing electrophysiological recordings of hippocampal slides from TWI mice, mice with GALC deletion restricted to oligodendrocytes (PLP-CreERT2/Flx-GALC-Flx) or neurons (CamKII-CreERT2/Flx-GALC-Flx). In turn, synaptic structure was evaluated by ultrastructural, immunohistochemical and biochemical analyses in wild-type (WT) or TWI mice brains. Also, the potential mechanisms of psychosine effects were analyzed by *in vitro* synaptic vesicle fusion measurements along with behavioral memory tests. Our results shown that ubiquitous GALC mutations lead to decreased Paired-Pulse Facilitation (PPF) of CA1 neurons in TWI compared to WT. Interestingly, decreased PPF was only observed upon GALC ablation in neurons but no in oligodendrocytes. Furthermore, we observed structural disruptions in pre- and postsynaptic domains of TWI brains, including decreased number of synaptic vesicles (SV) and dendritic spines. Psychosine reduced the fusion of SV and accumulated ~150-fold in the synaptosome of TWI at final stages of the disease. Finally, WT mice subjected to psychosine administration exhibited impaired memory performance. Altogether, our findings reveal a pathogenic mechanism where the local accumulation of undegraded psychosine at the synapse is sufficient to interfere with synaptic function in the TWI hippocampus by reducing SV fusion and altering synaptic structure.

Abstract: Huntington's disease(HD) is an autosomal dominant genetic disease caused by the huntingtin(htt) gene on chromosome 4. There is currently no effective treatment. Therefore, it is significant to study the molecular mechanism of HD. We found abnormal mitochondrial localization of heat shock transcription factor 1 (HSF1) in HD. Results showed that mislocalized HSF1 activates the phosphorylation of mitochondrial dynamin-related protein 1 (Drp1) S616 site and inhibits the oligomers formation of mitochondrial single-strand DNA-binding protein 1 (SSBP1), which in turn leads to mitochondrial dysfunction and neurodegeneration. The peptide DH1 which can reduce mitochondrial translocation of HSF1 can improve mitochondrial dysfunction and delay disease progression in HD.Based on the single-cell RNA sequencing and immunofluorescence experiment in previous studies, we found that the proportion of medium spiny neurons decreased in D60 HD striatal organoids which correlated with the fetal striatum at 12 to 19 weeks post-conception, and transcription of multiple genes is severely disrupted, while gene expression is regulated by chromatin remodeling complexes. In this study, we found that the expression of some subunits of the SWI/SNF chromatin remodeling complex of in HD mice YAC128/CAG140 was abnormal. Most subunits such as BAF170/SMARCA4/BAF60a were decreased at YAC128. Interestingly, BRD7 was increased and the other subunits were

unchanged. Furthermore, we found that BCL7B was less at CAG140. These results mean that the function of the SWI/SNF complex is impaired in HD mouse models. Meanwhile we also obtained consistent conclusions in HD iPSC and D30 cortical organoids. We supposed that HD may be caused by chromatin remodeling complexes changes leading to epigenetic abnormalities which contribute to the development of HD.

Abstract: Phosphodiesterase 1 signaling dysfunction associated with cognitive deficits in Alzheimer’s disease
Yuqing Yan, PhD, Ying Xu, PhD/MD
Department of Anesthesiology, Rutgers University, the State University of New Jersey, Newark, NJ 07103
Background: Alzheimer’s disease (AD) is a neurodegenerative disorder associated with irreversible cognitive impairment and memory loss. Phosphodiesterases (PDEs) consisted of 11 subtypes (PDE1 to PDE11) and over 40 isoforms that regulate levels of cyclic guanosine monophosphate (cGMP) and cyclic adenosine monophosphate (cAMP). Among them, PDE1 has been demonstrated to be a potential drug target for a variety of diseases ranging from cardiovascular disease and neurodegenerative disorders including AD.
Method: This study used public gene expression data from Gene Expression Omnibus (GEO) database (https://www.ncbi.nlm.nih.gov/geo/) to decipher the role of PDEs, particularly PDE subtype 1A dysfunction in pathology of Alzheimer’s disease by analyzing the mRNA and lncRNA differences in the GENECODE data resource V22 (https://www.gencodegenes.org/). The mRNA and lncRNA were extracted from the RNA-seq cohort with five eligible Alzheimer Disease (AD) cohorts included. Human Embryonic Kidney 293 cells were chosen for PDE1A ceRNA validation using dual-luciferase Assay.
Result: 12584 differentially expressed genes (DEGs) were identified when compared the difference between AD brain and age-matched control groups. Among them, there were 1459

mitochondrial related DEGs were found, while 1131 AD-related mitochondrial genes were significantly changes in AD brain by Venn plot analysis. The subsequent study found that among two clusters, mitochondrial genes regulated the pathogenesis of AD with interaction of PDE1A through
mitochondrial-related ceRNA network. Generation of AD-related mitochondrial signature (ARMS) by machine learning method found downstream immunity genes were to AD, may be activated by regulation of PDE1A dependent cellular immunity.
Conclusion: These findings implicate that PDE1A activity may affect cellular immunity by AD patients during regulation of mitochondrial metabolic process.
Key words: PDEs, PDE1A, ceRNA, mitochondrial function, cellular immunity, Alzheimer's disease

Title: Functional identification of the promoter regions of human NMNAT2 and SARM1 and investigation of human variants in these regions on gene expression

Authors: *E. R. WILSON[1], H. MORSY[2], L. CARLTON[1], J. GILLEY[1], H. HOULDEN[2], M. M. REILLY[2], M. P. COLEMAN[1];

Abstract: The programmed axon degeneration pathway (or Wallerian degeneration) has become an important drug target in a bid to tackle neurodegenerative diseases. Protein coding mutations in two of the key genes involved in this pathway, *NMNAT2* and *SARM1*, are associated with human neurodegenerative diseases including ALS and peripheral neuropathy (Huppke et al., 2019, Lukacs et al., 2019, Gilley et al., 2021, Bloom et al., 2022, Dingwall et al., 2022). Links to this pathway have also been proposed in other human diseases such as Alzheimer's disease, Parkinson's disease, multiple sclerosis, glaucoma and traumatic brain injury. SARM1, an NAD+ degrading enzyme, is considered the central executioner of programmed axon degeneration. In the uninjured axon, SARM1 activity is repressed by NMNAT2, an NAD+ synthesising enzyme. Mouse studies have highlighted that the relative levels of *NMNAT2* and *SARM1* could impact disease progression and neurodegenerative outcome (Gilley et al., 2013, Gilley et al., 2019, Gould et al., 2021). Thus, understanding how human *NMNAT2* and *SARM1* are regulated on a transcriptional level has the potential to identify critical regions of these genes in which variation

may modulate patient outcomes and disease progression. In the present study we use *in vitro* models and luciferase assays to identify the promoter regions of human *NMNAT2* and *SARM1* which are essential for their expression. Moreover, preliminary data indicates a non-coding region 5' of the canonical transcription start site of human *NMNAT2* that represses expression, specifically in neuronal cells. Finally, we identify human variants in the promoter regions of *NMNAT2* and *SARM1*, including a homozygous variant in peripheral neuropathy, and explore the impact of said variations on expression levels. In sum, this work describes the promoter regions important for human *NMNAT2* and *SARM1* expression, and begins to investigate how changes in expression levels of these genes may contribute to human disease. Advances in whole genome and exome sequencing studies and genomic databases are likely to expand our understanding of the role of the programmed axon degeneration pathway and in which human diseases it is most relevant.

Abstract: A balanced concentration of polyunsaturated fatty acids (PUFA) in the prenatal stage is essential for children's neurodevelopment. Also, animal studies showed that high levels of anti-inflammatory PUFA metabolites in the embryonic brain protect against genetic or environmental insults that would otherwise cause cognitive impairment. Here we used liquid chromatography - mass spectrometry to analyze oxylipins, the oxygenated metabolites of PUFA, in the placenta tissue (N=12) and cord blood plasma (N=39) of children from the INMA cohort (Valencia, Spain). Both tissues were characterized for total Hg levels as a reference for developmental neurotoxic MeHg exposure during pregnancy and distributed in low and high Hg groups. Deleterious effects of high Hg were confirmed in the placenta as decreased proteasome activity and inhibitory epigenetic changes. Children's neurodevelopment was assessed using the Bayley (14 months) and McCarthy (5 years) scales. Spearman correlation coefficients were calculated between scores and oxylipin levels. We also analyzed cortical brain tissue from wild type and transgenic Alzheimer's disease (5XFAD) mice dosed for 2 months with vehicle or a soluble epoxide hydrolase enzyme (sEH) inhibitor, UB-BJ-02 (5 mg/Kg, N=5/group). Inhibition of sEH increases levels of the potent anti-inflammatory epoxyeicosatrienoic acids (EETs) by inhibiting their hydrolysis to dihydro-EETs (DiHETs). We found that DiHETs were increased in the placenta of high Hg group. Furthermore, the mental and psychomotor development of 14-month-old children correlates positively with DiHETs levels in both placenta and cord blood tissues. Interestingly, cord blood DiEHTs positively correlate with working memory at 5 years. Thus we suggest that higher levels of DiHETs indicate higher synthesis of their anti-inflammatory EETs precursors. Accordingly, placenta levels of EETs correlate with mental development at 14 months of age. Other oxylipin changes also suggested an involvement of inflammatory mechanisms in the neurodevelopment of children exposed to MeHg. In general, higher levels of markers of resolved inflammation or final stable metabolites in the placenta and cord blood tissues correlate with better neuropsychological development in children exposed to environmental MeHg. Finally, mouse treatment with the drug UB-BJ-02 showed increased EETs and decreased pro-inflammatory markers in brain tissue. Both human and experimental results showed that EETs are prominent anti-inflammatory metabolites and support sEH inhibition as an anti-inflammatory treatment to increase brain resilience to environmental risk of neurodevelopmental damage.

Title: 17 beta estradiol enhances neurite outgrowth by activating ampk, pgc1a and atf3 in adult dorsal root ganglion neurons

Authors: *P. MISHRA[1,2], P. FERNYHOUGH[1,2], **B. ALBENSI**[1,3,2];
[1]Dept. of Pharmacol. & Therapeut., Univ. of Manitoba, Winnipeg, MB, Canada; [2]Div. of Neurodegenerative Disorders, St. Boniface Hosp. Res. Ctr., Winnipeg, MB, Canada; [3]Dept. of Pharmaceut. Sci., Col. of Pharmacy, Nova Southeastern Univ., Fort Lauderdale, FL

Abstract: Rationale: Dorsal root ganglion (DRG) sensory neurons express both estrogen receptors (ERs) alpha and beta in male and female rodents. 17-beta estradiol which is the most potent form of estrogen plays a crucial role in the development and survival of adult DRG neurons, as well as the regulation of neurite outgrowth. Additionally, AMP-activated protein kinase (AMPK) serves as a cellular energy sensor and can modulate the levels of activating transcription factor 3 (ATF3) and PGC-1α. These target proteins are involved in neuronal regeneration and mitochondrial biogenesis. In our study, we hypothesized that activation of ERs with 17-beta estradiol could enhance the energy metabolism in adult DRG neurons and also promote their axonal sprouting. **Objective:** Investigate the impact of 17-beta estradiol treatment and gain a comprehensive understanding of the ER signaling pathway in adult rat DRG neurons. **Methods:** DRG neurons derived from adult male or female Sprague Dawley rats were isolated and cultured under defined conditions for 24 hours. Subsequently, the cultured neurons were treated with 17-beta estradiol. The expression levels of pAMPK, ATF3, and PGC-1α were determined using western blotting. Furthermore, mitochondrial parameters, including basal respiration and ATP production, were assessed using the Seahorse XF24. Immunostaining for ER alpha and ER beta was also conducted. Additionally, DRG neurons were stained with β-tubulin III and captured images were subsequently analyzed using ImageJ to evaluate total neurite outgrowth. We also blocked AMPK using Compound C to investigate its effects on ATF3 and axonal sprouting. **Results:** Immunocytochemical analysis confirmed the presence of both ER alpha and ER beta in adult DRGs. Treatment with 17-beta estradiol resulted in a dose-dependent increase in phosphorylated AMPK (pAMPK) levels in male and female DRG neurons. Furthermore, protein levels of ATF3 and PGC-1α were also elevated in response to estradiol treatment. Additionally, estradiol treatment enhanced basal respiration in these cells and, DRG neurons derived from both male and female rats exhibited increased neurite outgrowth

upon estradiol treatment. Notably, inhibition of AMPK with Compound C also inhibited estradiol mediated ATF3 activation. **Conclusion:** Our findings suggest that 17-beta estradiol stimulates neuronal outgrowth in adult rat DRGs through the activation of pAMPK, PGC-1α, and ATF3, with AMPK acting upstream of ATF3. These results suggest that 17-beta estradiol may have therapeutic implications for treating neurodegenerative conditions, including peripheral neuropathy.

Title: Prophylactic Treatment with the Secretome of Cultured Amnion-Derived Multipotent Progenitor Cells Reduces the Consequence of Traumatic Optic Neuropathy

Authors: *B. MOUZON[1,2], M. BROWNING[1], N. CAROTHERS[1], M. KOPRIVICA[1], S. FERGUSON[1], L. BROWN[3], R. MCCARTAN[4], H. WESSEL[3], R. TZEKOV[5], F. CRAWFORD[1,2];

Abstract: Background: The proposed project investigates a prophylactic treatment of ST266 delivered intranasally to prevent cell death in the visual system of military personnel who are at high risk to experience traumatic head/eye injuries during training activities or deployment. ST266 is a proprietary secretome obtained by culturing a novel population of cells termed Amnion-derived Multipotent Progenitor cells under proprietary, pharmaceutical grade GMP conditions. ST266 contains hundreds of biologically active proteins and other factors that have been shown to be neuroprotective and anti-inflammatory; it promotes cell recovery and tissue healing. We used our preclinical mouse model of mild injury (mTBI), in which we have demonstrated TBI-dependent visual dysfunction. Here we report the results of a prophylactic treatment with a single intranasal dose of ST266 24 h prior to the first injury. **Method:** We tested a known therapeutic dose of volume of 10µL via intranasal delivery 24 h prior to the first injury and at 8 am on the day of the injury (with an impact scheduled at noon) and treated every morning for the next 9 days until the beginning of the behavioral tests in male C57BL/6 mice using our mouse model of traumatic optic neuropathy (TON). Learning, memory, and visual deficits were assessed with the Barnes Maze and optomotor behavioral tests starting 10 days post first-injury. **Results:** ST266 improved learning but not spatial memory within the Barnes Maze

starting at 10 days post injury. The optomotor response frequency significantly decreased with increasing Cycles Per Degree in response to injuries, but no treatment effect was observed. ST266 treatment significantly reduced the loss of retinal ganglion cells (RGC) as quantified by Brn3a immunolabeling at 10 days post injury compared to PBS-treated mice. ST266 treatment also attenuated astrogliosis, microgliosis, and leukocyte infiltration in the optic nerve of the injured mice. Sections immunostained with $Olig2^{+}$ showed a proliferation of oligodendrocytes at 10 days post last injury which was reduced after ST266 treatment. Biochemical analysis of the optic nerve revealed activation of the NLRP3 inflammasome in our model of TON that was alleviated after a prophylactic treatment with ST266. **Conclusion:** This study found that r-mTBI lead to TON and that increased inflammation in the optic nerves, acute neurobehavioral dysfunctions, and loss of retinal ganglion cells were mitigated by a prophylactic treatment with ST266.

Title: Maternal Exercise Improves Hippocampal Synaptic Plasticity And Depressive-like Behavior In Adult Offspring

Authors: *S. YAU, J. MADEDO;
Rehabil. Sci., Hong Kong Polytechnic Univ., Hong Kong, Hong Kong

Abstract: Maternal physical exercise during pregnancy has been reported to benefit offspring's brain health. We have previously shown that maternal exercise promotes adult hippocampal neurogenesis and reduces depressive behaviours. However, the underlying mechanisms of these transgenerational effects are largely unknown. We aim to further examine whether maternal exercise improves hippocampal neuroplasticity to reduce depression-like behavior in offspring. Pregnant female mice with C57BL/J background were allowed to access to running wheels in the housing cages throughout the gestational period. Male and female mice offspring at the age of 6 weeks were sacrificed for either electrophysiology or Western blot analysis. Our results showed that maternal exercise showed main effects in increasing hippocampal protein levels of PSD-95 and BDNF, and synaptophysin in offspring. These molecular changes were associated with a significant increase in long-term potentiation in the perforant path projections to the hippocampal

dentate region of both male and female offspring. To test whether maternal exercise increases stress resilience of offspring, we subjected the offspring to 21-day unpredictable chronic stress. Results showed that maternal exercise attenuated the increase in immobility time in forced swim test and reduction in grooming time reduced by 21-day chronic unpredictable stress in both male and female offspring. These findings have suggested that maternal exercise could improves hippocampal function and protect offspring against stress-induced hippocampal synaptic impairment.

Title: The neuroprotective effect of epoxyeicosatrienoic acids (EETs) during apoptotic neuronal death is partially mediated by ROS reduction

Authors: *C. NAVARRO-MABARAK[1], G. DOMÍNGUEZ[2], J. MORAN[3];
[1]Univ. Nacional Autónoma de México, CDMX, Mexico; [2]UNAM, UNAM, Mexico City, Mexico; [3]Natl. Univ. of Mexico, Natl. Univ. of Mexico, Ciudad de Mexico, Mexico

Abstract: Cytochrome P450 (CYP) epoxygenases and their metabolic products, epoxyeicosatrienoic acids (EETs), have been proposed as therapeutic targets in the brain due to its diverse and beneficial properties. In particular, EETs have been reported to have a protective effect against neuronal apoptosis and oxidative stress conditions. However, it has not been established a relationship between the EETs-mediated neuroprotection and its possible regulation of reactive oxygen species (ROS). Therefore, we studied the role of ROS in the EETs-mediated neuroprotection in a model of neuronal death. For this purpose, we used primary cultures of cerebellar granule neurons. We induced cell death with staurosporine (0.5 micromolar), glutamate (300 micromolar) or potassium deprivation (5 mM KCl, K5) treatments for 24 h. To enrich the content of EETs in neuronal cultures, cells were pre-treated for 2 h with TPPU (10 and 100 micromolar), a specific soluble epoxide hydrolase (sEH) inhibitor. Cell viability was assessed by calcein/propidium iodide staining and ROS levels were measured with dihydroethidine (DHE). Under these conditions, we found that TPPU pre-treatment induced a marked neuroprotective effect in staurosporine-induced death by significantly increasing cell viability and significantly decreasing ROS production in a TPPU dose-dependent manner. On the other hand, when cells were treated with glutamate or K5, cell viability was only recovered by 10

micromolar TPPU treatment. In both cases, we observed a reduction of ROS production. These results suggest that ROS reduction may be involved in the EET-mediated neuroprotection.

Abstract: 17α-Estradiol longevity treatment improves metabolic and peripheral nerve parameters in middle aged and older male mice

Magdalena Blaszkiewicz[1], Jake Willows[1], William David Arnold[1], Peter Reifsnyder[2], David Harrison[2], Kristy L. Townsend[1]
[1]Department of Neurological Surgery, The Ohio State University, Wexner Medical Center, Columbus, Ohio, USA[2]The Jackson Laboratory, Bar Harbor, Maine, USA

Sex differences underlie the onset and severity of numerous diseases, and biological sex likely interacts with genetics in the presentation of disease phenotypes. Age-related peripheral neuropathy (PN) is a top cause of small fiber neuropathy in humans, and we previously demonstrated that PN impacts subcutaneous adipose tissue of aged mice and humans as well. We and others have reported less severe diabetic PN in mice, and we have found protection from age-related PN until the age of reproductive senescence in female mice, but PN was not mitigated with rapamycin longevity treatment in aged HET3 mice of either sex. In fact, rapamycin exacerbated age-related dysregulation of adipose tissue. The genetically diverse HET3 mice are utilized by the NIA's intervention testing program (ITP) to identify longevity treatments, so given the likelihood that sex hormones play a role in PN, we tested another validated ITP longevity treatment,17α-Estradiol (17α-E2) for effects on adipose and PN across aging. This treatment is non-feminizing and previously proven to extend lifespan in male HET3 mice. Middle aged (~51 wks) and older (~84 wks) male HET3 mice received 17α-E2 treatment in the diet for 17 weeks. We observed increased grip and contractility torque and improved NMJ function in middle aged 17α-E2 treated mice. However, 17α-E2 treatment improved intraepidermal innervation (a histological measure of small fiber PN) in the older mice only. Reduced fat mass was seen in all 17α-E2-treated mice regardless of age, with improved glucose sensitivity evident only in the older male mice. Increased energy expenditure was seen in 17α-E2

treated middle aged mice. Interestingly, these metabolic and neural endpoint data also varied by genetic strain contribution. For example, grip strength improvement was most evident when C57BL/6 or DBA/2 strain contribution was low in the HET3 mice. Studies in female HET3 mice given 17α-E2 across aging are underway, but taken together, we found that 17α-E2 treatment is a translationally relevant way to maintain metabolic and nerve health across aging.

Title: Restore visual function in mice with glaucoma by optogenetic enhancement of mitochondrial function

Authors: *Y. WANG[1], B. YAN[2], J. ZHANG[2];
[2]Fudan Univ., [1]Fudan Univ., Shanghai, China

Abstract: Objective and rationale Glaucoma is the leading cause of irreversible blindness worldwide. People with glaucoma suffer from terrible visual deficits caused by progressive degeneration of retinal ganglion cells (RGCs). As predicted, over 100 millions people will be affected by glaucoma, however, there are no radical therapies up to now. There is an urgent need for developing effective therapies. Previous studies showed that mitochondrial abnormalities, both anatomical and functional, are highly associated with glaucoma. Here we explored whether optogenetic enhancement of mitochondrial function could restore visual function induced by glaucoma. **Methods and results** Here we used mtGAPR mice, one transgenic mice carrying opsins in mitochondria across body, along with a silicone-oil induced ocular hypertension model to imitate angle-closure glaucoma on mice. During the experiment, green light was given 4h per day to optogenetically enhance mitochondrial function within mice. To assess whether glaucoma was induced, intraocular pressure (IOP) of experimental mice was monitored weekly. Mice with relatively high IOP after injection were included in the experiment. RGCs counting showed that more percentage of RGCs survived in optogenetically enhanced transgenic mice compared to wildtype mice after injection, especially in the first two weeks. Together with visual acuity test, indicated by optomotor response, confirmed that glaucomatous visual deficits were partially rescued by optogenetic enhancement of mitochondrial function. Optogenetic activation of mitochondria could also delay the glaucomatous progress in mitochondria-linked AAV-intravitreally-injected mice. To further explore the protection mechanisms, we found that the protective effect might be associated with the interference of pyroptosis. **Conclusions** Our work showed that rescuing mitochondrial dysfunction could partially protect RGCs from degeneration in glaucoma.

Abstract: Netrin-1, a key player in embryonic axonal guidance, has been recognized as a significant factor in synaptic plasticity, neuroprotection, and inflammation regulation within the mature brain. Recent studies have reported altered Netrin-1 levels in neurodegenerative diseases such as Parkinson's Disease (PD) and Alzheimer's disease (AD), suggesting its potential role in disease pathogenesis. We explored Netrin-1's role in neurodegeneration via immunodepletion of Netrin-1 in iPSC-derived motor and dopaminergic neurons cultures, αSyn fibrils induced iPSC models of PD, and TDP43 iMotor neuron models of ALS (Q331K variant). Our data indicate that Netrin-1 depletion induces loss of synaptic proteins and cell death. Further experiments using two-compartmental microfluidic devices revealed axonal reduction caused by Netrin-1 deprivation. Treatment with recombinant Netrin-1 rescued some of these effects, elevating synaptic proteins and suggesting its potential to foster synaptic function and formation. We also noticed a significant impact of Netrin-1 treatment on neurons' functional connectivity and firing behavior, as indicated by changes in the mean firing rate and network burst frequency. In summary, Netrin-1 has demonstrated the potential to reverse key pathological features associated with PD and ALS, such as cell death and synaptic dysfunction. These findings pave the way for further exploration of the roles of Netrin-1 and its receptors in neurodegeneration, highlighting the promise of this pathway for future therapies.

Title: Exploring the Efficacy of Paeonol in Alleviating Chemotherapy-Induced Peripheral Neuropathy (CIPN): A Basic Research Study

Authors: *C.-C. HUANG[1,2], Y.-H. CHEN[3];
[1]An Nan Hospital, China Med. Univ., Tainan, Taiwan; [2]Sch. of Post-Baccalaureate Chinese Med., [3]Grad. Inst. of Acupuncture Sci., China Med. Univ., Taichung, Taiwan

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) causes disabling pain involving damage to the peripheral motor, sensory and autonomic neurons. Paeonol, the major component of Moutan Cortex, has neuroprotective effects by improving neuronal morphology, increasing neuronal activity, inhibiting microglia activating, reducing oxidative stress, and exhibiting anti-inflammatory effects. The mechanisms involved in CIPN include neuroinflammation and altered excitability of peripheral neurons. Adiponectin, a hormone primarily secreted by adipose tissue, plays a crucial role in the intricate interactions of the central and peripheral nervous systems. Through activation of AMP-activated protein kinase (AMPK) and peroxisome proliferator-activated receptor alpha (PPARα) signal pathway, adiponectin has been shown to regulate neurotransmitter release and modulate neuronal excitability, ultimately influencing cognitive functions, mood regulation, and neuroinflammation. To date, no trial has investigated the efficacy of paeonol in treating chemotherapy-induced peripheral neuropathy in cancer patients Intraperitoneal administration of paclitaxel (5 mg/kg i.p. on days 0 and 2) reduced the mechanical and thermal pain threshold in the hind paw, indicating an increased mechanical and thermal allodynia. Conversely, oral administration of paeonol at doses of 100 mg/kg and 200 mg/kg significantly reversed the decrease in mechanical pain threshold induced by paclitaxel on day 6, day 10, day 13, and day 15 in the mechanical pain test. In the thermal pain test, oral administration of paeonol at a dose of 200 mg/kg also reversed the decrease in thermal pain

threshold induced by paclitaxel on the same days. It indicates that paeonol improved in the mechanical and thermal allodynia. An RNA sequencing study was conducted to identify the genes affected by paclitaxel and paeonol in the dorsal root ganglion. The results revealed that genes related to adiponectin pathways were upregulated by paeonol. Western blot results demonstrated that paclitaxel increased the expression of adiponectin in both the spinal cord and serum, and these effects were further enhanced by paeonol. These findings suggest that paeonol may protect against the paclitaxel-induced peripheral neuropathy by increasing the expression of adiponectin in serum and nervous tissue. Our data are expected to provide evidence for the neuroprotective effects of paeonol on CIPN and contribute to the development of new approaches for its treatment.

Title: Morphological analysis and deep learning prediction for peripheral neurotoxicity using cultured neurons in microfluidics

Authors: *I. SUZUKI, X. HAN, N. MATSUDA;
Tohoku Inst. of Technol., Sendai, Miyagi, Japan

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a major common adverse event associated with neurological abnormalities. An accurate assessment is essential to improve knowledge about CIPN incidence, and cultured neurons (i.e., primary rodent dorsal root ganglia (DRG), human iPS derived sensory) have recently been developed as *in vitro* models to study CIPN at the mechanistic level. In the present study, we developed a microfluidic device for structured culture of DRG and human iPS derived sensory neurons, and predict neurotoxicity induced by anticancer drugs based on neurites morphological analysis. This microfluidic culture device could separate the cell body and neurites, so that elongated neurites morphology can be analyzed alone. COP (Cyclo olefin polymer), which has excellent observability and low drug adsorption, is used as the resin material, and the bottom surface is created thin and flat enough for a clear view by microscope. Next, DRG or iPS sensory neurons was cultured in the device coated with Poly-L-lysine and Laminin. After culturing with a specific medium containing insulin, neurites grew sufficiently to occupy almost the whole microfluidic channel area, and the axon elongated unidirectional along the horizontal direction. The morphological changes of neurites can be clearly analyzed by immunostaining. After administration of several typical anti-cancer drugs, the morphological characteristics were analyzed by calculating neurite-related

parameters, especially neurite aggregation and induced hollowing. In addition, peripheral neurotoxicity was predicted by a deep learning AI trained with neurites image datasets. After training, AI could accurately detected neurotoxicity even at low concentrations. Therefore, this microfluidic device combined with morphological analysis is an effective *in vitro* toxicity assessment platform for peripheral neuropathies.

Title: Long-term intraocular pressure fluctuation & epiretinal membrane in patients with glaucoma or glaucoma suspect

Authors: *K. JUNG[1], C. PARK[2];
[1]Catholic Univ. of Korea, Seoul, Korea, Republic of; [2]Dept. of Ophthalmology, Seoul St. Mary's Hospital, Col. of Medicine, The Catholic Univ. of Korea, Seoul, Korea, Seoul, Korea, Republic of

Abstract: Epiretinal membrane (ERM) is a phenotype of a reactive gliosis because formation of ERM involves glial proliferation in response to retinal injury or disease involving inflammatory and glial cells. Glaucoma is characterized by progressive degeneration of retinal ganglion cells, for which increased intraocular pressure (IOP) is the most important risk factor. The associations between ERM and glaucoma were suggested in several studies. In an animal model undergoing intermittent IOP elevations, a reactive gliosis, a phenotype of ERM, was found in the optic nerve head. We investigated the association between IOP fluctuation and idiopathic ERM in patients with glaucoma or glaucoma suspect. In this retrospective study, a total of 84 patients with glaucoma or glaucoma suspect were included. Among them, forty one patients had no ERM and forty three patients had ERM. Long-term fluctuation of IOP was defined as the standard deviation (SD) of IOP at all visits. Patients were divided into two groups according to the median value of SD of IOP: the low IOP fluctuation group and high IOP fluctuation group. Among patients with available heart rate variability (HRV) data, the relationship between the HRV parameter and IOP fluctuation was analyzed. Patients with ERM was older and had higher IOP fluctuation and higher proportion of having history of cataract surgery and greater macular thickness (P=0.018, 0.049, 0.013, <0.001). The high IOP fluctuation group showed higher proportion of patients with ERM (62.5%) than the low IOP fluctuation group (36.4%, P=0.028). In the multiple logistic analysis, higher IOP fluctuation group were associated with the presence of ERM (P=0.047). Among patients with ERM, eyes with stage 3 or 4 ERM had worse visual field defects based on mean deviation than those with stage 1 or 2 ERM (P=0.025). The high IOP fluctuation group showed higher level of low frequency HRV, an index of sympathetic cardiac

control than the low IOP fluctuation group (P=0.027). Intereye comparison in eyes with ERM and the fellow eyes without ERM, eyes with ERM (2.2±0.9 mmHg) had higher fluctuation of IOP than those without ERM (2.0±0.8 mmHg, P=0.029). In conclusion, long-term IOP fluctuation had the relevance to idiopathic ERM in patients with glaucoma or glaucoma suspect. In glaucoma patients with ERM, more advanced stage ERMs were associated with worse visual field damage. Further studies are needed to determine if long-term IOP fluctuation affects the progression of glaucoma and reactive gliosis.

Title: Persistent Impairment of Spatial Memory and Hippocampus Neuronal Plasticity long after Repeated Intraperitoneal Injections of Lipopolysaccharide.

Authors: *E. GUTIERREZ-LOPEZ[1], K. R. GUZMAN-RAMOS[2], D. OSORIO-GÓMEZ[3], F. BERMÚDEZ-RATTONI[4];

Abstract: Neuroinflammation has been implicated in cognitive impairments associated with various neurological disorders related to memory. In this study, we aimed to investigate the effects of repeated lipopolysaccharide (LPS) intraperitoneal injections on spatial memory and neuronal plasticity in the hippocampus. Adult Wistar male rats were subjected to either saline or 5 LPS injections (250 μg/kg or 500 μg/kg) every 72 hours. LPS effects, Memory test, and neuronal plasticity were evaluated 1 week and 8 weeks after injections in independent groups. LPS effects in animals were measured by weight, spatial memory was assessed using the Morris Water Maze test (MWM), and neuronal plasticity was evaluated by Long Term Potentiation (LTP) on Perforant Pathway - Dentate Gyrus in the hippocampus. Our results revealed that rats receiving repeated LPS injections (250 μg/kg and 500 μg/kg) exhibited a significant weight lost during the treatment, but they regain weight one week after the last injection and this persisted 8 weeks later. Rats that received LPS injections (250 μg/kg and 500 μg/kg) showed impairment in spatial memory 1 week after treatment compared to the saline-treated group ($p < 0.05$). Additionally, LPS 250 μg/kg-treated group caused a lower LTP than the control group, and LPS 500 μg/kg-treated group induced but did not maintain the LTP ($p < 0.01$). Furthermore, we

assessed the long-term effects of LPS injections. Remarkably, the spatial memory impairment persisted only in the LPS 500 μg/kg-treated group even at this time point ($p < 0.05$). Neuronal plasticity alterations continued similarly in the LPS 500 μg/kg-treated group ($p < 0.05$), but the LPS 250 μg/kg-treated group increased the LTP at the same level that the saline-treated group ($p < 0.01$). In conclusion, repeated intraperitoneal injections of LPS induce persistent spatial memory deficits and alterations in neuronal plasticity in the hippocampus. The persisting impairments observed even eight weeks after treatment suggest long-lasting consequences of neuroinflammation. Further investigations are warranted to elucidate the underlying mechanisms and potential therapeutic interventions to mitigate these detrimental effects.

Title: Sarm1 deficiency regulates neuron intrinsic and extrinsic mechanisms of axon regeneration in the injured mammalian PNS

Authors: *H. J. HAFNER[1], L. B. SCHMITD[1], M. ATHAIYA[1,2], E. ASGHARI-ADIB[3], R. KOHEN[1,2], A. L. KALINSKI[1,4], R. J. GIGER[1,2];

Abstract: Injury to the mammalian peripheral nervous system triggers programmed disintegration of distal nerve fibers, a process known as Wallerian degeneration (WD). The NAD hydrolase, Sarm1, is required for the timely progression of WD. Sarm1 deficiency has recently been shown to enhance neuron intrinsic growth programs and axon regeneration in flies and worms. However, in the Wld^s mouse, delayed WD is associated with delayed axon regeneration. To investigate whether Sarm1 dependent WD is required for timely axon regeneration, adult wildtype (WT) and *Sarm1-/-* mice were subjected to sciatic nerve crush (SNC) injury. Primary DRG neurons from injured *Sarm1-/-* mice show enhanced neurite outgrowth compared to WT. However, the enhanced growth capacity of sensory neurons *in vitro* was not associated with increased regeneration of $SCG10^+$ sensory axons *in vivo* at 7 days post SNC. We hypothesized

that changes within the nerve microenvironment contribute to this delay. In the current study, immunofluorescence staining showed that Schwann cell (SC) differentiation into $p75^+$ repair (r)SC was impaired in the distal stump of *Sarm1-/-* nerves. Western blot analysis at 1-, 3-, 7-, 14- and 21-days post SNC showed that rSC differentiation is delayed and more transient than in parallel processed WT nerves. To better understand whether the delayed appearance of rSC contributes to poor axon regeneration, we developed a double crush injury model in which injured sciatic nerves were subjected to a second SNC 10 days after the first injury to assay axon regeneration in the distal nerve where rSC are present in WT and *Sarm1-/-* mice. Reprograming of rSC in the double SNC *Sarm1-/-* distal nerve was confirmed by upregulation of rSC associated genes at the mRNA and protein levels, including p75, sonic hedgehog, and c-jun. Regeneration of sensory axons into the *Sarm1-/-* distal stump 3 days after double SNC was improved compared to *Sarm1-/-* nerves 3 days after single SNC but was reduced compared to WT mice subjected to double SNC. Flow cytometric analysis showed that innate immune cell infiltration into the *Sarm1-/-* double SNC distal nerve remained impaired compared to parallel processed WT nerves and was associated with an accumulation of myelin proteins, MBP and P0, observed by western blot analysis. These results suggest that while *Sarm1* deficiency may enhance the intrinsic regenerative capacity of peripheral neurons, timely progression of WD is required to generate a growth permissive environment composed of rSC and immune cells that contribute to the removal of fiber debris.

Title: Lysosomal cholesterol hyperactivates mTORC1 contributing to pathogenesis in a CLN1 disease model

Authors: *A. P. APPU[1], M. B. BAGH[2], N. PLAVELIL[3], A. MONDAL[2], T. SADHUKHAN[2], A. LIU[2], A. B. MUKHERJEE[4];
[1]NICHD/Eunice Kennedy Shriver Nat'l Inst. of Child H, Bethesda, MD; [3]NICHD, [2]NIH, Bethesda, MD; [4]NICHD (National Inst. of Child Hlth. and Human Development), Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: The CLN1-disease, a devastating neurodegenerative lysosomal storage disorder (LSD), is caused by mutations in the *CLN1* gene. *CLN1* encodes palmitoyl-protein thioesterase-1 (PPT1), which depalmitoylates S-palmitoylated proteins (constituents of ceroid lipofuscin). Despite this discovery, the mechanism of CLN1 disease-pathogenesis has remained elusive. Recently, lysosomal cholesterol has been reported to activate mTORC1 kinase suppressing autophagy, which cause neurodegeneration in most LSDs. We found that in the brain of *Cln1*$^{-/-}$ mice, which mimic INCL, the lysosomal cholesterol level is significantly higher compared with that in their WT littermates. Intriguingly, in *Cln1*$^{-/-}$ mice, the level of Niemann Pick C1 (NPC1) in lysosomal fractions was significantly lower compared with that in their WT littermates. Moreover, NPC1 requires dynamic S-palmitoylation for trafficking to the lysosomal surface and in *Cln1*$^{-/-}$ mice, lack of Ppt1 misrouted NPC1-protein to the plasma membrane instead of its normal location on lysosomal membrane. Further, we found that Ppt1-deficiency in *Cln1*$^{-/-}$ mice lack of dynamic S-palmitoylation of NPC1 prevented its handover from adapter protein-2 (AP-2) to AP-3. Consequently, NPC1 was not transported to lysosomal membrane and misrouted to the plasma membrane. Along with this defect, the level of oxysterol binding protein (OSBP) and its anchoring proteins-VAPA and VAPB mediated increased cholesterol on lysosomal limiting membrane mediating mTORC1-activation, which suppressed autophagy. To determine whether inhibition of OSBP may rescue autophagy, we treated cultured CLN1 disease lymphoblasts and *Cln1*$^{-/-}$ mice with a pharmacological inhibitor of OSBP, OSW1. The results showed a significant suppression of activated mTORC1-markers, pS6K1 and p4E-BP1 and autophagy markers, LC3B and p62 in both CLN1 disease lymphoblasts and in *Cln1*$^{-/-}$ mice treated with OSW1. Importantly, we found that pharmacological inhibition of OSBP suppressed mTORC1 activation, rescued autophagy and protected the neurons in the brain of *Cln1*$^{-/-}$ mice. Our findings uncover a previously unrecognized role of *Cln1/*Ppt1 in lysosomal cholesterol homeostasis and reveal a novel targetable pathway for CLN1 disease.

Title: Cuprizone-induced demyelination in the mouse - Immnunohistochemical characterization

Authors: *E. ESNEAULT, C. RONDEAU, S. COTTEREAU, S. PEDRON, F. SIMON; Porsolt, Le Genest St Isle, France

Abstract: Multiple sclerosis (MS), an auto-immune disease, is the most common disabling pathology in the young adult. Occurrence of plaques and demyelination are some hallmarks of this auto-immune disease and are mainly observed in the brain, optic nerves and spinal cord.

While advances in the understanding of the physiopathology of MS and in the treatment of relapsing disease have been made, there is still a need to improve the current therapies and find effective treatments to counteract the progression of the disease. This emphasizes the utility of translational animal models to evaluate new therapeutic approaches. The Cuprizone model is one of the more common MS models used to induce oligodendrocyte apoptosis at an early stage and demyelination after several weeks of exposure. The aim of the experiment was to determine functional and histopathological hallmarks of the cuprizone model in the mouse. C57/BL6 mice were fed with Cuprizone at 0.2% during 5 consecutive weeks. Time-course behavioral assessment was performed. The mice were evaluated in the rotarod and beam walking tests for motor coordination, in the wire hang test for muscular strength assessment and in the electronic Von Frey test for allodynia evaluation. Brains as well as spinal cords were collected at the end of the experiment for immunohistochemistry (IHC). Neuroinflammation and demyelination were assessed in different brain regions and at several spinal cord levels. The results showed that motor and muscular strength performances were not affected in cuprizone-intoxicated mice over the 5 weeks while a loss of body weight was observed. Pain sensitivity level evaluated by tactile allodynia was also not modified. An increase of Iba1 and GFAP immunostaining in the corpus callosum, and to a lesser extent in the cortex, were detected by IHC analysis. This was accompanied by a decrease of MBP immunostaining in the corpus callosum as well as in the cortex, suggesting a diffuse demyelination both in the white matter and in the gray matter. No clear effects were observed on Iba1, GFAP and MBP immunostaining in the spinal cord. Microglial and astrocyte activation followed by demyelination are the main histopathological hallmarks during the early phase of MS. The cuprizone model can therefore be a useful and predictive model for evaluating the potency of a new test item to induce remyelination, or its potency to accelerate an ongoing remyelination, following cuprizone intoxication.

Title: Inactivating mutations in the CLN1 gene dysregulate ER-Golgi trafficking of proteins causing ER-stress in CLN1 disease

Authors: *N. PLAVELIL, A. P APPU, A. MONDAL, A. B MUKHERJEE;
NIH, Bethesda, MD

Abstract: Inactivating mutations in the *CLN1* gene encoding a depalmitoylating enzyme, palmitoyl-protein thioesterase-1 (PPT1). Although *Cln1*$^{-/-}$ mice, which mimic human CLN1 disease, manifest ER-stress leading to neuronal apoptosis the mechanism underlying this defect has remained elusive. The newly synthesized proteins are transported from the ER to the Golgi via COPII vesicles. We tested a hypothesis that PPT1-deficiency impairs ER-Golgi transport causing ER-stress. We found that the levels of COPII-associated proteins are significantly higher in *Cln1*$^{-/-}$ mice compared with those in their WT littermates. Moreover, the level of these proteins in purified ER-fractions from *Cln1*$^{-/-}$ mouse brain was also elevated. We found that COPII proteins (e. g. Sec31A, Sec23A and Sec24A) require dynamic S-palmitoylation for their trafficking from the ER to Golgi. Intriguingly, in *Cln1*$^{-/-}$ mice, a reliable animal model of human CLN1 disease, the interaction of Sec23A and Sec24A with Sar1, required for COPII vesicle-formation, was significantly higher compared with those in WT littermates. The level of Sar1-GTP (active), which facilitates the export of proteins from the ER to the Golgi, was also increased in *Cln1*$^{-/-}$ mouse brain. To confirm this finding, we performed colocalization studies using cultured fibroblasts from CLN1-disease patients. The results showed that in CLN1-disease fibroblasts virtually all COPII-proteins except Sec13, a non-palmitoylated protein, were accumulated at a higher level in the ER compared with that in normal fibroblasts. Since CLN1 disease causes ER-stress and our results showed defective anterograde trafficking, we sought to determine the level of CLN8 in the ER. Remarkably, the levels of CLN8 in isolated ER fractions, were significantly higher in *Cln1*$^{-/-}$ mice compared with those in their WT littermates. Furthermore, the higher ER-localization of CLN8 in CLN1 disease-fibroblasts correlated with markedly lower colocalization with the Golgi-marker. Taken together, these results demonstrate that anterograde (ER-Golgi)-trafficking of proteins is defective in CLN1 disease. Our findings reveal a previously unrecognized function of *Cln1*/Ppt1 in ER-Golgi trafficking of proteins and explain, at least in part, a mechanism underlying ER-stress in CLN1-disease.

Title: Anti-myelin immunoglobulins from patients with multiple sclerosis may contribute to myelin pathology independently of demyelination

Authors: *A. S. LAPATO[1], K. GIVEN[1], N. J. JAHAHN[1], G. OWENS[2], J. L. BENNETT[3], W. B. MACKLIN[1];

[1]Cell and Developmental Biol., [2]Neurol., [3]Neurol. and Ophthalmology, Univ. of Colorado Anschutz Med. Campus, Denver, CO

Abstract: Multiple sclerosis (MS) patients acquire temporally disseminated demyelinating lesions that frequently do not repair. One under-examined mechanism of remyelination failure in MS may be persistence of immunoglobulins (Igs) after initial demyelinating injury. Using our ex vivo murine organotypic cerebellar demyelination/remyelination culture model, we show that myelin-binding recombinant IgGs (rAbs) cloned from MS patient intrathecal B cell repertoires hamper remyelination independently of complement activation. In this system, the myelin formed during remyelination in the presence of MS rAbs displays various abnormalities, including outfolding and lack of association with remaining axons, at a rate greater than control. Glutathione-S-transferase π immunoreactivity was less frequent among CC-1+ post-mitotic oligodendroglia in MS rAb-treated cultures, suggesting that MS rAbs are sufficient to impede oligodendrocyte maturation (n=25-40 folia). To understand this system, we investigated the effect of myelin-binding MS rAbs specifically on oligodendrocytes, studying differentiating primary rat oligodendrocyte precursor cells (rOPCs). When oligodendrocytes were differentiated as primary cells on cover slips in the presence of MS- or isotype control- rAbs, myelin-binding MS rAbs stimulated higher per cell myelin protein immunoreactivity relative to control rAb or vehicle, suggesting dysregulated myelination. MS rAb binding was associated with more robust phosphorylation of the Src family kinase, Fyn, which has been shown to drive myelination in vivo. However, MS rAb-treated cells also showed various membrane derangements, with a subset displaying dramatic labyrinthine membrane topology enriched for the microtubule associated protein, Tau. Tau+ membrane inclusions were immunoreactive for the hyperphosphorylated moiety typically seen in the context of tauopathy, suggesting aberrant signaling (n=30-60 cells). Intriguingly, when rOPCs were differentiated on inert 2 µm nanofibers, cells made fewer wraps and had shorter average wrap lengths in the presence of MS rAb relative to control (n=15-40 cells). Together, these data suggest that Ig deposition alone may interfere with myelin repair in MS, representing a heretofore under appreciated mode of remyelination failure.

Title: The pathogenic contribution of galactosylceramidase to late onset demyelination in the mouse and human brain

Authors: *N. SALDIVIA, D. ZELADA, J. WHITEHAIR, G. J. HELLER, M. I. GIVOGRI, E. R. BONGARZONE;

Abstract: The mechanisms underpinning adult brain demyelination in disorders such as Multiple Sclerosis (MS) are largely unclear. A cosmos of genes has been identified in GWAS studies as genetic risk factors, which in addition to environmental insults such as viral infections may lead to increased white matter vulnerability. Our research largely uses models of lysosomal storage diseases, as these provide excellent experimental models to test basic biological hypotheses. Krabbe disease (KD) is an autosomal recessive leukodystrophy caused by mutations in the lysosomal enzyme galactosylceramidase (GALC). Despite of being very distinct, KD bears some parallelism with MS. For example, GALC variants have been proposed as risk factors in MS, both conditions undergo neuroinflammatory demyelination, and both develop neuronal deficits. In KD, the toxic accumulation of galactosylsphingosine (psychosine) metabolite occurs owed to GALC deficiency, leading to an early onset of rapid and diffuse demyelination of white matter. This can largely be prevented using our gene therapy protocol with AAV9-GALC vectors delivered to newborn GALC deficient pups (Twitcher, TWI). Gene therapy normalized GALC activity, and significantly ameliorated central and peripheral neuropathology, with a significant extension in lifespan, and importantly, preservation of functional white matter in the brain for several months after treatment. However, as treated TWI mice aged, multiple focal demyelinating areas developed in white matter areas in their brains. These lesions showed deficits of GALC and elevation of psychosine content, in sharp contrast to neighboring normal-appearing white matter. Lesions were surrounded by inflammatory gliosis and affected by extravasation of fibrinogen from near blood vessels. Due to the similarity in the neuropathological presentation with demyelinating plaques observed in MS, we hypothesize that adult dysfunction of GALC metabolism in MS patients may contribute to local deficiencies in brain white matter and enhance vulnerability to demyelination. We are testing this hypothesis by determining GALC metabolic status of demyelinating plaques in human MS tissue.

Title: Moderation effects of cumulative hair cortisol and self reported stress on the relationship between brain atrophy and cognition in a diverse multiple sclerosis sample

Authors: *S. MOODY[1], M. MANUEL[2], J. LOVERA[3], B. COPELAND[3], A. A. WILLETTE[4], E. SHIRTCLIFF[5], D. DEVIER[6];
[1]Neurol., LSU Hlth. Sci. Ctr., New Orleans, LA; [2]Cell. Biol. and Anat., Augusta Univ., Augusta, GA; [3]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [4]Natl. Inst. On Aging, Baltimore, MD; [5]Univ. of Oregon, Eugene, OR; [6]Neurol. | Cell Biol., LSU Hlth. Sci., New Orleans, LA

Abstract: Exacerbation of symptoms in Multiple Sclerosis (MS) due to stress are documented for both onset and relapse. Social stressors are linked to early age of MS onset for individuals with high adverse childhood experience scores. The association between dampened and elevated cortisol levels and MS outcomes, as well as mutations in glucocorticoid receptors predicting both the likelihood of diagnosis and severity of MS indicates stress's role on a biological level as well. Race and sex are explicitly linked by way of social stressors and predict onset, severity, and mortality of MS. Despite the cumulative effect on stress and the differences in MS at the intersection of race and sex, few studies have examined how markers of stress impact MS in the context of race and sex. To examine this gap, we used regression models to test whether the relationship between brain atrophy (third ventricle width: 3VW) and clinical outcomes of MS are moderated by biological (e.g., cortisol) and psychosocial (e.g., perceived social stress: PSS) markers of stress. Black (N=47) and White (N=58) non-Hispanic MS patients, age (M: 45.87, R: 19-71, SD: 12.96) were recruited from the U.S. in the gulf coast region. Participants completed cognitive (e.g., symbol digit modalities test: SDMT) and physiological (e.g., Expanded Disability Status Scale: EDSS | MS Severity Scores: MSSS) assessments, questionnaires on demographics, reported experiences of stress, provided hair to assess cumulative levels of cortisol, and granted access to their clinical MRI scans.High cortisol was associated with worse scores on the SDMT [$F(1, 55) = 5.982$, $p = .018$], ($R^2 = [.098]$, $\beta = [-2.56]$) but when parsed by race, only remained in White participants [$F(1, 27) = 5.614$, $p = .025$], ($R^2 = [.172]$), $\beta = [-3.608]$). High cortisol was also associated with larger 3VW [$F(1, 38) = 7.236$, $p = .011$], ($R^2 = [.16]$, $\beta = [.511]$) and again only remained significant for White participants [$F(1, 24) = 11.866$, $p = .002$], ($R^2 = [.331]$) ($\beta = [.740]$).
Cortisol only moderated the relationship between 3VW and SDMT in Black participants [$F(3, 8) = 3.938$, $p = .040$], (▲ $R^2 = .301$), such that high cortisol and larger 3VW were associated with poorer SDMT scores. PSS only moderated the relationship between 3VW and SDMT in Black participants [$F(3, 7) = 2.28$, $p = .046$], (▲ $R^2 = .375$), such that participants with low levels of PSS and large 3VW were associated with lower SDMT scores. Black participants with high PSS showed little difference in SDMT performance regardless of large or small 3VW. These findings suggest that the impact of biopsychosocial indices of stress on clinical outcomes of MS may differ based on the race of an individual.

Title: STAT3 siRNA-encapsulated PLGA nanoparticles mitigate experimental autoimmune encephalomyelitis by inhibiting immune cell infiltration.

Authors: T. KWON[1], Y. SEO[2], I.-H. CHO[2];
[1]Dept. of Convergence Med. Science, Col. of Korean Medicine, Kyung Hee Univ., Seuol, Korea, Republic of; [2]Dept. of Convergence Med. Science, Col. of Korean Medicine, Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Background: Signal transducer and activator of transcription 3 (STAT3) is a transcription factor that is activated by cytokines and growth factors. Expression of STAT3 is increased in multiple sclerosis (MS) and experimental autoimmune encephalomyelitis (EAE). It contributes to peripheral-derived immune cell infiltration, demyelination and neuroinflammation. Therefore, regulation of STAT3 expression is expected to play an important role in disease improvement in MS and EAE. **Methods:** In this study, effectiveness of STAT3 siRNA-encapsulated PLGA nanoparticles (5, 10 and 20 mg/ml) in EAE was investigated using a rodent model of MS. **Results:** Inhibition of STAT3 with P-siSTAT3 at the onset point ameliorated motor impairment in EAE mice. In particular, P-siSTAT3 improved symptoms of EAE associated with demyelination, infiltration and activation of immune cells (resident microglia, monocyte-derived macrophage), increased expression levels of inflammatory mediators (iNOS and COX-2), inflammatory cytokines (IL-1β, IL-6 and TNF-α) and chemokines (MIP-1α, MCP-1 and RANTES) in the lumbar spinal cord compared to the control. It also reduced the infiltration of $CD4^+$/IFN-γ^+ (Th1) and $CD4^+$/IL-17^+(Th17) cells into the lumbar spinal cord in EAE mice with downregulated mRNA expression levels of IFN-γ, T-bet, IL-17 and RORγt. Additionally, it preserved the integrity of the blood-brain barrier. These positive effects of P-siSTAT3 are expected to regulate inflammatory responses of resident microglia. **Conclusions:** P-siSTAT3 can alleviate EAE by preserving inflammatory responses and BBB integrity. These results suggest that P-siSTAT3 might have potential therapeutic implications in autoimmune demyelinating diseases such as MS through maintenance of BBB integrity.

Title: Characterization of WD-910, a CNS-penetrant TYK2 Inhibitor for the treatment of CNS diseases

Authors: *N. WANG, M;
Zhejiang Wenda Pharma, Guilford, CT

Abstract: TYK2 (JH2, pseudokinase domain) is a key regulator of IL-12, IL-23 and type I interferons signaling pathways, which have been shown to be involved in the pathogenesis of multiple inflammatory and autoimmune diseases such as psoriasis, lupus, inflammatory bowel diseases (IBD), multiple sclerosis (MS), Parkinson's disease (PD), stroke, and Alzheimer disease (AD). Sotyktu™(deucravacitinib , BMS986165) blocks TYK2 signals and has been approved by FDA to treat adults with moderate-to-severe plaque psoriasis without toxicity potential and also is in phase III trial for lupus. Here, we report a potent CNS-penetrant oral TYK2 allosteric inhibitor, WD-910, with high selectivity and potency through optimized binding to the JH2 domain of the TYK2 protein. WD-910 inhibits IFNα triggered pSTAT5 potently in human whole blood assay. In addition, WD-910 has excellent selectivity against other JAK family kinases. Furthermore, therapeutic efficacy of WD-190 has been evaluated in an experimental autoimmune encephalomyelitis (EAE) mouse model that shares many features of human MS. The results show WD-190 significantly reduces the disease progress after starting its treatment at the peak of the disease even in low dose. In vivo pharmacodynamic study indicates that WD-910 significantly reverses IL12/18-induced IFNγ and Th17 development, decreasing IL-17, IL-22, and TNF-α production, with concomitant increase in Treg numbers, in mouse. WD-910 brain/plasma ratio has been evaluated by measuring brain and plasma concentrations to have outstandingly 1.3 ratio. In summary, WD-910 is a highly selective, potent and CNS-penetrant oral small molecule TYK2 inhibitor (JH2) exhibiting great therapeutics in CNS neuroinflammatory diseases, like MS, PD and AD.

Title: Exposure to Multiple Sclerosis Autoantibodies Impairs Remyelination

Authors: *G. PEET[1], A. LAPATO[3], B. FRIETZE[4], K. GIVEN[2], G. OWENS[2], J. L. BENNETT[2], W. B. MACKLIN[5];

Abstract: Multiple Sclerosis (MS) is an immune-mediated disorder of the central nervous system. Its pathogenesis is poorly understood. Myelin reactive antibodies are found in MS patient parenchyma and cerebrospinal fluid and treatments that target the antibody-producing B-cell compartment improve MS progression markedly. Still, the role of these antibodies in MS lesions remains largely obscure. We developed a novel mouse model of autoimmune demyelination of the central nervous system. MS patient-derived myelin-binding autoantibodies cause complement-mediated demyelination in the brain and in organotypic slice cultures. This model produces lesions characterized by massive oligodendrocyte cell death, microglial phagocytosis of myelin debris, and robust, but incomplete, remyelination. Interestingly, continued exposure to the autoreactive antibodies without complement during remyelination altered the quality of newly regenerated myelin, i.e., the production of more non-axon associated myelin, suggesting a deleterious role for myelin reactive antibodies beyond primary demyelination. We sought to understand if chronic myelin-reactive antibodies could cause remyelination failure in MS. We hypothesized that this remyelination failure could be caused by altered microglial function in the presence of myelin-reactive antibodies. Single-cell RNA sequencing of microglia from remyelinating cerebellar slices with or without chronic myelin-reactive antibody exposure revealed increased Gpnmb, a known modulator of myelination, as well as an interferon-responsive gene signature. To assess the relevance of increased Gpnmb expression, primary rat oligodendrocyte progenitor cells were cultured in the presence of 100 ng/mL GPNMB ectodomain. GPNMB increased O4+ oligodendrocyte density and induced integrin signaling via FAK and AKT in cells maintained in the OPC state but did not alter integrin signaling in differentiated oligodendrocytes. Treatment of remyelinating cerebellar slices with GPNMB did not reduce the quantity of mistargeted myelin noted above, but increased the quantity of myelin found on axons, suggesting GPNMB may improve myelination. Future work will dissect the contributions of microglial function and oligodendrocyte response driven by chronic exposure to myelin-reactive antibodies and seek to characterize these effects in vivo.

Title: Subjective Vs. Objective Cannabis Use Grouping: Implications for Cross-Sectional Analyses in People with Multiple Sclerosis

Authors: *J. R. DETERS[1], L. L. BOLES PONTO[2], D. J. MOSER[3], J. KAMHOLZ[4], P. E. GANDER[2], T. RUDROFF[5];
[1]Hlth. and Human Physiol., [2]Dept. of Radiology, [3]Dept. of Psychiatry, [4]Dept. of Neurol., [5]Dept Hlth. & Human Physiol., Univ. of Iowa, Iowa City, IA

Abstract: α-9-tetrahydrocannabinol (THC) and cannabidiol (CBD), constituents of *cannabis sativa*, are growing in popularity for Multiple Sclerosis (MS) treatment due to the purported medical benefits for symptoms such as pain and muscle spasticity. Regulation and oversight of medical cannabis products are currently not comparable to FDA-approved drugs, and unsurprisingly, variability in label accuracy for legally purchased medical cannabis products has been reported. Therefore, we sought to investigate whether this was the case in a community sample of people with MS (PwMS). PwMS (N=10) consuming legally purchased cannabis products reportedly containing THC and/or CBD for at least 6 months were recruited. Cannabis consumption habits were recorded. A blood draw was also performed on each subject at least four hours post last use to test for the presence/concentration of the main metabolites of THC (11-OH-THC, THC-COOH) and CBD (7-OH-CBD, 7-COOH-CBD). Additionally, brain glucose metabolism was assessed with Positron Emission Tomography using the glucose analog [^{18}F]-fluorodeoxyglucose. Standardized (to patient bodyweight) uptake values (SUV; g/mL) in addition to a relative regional metabolism value (RRM; normalized in reference to volume-weight global mean SUV) were calculated for brain regions known to have high concentrations of cannabinoid receptors (hippocampus, amygdala, basal ganglia, cingulate gyrus, cerebellum). These values were compared between groups using independent samples t-tests. When grouping by subject reporting (THC = 4, CBD = 3, THC+CBD = 3), there were no differences seen across all brain regions assessed, and only the right anterior cingulate gyrus approached significance when measuring RRM ($p = 0.09$). Importantly, plasma levels of THC and CBD metabolites in PwMS did not correspond with the reported product being consumed, and thus subjects were regrouped into CBD-only (N=3) and THC+CBD groups (N = 6; 1 subject had no CBD or THC metabolites). When the regions were re-analyzed with this objective grouping, the bilateral hippocampus and amygdala had higher RRM values in the THC+CBD group compared to the CBD-only group (i.e., increased metabolism; all $p < 0.04$). The right caudate nucleus, pallidum and posterior cingulate gyrus all were approaching significance but did not meet the threshold ($0.05 \leq p \leq 0.10$; THC+CBD group < CBD-only SUV in each region). This is significant, as much of the literature on cannabis does not objectively verify consumption. Thus, our data suggest that it is necessary to utilize objective verification methods for cannabis use, otherwise the validity of the results come into question with respect to actual drug usage.

Title: TPPB modulates the activity of innate immune cells and alleviates the neurologic symptoms in EAE model

Authors: *S. SHANMUKHA, W. GODFREY, P. GHARIBANI, M. D. KORNBERG, P. M. KIM;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Multiple sclerosis (MS) is a chronic neuroinflammatory disorder of the central nervous system resulting in demyelination of axons and loss of neurons. Available MS therapies with limited potential, rises the need for novel therapies with improved efficacy, safety, and targeted mechanisms of action to address the complex nature of the disease. The current research is aimed to find neuroprotective potential of TPPB (2S,5S)-(E,E)-8-(5-(4-(Trifluoromethyl)phenyl)-2,4-pentadienoylamino)benzolactam), a cell-permeable high affinity protein kinase C (PKC) modulator, in experimental autoimmune encephalomyelitis (EAE) model of MS. EAE was induced by immunizing the C57BL/6 mice with myelin oligodendrocyte glycoprotein peptide (MOG35-55). In this study we show that TPPB could alleviate the neurological deficits of EAE when administered intraperitoneally (IP) at a dose of 25 μg/kg, three days per week at the onset of MS clinical signs. Furthermore, in vitro treatment of bone marrow derived macrophages with TPPB resulted in a significant reduction in interleukin (IL)-12 levels, as determined by enzyme-linked immunosorbent assay (ELISA), and a concomitant increase in IL-10 levels indicating that TPPB promotes an anti-inflammatory phenotype. In addition, flow cytometric analysis revealed that the therapeutic treatment with TPPB suppresses the central nervous system inflammation as shown by the reduction in the elevated population of CD11B+CD45+ cells in brain and spinal cord and CD4+/IL-17+ T cells in the spinal cord of EAE mice. There was increased the population of CD4+Foxp3+ regulatory T cells (Treg) cells in brain and CCD11B+CD45+CD206+ cells in the spinal cord of TPPB treated group suggesting a regulatory mechanism aimed at dampening the immune response in EAE. Overall, this study suggests that TPPB, through its activity on PKC, could modulate innate immunity and promote a regenerative activity in these cells, which will have a significant clinical implication in MS treatment.

Title: Distinct brain cellular responses to chronic low-level arsenic exposure in mice

Authors: *M. ALAM, N. F. FITZ;
Envrn. & Occup. Hlth., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Abstract: Arsenic (As) is a naturally occurring metalloid element that is both widely distributed in the environment and chronic environmental As exposure affects the health of millions of people worldwide. One of the major sources of As exposure is through ingestion of contaminated groundwater. Arsenic can easily pass blood-brain barrier, accumulating in brain and epidemiologic studies demonstrate associations between As exposure and cognitive deficits in children and poor global cognition in adults. However, much less is known about the underlying molecular and cellular mechanisms in brain associated with As exposure. Recently, we have shown that chronic low level (100 ppb) As exposure caused significantly diminished cognition in wild-type mice and in whole brain tissue presented with a unique epigenetic signature associated neurodegeneration. No studies have determined how As exposure impacts particular brain cell types. We hypothesize that arsenic induces complex pathophysiological signaling mechanisms between neurons and glial cells through epigenomic and transcriptional changes, impacting healthy brain aging. To test this, we treated C57BL/6 wild-type mice for 4 months with 100 ppb sodium arsenite via drinking water and compared them to mice on control drinking water. We performed CUT&TAG and RNA-seq on MACS sorted microglia ($CD11b^{+}$), astrocytes ($ACSA\text{-}2^{+}$) & neuron (negative selection) from cortical tissue of both groups. The initial results of our experiments show that the number of differentially expressed genes (DEG) ($p < 0.05$) in astrocytes (772 genes) and neurons (873 genes) is higher than microglia (208 genes) when comparing the As group to controls. The examination of gene ontology (GO) indicates higher number of significantly down regulated genes in astrocytes associated with lipid metabolic process, brain development, synapse assembly following As exposure. In neurons, down regulated genes in the As group were associated with lipid metabolism, immune system process, and inflammatory response. Assessment of histone modifications follow As exposure support the transcriptional signatures. This indicates pathological mechanisms in response to As exposure could accelerate susceptibility to neurodegeneration or modify normal brain aging.

Title: Development of a functional cell-based assay and cellular thermal shift to screen for modulators of Phospholipase C-gamma 2, PLCG2.

Authors: *F. E. JEGANATHAN[1,2], L. MAGNO[2], E. MEAD[3], K. COSTELLOE[2], E. MURPHY[3], J. HENDERSON[3], F. SVENSSON[2], M. BICTASH[2], P. FISH[2], P. WHITING[2], P. BRENNAN[3], F. DUCOTTERD[2];
[1]Univ. Col. London, London, United Kingdom; [2]ARUK UCL Drug Discovery Institute, London, London, United Kingdom; [3]ARUK Oxford Drug Discovery Inst., Oxford, United Kingdom

Abstract: The PLCγ2 isoform is predominantly expressed in the immune and haematopoietic cells and is differentially regulated by receptor tyrosine kinases (RTKs) or non-receptor tyrosine kinases. It selectively hydrolyses 1-phosphatidyl-1D-myo-inositol 4,5-bisphosphate to secondary messengers' inositol-3-phosphate (IP3) and diacylglycerol. Genome Wide Association Studies (GWAS) have identified a novel coding variant (P522R) in the immune gene Phospholipase C-gamma 2 that is protective against the cognitive decline associated with late onset Alzheimer's Disease (LOAD) and identifying small molecules that target PLCγ2 is a novel therapeutic strategy for AD. To identify modulators of PLCγ2 we developed a B cell RAMOS assay, since the PLCγ2 pathway downstream of the B cell receptor is well characterised and complemented this with the **Ce**llular **T**hermal **S**hift **A**ssay®. PLCγ2 is the predominant PLC isoform in the RAMOS B cells and the protocol was optimised for use with cells in suspension. Reaction conditions were optimised to identify small molecule modulators of the B cell pathway using a biochemical IP1 HTRF endpoint as a readout of IP3 production. In the THP-1 macrophage cells, where PLCγ2 is highly expressed, the remaining intact PLCγ2 protein was measured after heat shock in the presence of compounds to determine that the compounds were either on target or proximal to PLCγ2 whilst eliciting the desired pharmacological profile. We used these approaches in parallel to screen a library of 20,000 diversity compounds and identified 62 potentiators that were concordant across both. The compounds were screened in single-point and selected compounds were run to determine EC_{50}. Cut-off criteria for failing plates were Z prime < 0.5 and CV>10%. B scoring normalisation was used to correct for plate and positional effects. % Effect was calculated over DMSO controls. These approaches identified novel modulators of the PLCγ2 pathway with an overall hit rate of 0.31%. We used functional and biophysical cell-based approaches to identify positive modulators of PLCγ2. This offered the advantage of identifying compounds engaging with the activated form of PLCγ2 in the cellular environment where the membrane, native substrate and other interacting partners of the complex are present. It is unclear how the PLCγ2 P522R variant exerts its protective effect but the higher PLC activity could be achieved by adopting a more stable active form or by enhanced interactions with regulatory proteins or membrane. The combination of these approaches allowed identification of novel modulators of the PLCγ2 pathway.

Title: Increased activity of IRE1 improves the clinical presentation of EAE

Authors: *V. BRACCHI-RICARD[1], K. NGUYEN[1], D. RICCI[2], B. GAUDETTE[2], J. HENAO-MEIJA[2], R. BRAMBILLA[3], T. MARTYNYUK[1], T. GIDALEVITZ[1], D. ALLMAN[2], J. R. BETHEA[1], Y. ARGON[2];
[1]Drexel Univ., Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Activation of the ER stress sensor IRE1α contributes to neuronal development and is known to induce neuronal remodeling *in vitro* and *in vivo*. On the other hand, excessive IRE1 activity is often detrimental and may contribute to neurodegeneration. To determine the consequences of increased activation of IRE1α, we used a mouse model expressing a C148S variant of IRE1α with increased and sustained activation. Surprisingly, the mutation did not affect the differentiation of highly secretory antibody-producing cells but exhibited a strong protective effect in a mouse model of experimental autoimmune encephalomyelitis (EAE). Significant improvement in motor function was found in IRE1C148S mice with EAE relative to WT mice. Coincident with this improvement, there was reduced microgliosis in the spinal cord of IRE1C148S mice, with reduced expression of pro-inflammatory cytokine genes. This was accompanied by reduced axonal degeneration and enhanced CNPase levels, suggestiing improved myelin integrity. Interestingly, while the IRE1C148S mutation is expressed in all cells, the reduction in proinflammatory cytokines and in the activation of microglial activation marker IBA1, along with preservation of phagocytic gene expression, all point to microglia as the cell type contributing to the clinical improvement in IRE1C148S animals. Our data suggests that sustained increase in IRE1α activity can be protective *in vivo*, and that this protection is cell type and context dependent. Considering the overwhelming but conflicting evidence for the role of ER stress in neurological diseases, a better understanding of the function of ER stress sensors in physiological contexts is clearly needed.

Title: Analysis of neuropathology of multiple sclerosis brain using Akoya's PhenoCycler-Fusion Technology with particular attention to Epstein Barr Nuclear Antigen-1 and its related molecular mimics Including glialCAM, anoctamin-2, myelin basic protein, alpha-crystallin B, myocyte enhancer factor 2B

Authors: N. OR-GEVA[1], A. KHAN[2], C. RAPOSO[3], A. PRATAPA[2], B. TACKENBERG[3], R. PEDOTTI[3], N. MAMMADOVA[2], ***L. STEINMAN**[1];

Abstract: Epstein Barr Virus (EBV) has been identified as the trigger for multiple sclerosis (MS). Antibody to Epstein Barr Nuclear Factor-1 (EBNA1) is present in nearly 100% of patients with MS before the development of clinical symptoms appears. Infection with EBV is necessary, but not sufficient, for causation of disease. Within a region of fifty amino acids in EBNA1 are molecular mimics of portions of four molecules, GlialCAM, Anoctamin-2 (ANO2), Myelin Basic Protein (MBP), and alpha Crystallin-B (CRYAB). Immune responses via T cells and antibodies to these four molecules, play key roles in the pathogenesis of MS. These molecular mimics within EBNA-1 include portions of a channel protein ANO2, a chloride channel. GlialCAM is a chaperone of another channel protein, aquaporin 4 (AQP4). The third mimic in this hotspot of molecular mimicry includes portions of an abundant structural protein of myelin, MBP. The fourth notable molecular mimic is a portion of a small heat shock protein alpha-crystallin B, CRYAB. CRYAB has protective properties against neuroinflammation, and immunity to CRYAB exacerbates damage to the nervous system. Some of the peptide motifs contained in this region of EBNA-1 are congruent with similar motifs in the U24 protein of human herpes virus 6, and in the myocyte enhancer factor 2B, MEF2b. MEF2b, like EBNA-1 itself, is critical for maintaining the latency of EBV. Using Akoya's PhenoCycler-Fusion, an ultra-high multiplexed imaging system to interrogate 40+ biomarkers (including immune, neuronal, and viral markers) at the single cell level, allows unprecedented high dimensional profiling of MS tissue, revealing spatial locations of critical cells and molecules involved in the pathogenesis of MS. Using this method, the investigators have identified CD20 B cells in perivascular regions of MS brain expressing EBNA1 and latent membrane protein 1 (LMP1). Neuronal loss, microglial and astrocytic involvement are evident as is the presence of $CD4^+$ and $CD8^+$ T cells in the MS brain. This research highlights the importance of understanding the role of EBV and the potential of high-dimensional profiling techniques in unraveling the pathophysiology of MS.

Abstract: Methyl bromide is a colorless, nearly odorless, gas used to fumigate against insects, nematodes and rodents in agriculture and shipping. Methyl bromide is a neurotoxicant known to elicit neurological deficits from acute and chronic inhalation exposures. Although multiple clinical reports have shown methyl bromide induced neural deficits, the cellular and functional impacts of low-level occupational exposures have not been fully characterized. The primary objective of this study was to identify functional and anatomical changes from repeated exposure to methyl bromide. To achieve our objective, we used a nose-only exposure system to expose adult male Sprague Dawley rats to either room air, 50, 150, or 300 ppm of methyl bromide for 2 hours a day, 5 days a week for 4 weeks. The week following exposures, the rats were examined for voluntary locomotor gait changes, and significant changes in gait of multiple aspects of both the stance and swing phases of locomotor movement were observed. Likewise, we found a 10% increase in the base of support during voluntary locomotor gait suggesting additional stability requirements. Neuromuscular or cerebellar changes often underlie locomotor changes, so we analyzed the cerebellum, spinal cord, and neuromuscular junctions. We found approximately a 10% increase in reactive astrocytes in the cerebellum, but no glial changes in the ventral horn of the spinal cord where motoneurons are located. Interestingly, we also found a 14% increase in

denervated neuromuscular junctions in the extensor digitorum longus muscle of methyl bromide exposed rats. Collectively, our results suggest that repeated low-level inhalation of methyl bromide causes locomotor changes likely through central and peripheral altered mechanisms.

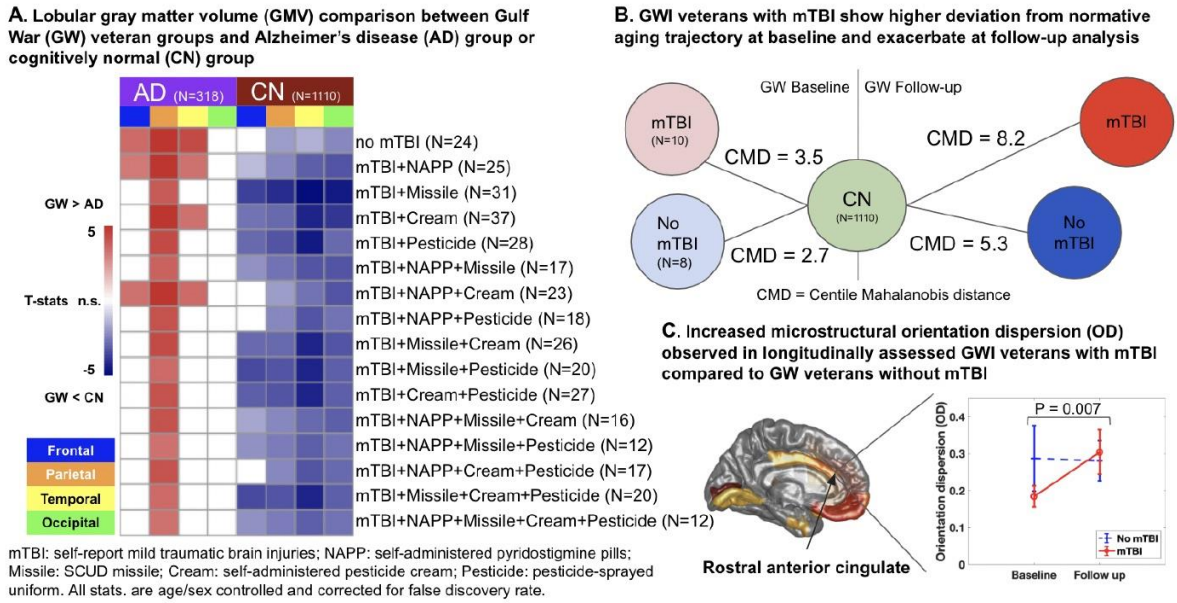
Title: Long-term effects of mild traumatic brain injury (mTBI) and toxicant exposures display accelerated pathological aging profiles: insights from structural and complex diffusion magnetic resonance imaging (MRI) analysis on Gulf War veterans

Authors: *C. CHENG[1], Y. GUAN[1], D. KIM[1], Y. OU[2], L. STEELE[3], K. SULLIVAN[4], B.-B. KOO[1];
[1]Anat. & Neurobio., Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA; [2]Boston Children's Hospital, Harvard Med. Sch., Boston, MA; [3]Baylor Col. of Med., Houston, TX; [4]Boston Univ. Sch. of Publ. Hlth., Boston Univ. Sch. of Publ. Hlth., Boston, MA

Abstract: Thirty years after the 1990-1991 Gulf War, over one-third of the 700,000 U.S. Gulf War veterans (GWV) still suffer from Gulf War illness (GWI). Many of these veterans also experienced mild traumatic brain injuries (mTBI) during the war, and the combined impact of these injuries along with exposure to toxicants and stress may raise the risk of neurodegenerative conditions in the future. Given the emerging evidence suggesting that mTBIs may contribute to long-term pathological aging and increased risks of developing Alzheimer's disease (AD) (Barnes, 2018), here we investigate the aging profiles of GWV (N=166, 142 GWI, 134 males, 53±6.2 yrs.) in comparison to AD subjects (N=318, 179 males, 75.64±6.9), and cognitively normal (CN) subjects (N=1110, 510 males, 65.36±14.8). Based on gray matter volume (GMV) segmented with FreeSurfer (v6), we observed overall significant GMV reduction in GWV compared to the CN group, with more severe reduction seen in GWI veterans with mTBI and exposures (Fig.1A). Morphologically, GWI veterans with mTBI and exposures resembled the AD group in lower frontal and temporal volumes. In a subset of longitudinally assessed GWV (N=53, 43 GWI, 43 males), using a normative brain aging model on GMV showed increased cumulative deviation from baseline to follow-up in GWI veterans with mTBI compared to those without mTBI, indicating greater deviation of brain aging in this group (Bethlehem, 2022) (Fig.

1B). Further, longitudinal analysis on gray/white matter intensity ratio (GWR), which is known to decrease with aging (Salat et al., 2009), showed significant decreases (P=0.03, T=-2.44) in the rostral cingulate cortex in exposed GWI veterans with mTBI compared to their non-exposed, non-mTBI counterparts. Diffusion MRI analysis also displayed microstructural changes indicative of potential neuroinflammation in the same region (Cheng et al., 2020) (Fig. 1C). Overall, cross-sectional and longitudinal analyses using MRI measures demonstrated that toxicant exposures in GWI veterans may accelerate abnormal aging similar to AD, and was further exacerbated by mTBI.

Figure 1. Results overview



mTBI: self-report mild traumatic brain injuries; NAPP: self-administered pyridostigmine pills; Missile: SCUD missile; Cream: self-administered pesticide cream; Pesticide: pesticide-sprayed uniform. All stats. are age/sex controlled and corrected for false discovery rate.

Title: Neutrophil Extracellular Traps are Needed for Normal Myelin Clearance after a Sciatic Nerve Transection

Authors: *B. M. BALOG[1], J. P. NIEMI[1], T. J. DISABATO[1], R. E. ZIGMOND[2];
[1]Dept. of Neurosciences, Case Western Reserve Univ., Cleveland, OH; [2]Dept. of Neurosciences, Case Western Reserve Univesity, Cleveland, OH

Abstract: Neutrophils are required for normal Wallerian degeneration in the peripheral nervous system. This was demonstrated in *Ccr2* knockout (KO) mice, which have a reduced number of infiltrating macrophages, but normal myelin clearance. When neutrophils were inhibited with a Ly6G antibody after sciatic nerve transection, wild type (WT) and *Ccr2* KO mice showed reduced myelin clearance. Similarly, knockout mice for CXCR2, a receptor needed for neutrophil chemotaxis into the injured sciatic nerve have a reduction in neutrophil infiltration and myelin clearance. Neutrophils produce extracellular traps (NETs), which involve the release of chromatin outside of the cell, to aid in clearing pathogens. This process requires peptidyl-arginine deiminase 4 (PAD4) to citrullinate histone 3 (CitH3), so the DNA can decondense before being released outside of the cell. This is important as NETs are found in neurological disorders, but their purpose is not known. Using a peripheral nerve injury model, we investigated if NETs are required for normal myelin clearance. WT mice received a right sciatic nerve transection and the left served as an operated control. A PAD4 inhibitor or vehicle was injected into the nerve daily. Two days after the injury, animals were euthanized, and the tissue was fixed, sectioned, and stained for neutrophils (Ly6G), CitH3, and DAPI. Cell counts of Ly6G cells were not significantly different between vehicle or inhibitor groups, but the inhibitor group had a significant decrease in the number of Ly6G+, CitH3+, and DAPI+ NET structures compared to the vehicle group. Sections of nerves from animals treated for 7d after the injury were stained with luxol fast blue to detect myelin clearance. The vehicle groups showed a significant decrease in the percent area stained in the distal injured nerve compared to the sham injured. There was greater clearance in the vehicle injured group than in the inhibitor injured group. These results suggest that NETs are required for normal myelin clearance after a peripheral nerve transection. This contradicts a recent publication that suggested NETs are inhibitory to myelin clearance after a sciatic nerve crush injury. We are currently comparing the effects of transection and crush of the sciatic nerves in WT mice.

Abstract: Tubulinopathies refer to a wide group of diseases affecting the central nervous system (CNS) with a mutation in tubulins. Particularly, mutations in the tubulin β 4A (TUBB4A) gene cause in humans leukodystrophy named the hypomyelination with atrophy of the basal ganglia and cerebellum (H-ABC). Motor signs such as ataxia and gait disturbances are the leading cause of disability in humans with H-ABC. The *taiep* rats were obtained at Institute of Physiology of Benemérita Universidad Autónoma de Puebla, and they had a progressive motor syndrome whit tremor, ataxia, immobility episodes, epilepsy, and paralysis. *Taiep* rat is the first model of tubulinopathy of human H-ABC whit a point mutation in the tubulin β 4A gene with a similar alteration in MRI image. The aim of this study was to evaluate the effects of leuprolide acetate, an agonist of gonadotropin release hormone (GnRH), on gait parameters in adult male *taiep* rats. We evaluated eight male *taiep* rats divided into two groups each with four subjects. Control group receive an intramuscular injection of physiological saline solution a second group with the 10 µg/Kg dose of leuprolide acetate (Sigma Aldrich, USA). The stepping pattern were analyzed using Catwalk™ system (Noldus Technologies, The Netherlands), and we measured the support base, the speed, the stride length, the duration of support, the swing and stand phase durations, as well the stepping sequence.The administration of leuprolide acetate improved coordination between the limbs ($P<0.05$). gait speed ($P<0.05$), and decreased the stance phase and the base of support ($P<0.05$), the gait that are clearly improved. In conclusion, the use of GnRH agonist improves four of the gait parameters evaluated. This drug has been a potential tool for treatment in humans affected with H-ABC and other leukodystrophies or leukoencephalopathies.

Abstract: COVID-19, caused by the SARS-CoV-2 infection, led to a global health crisis. Growing evidence suggests that unsettled inflammatory processes resulting from the disease leads to 45% of survivors experiencing unresolved symptoms at least 4 months post-infection, rising with case severity. Neurological-related issues range from loss of smell to stroke and may further exacerbate pre-existing conditions, potentially contributing to the future development of neurodegenerative diseases (NDDs), such as Alzheimer's disease (AD). Based on the hypothesis that increased chronic inflammation in the body and brain during COVID-19 can lead to changes in brain function, we aim to use a non-invasive method to identify key behavioral markers to study the chronic neurological alterations associated with Long COVID-19.We recruited a Brazilian cohort of patients 6 months to 1 year after hospitalization caused by severe COVID-19 (N = 34, 58.8 +/- 9.5 y/o; 24 males, and 10 females) and a control age and sex-matched cohort who either had mild, asymptomatic, or no infection (N = 61, 56.6 +/- 14.4 y/o; 25 males, and 36 females). The control of eye movements (EM) is linked to several brain regions that often overlap with the pathophysiology of NDDs. Thus, the EM system can be used as a non-invasive tool to probe details of sensory, motor, autonomic, and cognitive function, assessing the integrity of these brain circuits through quantitative video-based eye-tracking analysis. Subjects performed the Interleaved Pro-Anti Saccade Task (IPAST) paradigm, which evaluates the inhibitory control. The color of a central fixation point informs participants to look towards a visual stimulus (pro-saccade) or away from it (antisaccade), direction errors in the antisaccade task (failure of saccade suppression) suggests deficits in the cognitive control. Patients recovering from severe COVID-19 made more antisaccade direction errors compared with controls (Cohen's d = 0.58, p = 0.02), had increased antisaccade reaction time (d = 0.33, p = 0.01) and displayed a trend for increased voluntary override time (d = 0.48, p = 0.06), required to correctly perform antisaccade trials. These results suggest impairment in the inhibitory control signals emanating from the frontal cortex and basal ganglia to the superior colliculus, which is similar to other NDDs. Task-related pupil and blink responses remained preserved in COVID-19 patients. Our findings may aid in understanding and addressing long-term COVID-19-associated neurologic disorders, potentially informing future treatments and improving patient follow-up by highlighting the disease's long-term neurological effects.

Title: Post-covid-19 patients exhibited decreased globus pallidus activity independent of fatigue status - an exploratory fdg-pet study

Authors: *Y. LUO[1], P. GANDER[2], Y. WANG[1], L. PONTO[2], T. RUDROFF[1];
[1]Dept. of Hlth. and Human Physiol., Univ. of Iowa, Iowa City, IA; [2]Dept. of Radiology, Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: Persistent fatigue is the most common and debilitating symptom of post-COVID-19 syndrome (PCS), profoundly impacting people's quality of life following acute COVID-19. However, the underlying pathophysiological mechanisms of PCS fatigue remain unclear. Fluorodeoxyglucose (FDG)-Positron Emission Tomography (PET) is a neuroimaging technique that can be used to study the neuropathophysiological underpinnings of PCS fatigue. Recent neuroimaging studies have reported metabolic alterations of the brain in post-COVID-19 patients, specifically, hypometabolism in the basal ganglia (BG), especially the globus pallidus (GP) area. This is significant as GP dysfunctions are also associated with fatigue in other neurological disorders (e.g., Parkinson's Disease). Therefore, the aim of this study was to investigate the influence of fatigue status on the GP activity in post-COVID-19 patients compared to a healthy normative database. Thirty-two post-COVID-19 patients (16 females) were recruited to undergo an FDG-PET scan in a single session. PCS fatigue was determined by Chalder Fatigue Scale (CFQ-11) ≥ 5. 16 subjects (age: 38.5 ± 14.3 years, 8 females) were included in the fatigued (FT) group (CFQ-11 Score: 8.1 ± 2.4). 16 subjects (age: 28.2 ± 8.2 years, 8 females) were included in the non-fatigued (NF) group (CFQ-11 Score: 1.4 ± 1.5). Time since infection was similar between groups (6.9 ± 4.8 and 8.5 ± 5.7 months, $p = 0.38$). Z-scores were then computed to determine the deviation of values for each subject from the normative database. A z-score of ≥ 1.96 or ≤ -1.96 for the GP suggested relative hypermetabolism or hypometabolism, respectively, compared to the normative database. Hypometabolism was observed in the GP in both the FT ($z = -2.16 \pm 0.4$) and NF ($z = -2.65 \pm 0.4$) groups relative to the healthy normative database. A group (NF vs FT) × hemisphere ANOVA revealed no significant interaction ($F = 0.2$, $p = 0.65$). However, a main effect of group was observed ($F = 21.1$, $p < 0.001$) as the NF group demonstrrated greater GP hypometabolism (post-hoc $p < 0.001$,

d = 1.06). Additionally, a hemisphere main effect (F = 14.3, $p < 0.001$) showed higher z-scores for the right GP in both the FT (left z = -1.93 ± 0.4 and right z = - 2.28 ± 0.5; post-hoc $p < 0.001$, ***d*** = 0.76) and NF groups (left z = -2.36 ± 0.4 and right z = -2.8 ± 0.4; post-hoc $p < 0.001$, ***d*** = 1.17). Other BG regions did not differ from the normative database (≥1.96 or ≤-1.96). Our preliminary findings showed decreased GP activity at rest in post-COVID-19 patients independent of fatigue status, indicating that other potential factors (e.g., neuroinflammation, hypoxia, stress, anxiety, depression) may contribute to reduced glucose uptake in the GP.

Title: Degeneration of tumor associated nerves promotes resistance to anti-PD-1 therapy in cancer

Authors: *M. AMIT, J. MYERS, E. N. BARUCH, P. NAGARAJAN, F. O. GLEBER-NETTO, X. RAO, T. XIE, S. AKHTER, A. ADEWALE, B. J. MATTSON, R. FERRAROTTO, M. K. WONG, M. A. DAVIES, J. SONALI, B. SREYASHI, N. J. AJAMI, R. P. GOEPFERT, J. WANG, G. A. CALIN, M. R. MIGDEN, J. K. BURKS, J. GOMEZ, P. M. DOUGHERTY, J. P. ALLISON, P. SHARMA, J. WARGO, N. D. GROSS;
M.D. Anderson Cancer Ctr., houston, TX

Abstract: The nervous system has reciprocal interactions with both cancer and the immune system, however, little is known about the potential role of tumor associated nerves (TANs) in modulating anti-tumoral immunity. Here, we analyzed tumor samples of head and neck squamous cell carcinoma (HNSCC) patients who underwent neoadjuvant anti-PD-1 therapy. One third of the patients presented with invasion of cancer cells to TANs, and this invasion was associated with resistance to anti-PD-1. RNA sequencing data of The Cancer Genome Atlas data,

showed that invasion to peripheral nerves is associated with a neurodegeneration on Gene Set Enrichment Analysis (GSEA) and poor outcome. Using electron microscopy and electrical conduction studies, we showed that cancer cells can destroy myelin sheet and induce TANs degeneration. Multi-omics and spatial analyses demonstrated that anti-PD-1 non-responders had higher rates of TANs degeneration compared to responder, both at baseline and following the neoadjuvant treatment. Tumors from non-responders were characterized by a sustained signaling of interferon type I (IFN-I) in the tumor microenvironment- known to both promote nerve degeneration and suppress anti-tumoral immunity. Luminex analysis showed that neurons but not cancer cells, secrete INF-I and interleukin-6, upon stressful conditions in vitro. Spatial transcriptomic validated by high-plex immunofluorescence, showed that peri-neural niches of non-responders were characterized by higher immune activity compared to responders, including immune-suppressive activity of M2 macrophages, and T regulatory cells. This immune-suppressive infiltration expanded to the rest of the tumor microenvironment in non-responders. Anti-PD-1 efficacy was dampened by inducing nerve insult prior to treatment administration in syngeneic as well as humanized demyelination murine model of HNSCC. In contrast, anti-PD-1 efficacy was enhanced by denervation and by IFN-I or interleukin-6 blockade in-vivo. These findings suggested a potential novel anti-PD-1 resistance mechanism driven by cancer induced peripheral neurodegeneration with potential therapeutic implications.

Title: The Immune Response to Prolonged Unilateral IOP Elevation in the Human Eye

Authors: *M. M. SOMERVILLE[1], M. GARNER[1], R. G. STRICKLAND[1], A. K. GROSS[1], C. A. GRIKIN[2];

Abstract: Using an *in vivo* model of unilateral elevation in intraocular pressure (IOP) in research-consented brain-dead organ donors, our lab investigates the early cellular responses to acuteIOP elevation for the first time in the living human eye. We have found an increase of microglialreactivity regionally in the retina as well as in the posterior lamina cribrosa (LC) within the opticnerve head. Additionally, we have found regionally elevated astrocytic reactivity within theinferior and temporal LC, consistent with regions of greater susceptibility in glaucomatousneurodegeneration. Using immunohistochemistry in conjunction with in-situ hybridization, weare beginning to uncover the neuroinflammatory responses of the retina at the transcriptomiclevel and are targeting chemotactic ligand receptor expression levels as well as the expressionlevels of inflammatory cytokines and damage-associated molecular patterns (DAMP). Based onour preliminary data, we expect to find evidence to support a detrimental neuroimmunologicresponse that contributes to glaucomatous pathology.

Title: Subarachnoid haemorrhage leads to desialilation of hippocampal glycocalyx followed by complement system activation

Authors: *E. GOLANOV, A. REGNIER-GOLANOV, H. GOODWIN, N. KVIRKVELIA, R. LE, G. W. BRITZ;
Neurosurg., The Methodist Hosp., Houston, TX

Abstract: Subarachnoid haemorrhage (SAH) -- the accumulation of blood in the subarachnoid space - is the most fatal stroke, with a 40% mortality rate and 95% of survivors suffering permanent disabilities. Hippocampal neuroinflammation following SAH has been recognized as a potential cause of post-SAH syndrome, and the complement system (CS), in particular, has been identified as a major player. Levels of C1q, the activating protein of the classical pathway of the CS, are significantly higher in hippocampus (HPC) following SAH. However, mechanisms of C1q activation, the first step in CS activation, remain unknown. Our earlier data demonstrated that SAH-induced neuroinflammation, involves activation of astro- and microglia, leading to synaptic loss. While neuroinflammation of HPC involves activation of CS, specific mechanisms of its activation remain unknown. We hypothesize that damage of perforant pathway connecting blood exposed entorhinal cortex and HPC triggers release of sialidase and subsequent “trimming” of terminal glycocalyx - sialic acid (SA) - exposing potential binding sites for C1q and activation of the CS cascade. To test this hypothesis in perforation of the Willis circle model of SAH, we employed immunohistochemical staining using various lectins to detect

changes in sialylation and sialidase inhibitor (SI) treatment to explore changes in the hippocampal layers in SAH and Sham mouse brains. Levels of C1q increased significantly in the hippocampal molecular layer and stratum lacunosum moleculare ($P<0.002$ and $P<0.03$, resp. $n=6$) following SAH (areas of perforant pathway termination). Calculation of C1q/SA immunostaining ratio showed an increase ($P<0.005$, $n=3$) ratio in SAH versus Sham animals suggesting increased C1q binding due to cleavage of SA. Cleavage of terminal SA was confirmed by increased exposure of β-Galactose and N-acetyl-galactosamine ($P<0.04$, $n=3$, $P<0.005$, $n=3$, resp.) after SAH. Intra ventricular administration of SI reversed hippocampal synaptic loss ($P<0.0004$, $n=6$). Slice treatment with exogenous SI resulted in ($P<0.02$, $n=4$) higher levels of SA in Sham than in SAH animals. Our findings suggest that desialylated glycans form a substrate for C1q binding and its subsequent activation respective activation of innate complement system.

Title: Hexokinase-2 (HK2) inhibition attenuates pro-inflammatory gene expression by microglia / macrophages in peri-infract cortex as assessed by digital spatial profiling.

Authors: *G. URUK, S. WON, K. ARKELIUS, N. SINGHAL, C.-L. TU, W. CHANG, R. SWANSON;
Univ. of California San Francisco, San Francisco, CA

Abstract: Brain ischemia, infection, tissue injury, and other signals cause microglia and infiltrating macrophages (M/M) to become activated and release cytotoxic ROS and cytokines that may exacerbate brain injury. M/M exhibit a marked increase in glycolytic rate. Importantly, pro-inflammatory effects of activated M/M can be suppressed by limiting their glycolytic flux through inhibition of hexokinases. There are 4 isoforms of hexokinase, of which HK1 is the predominant isoform in most tissues whereas HK2 is the predominant isoform in cells of the M/M lineage. Availability of brain penetrating HK2-selective inhibitors provide a mechanism for selectively suppressing glycolytic rate in activated M/M. The aim of this study is to determine if HK2 inhibition can suppress pro-inflammatory gene transcription in M/M after permanent ischemia (photothrombotic stroke) in the mouse. HK2 inhibitors 3-bromopyruvate and lonidamine were administered i.p. after induction of permanent ischemia. We assessed pro-inflammatory gene expression changes in peri-infarct M/M and neurons using the DSP GeoMx

spatial genomics. This method allowed the entire M/M transcriptome to be analyzed in-situ with no need for isolation of them from brain, a process which itself causes some activation. This approach also enabled us to investigate the M/M at the infarct border and peri-infarct areas, preserving the crucial anatomical information and unaltered transcriptomic profile. Both HK2 inhibitors suppressed pro-inflammatory gene expressions such as ccl3, ccl4, cd14, plek, and hmox1 in peri-infarct M/M. Suppressing M/M HK2 activity thus provides a means for attenuated post-stroke activation of M/M at the transcriptional level.

Title: Hexokinase-2 inhibition reduces neuroinflammation-mediated brain damage after stroke

Authors: *S. WON, G. URUK, K. AWAKOAIYE, E. MOCANU, D. OGUT, R. SHON, N. SINGHAL, R. A. SWANSON;
VAMCSF & UCSF, San Francisco, CA

Abstract: Activated microglia can exacerbate brain injury after ischemic stroke through the innate immune response. Activated microglia also exhibit an increased glycolytic rate, and - crucially - the pro-inflammatory effects of activated microglia can be suppressed by limiting their glycolytic flux. Unlike other brain cell types, microglia (and macrophages) use primarily hexokinase-2 (HK-2) rather than hexokinase-1 to catalyze the initial step of glycolysis. HK-2 - selective pharmacological inhibitors are now available, thus providing a mechanism for selectively suppressing glycolytic rate in activated microglia / macrophages. The aim of this study is to determine if HK-2 inhibition can suppress pathogenic aspects of microglia / macrophage activation and improve the behavioral dysfunction after a model of permanent ischemia (photothrombotic stroke) in the mouse. The HK-2 inhibitors 3-bromopyruvate and lonidamine were administered i.p. after induction of permanent ischemia. Both drugs suppressed the morphological microglial activation, and by digital spatial profiling these drugs also suppressed pro-inflammatory gene expression in peri-infarct microglia. Histological studies showed reduced DNA-damage in peri-infarct neurons and reduced cofilin-actin rod formation in peri-infarct neurites in mice treated with the HK-2 inhibitors. Behavioral studies indicate reduced motor deficit in mice treated with 3-bromopyruvate after stroke. These results suggest that, by selectively suppressing glycolytic rate in activated microglia / macrophages after stroke, HK-2 inhibitors can improve outcome after permanent ischemia.

Abstract: Ischemic stroke represents 87% of all strokes being a major cause of death and permanent disability worldwide. Atherosclerosis characterized by fatty deposits (plaques) in the inner walls of major arteries is the main risk factor for ischemic stroke. The lectin pathway (LP) of complement activation has pathogenetic functions in acute ischemic stroke, with implication in thromboinflammatory events. We reported that elevated circulating levels of the LP initiator ficolin-2 are associated with vulnerable atherosclerotic plaques, those that upon their rupture increase stroke risk. We here aimed at investigating ficolin-2 circulating levels after an acute ischemic stroke and their potential use as a biomarker able to differentiate stroke etiologies, namely atherosclerotic vs. others.300 patients (68.6y ± 16) were enrolled at Lyon Stroke Center for an acute ischemic stroke due to large vessel occlusion treated with mechanical thrombectomy. Blood was withdrawn at H0: admission, H6: hour 6, H24: hour 24, H48: hour 48, M3: month 3. Ficolin-2 circulating levels were measured by ELISA.Considering the whole cohort, circulating ficolin-2 levels were 5620 ± 2006 of ng/mL ± SD at H0 and decreased at H6 (4821 ± 1936, $p<0.001$ vs. H0), H24 (4928 ± 1811, $p<0.001$) and H48 (5182 ± 1851, $p<0.05$). Data indicate an early consumption of ficolin-2 after acute ischemic stroke, due to target binding and lectin pathway activation. A large-artery atherosclerosis (LAA) etiology regarded 40 patients (13%), showing lower circulating ficolin-2 at H6 (3810 ± 1775) compared to other causes of stroke (4971 ± 1917). The area under curve (AUC) reflected different ficolin-2 levels over time, namely AUC of 1.077e+007 ± 2997205 in stroke patients with LAA vs. 1.195e+007 ± 2914745 in those with other etiology ($p=0.02$, Unpaired t-test). Contingency analysis by Fisher's exact test showed that lower ficolin-2 levels at H0 and H6 were associated with LAA. Ficolin-2 levels

were seemingly independently associated with LAA since other risk factors including ASPECT score, obesity, dyslipidemia, coronopathy smoke, diabetes and hypertension were not.Our data indicate increased ficolin-2 usage in patients having a symptomatic atherosclerotic plaque, in line with the association of ficolin-2 circulating levels with vulnerable plaques. As such ficolin-2 circulating levels could predict the risk of stroke in atherosclerotic patients standing as a new biomarker with future diagnostic value to help develop stroke prevention and treatment.

Title: Senescence Associated Secretory Phenotype (SASP) Influences the Stroke Outcome of Aged Mice

Authors: *B. OUVRIER, S. ISMAEL, G. J. BIX;
Clin. Neurosci. Res. Ctr., Tulane Univ. Sch. of Med., New Orleans, LA

Abstract: Ischemic stroke is a devasting brain injury and a leading cause of morbidity and mortality worldwide. While there is extensive research into stroke pathology, the effect of age, in relation to stroke severity has not been fully elucidated. Aging is a non-modifiable risk factor for stroke incidence and morbidity. In the aged brain, cells induce neuroinflammation through the activation of senescence associated secretory phenotype (SASP). Interleukin-1α (IL-1α), a pro-inflammatory cytokine is a major-upstream regulator of SASP and is heavily involved in the post-stroke inflammatory response. Additionally, ischemic stroke has also been found to induce SASP in the infarcted and periinfarct regions. However, the interplay between the already SASP-abundant aged brain and the impact on stroke may be worthy of elucidation. The study is aimed to understand the impact of proinflammatory cytokine, IL-1α, on the aged brain after stroke due to its dual involvement in post-stroke neuroinflammation and a critical upstream inducer of SASP. Middle cerebral artery occlusion was induced in young (9-week) and aged (16-month) mice, n=5/group, using the photothrombotic model. 30ul of Rose Bengal dye was injected retro-orbitally and the distal middle cerebral artery was laser illuminated for 10min. Brain was perfused and then hemispheres were harvested and fresh frozen separately for protein and mRNA analysis of markers of senescence and SASP expression. qPCR analysis of inflammatory, senescent, and SASP markers; IL-1α, IL-6, P16, P21, CXCR2, and CXCL1, found that there is inverse association of inflammatory and SASP markers with aged stroked mice comparing the young stroked groups. The aged sham showed higher senescent and SASP markers compared to young sham. Interestingly, while both age groups showed an increase in SASP marker in the

stroke versus sham, young stroke had significantly higher increase compared to even the aged stroke group and is further confirmed by immunofluorescence and western blot analysis. We found that there is increased SASP expression in the stroked ipsilateral hemisphere compared to the contralateral hemisphere in an age-dependent manner representing that there may be an inflammatory compensatory mechanism in the aged brain based on already present SASP expression. These results suggest that senescence and SASP are heavily integrated with stroke in an age-dependent manner and that the IL-1α SASP pathway may be a critical modulator of this phenomenon.

Title: Astrocytic $Na^+/HCO3^-$ cotransporter 1 (NBCe1) in BBB damage in stroke mice

Authors: *O. CAPUK, S. SONG, S. METWALLY, G. BEGUM;
Dept. of Neurol., Univ. of Pittsburgh, The Pittsburgh Inst. for Neurodegenerative Dis., Pittsburgh, PA

Abstract: Astrocytes play a critical role in preserving the integrity and function of the blood-brain barrier (BBB). The perivascular astrocytic end-feet express a variety of channels and ion transporters that are crucial for maintaining ion and osmotic homeostasis, important for BBB functional integrity. Disruption of the BBB is a characteristic feature of ischemic stroke and contributes to the progression of neurodegeneration. Here, we investigated the role of electrogenic sodium bicarbonate transporter 1 (NBCe1/SLC4A4) in stroke-induced BBB damage. NBCe1 is predominantly expressed in astrocytes and plays important role in regulating brain pH homeostasis. Increased NBCe1 expression in reactive astrocytes correlates with neurological function impairment in ischemic stroke mice, yet the underlying mechanisms remain unclear. In our study, we used inducible *Gfap-Cre$^{ERT2+/-}$;Nbce1$^{f/f}$* mice to specifically delete NBCe1 in $GFAP^+$ reactive astrocytes. Astrocyte selective *Nbce1* deletion in *Gfap-Cre$^{ERT2+/-}$;Nbce1$^{f/f}$* (*Nbce1* cKO) mice displayed reduced infarct volume, brain swelling, and neurological function deficits at 1-7 days after ischemic stroke. Immunocytochemical analysis showed increased BBB damage and dysregulation of perivascular AQP4 polarity in wild-type ischemic brains. In contrast, *Nbce1* cKO brains exhibited improved BBB integrity, and preservation of perivascular AQP4 polarization and reduced loss of neuronal cells ($NeuN^+$ cells) at 3-day post-stroke. Furthermore, *Nbce1* cKO significantly increased regional cerebral blood

flow in the ischemic hemisphere at 3-day post-stroke. Taken together, our study provides the first line of evidence that pathological stimulation of astrocytic NBCe1 protein plays a role in ischemic BBB damage. These findings highlight the importance of astrocytes and NBCe1 in the pathogenesis of stroke and its potential as therapeutic targets for preserving BBB integrity in ischemic conditions.

Title: Inhibition of TREM1-mediated neuroinflammation attenuates global ischemic stroke pathology

Authors: *R. URQUHART, H. KIM, G. P. JADHAV, J.-Y. HWANG;
Pharmacol. & Neurosci., Creighton Univ., Omaha, NE

Abstract: Global cerebral ischemia occurs when the blood flow to the entire brain is blocked or significantly impeded and is most often caused by cardiac arrest. Global ischemia induces delayed and selective hippocampal CA1 pyramidal neuronal death which leads to impaired learning and memory. Current therapies for cardiac arrest only focus on restoring cardiac function and blood flow - no treatments prevent long term effects of global ischemia. Thus, identifying the molecular mechanisms and therapeutic targets is essential for developing novel treatments to rescue global ischemia induced neuronal death and cognitive deficits. In this study, we sought to explore how dysregulation of genes might promote the neurodegeneration associated with global ischemia. Toward this end, we subjected rats to global ischemia via 4-vessel occlusion (4-VO) and performed RNA-seq to investigate alterations of mRNAs in post-ischemic CA1. Ingenuity Pathway Analysis showed the pathways related to inflammatory response including ‘neuroinflammation’ and ‘TREM1 signaling’ as the top canonical pathways. TREM1 is a myeloid-derived surface receptor involved in immunity and inflammation. TREM1 has known roles in myocardial ischemia and sepsis, but the role of TREM1 in global ischemia remains unclear. Based on our RNA-seq analysis, we hypothesized TREM1 mediated neuroinflammation drives global ischemia induced neuronal death and cognitive deficits, and TREM1 inhibition attenuates this pathology. RTqPCR and Western blot analyses revealed that TREM1 expression is elevated within 48HR of ischemia, and downstream inflammatory cytokines and transcription factors are also differentially expressed 3-48HR post 4-VO. These results validate RNAseq and IPA and confirm that TREM1 and its signaling cascade are

activated after global ischemia. To establish a causal relationship between TREM1 and global ischemia, the neuroprotectiveness of TREM1 inhibitory peptide LR12 was measured. LR12 administration reduced neurodegeneration in the hippocampal CA1 after ischemia, measured by histological staining, establishing LR12 as a neuroprotective peptide. Current experiments will address the hypothesis that LR12 prevents TREM1-mediated neuroinflammation, ameliorating global ischemia induced neuronal death and cognitive deficits. This research establishes the role of TREM1-mediated neuroinflammatory signaling in global ischemia pathology and identifies TREM1 as a potential therapeutic target for attenuating global ischemia-induced neurodegeneration and cognitive deficits.

Title: Intranasal erythropoietin protects granular cells and reduces astrogliosis in the dentate gyrus after ischemic damage, an effect associated with molecular changes in erythropoietin and its receptor

Authors: *R. MACIAS-VELEZ, A. MARIN-LOPEZ, M. RIVERA CERVANTES;
Dept. de Biologia Celular y Mol., Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Within the hippocampus, the CA1 and dentate gyrus (DG) regions are considered the most and the least susceptible to damage by cerebral ischemia, respectively. In addition, it has been tested that rHuEPO exhibits neuroprotective properties. The present study investigates the effect of different intranasal doses of rHuEPO, applied in different post-ischemic damage times in the DG, on the granular cell layer preservation as well as on astroglial reactivity after cerebral ischemia. Additionally, an effective dose and an administration time for neuroprotection were used to evaluate gene and protein expression changes of EPO and EPOR in the DG region. We observed a considerable loss of cells on the granular layer and an increased number of GFAP immunoreactive cells in this region 72 h after the onset of ischemic damage. When rHuEPO was intranasally administered, the number of morphologically abnormal cells and astroglial immunoreactivity decreased. Regarding to the protein and gene expression analysis, there is no correlation between the expression levels of these molecules, although the rHuEPO application amplifies the response of EPO and EPOR gene expression to ischemia in each evaluated time; in the case of protein expression, this effect was observed only 2h after damage. In summary, using a 2VO model in rats, we demonstrated that 20 min of bilateral occlusion are enough to detect a susceptibility of the DG to ischemic injury, which was observed in both granular cells alterations

and astrocytic response, which is accompanied by molecular changes on EPO and EPOR at particular post-damage times that might mediate the protective effect triggered by rHuEPO intranasal administration.

Title: Rna-sequencing reveals inflammatory and synaptic structure pathways to differentially expressed after cerebellar stroke

Authors: G. HUNN, C. MINJAREZ, D. MITCHELL, M. MORENO GARCIA, *N. QUILLINAN;
Anesthesiol., Univ. of Colorado, Anschutz Med. Campus, Aurora, CO

Abstract: More than 20,000 people suffer from cerebellar ischemic stroke yearly. Neuroimaging of the human cerebellum shows that an anterior lobule infarct produces motor deficits, while a posterior infarct likely leads to nonmotor deficits. Our rodent model injures the cerebellar cortex and emphasizes the same topographical deficits. However, there is a lack of knowledge of the mechanisms underlying the behavioral deficits seen in patients with cerebellar stroke. To further characterize this, we used deep cerebellar nuclei (DCN) and ventrolateral thalamus (VLT) tissue of stroke and sham brains to measure gene expression with bulk RNA-sequencing. This is because Purkinje cells in the cerebellar cortex project to the DCN, which is functionally connected to the VLT. Using photothrombosis, the superior cerebellar artery (SCA) was occluded in adult (8-16 wk) male C57/Bl6 mice. Infarcts were localized to the anterior (n=3) or posterior (n=3) regions of SCA or were shams (n=3). At 7 days post-stroke, DCN and VLT tissue was collected for RNA isolation and quality control. We did a PolyA preparation of RNA libraries and NovaSeq sequencing at a read depth of 30 million pairs per sample. Sequences aligned to the mouse genome and SALMON analysis produced gene counts. RStudio Principal Component Analysis revealed a large variation (85%) between the two regions and a small variation (9%) between the two types of strokes. We next focused on the DCN to assess the beginning of the circuit. DESeq2 analysis identified 239 differentially expressed (DE) genes in anterior compared to sham stroke, which consisted of 199 upregulated and 40 downregulated. Posterior compared to sham stroke produced 3621 DE genes in which 1966 were upregulated

and 1655 were downregulated. Using these genes, the Gene Ontology database showed an upregulation of inflammatory pathways in anterior compared to sham stroke. In addition to an upregulation of similar inflammatory pathways, posterior stroke mice also showed a downregulation in synaptic structure pathways. To validate our RNA-seq, immunohistochemistry assessed microglia activation. Imaris software showed a decrease in filament branch, along with an increase in soma volume and cell number, all indicating upregulation of microglia activation in anterior (n=4) and posterior (n=4) stroke compared to shams (n=4). Phagocytic activity of microglia measured with CD68 also increased in stroke compared to sham. Overall, while the DCN is not directly injured, this data identifies significantly different biological pathways in this brain region after cerebellar stroke, which led us to upregulated microglia activation that could contribute to functional changes.

Title: Determination of neuroinflammatory biomarkers in plasma of rats with acute global cerebral ischemia.

Authors: *O. MONTES[1], M. GARCÍA[1], O. GONZALEZ[1], R. J. DELGADO[2];
[1]Ctr. Tlaxcala de Biología de la Conducta, Univ. Autonoma De Tlaxcala, Tlaxcala, Mexico; [2]Ctr. de Investigación en Biotecnología Aplicada, Inst. Politécnico Nacional, Tlaxcala, Mexico

Abstract: Cerebral ischemia (CI), is the most common type of stroke, representing more than 80% of all cases and accounting for 5.2% of all deaths worldwide. CI is characterized by decreased blood flow to the brain causing neuroinflammation and cell death. During postischemia neuroinflammation, interleukins (ILs) play a key role in the severity of brain damage. Some ILs such as IL-6 are known to be proinflammatory, in contrast, other ILs such as IL-10 have anti-inflammatory effects. The pharmacological modulation of both ILs and their detection in ischemic patients is a priority in the clinic; for these reason, in the present work, we propose the plasma detection of IL-6 and IL-10 at different postischemia times by using a novel technique known as attenuated total reflectance-Fourier transform infrared spectroscopy (ATR-FTIR). The ATR-FTIR allows monitoring structural and concentration changes in biomolecules present in plasma samples quickly, inexpensively, without the need for sample preparation and using a small amount for detection. In this study we used male rats of the Sprague Dawley strain, these animals were included in an acute global cerebral ischemia (AGCI) protocol and their

blood plasma was obtained at; 0,2,4,6,12 and 24 hours after the ischemic event. Animals that received neuroprotective drug treatment were administered a single intraperitoneal dose of estradiol benzoate (EB) at a concentration of 4mg/kg. For the first statistical exploration of the data, we used the average values of each group obtained in the mid-infrared region (400-4,000cm-1) and principal component analysis (PCA) was performed. Our partial results show the highest plasma IL-6 concentration at 2 hours post-ischemia in animals that did not receive neuroprotective treatment, in contrast, the animals that received EB treatment showed low IL-6 levels at 2 hours and elevated IL-10 concentration at 6 hours post-ischemic event. The spectra obtained by ATR-FTIR measurements show different absorbance values, as well as modifications in the spectral peaks in the different experimental groups that are attributable to the pharmacological conditions of each group and to the time elapsed after the ischemic event. These results suggest that treatment with EB in ischemic individuals negatively modulates IL-6 proliferation in the acute phase of ischemia and, conversely, promotes IL-10 synthesis in the subacute phase of ischemia, in addition, we were able to standardize the methodology for the plasma measurement of IL-6 and IL-10 using (ATR-FTIR) and we characterized the plasma spectra of ischemic animals.

Title: Noggin-induced changes in metabolism of microglia and oligodendrocytes after ischemic insult

Authors: J. LEE[1], E.-M. LEE[2], J. A. SHIN[1], ***E.-M. PARK**[2];
[1]Korea Basic Sci. Inst., Seoul, Korea, Republic of; [2]Ewha Womans Univ. Med. Col., Seoul, Korea, Republic of

Abstract: Recent studies show that shifts in energy metabolism in activated microglia are linked to their functions and immune responses in the ischemic brain. We previously reported that an antagonist of the bone morphogenetic protein, noggin, enhanced myelination in the ischemic brain during the chronic phase, and conditioned media (CM) from activated BV2 microglia treated with noggin after ischemia/reperfusion (I/R) increased the expression of myelin basic protein (MBP) in oligodendrocytes (MO3.13). To determine whether noggin induced changes in cell metabolism, metabolite profiles in BV2 and MO3.13 cells were analyzed by untargeted

metabolomics using ^{1}H nuclear magnetic resonance spectroscopy. Compared to vehicle-treated BV2 cells, noggin treatment (100 ng/mL for 3 h after I/R) suppressed the I/R-induced increase in intracellular glucose and lactate levels but increased extracellular levels of glucose and several amino acids. When MO3.13 cells were exposed to noggin CM from BV2 cells, most of the vehicle CM-induced changes in the levels of metabolites such as choline, formate, and intermediates of oxidative phosphorylation were reversed, while the glycerol level was markedly increased. An increase in glycerol level was also observed in the noggin-treated ischemic brain and was further supported by the expression of glycerol-3-phosphate dehydrogenase 1 (required for glycerol synthesis) in the cytoplasm of MBP-positive oligodendrocytes in the ischemic brains treated with noggin. These results suggest that noggin-induced changes in the metabolism of microglia provide a favorable environment for myelin synthesis in oligodendrocytes during the recovery phase after ischemic stroke.

Title: Microglial phagocytosis of neurons protects brain during ischemic stroke

Authors: E. WANG, H. CHEN, M.-C. WU, Y. YANG, *T. LAI;
China Med. Univ., Taichung, Taiwan

Abstract: Ischemic stroke is responsible for a substantial number of incapacitations and fatalities worldwide. Following the onset of ischemic stroke, a robust neuroinflammatory response is triggered. Microglia, a brain-resident macrophage, can become activated and impact the development of stroke. Recent research indicated that microglia have a biphasic role in the outcome of stroke; however, the precise influence of microglia on stroke remains unclear. In this study, we elucidate the potential contribution of microglial phagocytosis in the clearance of degenerating neurons subsequent to stroke. Our findings demonstrate that the depletion of

microglia leads to an increase in the number of degenerating neurons after stroke, ultimately resulting in an increased infarct volume. Lipopolysaccharide (LPS) has been identified as an activator of microglia, promoting the engulfment of neurons both in vitro and in vivo. Furthermore, Milk-fat globule EGF factor-8 (MFG-E8) played a pivotal role in facilitating the interaction between microglia and neurons, thereby mitigating infarct volume by reducing the accumulation of dead neurons. Thus, our data strongly indicate that microglia exhibit a protective function in the context of stroke through the phagocytosis of dying neurons and alleviation of stress in the infarcted area.

Title: The role of epigenetic regulator, BRD4 in neuroinflammation following global cerebral ishcemia

Authors: *H. KIM[1], J. BAHN[2], R. URQUHART[1], J.-Y. HWANG[1];
[1]Dept. of Pharmacol. and Neurosciences, Creighton Univ., Omaha, NE; [2]Creighton Univ. Sch. of Med., Omaha, NE

Abstract: Global cerebral ischemia initiates cascade reactions that lead to brain damage and cognitive impairment, of which inflammation is one of the major contributors. However, molecular mechanisms by which global cerebral ischemia induces neuroinflammation, delayed and selective neuronal death in the hippocampal CA1, and cognitive impairment are not fully delineated. In this study, we performed RNA-sequencing using hippocampal CA1 tissue from early time points (24 and 48 h) after global cerebral ischemia to find the risk factors affecting neurons destined to die. Our bioinformatic analysis of the differentially expressed genes through the Ingenuity Pathway Analysis (IPA) revealed the pathways associated with immune and inflammatory response including TREM1 signaling as the top canonical pathways and a set of genes including BRD4 as the predicted transcriptional upstream regulators that can activate these canonical pathways. Because the epigenetic regulator BRD4 is highly associated with inflammatory mechanisms and TREM1 expression, among the upstream genes and canonical pathways, we focused on BRD4 and TREM1 signaling pathway to study their role in global ischemia. Using immunohistochemistry, we first examined protein expression of BRD4 in TREM1 positive cells in hippocampal CA1 region after global ischemia. The confocal images showed that BRD4 protein is expressed in the nucleus of TREM1 positive cells after global

ischemia. We further examined whether protein level of BRD4 correlates with changes in TREM1 mRNA and protein expression in hippocampal CA1 by qRT-PCR and Western blot analysis. BRD4 was significantly increased at 48 h after global ischemia, and TREM1 mRNA and protein levels were also increased at the same time point. Consistent with this, proinflammatory cytokines (NF-kB, IL-6 and IL-1β) were significantly increased in the hippocampal CA1 at 48 h after global ischemia indicating an increase in TREM1 activated neuroinflammation. TREM1 was localized in CD31 (Endothelium) and CD11b (monocytes/macrophage) positive cells, but not Iba-1 (microglia), GFAP (astrocytes) and NeuN (neurons) positive cells after global ischemia, suggesting that global ischemia increases TREM1 in infiltrating peripheral immune cells, which in turn activates neuroinflammation in hippocampal CA1 region. In addition, BRD4 inhibition by JQ1 treatment significantly attenuated global ischemia-induced neuronal death in hippocampal CA1. Taken together, these findings indicate that BRD4-dependent epigenetic regulation of neuroinflammation may be a novel therapeutic target for global cerebral ischemia.

Title: Rapid complement activation induced by acute hyperglycemia worsens blood-brain barrier leakage and ischemic stroke outcome

Authors: *H. CHEN[1], T. CHIANG[2], R. KOPCHOCK, III[1], A. KIM[3], S. TOMLINSON[7], T. BLISS[4], M. Y. CHENG[5], G. K. STEINBERG[6];
[1]Neurosurg., Stanford Univ., Palo Alto, CA; [2]Stanford Univ., Stanford, CA; [3]Neurosurg., Stanford Univ., Redwood City, CA; [4]Dept of Neurosurg, Stanford Univ., STANFORD, CA; [5]Neurosurg., Stanford Univ., Stanford, CA; [6]Stanford Univ., STANFORD, CA; [7]Med. Univ. of South Carolina, Charleston, SC

Abstract: Background: Acute hyperglycemia, which occurs in over 40% of ischemic stroke patients, regardless of pre-existing diabetes, worsens stroke outcome. Understanding the mechanisms of hyperglycemia-exacerbated stroke injury is vital for developing novel treatments. Here we investigate the role of complement activation in hyperglycemic-exacerbated damage in rodent stroke. **Method:** Male C57/BL6 mice (10-11 weeks) were subjected to 30 min suture induced-middle cerebral artery occlusion, followed by suture removal to mimic thrombectomy-

induced recanalization in clinical stroke. Acute hyperglycemia was induced by glucose injection 10 min before stroke. Mice were sacrificed at 4.5 and 24 hr post-stroke to analyze brain swelling, blood-brain barrier (BBB) leakage and hemorrhagic transformation (HT); or survived to 14 days to examine mortality rate, neurological deficit and motor-sensory functions. Complement activation was evaluated by immunostaining for the activation product C3d. To investigate the significance of C3 activation in hyperglycemic-exacerbation of stroke pathology, we utilized C3 knock-out mice or pharmacological inhibition of C3 activation using targeted complement inhibitor CR2-Crry fusion protein (injected intraperitoneally 30 min after reperfusion). **Result:** Hyperglycemia rapidly worsens stroke outcomes as evidenced by increased BBB leakage ($p<0.0001$), brain swelling ($p<0.05$), and HT ($p<0.0001$) at 4.5 hr after stroke, compared to normoglycemia. Hyperglycemic stroke mice also exhibit higher mortality (100% vs 25%, $p=0.0008$), body weight loss, and impaired behavioral performance at the sub-acute phase. Notably, acute hyperglycemia rapidly increased plasma complement C3 levels at 1 and 2 hr after stroke ($p<0.01$), accompanied by rapid and time-dependent activation of C3 in ischemic brain vessels as indicated by increased vascular C3d; C3d levels positively correlated with brain swelling and HT ($p<0.01$). Vascular C3d was markedly reduced in the absence of reperfusion. Blocking complement activation either using C3 knock-out mice or pharmacologically, by injecting the C3 inhibitor CR2-Crry after reperfusion, significantly reduced the detrimental effects of hyperglycemia. **Conclusion:** Rapid vascular activation of complement C3 is a significant driver of hyperglycemic-exacerbated pathology in experimental stroke. Inhibiting C3 activation could be a potential therapeutic approach to improve hyperglycemic stroke outcome. The role of systemic C3 in other pathologies with increased BBB leakage such as aging, should be explored.

Title: Synaptic Zn^{2+} accumulation and non-canonical Ca^{2+} channel activity in vulnerable brain: an unconventional mechanism of spreading depolarization related injury

Authors: *M. BENNETT[1], J. WEISEND[1], R. A. MORTON[1], A. P. CARLSON[2], C. W. SHUTTLEWORTH[1];

[1]Univ. of New Mexico, Albuquerque, NM; [2]Neurosurg., Univ. of New Mexico, Sch. of Med., Albuquerque, NM

Abstract: Introduction: Spreading depolarizations (SDs) are strongly linked to injury progression in energy-depleted brain tissue. We have previously shown that L-type voltage-gated Ca^{2+} channels (VGCC) and synaptic Zn^{2+} accumulation contribute to initiation and propagation of SD in brain slices. In the current study we tested contributions of Zn^{2+} and L-type VGCCs to detrimental consequence of SD in metabolically depleted tissue. **Method:** SD was induced in coronal brain slices from mice, by focal microinjection of KCl in a previously-described model of metabolic depletion (Exp Neurol 305 (2018) 121-128). SD was monitored using intrinsic optical signals (IOS), extracellular recordings, and fluorescence imaging used to monitor both extracellular Zn^{2+} accumulation and (FluoZin-3) and neuronal Ca^{2+} (GCamP6s). **Results:** As previously reported, reduction in metabolic substrate availability impaired recovery after SD (-24.8% decrease in IOS signals and 51.8% fEPSP recovery, post-SD, n=5-6). Nimodipine pre-exposure (10μM) prevented deleterious effects of SD (0.25% IOS increase and 77.4% fEPSP recovery; n=7-10). GCamP6s imaging did not reveal a detectable decrease in Ca^{2+} accumulation following nimodipine blockade (n=5), raising the possibility of a non-Ca^{2+} dependent VGCC mechanism of neuronal impairment. ZX1 (100μM) chelation improved tissue recovery (0.55% IOS increase and 95.3% fEPSP recovery; n=6). Tissues from ZnT3 knockout animals showed similar protection (22.1% IOS increase and 93.1% fEPSP recovery; n=5-6). FluoZin-3 imaging was consistent with a synaptic source of Zn^{2+} in effects described above. **Conclusions:** These results are consistent with synaptic Zn^{2+} release and accumulation via L-type VGCCs contributing to excessive ionic burden and impaired recovery from SD events. Selective pharmacological targeting of synaptic Zn^{2+} accumulation may be a useful adjunct approach to target deleterious consequences of SD in ischemic brain.

Title: Spreading Depolarization modifies genes expression levels differently between the stroke core and the penumbra.

Authors: *M. DELL'ORCO[1], M. C. BENNETT[1], L. LI[1], J. E. WEISEND[1], N. I. PERRONE-BIZZOZERO[1], L. CUNNINGHAM[1], A. P. CARLSON[2], C. W. SHUTTLEWORTH[1]; [2]Neurosurg., [1]Univ. of New Mexico, Albuquerque, NM

Abstract: Spreading depolarization (SD) occurs in stroke brain and are strongly linked to infarct enlargement. SDs usually originate near ischemic foci and propagating relatively widely throughout peri-infarct and surrounding tissues. Our previous studies in uninjured brain have shown SD-induced changes in expression levels of genes known to regulate synaptic plasticity and neurogenesis. The aim of the current study was to analyse SD influences on gene expression changes in stroke core and penumbra. SDs were induced repetitively with focal KCl application (4 SDs at 30 min intervals) in a distal middle cerebral artery stroke model (dMCAO) in C57Bl/6 mice. Two hours after onset of the initial SD, cortical slices were collected and RNA was extracted 1) from either total hemisphere (to compare ipsilateral and contralateral), or 2) from 2 different regions of the ipsilateral hemisphere: stroke core and stroke penumbra. Total RNA was subjected to either RNA-seq or spatial genomics to identified differentially expressed genes (DEGs). In the stroke core, compared to the contralateral cortex, top DEGs include genes encoding the neurotrophic factor BDNF, intermediate early genes FOS, and NPAS4, previously associated with ischemic preconditioning. We also found significantly increased levels of other cell proliferation related genes including DUSP6, plasticity related gene ARC, and inflammation related genes as PTGS2, EGR2 and NR4A1. When comparing the penumbral area with the core, we found differential expression of genes related to synaptic activity rather than proliferation, including SCN4, DRD2, ADORA2A and CamKIIb. Finally, when we compared the penumbra with contralateral tissue, we found increased levels of plasticity and proliferation associated genes (BDNF, NPAS4, ARC, FOS, EGR1, and PTGS2) and decreased levels of neuronal activity related genes (SCN4, ADORA2A, and DRD2). These results suggest that SDs regulate gene expression changes inducing activation of long-term repair process in the stroke penumbra, while short-term survival pathways are preferentially activated in core regions. This study identified novel targets that could be used to test to hypotheses of SD involvement in plasticity or recovery in surviving peri-infarct tissue.

Title: Investigating the Mechanism and Identity of an Activator of Spreading Depolarization

Authors: *J. A. HELLAS[1], P. J. GAGOLEWICZ[2], C. A. LOWRY[1], D. ANDREW[3];
[1]Ctr. for Neurosci. Studies, [2]DBMS, [3]Pharmacol. and Toxicology, Queen's Univ., Kingston, ON, Canada

Abstract: Stroke leads to irreversible ischemic brain injury and is the second leading cause of death globally, with incidence rising each year [1]. The brain is highly metabolically demanding and requires a steady blood flow containing sufficient oxygen and glucose for normal function. During stroke, traumatic brain injury (TBI), or sudden cardiac arrest (SCA), cerebral blood flow is halted locally, with reduced flow in collateral regions [2]. With a lack of oxygen and glucose, neurons cannot generate adenosine triphosphate (ATP), causing rapid failure of ATP-dependent cellular pumps and thus loss of neuronal function within minutes [3]. The sodium-potassium transporter fuelled by ATP (Na^+/K^+ pump) fails within minutes of stroke onset, and quickly promotes spreading depolarization (SD). SD is a propagating wave of inactivation traversing the higher brain grey matter. SD can recur over hours or days, thereby expanding the ischemic core [4-8]. The resulting neuronal injury caused by SD can leave patients with permanent neurological deficits, yet there are no pharmacological treatments [4, 6, 7, 9]. Fundamentally, we do not understand the molecular events driving either the spread *or* the depolarization.
At picomolar concentrations, a marine poison palytoxin (PLTX) converts the Na^+/K^+ transporter into an open Na^+/K^+ channel, thereby inducing SD in brain slices, as well as prehemolytic swelling and then hemolysis of red blood cells. Here, we developed a bioassay for a proposed endogenous SD activator (SDa) that we suspect is released by stressed grey matter to initiate and drive SD in a PLTX-like manner. We first captured an SDa sample by exposing ~30 rodent brain slices to oxygen and glucose deprived (OGD) artificial cerebrospinal fluid (aCSF), removed the slices, and replaced O_2 and glucose. This 'Post-SD aCSF' evoked SD in naïve slices with 78-82% frequency. 'Pre-SD aCSF' from slices not exposed to OGD had no such activity. We then ruled out that pH changes, released K^+, or glutamate were responsible. Finally, we built upon previous work from the Andrew lab where trace amounts of PLTX seemed to 'prime' the Na^+/K^+ pump for opening, facilitating hemolysis. We found that this priming phenomenon could be replicated in tissue slices.
The isolated Post-SD aCSF should serve as a reasonably purified SDa solution, given the absence of cellular disruption/extraction procedures. A stronger understanding of the activity and identity of an endogenous SDa and an improved understanding of the molecular mechanisms driving SD will help elucidate novel targets for reducing or stopping recurrent SDs in clinical populations suffering stroke, TBI or SCA.

Furchgott Ctr. for Neural and Behavioral Sci., Brooklyn, NY

Abstract: Spreading depolarization (SD) is a neuronal phenomenon characterized by the propagation of a depolarization wave at a rate of approximately 2-7 mm per minute, accompanied by ion homeostasis disruption and subsequent minutes-long neuronal silence/depression. SD is observed in neurological disorders like migraine aura, traumatic brain injury, and ischemic stroke, where it worsens the energy crisis by increasing ATP and oxygen demand in affected tissue. The interplay between SD and ischemia can contribute to secondary brain injury. Blood vessels play a contributing role in SD by as a source of oxygen and nutrient supply to the affected tissue. Understanding these mechanisms is important for targeted interventions in conditions like ischemic stroke.

We developed NEURON/NetPyNE simulator models to investigate ion homeostasis at subcellular and tissue scales. At the subcellular scale, we optimized a CA1 pyramidal neuron model to maintain ion homeostasis under physiological conditions. Under ischemic conditions our model predicted greater calcium accumulation in basal dendrites, making them more vulnerable to excitotoxicity. In contrast, the distal-apical dendrites suffered more chloride influx, a contributor to dendritic beading.

At the tissue scale we used an established cortical microcircuit model; equipping neurons with additional homeostatic mechanisms (Na^+/K^+-ATPase, KCC1, NKCC2) and adding energy-dependent clearance of extracellular K^+ by glia. We used RxD to track the intracellular and extracellular concentration dynamics of Na^+, K^+, Cl^- and O_2. Histologic images of a 2.0 x 2.3cm cross-section of the human cortical plate in V1 with immunostaining for CD34, determined the locations of 918 capillaries (mean capillary density: 199.6/cm^2; mean±SD capillary cross-sectional area: 16.7±11.9μm^2). These loci provided the sources of oxygen for our in vivo model. SD was reliability triggered in this in vivo network model by a bolus of K^+ in layer 4. Neuronal Depolarization occurred in all cortical layers, with pathological activity spreading both through

connectivity and extracellular diffusion. Neuronal proximity to an oxygen source was a good predictor of its ability to maintain physiological firing rates.

Title: Molecular heterogeneity of ischemic injury-induced reactive astrocytes.

Authors: *R. D. KIM[1], A. E. MARCHILDON[1], P. HASEL[1], P. W. FRAZEL[1], A. X. GUO[1], S. A. LIDDELOW[1,2,3];
[1]Neurosci. Inst., [2]Dept. of Opthalmology, [3]Parekh Ctr. for Interdisciplinary Neurol., NYU Sch. of Med., New York, NY

Abstract: Astrocytes undergo robust gene expression changes in response to a variety of perturbations such as infection, disease, and acute insults, including ischemic injury. How these transitions are affected by time and sex, as well as how heterogeneous and spatially distinct various reactive astrocyte populations are, remain unclear.
To better understand the molecular and temporal diversity of various astrocyte populations in response to injury, we performed spatial transcriptomics and single nucleus RNAseq of ~138,000 forebrain astrocytes isolated from Aldh1l1-EGFP/Rpl10a mice at 1, 3, and 14 days after ischemic injury induced by Rose Bengal photothrombosis.
We found that injury induces a widespread and temporally diverse response across many astrocyte subtypes. We also identified clusters unique to injury-induced reactive astrocytes, including interferon-responsive reactive astrocytes (IRRAs) that are rapidly induced at 1 day and persist up to 14 days post-injury; this population, in addition to expressing many interferon response genes (e.g. *Igtp, Iigp1, Ifit3,* etc.), appears to be Infar1-dependent. Another unique injury-induced reactive astrocyte cluster expresses proliferative markers (e.g. *Mki67, Top2a, Pola1,* etc.) only at 3 days post-injury. Spatial transcriptomics and *in situ* cluster validation indicated that these lowly abundant reactive astrocyte populations (0.6% and 0.4% for interferon-

responsive and proliferative reactive astrocytes, respectively) are spatially restricted to locations that are likely functionally important in the stabilization and resolution stages following injury. This work highlights the utility of combining multiple profiling modalities, as well as the importance of properly powering the study of rare but potentially biologically meaningful reactive astrocyte populations. Together, these datasets provide a powerful resource for probing injury-induced reactive astrocyte heterogeneity and can be used to guide functional interrogation of biologically meaningful reactive astrocyte substates to understand their pro- and anti-reparative functions following acute injuries such as stroke.

Title: Trpm2 channel deletion in neurons reduces injury following ischemic stroke and improves post-stroke cognitive function

Authors: ***K. A. COAKLEY**[1], J. E. ORFILA[2], C. M. ANDERSON[2], A. M. LOEHFELM[2], V. P. WRIGHT[2], P. K. WAITS[2], P. S. HERSON[3];
[1]Neurolog. Surgery, Ohio State Univ., Columbus, OH; [3]Neurolog. Surgery, [2]The Ohio State Univ., Columbus, OH

Abstract: Background: Emerging evidence implicates post-stroke cognitive impairment as a major contributor to long-term disability. Therefore, optimal therapeutic targets reduce acute ischemic injury and enhance post-stroke brain function. Strong data demonstrates that a novel TRPM2 channel antagonist (tat-M2NX) provides neuroprotection and improves synaptic function, thereby reducing post-stroke cognitive impairment (PSCI). Hypothesis: Knockout of neuron-specific TRPM2 channel expression reduces infarct volume and enhances functional recovery following MCAO Methods: Transient MCAO (60 min) was performed on adult (8-10 week) male and female TRPM2 neuron-specific KO (TRPM2fl/fl, CaMKII Cre) and TRPM2 floxed controls (TRPM2fl/fl). Hemispheric infarct volume analyzed from MRI (T2) images 3 days and 30 days post-injury by a blinded investigator. Extracellular field recordings of CA1 neurons were performed in acute hippocampal slices prepared both 7 days and 30 days after recovery from MCAO to analyze synaptic plasticity (LTP). Results: We observed that neuronal-specific TRPM2 channel knockout reduces acute ischemic injury (infarct volume) in male

animals, while having minimal effect on female mice. Consistent with the hypothesis that neuronal TRPM2 channels contribute to ischemia-induced synaptic dysfunction, recordings obtained in brain slices from neuronal TRPM2 channel KO mice (TRPM2fl/fl-CaMKII CRE) mice 7 days after recovery from 60 min MCAo exhibited intact hippocampal plasticity compared to control TRPM2fl/fl mice not expressing CRE. Male sham control mice exhibit robust LTP of 163±10.4% (n=3) compared to 115±5.6% (n=4) in TRPM2fl/fl mice after MCAO. Neuronal KO exhibited 175±9.8% (n=2). Similarly, female mice had control LTP of 170±6.8% (n=4) compared to 125±6.8% (n=3) in TRPM2fl/fl mice after MCAO. Neuronal KO exhibited 208±7.8% (n=5, $p<0.05$ ANOVA compared to TRPM2fl/fl MCAO). Conclusion: Our data highlight that TRPM2 channels expressed in neurons contribute to both acute injury following transient ischemic stroke and subacute/chronic functional recovery.

Title: Spon1 as a candidate driving oligodendrocyte remyelination in white matter stroke

Authors: *V. LUBERA, Y. KOMURO, E. FONT BELMONTE, J. D. HINMAN;
UCLA, Los Angeles, CA

Abstract: Stroke is a leading cause of long-term disability and is the second most common cause of death worldwide. Small vessel ischemic strokes account for 25% of all strokes and occur silently in the brain with a far higher incidence. Ischemic injury to brain white matter preferentially damages myelin-forming oligodendrocytes. The identification of molecular targets in mature myelinating oligodendrocytes that can promote remyelination after stroke are needed to minimize stroke's devastating impact on the brain and drive neurological recovery. White matter ischemic injury is recognized to enhance oligodendrogenesis, whereby stroke-responsive oligodendrocyte progenitor cells migrate to the lesion and differentiate into mature myelinating oligodendrocytes. This OPC-oligo differentiation after stroke is severely limited and shunts cells to a predominant astrocyte fate. However, the self-repair mechanism of injured but surviving oligodendrocytes in the peri-infarct area of stroke remains poorly understood. To identify molecular pathways that can promote remyelination in mature stroke-injured oligodendrocytes, we used TRAP-seq from CNP-Rpl10a-EGFP transgenic mice (*n*=5/grp) at 3 days following the induction of subcortical ischemic stroke vs. sham. Stereotaxic induction of stroke in the

subcortical white matter using N(5)-(1-Iminoethyl)-L-Ornithine HCl (L-NIO) produces a focal white matter stroke in 3-4 month old male mice. After 3 days post-stroke, white matter tissue directly underneath the left sensorimotor cortex was dissected. TRAP-seq from EGFP+ mature oligodendrocytes results in enrichment of mature oligodendrocyte marker genes and isolates the mature oligodendrocyte transcriptome after stroke. Gene ontology analysis demonstrates enrichment for cell-cell adhesion pathways and among the top differentially regulated genes in stroke-injured oligodendrocytes is the transmembrane cell adhesion molecule, Spon1. Spon1 is essential for neural growth and cell adhesion, and its overexpression in a mouse model of Alzheimer's disease leads to cognitive improvements. Using TRAP-qPCR and in situ RNA detection, we show that Spon1 is progressively up-regulated by oligodendrocytes at 1, 3, and 7 days after stroke. Gain of function expression of Spon1 in stroke-injured white matter results in improved remyelination after stroke and stimulates both mature oligodendrocytes to remyelinate but also promotes post-stroke axonogenesis as well as OPC differentiation. The findings suggest Spon1 is a critical cell adhesion molecule temporally regulated by mature oligodendrocytes after stroke and can trigger post-stroke remyelination.

Abstract: Stroke is the leading cause of disability in the United States. Following stroke, the central nervous system experiences various forms of plasticity. One form of this plasticity is the innervation of axon collaterals from the contralesional motor region of the brain and uninjured corticospinal tract (CST). Prior studies have found early reactive gliosis in the distal end of the injured CST. However, the time course of reactivity of glial cells and their role in facilitating plasticity after stroke remain largely unknown. We used immunofluorescence assays and AAV injections to measure the time course of glial activation and label the emergence of axonal sprouting in the distal spinal cord and contralesional motor cortex, respectively. Additionally, we

established a data analysis pipeline to visualize and quantify results obtained from confocal microscopy and serial two-photon tomography (TissueCyte). We show growth cones in typical motor neuron innervating regions and reactive gliosis in the uninjured CST across various time points after unilateral photothrombotic stroke. Visualizing growth cones in vivo may allow for further study into the mechanisms of collateral axonal sprouting from the uninjured CST of the adult CNS. Further, our results help to understand the role of the glial environment during stroke recovery.

Title: Corticospinal neurons form monosynaptic connections to ipsilesional spinal cord alpha motor neurons following focal cortical strokes in mice

Authors: *M. KENWOOD[1], K. POINSATTE[3], A. AJAY[3], A. NAWABY[3], W. XU[3], D. BETZ[2], E. J. PLAUTZ[3], D. M. RAMIREZ[3], M. P. GOLDBERG[2];

Abstract: Stroke leaves many patients with significant motor impairment. Sprouting of the contralesional corticospinal tract (cCST), into the injured spinal hemicord is associated with improved motor recovery after unilateral primary motor cortex stroke. In adult mice, most corticospinal neurons project to spinal interneurons, and few synapse directly on alpha motor neurons. We examined the distribution of newly formed corticospinal synapses in the mouse spinal cord, using genetically encoded tracers, 3D microscopy, and a spinal atlas with machine learning-based automated classification and registration. We tested the hypothesis that subsets of cCST neurons form direct connections with AMNs in the injured hemicord after unilateral motor cortex stroke in adult mice. We induced a photothrombotic motor cortex stroke or performed sham surgery (n=4 per group) in 8-11 week old male C57/B6 mice and administered a contralesional motor cortex injection of an anterograde adeno-associated virus expressing both membrane-targeted tdTomato and synaptically-targeted eGFP. Cervical spinal cords were subjected to volumetric imaging via serial two-photon tomography (TissueCyte 1000) to characterize synaptic and axonal density of cCST collaterals in whole cervical spinal cords in both stroke and sham mice. Unbiased, global quantification of axonal and synaptic density across the entire cervical cord was accomplished by the development of a custom automated image analysis pipeline, incorporating a novel 3D spinal cord reference volume, published spinal cord annotations comprising 47 distinct anatomical regions (SpinalJ), and machine learning based

pixel classification. We observed cCST synapses in the 6-week post-stroke ipsilesional hemicord, with direct connections to alpha motor neurons controlling the levator scapula, phrenic muscles, supraspinatus & infraspinatus, trapezius & sternomastoid, infrahyoid, biceps, deltoid, and forearm extensor (Log2 FC > 4). Formation of new direct connections from uninjured contralesional primary motor cortex to alpha motor neurons may contribute to recovery of motor function after stroke.

Title: Spatiotemporal characterization of unilateral electrophysiological depression in two pediatric patients

Authors: ***M. LOE**[1,3], A. L. SCHWAMB[3], J. WAGNER[3], R. LANDRE[4], M. MORRISSEY[4], S. R. TOMKO[2], R. M. GUERRIERO[2], S. CHING[3];

Abstract: EEG monitoring is used to detect changes in brain electrical activity of pediatric patients with a variety of conditions, including acute ischemic, traumatic, or metabolic injury to the brain. In this retrospective analysis, two pediatric patients without a history of stroke or cerebrovascular disease presented to the ICU with new-onset stroke symptoms, without magnetic resonance imaging (MRI) evidence of stroke. Despite this, both patients demonstrated unilateral changes in EEG power contralateral to their stroke symptoms. Patients received standard clinical care, as well as continuous EEG monitoring. Both patients' stroke symptoms resolved and EEG activity normalized over the course of days. Subsequently, both patients developed stroke symptoms corresponding to the contralateral hemisphere. Again, EEG monitoring demonstrated similar changes in EEG power in the contralateral hemisphere to symptoms. Each patient had over 72 hours of EEG data, non-contrast brain MRI, and brain MR angiography. Additional quantitative EEG analysis was conducted to describe the spatial propagation of electrophysiological changes observed in acute, alternating hemiparesis during EEG monitoring. We quantified the alternating asymmetry using analytical tools previously developed by our group to characterize the rate and spatial orientation of these unilateral depressions and subsequent recovery. These unilateral depressions correlated with known hemodynamical

changes confirmed on cerebral angiography; these cerebrovascular changes are posited to drive the abnormal brain electrical activity. The unilateral depression found may be an exaggerated correlate of cortical spreading depressions (CSDs), which are hypothesized to be the electrophysiological consequence of cerebrovascular changes in strokes and migraines. While this case study is limited by size and the availability of data retroactively, it provides useful insight into the mechanisms by which we might refine methods for the detection of similar cerebrovascular insults in the future.

Title: Psilocybin improves motor outcomes following photothrombotic stroke and increases peri-infarct plasticity

Authors: *H. STRONG[1], R. M. HINES[2], D. J. HINES[2];
[1]Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV; [2]Psychology, Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Narrow time windows of intervention after stroke onset limit recovery and contribute largely to long term disability. Endogenous mechanisms of recovery contribute to restricting boundaries of damaged tissue and regulating cell death and survival. Glial cells modulate tissue survival and successful formation of synaptic connections regulating peri-infarct plasticity. Identifying therapeutics capable of enhancing recovery of damaged tissue through increasing or strengthening synaptic connections of peri-infarct tissue would widen the time window of treatment. Persistent synaptic plasticity enabled by psilocybin indicates its potential for therapeutic use to enhance endogenous mechanisms of recovery after stroke. The capacity of psilocybin to incite plasticity synergistic with endogenous peri-infarct recovery after stroke remains unknown. In this study, we examine the ability of psilocybin to alter stroke recovery by comparing peri-infarct plasticity and behavioral sparing after photothrombotic motor cortex stroke. Administering psilocybin after stroke led to increased dendritic arborization and spine density in peri-infarct tissue along with glial cell morphology changes. To identify if dendritic recovery was accompanied by behavioral sparing we tested motor outcomes using ladder rung walking and saw improved performance when psilocybin was administered after photothrombosis. These results show psilocybin improves post-stroke motor recovery through increasing dendritic plasticity without exacerbating endogenous recovery mechanisms. Enhancing endogenous mechanisms of peri-infarct recovery through psychedelics provides evidence of a synergistic relationship between glial cells and psychedelics after stroke. Ongoing

work examining the mechanisms of psilocybin plasticity in relation to glial cells after stroke provides novel therapeutics and understanding of the mechanisms that necessitate recovery.

Title: Activated protein C analog protects ischemic brain injury in mice via β-arrestin-2-dependent signaling

Authors: *B. XIANG[1], Y. WANG[1], M. ZHANG[1], J. A. FERNÁNDEZ[2], J. H. GRIFFIN[2], B. V. ZLOKOVIC[1];
[1]USC, Los Angeles, CA; [2]The Scripps Res. Inst., San Diego, CA

Abstract: 3K3A-APC is a recombinant analog of activated protein C (APC) which is an endogenous protease with multiple functions in the body. Compared to APC, 3K3A-APC has reduced anticoagulant activity but preserved cell signaling activities. In the brain, 3K3A-APC exerts neuroprotective effects after an acute or chronic injury. 3K3A-APC is currently under clinical assessment (Phase 3) as a neuroprotective agent following acute ischemic stroke. β-arrestin-2 is expressed in many types of cells and plays important roles in various physiological processes. We hypothesized that β-arrestin-2 is required for the blood-brain barrier (BBB) integrity and neuroprotection after stroke. Using a transient proximal middle cerebral artery occlusion (tMCAO) stroke model, we studied whether the neuroprotection effect of 3K3A-APC depends on β-arrestin-2. Our data show that murine 3K3A-APC (0.8 mg/kg), administered intraperitoneally 10 min and 4 h after tMCAO in wild-type mice compared to vehicle, reduced infarct and edema volume and motor neurological score by 55-61%. Similar reductions in BBB breakdown and number of degenerating neurons were observed. The effects of 3K3A-APC on neuroprotection and blood-brain barrier protection were lost in β-arrestin-2 null mice. Thus, our data supports that 3K3A-APC reduces ischemic brain injury via β-arrestin-2-dependent signaling pathways.

Title: Investigating the impact of novel personalized neurostimulation strategies to promote recovery after an ischemic lesion in anesthetized rats

Authors: *M. CARÈ[1], F. BARBAN[1], R. GRECO[2], M. DI FLORIO[1], D. J. GUGGENMOS[3], C. TASSORELLI[2], M. CHIAPPALONE[1];
[1]Univ. of Genoa, genova, Italy; [2]Headache Sci. & Neurorehabilitation Ctr., IRCCS Mondino Fndn., Pavia, Italy; [3]Univ. of Kansas Med. Ctr., Univ. of Kansas Med. Ctr., Prairie Village, KS

Abstract: Stroke is a major global cause of death and disability, but current therapies are limited as standard post-stroke rehabilitation with physical therapy rarely leads to full restitution of function. This is in part due to impaired communication between unaffected brain areas following the lesion. New techniques, especially those using tailored stimulation patterns that match the dynamics of brain networks have shown promise in promoting plasticity and motor recovery. However, clinical stimulation-based therapies rely on standardized protocols, which may explain inconsistent outcomes. Creating personalized stimulation protocols based on the intrinsic activity may significantly improve efficacy of these approaches. The purpose of this study was to advance neurostimulation techniques by customizing electrical stimulation based on individual electrophysiological features. Our main goals were: to examine the neurophysiological outcomes of an ischemic lesion and to design and characterize short-term effects of novel personalized neurostimulation techniques in an animal model of stroke. We implanted Long Evans male rats with MEAs (microelectrode arrays) in the rostral forelimb area (RFA) and Somatosensory cortex (S1) following ischemic lesion induction in the caudal forelimb area (CFA) using local Endothelin-1 injections. We evaluated the immediate impact of the lesion and tested personalized stimulation protocols using an open-loop paradigm on anesthetized rats. Personalization involved designing stimulation patterns to replicate the intrinsic dynamics in the target area. Three methods were employed: 1) Exponential Stimulation, which created a new spike sequence based on an exponential distribution with mean value equal to the average firing rate of the target brain area; 2) Repeated Stimulation, which generated a stimulation pattern by replaying and repeating recorded spontaneous activity; 3) Shuffled Stimulation, which generated a new spike sequence based on inter-spike intervals (ISI) using data acquired from the experimental network. We found that the lesion significantly reduced spontaneous firing activity in S1 and RFA. The repeated stimulation protocol notably increased spiking activity, consistent with the effects of Activity-Dependent Stimulation, a closed-loop

paradigm known to promote post-lesion recovery. Non-periodic, tailored stimulation is a promising avenue for restoring firing patterns in the damaged brain. These findings have significant implications for advancing therapeutic strategies for neurological diseases and facilitating the translation of personalized electroceutical to clinical practice.

Title: Polyunsaturated fatty acid (PUFA)-enriched diet mitigates secondary sequelae following VCID-associated cerebral hypoxia

Authors: *J. TOMBERLIN[1,2], J. KURTZ[2], J. EDWARDS[2], E. KARAKAYA[2], S. BEYAZ[3], A. ERGUL[2], O. ALBAYRAM[2,1];
[1]Neurosci., [2]Pathology and Lab. Med., Med. Univ. of South Carolina, Charleston, SC; [3]Cancer Ctr., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Vascular contributions to cognitive impairment and dementia (VCID), an umbrella term encompassing multiple vascular disorders, is the second leading cause of dementia behind Alzheimer's disease and related dementia (ADRD). Additionally, VCID and ADRD have overlapping risk factors, which can be managed by improving cardiovascular health. Compelling evidence supports that diets rich in polyunsaturated fatty acids (PUFAs) derived from fish oil (FO) can reduce ADRD-associated cognitive decline, potentially through lowered neuroinflammation and reduced white matter (WM) degeneration. However, how long-term PUFA enrichment affects WM integrity, fatty acid metabolism and trophic response in a model of VCID-associated cerebral hypoperfusion has not been assessed. In our model, C57/BL6 male mice were given either a purified control diet (Control Diet) or novel 2% FO-supplemented diet (2%-FO-Supp Diet) for 3 months (3M) prior to either a sham or bilateral carotid artery stenosis (BCAS) surgery model of VCID. Purified or 2%-FO-Supp Diet was continued for up to 6M post-

injury and body weight and food consumption were monitored on a weekly basis. Mice were subjected to a neurobehavioral battery at baseline and 1, 3, & 5M post-injury alongside cerebral blood flow assessment at 5 days, 1, 3, & 5M via laser doppler flowtometry. Finally, mice were euthanized and tissue samples from the carotid arteries, brain, and heart were collected 6M post-injury. Preliminary results indicate that 2%-FO-Supp Diet BCAS mice maintained a significantly healthier weight following injury compared to control BCAS mice. All BCAS mice also had observable cognitive decline and lowered cerebral blood flow (CBF) starting at 3M post-injury that worsened over time compared to controls. Additionally, 2%-FO-Supp Diet BCAS mice potentially had slowed cognitive decline compared to control diet BCAS mice at both 3M and 5M assessed via Barnes Maze and Morris Water Maze respectively. Notably, we observed that 2%-FO-Supp Diet-BCAS mice have improved trophic function, white matter integrity, and increased free fatty acid signaling response compared to Control Diet BCAS mice. Further, analysis pending, we anticipate that 2%-FO-Supp Diet-BCAS mice will have lowered brain hypoxia and neuroinflammation compared to Purified Diet-BCAS mice. Successful completion of these translational studies will provide novel insights into the long-term vaso-neuronal protective effects of PUFAs in VCID.

Title: Hemoglobin mRNA is diminished in the caudate nucleus with chronic hydrocephalus

Authors: G. IVEY, E. BARRETT, M. HART, *J. W. SHIM;
Biomed. engineering, Marshall Univ., Huntington, WV

Abstract: The expression of hemoglobin genes, such as the alpha and beta globin genes, is tightly regulated, and once hemoglobin gene expression is reduced in the brain, it is likely that cerebral hemoglobin protein is also decreased. However, that is not always the case for less tightly regulated molecules such as haptoglobin, CD163, and vascular endothelial growth factor (VEGF). We have conducted whole transcriptome RNA-sequencing (RNA-seq.) using human postmortem brains at age >65 years with chronic hydrocephalus (CH) and found that genes encoding globin proteins are ranked in the top 5 among roughly 2,000 differentially regulated candidates sorted by effect size and statistical significance. Specifically, genes encoding haptoglobin (HP; top 1 of 2,144) and hemoglobin (HBA2; top 2 and HBA1; top 4 of 2,144) are significantly diminished ($P<0.0001$) while VEGF-A (top 1955 of 2144) gene expression is

elevated (P=0.04) in the caudate nucleus with CH as compared to age-matched controls. These results suggest that haptoglobin and hemoglobin may play a role in the development of hydrocephalus, and their decreased levels may contribute to the progression of this condition. VEGF-A may also play a role in hydrocephalus, as it can increase the permeability of blood vessels and lead to an increase in the volume of cerebrospinal fluid (CSF).

Title: Lactic acidemia as a predictor and prognosticater of vasospasm in Subarachnoid Hemorrhage

Authors: *D. LAL;
Neurosurg., Natl. Hosp. Kandy, Kandy, Sri Lanka

Abstract: Background: Lactic acidemia is a known sequale of organ ischemia and indicates the severity and prognosis. It’s not rare to see lactic acidemia with or without acidosis in ischemic conditions of the brain.
The objective of this study is to find the relationship between lactic acidemia and cerebral ischemia in aneurysmal subarachnoid hemorrhage causing vasospasms.
Methods: Lactic acid levels were measured using arterial blood gas analyzer as part of the clinical evaluation of patients presenting with computerized tomographic evidence of subarachnoid hemorrhage following rupture of intracranial aneurysms and traumatic brain injuries. Patients with CT evidence of significant intracranial mass effects (hydrocephalus, Hematomas) were excluded. Patients were stratified in to three groups based on Glasgow Coma Scale.
Results: 30 patients were included in each group and stratified according to Glasgow Coma Scale. The aneurysm group had mean lactic acid level of 2.7 mmol/l and the trauma group had 1.8 mmol/l. Stratification in aneurysm group showed 2.2 mmol/l, 2.7mmol/l and 3.2mmol/l in GCS 15-13, 12-9 and 8-3 groups respectively. Stratification in trauma group showed 1.6mmol/l and 2.1mmol/l in GCS 15-13 and 12-9 groups respectively. There were no trauma patients having GCS bellow 8.
Conclusion: Aneurysmal sub arachnoid hemorrhage has tendency to cause lactic acidemia than traumatic subarachnoid hemorrhage. vasospasm leading to ischemic injury in aneurysmal SAH is the likely pathophysiology.
Severity of the lactic acidemia shows a correlation with severity of cerebral dysfunction, so likely play a prognostic value.

Title: Neuromuscular junction dynamics following ischemia associated with chronic kidney disease after nanostimulator-tethered stem cells enhanced treatment

Authors: *Y. AN, S. DING, H. KONG;
Univ. of Illinois, Urbana-Champaign, Urbana, IL

Abstract: The neuromuscular junction is a specialized chemical synapse between motor neurons to skeletal muscles, and its dysfunction causes various muscle diseases. Ischemia, the severe peripheral artery disease, causes significant damage and changes to skeletal muscle homeostasis. Ischemia-induced disruption of vasculature leads to myofiber atrophy and damage to the neuromuscular junction. In particular, the ischemia associated with chronic kidney disease is challenging to treat because of skeletal muscle mitochondrial dysfunction caused by substantial decreases in mitochondrial oxidative phosphorylation or elevated mitochondrial reactive oxygen species with accumulated serum metabolites. In this study, we demonstrated that the nanostimulator-tethered stem cells enhanced treatment promoted vascularization in the hind ischemia mouse model associated with chronic kidney disease. We confirmed that enhanced perfusion recovery in the hind limb suppressed the damage in the neuromuscular junction. First, we tethered the mesenchymal stroma cells (MSCs) surface with poly(lactic-co-glycolic acid)-block-hyaluronic acid conjugated with integrin-binding RGD peptides (PLGA-HA-RGD) as a nanostimulator releasing tumor necrosis factor α (TNFα) and stimulating cellular secretory activity. HA-CD44 and RGD-integrin bonds increased the adhesion strength of nanosumulators to the cell surface, allowing them to remain stable during the injection. Following ischemic surgery with femoral artery ligation on a model of chronic kidney disease developed with a 0.2% adenine diet for four weeks, nanostimulator-tethering MSCs injected into the tibialis anterior and gastrocnemius muscle. We monitored the perfusion recovery using a laser doppler perfusion imaging system for four weeks after treatment and harvested the tissue from the tibialis anterior and gastrocnemius muscle in the second and fourth weeks. To quantitatively analyze the neuromuscular junction morphologies, we labeled the alpha-bungarotoxin as a postsynaptic marker and the synaptophysin as a presynaptic marker and acquired the fluorescence images using the confocal microscope. As a result, the perfusion in the hind limb was recovered in the treated group, and the morphologies of the neuromuscular junction and colocalization between presynaptic and postsynaptic maintained heathy conditions compared to the saline-injected

control group. In conclusion, the stem cells tethered with the nanostimulators improved vascularization and perfusion recovery and prevented neuromuscular junction damage following ischemic injury associated with chronic kidney disease.

Title: Distinct Gene Expression Profiles in Human Cerebral and Coronary Artery Smooth Muscle Cells

Authors: *H.-S. KIM[1], S. LEE[2];
[1]Chonnam Natl' Univ., Gwangju, Korea, Republic of; [2]Chonnam Natl. Univ. Med. Sch. and Hosp., Gwangju, Korea, Republic of

Abstract: Background: Human cerebral artery smooth muscle cell layers exhibit unique embryologic, histologic, physiological, and pathological characteristics compared to coronary arteries, suggesting differential mechanisms for fatal outcomes, such as atherosclerosis. This study aimed to elucidate the differences in gene expression between human cerebral artery and coronary artery muscle cell layers. Methods: We obtained human vascular smooth muscle layers of the middle cerebral artery (MCA) and left anterior descending coronary artery (LAD) from the same individual through autopsy (n=10) and compared them using cDNA microarray (n=3). Microarray-based gene expression was analyzed using KEGG and Gene Ontology, and significant gene groups were validated for differential gene expression through qRT-PCR. We established cell lines through ex vivo culture and compared and confirmed the expression of genes related to vascular plasticity. Results: A total of 341 genes exhibited differential expression levels between the two blood vessels; 256 genes were upregulated, and 85 genes were downregulated in cerebral artery-derived vascular smooth muscle cells. Cerebral artery vascular muscle cells demonstrated higher expression of genes involved in angiogenesis, extracellular matrix, cell migration, neurogenesis, and inflammatory response compared to coronary arteries. Among the 256 upregulated genes, the top 13 genes are ApoD, Desmin, Claudin-11, and Netrin-1. According to KEGG and GO analysis, these genes were closely related to atherosclerosis, inflammatory cell migration, and retinal metabolism regulation signal transduction systems in the great arteries. Highly expressed gene clusters in the MCA were associated with type 2 diabetes mellitus (DM) and hypertension, which are well-known as major risk factors for atherosclerosis.

Finally, cell lines of human LAD and MCA established through ex vivo culture showed differences in gene expression related to vascular plasticity including cell cycle and contractility. Conclusion: Our study provides evidence of distinct gene expression profiles between human middle cerebral artery and coronary artery vascular muscle cells, offering insights into the differentiation of arterial function regulation and susceptibility to specific disease conditions. These findings can be utilized as a basis for further investigation, potentially leading to targeted diagnostic and therapeutic approaches for specific vascular diseases.

Title: Modulating $GABA_A$ receptor function in cerebral ischemia-induced brain damage and dysfunctional plasticity

Authors: *H.-C. LIN, H. CHI, M.-C. CHU, C.-H. CHANG;
Dept. and Inst. of Physiology, Natl. Yang Ming Chiao Tung Univ., Taipei, Taiwan

Abstract: Stroke is now one of the most common cause of death and disability in the world. The pathological form of synaptic plasticity, ischemic long-term potentiation (iLTP) induced by oxygen and glucose deprivation (OGD), is implicated in the acute phase of stroke with the potentiation of N-methyl-D-aspartate receptor (NMDAR). While there has been widespread attention on the excitatory system, a recent study reported that γ-aminobutyric acid (GABA)ergic system is also involved in iLTP. In the present study, a brief exposure of OGD on the hippocampal slices and the induction of photothrombotic ischemia (PTI) were used as ex vivo and in vivo models of ischemic stroke, respectively. Here we propose that valproic acid (VPA), a histone deacetylase inhibitor, plays protective role against ischemic damage. Our results demonstrated that VPA treatment abolished hippocampal iLTP via enhancement of GABAA receptor and reduction of extracellular signal-regulated kinase (ERK) phosphorylation. Administration of VPA reduced brain infarct volume and motor dysfunction in mice with PTI. Moreover, VPA protected against ischemic injury by upregulating the GABAergic system, as well as downregulating ERK phosphorylation and matrix metalloproteinase in a PTI-induced ischemic stroke model. Our study demonstrated that VPA treatment rescued pathological form of synaptic plasticity following ex vivo OGD-induced ischemia and the brain infarct damage produced by in vivo PTI-induced ischemia. This study revealed the novel therapeutic impact of

VPA on ischemic stroke via restoring GABAergic deficits and the pathological hallmarks of ischemia.

Title: Proteomic Response in Appalachian Emergent Large Vessel Occlusion Subjects Treated with Mechanical Thrombectomy

Authors: B. MAGLINGER[1], C. J. MCLOUTH[2], J. F. FRASER[3], H. S. HAZELWOOD[4], J. A. FRANK[3], S. PAHWA[3], J. P. HARP[4], D. DORNBOS, III[3], A. M. STOWE[4], A. L. TROUT[3], ***K. R. PENNYPACKER**[4];
[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Biostatistics, [3]Neurosurg., [4]Neurol., UNIVERSITY OF KENTUCKY, Lexington, KY

Abstract: Appalachia contains a subpopulation of the country that has gathered significant attention due to its healthcare accessibility, health disparities, and health outcomes. Individuals from Appalachia exhibit a higher incidence for stroke-related comorbidities including diabetes, obesity, and increased tobacco usage. The objective of this study was to identify proteomic biomarkers predictive of stroke outcomes specific to subjects residing in Appalachian counties. Eighty-one subjects met inclusion criteria for this study. These subjects underwent mechanical thrombectomy (MT) for emergent large vessel occlusion (ELVO), and systemic blood samples acquired at time of intervention were sent for proteomic analysis. Statistical analyses were then employed to examine whether the relationship between protein expression and outcomes differed by Appalachian status for functional outcomes (NIH Stroke Scale; NIHSS and Modified Rankin Score; mRS), cognitive outcomes (Montreal Cognitive Assessment; MoCA) and mortality. No significant differences were found in demographic data nor co-morbidities when comparing Appalachia to non-Appalachia subjects. However, time from stroke onset to treatment (last known normal) was significantly longer in patients from Appalachia. Comparison of Appalachia to non-Appalachian subjects revealed significant differences in functional/cognitive outcomes including NIHSS, MoCA, mRS, as well as neuroradiographic outcomes including infarct volume and edema volume. A comprehensive analysis of 184 cardiometabolic and inflammatory proteins revealed 13 proteins predictive of functional outcomes, 14 predictive of cognitive outcomes, six proteins identified were associated with mRS, and 7 proteins related to mortality. All these proteins were differentially correlated with these functions dependent on whether the patient was from Appalachia or non-Appalachian county. Our study utilizes an ELVO tissue bank and

registry to investigate the intracranial/intravascular proteomic environment occurring at time of thrombectomy. We found that patients presenting from Appalachian areas have a different proteomic response at the time of MT when compared to patients presenting from non-Appalachian areas. These differentially expressed proteins relate to stroke outcome and could be used as prognostic biomarkers, or as targets for novel therapies. The identification of a disparate proteomic response in Appalachian patients suggests a connection with environmental exposures. Further investigations through community-based studies are imperative to elucidate the underlying causes of this differential response.

Title: Stroke and Neural Dynamics: Exploring the impact of focal ischemic infarcts in the latent space

Authors: ***F. BARBAN**[1,2], M. NISHIMOTO[3], H. M. HUDSON[4], M. CHIAPPALONE[1,2], R. NUDO[4,5], D. GUGGENMOS[4];
[1]Univ. of Genoa, Genova, Italy; [2]Rehab Technologies Lab., Inst. Italiano di Tecnologia, Genova, Italy; [3]Univ. of Kansas, Lawrence, KS; [4]Dept. of Physical Med. and Rehabil., [5]Landon Ctr. on Aging, Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Acquired brain injuries, such as stroke, are a leading cause of long-term disability worldwide. When an injury occurs within primary motor cortex (M1), it disrupts both the descending signals to the spinal cord controlling movement and the integration of somatosensory and premotor inputs leading to motor deficits. Luckily, the amount of impairment is not fixed, as some spontaneous recovery of function can occur and can be enhanced through rehabilitative therapies. The underlying mechanisms for recovery are still under investigation but are likely driven by reorganization in spared premotor (PM) and somatosensory (S1) regions. Understanding how these areas undergo neurophysiological changes following M1 injury is therefore crucial to understand the recovery process.
The purpose of this study was to determine: 1) whether neural population dynamics were

disrupted by the infarct within the sensorimotor network, and 2) if a loss of between-area activity and integration could be detected in the low-dimensional space. To investigate these questions, we employed a within-subject design. Twelve Long-Evans rats were trained on a skilled pellet retrieval task before receiving unilateral chronic 32-channel microelectrode array (MEA) implants in PM and S1. Neural data were recorded during task performance before and on Day 5 and Day 7 following a focal ischemic infarct in M1 and processed for single-unit spiking data. Gaussian Process Factor Analysis (GPFA) was used to estimate neural population dynamics, while Canonical Correlation Analysis (CCA) was employed to investigate sensorimotor integration. Additionally, classical metrics such as mean firing rate (MFR) and local variation of refractoriness (LvR) were calculated.
Our findings revealed that PM and S1 showed very similar MFR and LvR pre- and post-injury, indicating that by Day 5, there is a return to normal firing patterns. Despite this, the focal ischemic injury disrupted the task-related population dynamics in both areas. These perturbations in dynamics suggest that critical features of neural activity are represented in this low-dimensional embedding. Further, the task-related shared information between PM and S1 (as shown by CCA) was also disrupted. Taken together, the M1 lesion leads to a disruption in somatosensory-motor integration and task-related motor dynamics despite having little change in the underlying activity. Understanding of how spared areas reorganize activity to execute motor functions has the potential to shape the development of novel therapeutic approaches for individuals with acquired brain injuries.

Title: Transient focal ischemia in middle aged mouse caused circadian desynchrony in the affected brain region

Authors: *A. CHISCHOLM[1], R. SHARMA[3], M. THAKKAR[4], M. PARIKH[2];
[1]Neurol., Univ. of Missouri, Columbia, Moberly, MO; [2]Univ. of Missouri, Columbia, Columbia, MO; [3]Neurol., Univ. of Missouri, columbia, MO; [4]Neurol., HSTMV Hospital/University of Missouri, Columbia, MO

Abstract: Background: Ischemic stroke (IS), the most common type of stroke, is the highest contributor to disability and fifth leading cause of mortality. Current treatment strategies are limited by time constraints and/or patient compliance, hence it is important that new therapeutic targets be identified to treat stroke. Circadian disruptions are the frequently observed in patient with stroke and are considered as unique, novel, and modifiable treatment target as these are associated with worse motor outcomes and slower functional recovery post-stroke. Circadian rhythms are controlled by a central clock located in the suprachiasmatic nucleus (SCN). Most of the physiological rhythms, including body temperature, sleep-wakefulness, are controlled by SCN and its entraining signals to the peripheral oscillators. These peripheral oscillators, present in all kinds of cells throughout the brain and periphery, regulates many non-circadian functions such as motor skills, memory and cognition. Hence, we hypothesized that IS affect circadian gene expression in the SCN and other affected brain region?**Methods**: To test our hypothesis, middle-aged C57BL/6J mice (10-12 months old) were used to target young adult human population. Under sterile conditions and inhalation (isoflurane) anesthesia focal cerebral ischemia was induced by middle cerebral artery occlusion (MCAO), via intraluminal technique, for 1h. In sham controls, similar surgery was performed except no occlusion was performed. Subsequently, animals were allowed to recover from surgical stress and left undisturbed. After 48h, animals were euthanized by decapitation and brain regions supplied by middle cerebral artery (MCA; motor cortex, striatum and hippocampus) were isolated from peri-infarct and contralateral region of the brain. In addition, SCN was also isolated. The tissues were processed for RT-PCR to examine the gene expression.**Results**: Our preliminary results showed that mice subjected to IS (N=4) displayed a) sensorimotor deficit mimicking human IS symptoms, b) Circadian desynchrony (CD) as evident by a significant reduction of Bmal1 gene expression in the motor cortex as compared to sham animals (N=4), however, no change was observed in the SCN. **Conclusion**: Our results suggest that that IS caused CD in middle aged mice. CD has the potential to interfere with the synchronization signals between the SCN and peripheral oscillators, potentially contributing to the development of various psychiatric and neurological disorders. Understanding the role of circadian genes in the post-stroke recovery process will help devise new and better therapeutic strategies for stroke rehabilitation.

Title: Inhibition of iNOS Reduces Vasoconstriction from Chronic Cocaine in Mice Brain

Authors: *Y. LIU[1], Y. JETALPURIA[1], J. REN[2], Y. HUA[1], N. D. VOLKOW[3], Y. PAN[1], W. YIN[1], C. DU[1];
[1]Biomed. Engin., [2]Computer Sci., Stonybrook Univ., Stony Brook, NY; [3]Natl. Inst. on Drug Abuse, Bethesda, MD

Abstract: Cocaine is a highly addictive drug that can result in neurovascular complications such as transient ischemic attacks (TIA) and strokes. Neuroimaging studies have documented marked decreases in cerebral blood flow in the cortex of cocaine abusers. In preliminary studies in rodents, we observed that astrocytes in the brain contribute to cocaine-induced vasoconstriction and ischemic responses, which we hypothesized was associated with iNOS- (inducible Nitric Oxide Synthase) regulation. However, iNOS involvement in cocaine's vascular effects has not been studied. Here, we hypothesized that inhibition of iNOS expression could prevent cocaine-induced vasoconstriction and reduce cerebral ischemia. To test these hypotheses, we used ultra-high resolution optical coherent tomography (μOCT) to capture 3D vascular images from the prefrontal cortex (PFC) of mice before and after chronic cocaine treatment to compare the vascular changes in PFC including changes in vascular diameter and microvascular density. Specifically, three groups of animals were used: 1) wild type (WT) mice treated with cocaine (30mg/kg/day, i.p., for 14 days); 2) iNOS-Knock Out (KO) mice treated with cocaine (30mg/kg/day, i.p., for 14days); 3) wild type mice pretreated with L-NMMA (a non-specific NOS inhibitor, 40mg/kg/day, i.p.) 30 minutes prior to cocaine administration (30mg/kg/day; i.p., for 14 days). At Day 0, a cranial window was implanted on the area of the PFC, 3D optical angiography (μOCA) and cerebral blood flow images (μODT) in PFC were acquired at baseline and repeated at Day 16 (i.e., after 14 days cocaine treatment with one day withdraw). Comparing the neurovascular trees between Day 0 and Day16 (after chronic cocaine), our images observed cocaine induced vessel constriction in WT animals. However, vasoconstriction was reduced in iNOS-KO mice and L-NMMA-pretreated mice. Specifically, the vascular diameters were decreased ~15% in WT mice after chronic cocaine, but only ~7% and ~9% in iNOS-KO mice and L-NMMA-pretreated animals, respectively. The reduction of vasoconstriction effects of cocaine on iNOS-KO and L-NMMA-pretreated animals indicates iNOS's involvement in the vascular changes triggered by cocaine. Interestingly, we also observed increases in microvascular density more in iNOS-KO mice and L-NMMA-pretreated mice than in WT mice, indicating increase vessel recruitment or angiogenesis, which might help mitigate cocaine's vasoconstriction effects in CBF. These results indicated that iNOS plays an important role in cocaine-induced vasoconstriction and that inhibition of iNOS could therapeutically valuable for reducing cerebral ischemia risk in cocaine users.

Title: Effect of physical activity prior to cerebral ischemia on memory consolidation

Authors: *J. TOLEDO MOTTA, J. IBARRA HERNANDEZ, M. PERALES QUINTANA, V. NOVELO HERNANDEZ, S. GUTIERREZ ANGUIANO, D. ALVARADO LARA, K. PALOMO BARBOSA, M. SANTANA BRISEÑO;
Physiology. Fac. of Med., Univ. Autónoma de Nuevo León, Monterrey, Mexico

Abstract: Ischemic cerebrovascular disease is characterized by decreased blood flow that causes hypoxia and inflammation. The most reported sequelae are cognitive deficits and memory problems in up to 90% of the cases. Physical activity has been reported to increase the volume of the prefrontal cortex and the hippocampus, thereby improving memory. This study aimed to evaluate the effects of physical activity prior to a cerebral ischemia event on spatial memory in rats. Male Wistar rats (1 month old) were divided into four groups: 1) sedentary group, 2) exercise group, 3) sedentary-ischemia group, and 4) exercise-ischemia group. According to the group, the rats underwent a voluntary exercise program in a rodent wheel for 3 weeks where the distance and time invested per day were quantified. The Barnes maze test was used to assess spatial memory. After 4 days of training and short-term memory (STM) testing, the rats underwent bilateral common carotid artery occlusion for 15 min. After seven days, long-term memory (LTM) was assessed. The latency to find the escape box, number of successes and errors, and time spent in the escape box quadrant were analyzed using an ANOVA test. A $P<0.05$ was considered a significant difference. Physical activity had no significant effect on STM evaluation between groups. Physical activity decreased the latency to find the escape box during LTM evaluation compared to the sedentary group and increased the number of successes in finding the escape box ($P<0.05$); however, physical activity prior to cerebral ischemia increased the latency in which the escape box was found up to five times compared to the STM evaluation and was significantly higher compared to the other groups. In conclusion, our results show that exercise improves short- and long-term memory. However, in the ischemia groups, exercise showed increased latency compared to the sedentary group, which may be secondary to the structural changes that occur in the hippocampus due to aerobic exercise and vulnerability to ischemia-reperfusion injury.

Title: Temporal coding disruptions in the rat hippocamps following traumatic brain injury

Authors: *C. D. ADAM[1], E. MIRZAKHALILI[2], M. HABIB[2], J. A. WOLF[3];
[1]Univ. of Pennsylvania Neurosci. Grad. Group, Philadelphia, PA; [3]Neurosurg., [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Learning and memory deficits are commonly reported following traumatic brain injury (TBI) and often occur when TBI pathologies disrupt the neuronal circuits that normally support these processes. Learning and memory deficits are especially prevalent when the hippocampus and/or its afferent and efferent pathways are directly affected by TBI; however, the physiological mechanisms underlying these deficits are still poorly understood. To address this gap in knowledge, we subjected rats to a lateral fluid percussion injury (FPI) of ~1.8atm, implanted the injured hippocampus with high-density, laminar electrode arrays, and chronically recorded from awake rats as they explored a familiar and novel environment. Using current source density (CSD) we were able to localize specific layers within the CA1 region of the hippocampus and found a layer-specific loss of oscillatory power in TBI rats compared to sham-injured controls. We also found that theta-gamma phase-amplitude coupling (PAC) was drastically reduced in injured rats. Additionally, we found that individual units in injured rats were less entrained to the theta oscillation recorded in the local field potential. Using different spike features we were able to separate pyramidal cells and interneurons and found that interneurons in injured rats had a lower firing rate and drastically reduced entrainment to theta oscillations. These changes likely contribute to the loss of oscillatory power and PAC we observed, as interneurons are known to support the generation and interaction of theta and gamma oscillations in the hippocampus. When comparing firing properties across the familiar and novel environment, we found that there was a greater overlap in the number of pyramidal cells that were active in both environments in TBI rats compared to sham and that firing rates were more correlated between the environments in injured rats. Both results suggest a potential deficit in pattern separation, an important function attributed to the hippocampus. We are currently investigating how these TBI-associated physiological changes contribute to learning and memory behavior in a radial arm maze task. We are also characterizing differences between the hippocampus ipsilateral and contralateral to injury, and are investigating the effects of medial septal stimulation on learning and memory behavior and physiology. Preliminary results show that electrically stimulating the medial septum at theta frequency elicits a gamma frequency response in the hippocampus which could potentially be a means to artificially restore PAC lost from TBI.

Title: Consistent effects of TBI on Hippocampal HFOs across small and large animal models

Authors: *E. MIRZAKHALILI, C. D. ADAM, A. V. ULYANOVA, H.-C. I. CHEN, V. E. JOHNSON, J. A. WOLF;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: High-frequency oscillations (HFOs) are believed to reflect synchronous activity of subpopulations of neurons. They have been extensively investigated in rodents and their role in memory functions is well-established, especially when they occur during sharp waves. Moreover, these oscillations have been proposed as biomarkers for neurological disorders in animal models as well as humans. We examined how HFOs are affected by traumatic brain injury (TBI) in small (male Long-Evans rats: 4 shams and 5 injured using Lateral Fluid Percussion injury model) and large (male Yucatan miniature swine: 3 shams and 3 injured using Controlled Cortical Implant injury model) animal models of TBI. We recorded chronically from the hippocampus of both animal models using laminar probes, and utilized our newly developed HFO detector to investigate how HFOs are affected by TBI. Our method uses continuous wavelet transform to detect HFOs using time-frequency maps and has been validated using benchmark datasets. We categorized the detected HFOs as ripples (80-250 Hz) and fast-ripples (250-500 Hz) and studied multiple metrics associated with these oscillations. In particular, we quantified the number of these events as well as the interval between the events, their duration, amplitude, and their oscillatory frequency. Our results indicate that the number of all HFO events in both animal models increases in injured animals. Consequently, the interval between the events also decreases. Our results indicated that the number of all high frequency events increased and consequently, the interval between the events decreased in injured animals. However, the average duration of an event, for both ripple and fast-ripple, did not change between groups. Yet, the average power of both ripple and fast-ripple events decreased in small and large animal models. The mean oscillation frequency also did not differ between sham and injured animals; however, the distribution between the two groups differed in that the distribution of the frequency for fast-ripples in injured group was more uniform and had lost its peaks. Collectively, these data suggest that traumatic injury disturbs the precise communications in the interconnected networks of the brain necessary for proper cognitive function. Future work will investigate how HFOs during sharp waves are affected by TBI. This would allow us to increase our understanding of how TBI can lead to cognitive impairment including memory dysfunction in humans and how therapies such as neuromodulation may help to resolve them.

Title: Reductions in hippocampal synaptic proteins associated with vesicular pool health in female and male rats after traumatic brain injury

Authors: A. ROBERTS[1], S. SVIRSKY[1], J. HENCHIR[1], M. PARRY[1], E. HOLETS[1], C. DIXON[1], T. C. JACKSON[2], ***S. CARLSON**[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. Florida, Gainesville, FL

Abstract: Traumatic brain injury (TBI) results in chronic functional impairments, including in cognitive, emotional, and somatic faculties, which may be mediated in part by impaired synaptic neurotransmission. We previously reported that a controlled cortical impact (CCI) brain injury significantly disrupts the vesicular pool at pre-synaptic nerve terminals. Through an improved understanding of the pathological mechanism(s) involved, this can facilitate development of improved therapeutic strategies for restoring neurotransmission. Dysregulation of endocytosis is a prime candidate as it functions to maintain the pre-synaptic vesicle pool through the process of recycling and replenishing vesicles. We hypothesize that traumatic brain injury (TBI) decreases the abundance of key endocytic machinery proteins post-injury. To test this, we compared the levels of hippocampal clathrin light and heavy chains, AP180, dynamin and Rab5 in CCI-injured (2.7mm, 4m/sec) or sham rats at 2wks post-injury. Synaptosomes were isolated from the female and male hippocampus (n=6 per sex per group) and synaptic levels of the target protein targets were measured by immunoblotting. TBI significantly reduced clathrin light chain, clathrin heavy chain, AP180, dynamin and Rab5 ($p<0.05$) in the hippocampus in tissues from both sexes. Synaptophysin was significantly decreased in male ($p<0.05$) but not in females post-CCI. These findings provide the first evidence of endocytosis protein changes after TBI, and highlight that changes in these key synaptic proteins are generalizable to both sexes. Ongoing work by our group is examining the impact of impaired endocytosis on altered neurotransmission after TBI, and to test if restoration of this novel pathway can improve neurobehavioral outcomes after experimental TBI.

Title: Interneuron regulation of inhibition in the hippocampus after traumatic train injury

Authors: *A. HERNANDEZ[1], B. N. JOHNSON[1], A. FARRUGIA[1], A. S. COHEN[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Children's Hosp Philadelphia, UPENN, Children's Hosp Philadelphia, UPENN, Bala Cynwyd, PA

Abstract: Traumatic brain injuries (TBI) afflict approximately two million people annually in the U.S. Many TBI survivors have chronic cognitive problems, which include deficits in learning and memory. Importantly, the hippocampus, a brain structure highly involved in learning and memory, is susceptible to impairment from TBI. A subregion of the hippocampus, area CA1, undergoes changes after TBI resulting in increased inhibitory synaptic transmission thereby leading to a decline in hippocampal network activation. However, the underlying circuit-mechanism that contributes to increased inhibition in area CA1 after injury is not well understood. The action potential firing of pyramidal neurons, the principal excitatory cells of CA1, is modulated by inhibitory interneurons. Indeed, reduced CA1 output due to augmented inhibition was demonstrated as a decrease in pyramidal neuron action potential firing, which was restored with the application of WIN55,212-2, a synthetic agonist of cannabinoid type 1 receptors (CB1R). The only interneuron that is cannabinoid sensitive and expresses CB1Rs are cholecystokinin interneurons (CCK INs). In fact, CB1Rs on CCK INs mediate depolarization induced suppression of inhibition (DSI) a phenomenon which serves to suppress GABA release from CCK IN onto pyramidal neurons. Since WIN can restore pyramidal neuron firing in injured slices and CCK INs are the only cannabinoid sensitive interneuron in area CA1, this work aims to investigate the changes in CCK IN inhibitory signaling and DSI after mild TBI using a well-validated lateral fluid percussion injury model of TBI and electrophysiology. We predict that mild TBI will increase CCK IN signaling, increasing their inhibitory input onto pyramidal neurons, and reduces DSI. This work will investigate the circuit-level mechanisms that contribute to the increased inhibition in hippocampal CA1 after TBI to further our understanding of the precise mechanisms by which injury drives learning and memory deficits to aid in the development of therapies for TBI survivors.

Title: Examining sex dependent effects on hippocampal shifts in excitability after mild traumatic brain injury

Authors: *I. A. DÍAZ NIEVES[1,2], A. FARRUGIA[3], A. S. COHEN[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia Univ. of Pennsy, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) has steadily remained one of the leading causes of death and disability among young people worldwide. People commonly experience some level of cognitive impairment following traumatic injury that can last from days and weeks, to several months or even years. Animal studies have linked these cognitive impairments to opposing shifts in the excitability of different regions of the hippocampus, an important structure necessary for learning and memory. After injury there is a decrease in network excitability in area CA1 of the hippocampus of male mice that is associated with declined performance in a cognitive task. It is still unclear if the degree of cognitive impairment observed in males after injury would recapitulate in females. Thus, the goal of this project is to assess sex differences by examining hippocampal shifts in excitability after TBI. We model TBI using the lateral fluid percussion (LFP) injury device as this injury model mimics human TBI pathology in animals. We used a cohort of 6- to 8-week-old male and female C57BL/6 mice split into four groups: sham male, sham female, injured male, and injured female. Extracellular field recordings in the stratum radiatum of CA1 were conducted in ex vivo slices 6-10 days after LFP injury. We hypothesized and found that injured male mice had a decrease in area CA1 excitability after injury. On the other hand, preliminary data for injured female mice did not show a noticeable shift in excitability when compared to sham females. These results suggest that there might be sex dependent differences in TBI-induced shifts in excitability. Our findings serve to underscore the importance of considering possible sex differences in the pathophysiology of TBI in other contexts besides learning and memory.

Title: Controlled Cortical Impact Increases Hippocampal Epichaperome Formation in male and female rats.

Authors: S. SVIRSKY[1], Y. LI[1], J. HENCHIR[1], A. RODINA[2], S. W. CARLSON[1], G. CHIOSIS[2], *C. DIXON[1,3];
[1]Neurolog. Surgery, Univ. of Pittsburgh, Pittsburgh, PA; [2]Chem. Biol., Mem. Sloan Kettering Cancer Ctr., New York, NY; [3]VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstract: Under normal conditions, heat shock proteins work in unison through dynamic protein interactions collectively referred to as the "chaperome." Recent work revealed that under conditions of cellular stress, the functional interactions of the chaperome are modified to form the "epichaperome," which results in improper protein folding, degradation, aggregation, and transport. This study is the first to investigate this novel mechanism of protein dyshomeostasis in traumatic brain injury (TBI). Male and female adult, Sprague-Dawley rats received a controlled cortical impact (CCI, 2.5mm deformation, 4m/sec) and the ipsilateral hippocampus was collected 24hrs 1, 2, and 4wks after injury (n=6 per injury/time-point/sex). The epichaperome complex was visualized by measuring HSP90, HSC70 and HOP expression in native SDS-PAGE and normalized to monomeric protein expression. A two-way ANOVA examined the effect of injury and sex at each time-point. Native HSP90, HSC70 and HOP protein expression showed a significant effect of injury effect across all time-points ($p<0.05$). Additionally, HSC70 and HOP showed significant sex effects at 24 hours and 4 weeks ($p<0.05$). Altogether, CCI increases epichaperome formation at all time points assessed between 24 hour and 4 weeks post-injury. Further investigation of this pathological mechanism can lead to a greater understanding of the link between TBI and increased risk of neurodegenerative disease and targeting the epichaperome for therapeutics.

Title: Effects of traumatic brain injury combined with hemorrhagic shock on hippocampal synaptic plasticity

Authors: *K. E. BAHAMONDE, K. A. COAKLEY, C. M. ANDERSON, J. E. ORFILA, P. S. HERSON;
Dept. of Neurolog. Surgery, The Ohio State Univ., Columbus, OH

Abstract: Millions of Americans suffer from traumatic brain injuries (TBI), which is often suffered in combination with other injuries, including hemorrhagic shock. TBI and hemorrhage are common causes of morbidity and mortality in severe TBI and in combat, and often occur in combination. However, the influence of hemorrhagic shock on TBI outcomes and cognitive

recovery remains poorly understood. It is hypothesized that TBI and concurrent hemorrhagic shock mice will show greater memory impairment and reduced plasticity compared to either insult alone. This study used electrophysiology to assess memory impairments following a TBI with and without hemorrhagic shock. Extracellular field recording of the CA1 neurons in the hippocampus were performed to assess the effect of TBI and hemorrhagic shock on hippocampal long-term potentiation (LTP). Recordings were performed in acute hippocampal slices prepared 7 days and 30 days after injury. Under control conditions, a physiological theta burst stimulation (40 pulses, 100Hz) resulted in LTP that increased the slope of fEPSP to 171.5± 9.11% (n=10) of baseline. TBI injured mice and hemorrhagic shock only injured mice showed LTP of 167.5± 19.94% and 162.9± 6.44% respectively. There was no impairment present. The TBI and hemorrhagic shock injured mice had impaired LTP (122.0± 3.66%, n=5). This study is ongoing, and it hypothesized that there will be greater impairment in the TBI and hemorrhagic shock mice 30 days after injury. Preliminary data suggests that the TBI and hemorrhagic shock have impaired memory function and reduced long-term functional outcome 30 days post injury.

Title: Interrupted hippocampal-cortical coupling associated with the decline of learning and memory performance after posttraumatic epilepsy.

Authors: *X. TAO[1], U. DEVARAJ[2], R. STABA[2,3], A. BRAGIN[2,3], J. ENGEL, Jr.[2,3,4,5], L. LI[1,2]; [1]Univ. of North Texas, Denton, TX; [2]Dept. of Neurol., [3]Brain Res. Inst., Univ. of California Los Angeles, Los Angeles, CA; [4]Dept. of Neurobio., [5]Dept. of Psychiatry and Biobehavioral Sci., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: Impaired learning and memory is one of the neurobehavioral comorbidities of epilepsy, and understanding the underlying mechanisms may lead to improved therapeutics. The current study aims to explore the potential neuronal changes that lead to learning and memory impairment in a rodent model of post-traumatic epilepsy. In particular, we are interested in studying the changes in hippocampal-neocortical coupling due to the occurrence of pathological high frequency oscillations (pHFOs). This translational research focused on the latent period when no spontaneous seizure occurred. We used a traumatic brain injury (TBI) model of

temporal lobe epilepsy with microelectrodes implanted bilaterally in the neocortex, hippocampus, and striatum in thirty-three (n = 33) rats. A sham control group (n = 8) of age-matched naïve rats was used with the same electrode implantation assembly. Broadband brain electrical activity (1-3000 Hz) was recorded intermittently from day 1 of TBI until 21weeks after TBI. The experimental period of 3 to 21 weeks were used to identify which rats became epileptic (E+ group) and which did not (E- group).The Cheeseboard maze test was introduced to evaluate learning and memory performance before TBI, 2weeks, 3 months and 6 months after TBI. HFOs were detected and classified as pathological and physiological events by separating the ripple-on-spike (ROS) and ripple-without-spike (RWS) patterns, respectively. Coupling between hippocampal HFOs and prefrontal spindles was performed during the NREM sleep period over eight weeks. Neural correlates between hippocampal-neocortical coupling and behavioral performance were analyzed. The E+ group (n=14) demonstrated a significant ($p<0.001$) increase in hippocampal ROS rate compared to the E- and control groups. No changes in prefrontal spindles were found in the three groups. We observed a significant ($p < 0.001$) increase in synchrony between hippocampal ROS and prefrontal spindles in the E+ group (compared to the E- group), but not on RWS-spindle coupling. A strong correlation($r = 0.54$) was found between ROS-spindle coupling and decreased learning ability in E+ animals, but not in E- animals. Our data suggest a potential neural mechanism of impaired learning and memory in post-traumatic epilepsy. The normal memory consolidation process by the coupling of hippocampal ripples and prefrontal spindles was interfered by the occurrence of pHFOs. The hypersynchrony of pHFOs and prefrontal spindles may disrupt the normal process of memory consolidation. This study helps to improve our understanding of possible neural mechanisms of learning and memory difficulties in post-traumatic epilepsy.

Title: Sex-dependent cognitive dysfunction following repeated mild TBI in adolescent rats may rely on corticotrophin-releasing factor mediated alterations to the septo-hippocampal cholinergic system

Authors: *T. A. MCCORKLE, R. RAGHUPATHI;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sports-related concussions (SRC, a subset of mild TBI) are a leading cause of long-term cognitive deficits in adolescents. Previously, we reported that repeated mild injuries in adolescent male and female rats resulted in spatial memory deficits in the novel object location task at 1-and-4-weeks post-injury in male rats. Female brain-injured animals, however, only showed impairment at 4-weeks. Since moderate TBI and chronic stress in animals lead to alterations in the expression of choline acetyltransferase (ChAT) and corticotrophin releasing factor (CRF) within the medial septum (MS), respectively, we hypothesized that disrupted cholinergic transmission between the MS and hippocampus may be the mechanistic basis for impairments in hippocampal-dependent memory, and that CRF expression in the amygdala regulated ChAT expression in the MS. Following behavioral assessment at each time point, rats were sacrificed for quantitative real-time PCR and immunohistochemistry. Our data demonstrated that there is a decrease in ChAT immunoreactivity in the MS of male brain-injured animals at 1-and-4-weeks, but fewer ChAT(+) cells were observed in female brain-injured animals only at the 4-week time point. While there was no significant difference in CRF mRNA expression in the amygdala or MS for either sex at either timepoint, injection of a CRFR1 antagonist into the MS of brain-injured animals showed an attenuation of the cognitive deficit and of the reduction in ChAT+ cells in female brain-injured animals only. In contrast, the CRFR1 antagonist did not reverse cognitive deficits in male brain-injured animals, and it impaired spatial memory in male sham-injured animals. Together, these data demonstrate that the role of CRF in altering cognitive functioning post-injury may be sex dependent. Further, they provide novel associations between ChAT and CRF expression and cognitive impairments following mild TBI, offering further insight into a potential mechanism of action in SRC.

Title: Toll-like receptor 4 and matrix metalloproteinase-9 signaling contribute to synaptic and circuit alterations in the hippocampal dentate gyrus after brain injury.

Authors: *D. SUBRAMANIAN[1], E. CONTRERAS[2], L. DOVEK[3], V. SANTHAKUMAR[2]; [1]UC Riverside, Riverside, CA; [2]Mol. Cell and Systems Biol., Univ. of California, Riverside, Riverside, CA; [3]Univ. of California, Riverside Biomed. Sci. Grad. Program, Riverside, CA

Abstract: Traumatic Brain Injuries (TBI) often trigger a robust immune response characterized by the activation of inflammatory mediators that subsequently result in cell death, altered neuronal excitability, memory deficits and promotes epileptogenesis. We recently identified a key role for Toll-like receptor 4 (TLR4), an innate immune receptor, in augmenting posttraumatic network excitability. Importantly, pharmacological inhibition of TLR4 within the first 48 hours after TBI effectively reduced epileptogenesis and memory deficits in rodents. Here we examined whether TLR4 signaling recruits Matrix Metalloproteinase-9 (MMP-9), a potent Zn^{+} activated endopeptidase critically involved in circuit remodeling, and if the TLR4: MMP-9 signaling axis alters circuit function in the hippocampal dentate gyrus (DG) after concussive brain injury. Rats (p24) subjected to moderate lateral Fluid Percussion Injury (l-FPI) or sham injury were treated with antagonists of TLR4 (CLI-095, 0.5mg/kg, i.p.), MMP-9 (SB-3CT, 50mg/kg, i.p.) or vehicle 30min to 24hrs post-injury and examined at 48 hrs for MMP-9 activity. *In situ* zymography revealed an increase in MMP-9 activity 48 hrs after l-FPI, which was reduced by CLI-095 treatment. Early (1week post injury) and long-term (6-8 weeks post injury) changes in DG Granule Cells (GC) synaptic inputs were examined using whole-cell patch clamp technique. We observed an increase in the frequency of spontaneous excitatory postsynaptic currents and a decrease in spontaneous inhibitory postsynaptic currents to GCs 1 week and 6-8 weeks post-injury. Interestingly, these changes were prevented by early treatment with either CLI-095 or SB-3CT. In vivo recordings from urethane anesthetized rats showed an increase in perforant path evoked DG excitability one week after l-FPI, which were reduced by treatment with CLI-095 or SB-3CT. Together, our results suggest a TLR4 mediated increase in MMP-9 activity after TBI and identify a role for TLR4:MMP-9 signaling in altered dentate excitability following TBI.

Title: Investigating the Effects of Microglial Depletion on the Hippocampal Circuitry after Acute Mild Traumatic Brain Injuries.

Authors: *S. A. S. DELCY[1], A. M. FARRUGIA[2], A. S. COHEN[3];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol., Children's Hosp Philadelphia, UPENN, Philadelphia, PA; [3]Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia Univ. of Pennsy, Philadelphia, PA

Abstract: Traumatic Brain Injury (TBI) affects 69 million people worldwide, and approximately 2.5 million in the United States alone. TBI is defined as a force or blow to the head and involves two distinct phases. In phase 1, tissue is damaged due to initial impact, whereas phase 2 includes secondary injury cascades and physiological changes that take place as a result of the primary injury. Neuroinflammation is a common immune response observed post-TBI that can result in neuronal death when prolonged. This phenomenon is not fully understood; however, scientists have reported that increased microglial response leads to increased inflammation in the brain, which contributes to secondary injuries. Furthermore, microglial activation may contribute to excitability shifts in the hippocampus due to cytokines and chemokines being released. Interestingly, the Cohen lab has reported increased network excitability in the dentate gyrus (DG) and decreased network excitability in area CA1. These regional hippocampal shifts in excitability contribute to deficits in learning and memory post TBI. Recent findings suggest that pharmacologically depleting microglia, using a CSF1-R inhibitor, improves TBI symptoms; however, little is known about physiological changes post-depletion. Given the relationship between microglial activation and neuroinflammation and the excitability shifts post-injury, this study investigates the role of microglial activation in physiological alterations in the hippocampal circuit to (1) better understand TBI pathophysiology and (2) introduce potential therapeutic targets to mitigate cognitive deficits post-injury. Preliminary results suggest that microglial depletion post-injury decreases neuroinflammatory factors which in turn reduce excitability shifts and improve learning. Future directions include depleting and repopulating microglia post-TBI; there are homeostatic/defensive properties associated with regenerated microglia which could further improve recovery of surviving neurons and restore E/I balance in the hippocampal circuitry. The proposed studies have the potential to introduce microglial depletion and repopulation as a therapeutic measure for chronic neuroinflammation and neuronal cell death which are both contributors of secondary injury presentation.

Sch., Newark, NJ; [3]Biomed. Engin., Acibadem Univ., Istanbul, Turkey; [4]Burke Med. Res. Inst., White Plains, NY

Abstract: INTRODUCTION: Repetitive Transcranial Magnetic Stimulation (rTMS), a non-invasive exploratory and neuromodulatory technique, has shown therapeutic effects not only in animal models, but also in individuals with spinal cord injury (SCI). Recently, high-frequency rTMS (HF-rTMS; >1 Hz) effect on corticospinal excitability has also been investigated in SCI with promising outcomes for recovery. However, depending on the rTMS repetition rate, recording meaningful Motor Evoked Potential (MEP) responses can be challenging due to the presence of rTMS and movement artifacts, which is further magnified using a HF-rTMS protocol wherein the artifacts could overshadow the actual MEP. This retrospective study evaluated the application of narrow notch filters to only remove the HF-rTMS artifacts without altering the MEP responses.
METHODS: With a study protocol approved by the local Institutional Review Board, HF-rTMS was delivered in 10 trains of 75 biphasic stimuli at 15 Hz, through a B65 figure of eight coil connected to a MagPro X100 stimulator, at suprathreshold stimulus intensities ranging from 80 to 110% of the individual resting motor threshold. The analysis included offline data of 94 sessions, obtained from 12 individuals (6 SCI and 6 able-bodied). Continuous surface EMG data recorded from forearm muscles were first band filtered at 20-350 Hz. A narrow notch (4th order Butterworth with 3 dB stopband) filter with a center frequency of 15 Hz and a width of 1 Hz was then applied, together with its 4 harmonics, immediately before the 75 stimuli train.
RESULTS: Preliminary results showed that, regardless of the HF-rTMS intensity and the population studied, the stimulation artifacts were on average reduced (-32 dB), with minimal negative impact on the MEP amplitude response ($\leq$ - 7%).
CONCLUSION: Removing HF-rTMS artifact might be of interest, particularly with data where MEP response is the main outcome and thus could be overestimated due to the artifact. The filtering strategy seems promising to obtain cleaner EMG data. Further analysis is needed to verify the preliminary results, with rTMS applied at different repetition rates.

Title: Repetitive Transcranial Magnetic Stimulation Intensity versus Number of Bursts Effects on Corticospinal Excitability in Able-Bodied and SCI-Affected Individuals

Authors: *N. BRIHMAT[1,2], M. B. BAYRAM[2], S. H. SALEH[3], J. ZHONG[4], G. H. YUE[5,1], G. F. FORREST[2];
[2]Reynolds Ctr. for Spinal Stimulation, [1]Kessler Fndn., West Orange, NJ; [3]Rutgers, The State Univ. of New Jersey, Newark, NJ; [4]Weill Cornell Med. Col., Burke Med. Res. Inst., White Plains, NY; [5]Human Performance and Engin., Kessler Fndn. Res. Ctr., West Orange, NJ

Abstract: Repetitive transcranial magnetic stimulation (rTMS) is a non-invasive brain stimulation strategy with a potential to induce neuroplasticity and reinforce the residual spinal and supraspinal pathways after a CNS injury. Recent and increasing evidence suggests the benefits of high-frequency rTMS (HF-rTMS) to boost functional recovery in individuals with spinal cord injury (SCI). The stimulation parameters, such as the stimulation intensity (SI) and the number of bursts (nB), are known to affect the motor evoked potential (MEP) responses recorded from the targeted muscle. Our goal was to investigate how the modulation of these parameters affect the rTMS responses in uninjured and spinal cord injured individuals. We used surface EMG data recorded continuously from hand and forearm muscles of 4 able-bodied (AB) and 6 chronic SCI individuals, during the administration of a HF-rTMS protocol (75 pulses per burst, 15 Hz, B65 figure-of-eight coil connected to a MagPro X100/X30 machines). During the first visit (V1), the participants from the two groups were administered single bursts of HF-rTMS at different SI (**AB**: 90-100-105%; **SCI**: 80-90-100-105%, of the individual resting motor threshold, RMT), to test the participant tolerability. During the following visit (V2), the participants were administered 10 bursts at the same SI, defined during V1, with a 60 sec inter-train interval for 10 min. MEPs were extracted from the targeted muscles EMG and their amplitude modulation analyzed across bursts using the TMS Analysis Toolbox. An intensity-dependent effect was observed with the data from the AB and SCI individuals at V1. The HF-rTMS SI significantly affected the MEP amplitude across bursts with a progressive increase of the MEP amplitude with the SI used. No such effect was observed when increasing the nB. These results show that increasing the number of bursts, unlike increasing the SI, does not result in the concomitant and continuous increase of MEP amplitude. This finding needs to be considered when planning HF-rTMS for therapeutic purposes.

Title: Effects of gait symmetry with spinal cord transcutaneous stimulation on muscle activity in individuals with SCI

Authors: *M. ANJARIA[1], K. MOMENI[2], M. RAVI[1], A. BHEEMREDDY[1], M. B. BAYRAM[1], S. HABER[1], G. FORREST[1];
[1]Kessler Fndn., West Orange, NJ; [2]Koneksa Hlth., Newyork, NY

Abstract: A previous study by our group showcased that use of optimal and individualized spinal cord transcutaneous stimulation (scTS) parameters during overground gait training facilitate coordination in kinematics profiles in individuals with incomplete spinal cord injury (SCI). We extended our work to evaluate the immediate motor response changes from stimulation and the motor response after scTS combined with gait training. Three-dimensional kinematics were evaluated for several chronic incomplete SCI participants who completed gait training with and without scTS along with multi-channel EMG analysis. Multiple, targeted cohorts of scTS were delivered using cathodes at the lumbosacral and thoracic spinal sites and several sites for anodes. The stimulation waveforms consisted of a rectangular pulse (width of 1ms) with 5kHz carrier frequency. Individuals were tested before, at midpoint and after training. Full-body kinematics (Motion Analysis, California) were collected while participants walked overground with and without scTS and surface EMG electrodes (Motion Lab Systems Inc., Baton Rouge, LA) for muscle activation were collected for both upper and lower extremity muscle groups. For scTS trials, there was an immediate effect on the intralimb and interlimb coefficient of variation for lower-extremity muscle groups compared to trials without scTS. Moreover, when trials of overground gait training combined with stimulation were compared to trials with stimulation but no prior training, the results showed reduced interlimb coefficient of variation in muscles corresponding to spinal stimulation sites. These changes suggest that voluntary motor gains persisted with trials without stimulation, demonstrating the effectiveness of targeted scTS + training, and its sustenance post training, across the participant population. Moreover, further gains were observed up to 2 years post training. The data shows the immediate impact to the spinal excitability through neuromodulation and its longer-term impact when combined with training to include the peripheral circuitry.

Title: Analysis of Spinal Cord Transcutaneous Stimulation induced EMG Responses in individuals with Intrathecal Baclofen Pump after SCI

Authors: *M. RAVI[1], K. MOMENI[2], A. BHEEMREDDY[1], M. ANJARIA[1], M. B. BAYRAM[1], J. LOPEZ[3], S. KIRSHBLUM[3], G. F. FORREST[1];

[3]Kessler Inst. for Rehabil., West Orange, NJ

Abstract: Approximately 18,000 people in the United States alone suffer a Spinal Cord Injury (SCI) each year. SCI affects the nervous system in several ways including causing affected individuals to suffer loss of mobility and sensation below the level of lesion. One major secondary medical complication associated with SCI is spasticity and it affects up to 65% of people with SCI. Spasticity is characterized by involuntary muscle contractions and increased muscle tone that can interfere with daily activities, mobility, and sleep in addition to causing pain, contractures, stress, and reduced quality of life. One common intervention for severe spasticity is an Intrathecal Baclofen (ITB) pump delivery system. Spinal Cord Transcutaneous Stimulation (scTS) has been shown to significantly improve sensorimotor function in addition to improving some secondary effects of SCI including stabilizing blood pressure and decreasing spasticity. To our knowledge, no other scTS studies have been performed on people with an implanted ITB system. In this study, we examine the scTS induced Electromyography (EMG) responses on people with an implanted ITB pump after SCI and compare them with responses for people without an ITB pump after SCI. We recruited individuals with SCI (both complete and incomplete) and applied scTS with T11-12 spinal segment as cathode and bilateral Anterior Superior Iliac Spine (ASIS) as anode. Carrier-wave frequency was set at 5 kHz for monophasic waveform and EMG was recorded from key lower limb muscles. The amplitude of scTS was modulated systematically and EMG responses corresponding to each amplitude were analyzed for all bilateral lower limb muscles. The responses were also analyzed by latency - Early response (<15ms after stimulation pulse), Late response (15-60ms) as well as for Whole response (0-60ms after stimulation pulse). Results of the analyses show that the peak-to-peak EMG responses (early, late and whole) for individuals with an SCI + ITB system were significantly lower than the responses for individuals without the ITB system. Therefore, the amplitude at which scTS is delivered may have to be different for those with an implanted ITB pump due to reduced responsiveness caused by presence of Baclofen in the nervous system. Further research is needed to establish safety and efficacy of scTS neuromodulation for multiple spinal sites, amplitudes, and frequencies for individuals with an ITB pump.

Title: Effects of Spinal Cord Transcutaneous stimulation and Activity-Based Training on Spasticity

Authors: *A. BHEEMREDDY, M. ANJARIA, M. B. BAYRAM, M. RAVI, F. ZHANG, S. HABER, G. F. FORREST;
Kessler Fndn., West Orange, NJ

Abstract: Spasticity is a common movement disorder that develops in 65-70% of individuals following a spinal cord injury (SCI) within one-year post-injury. Current methods to manage severe spasticity involve pharmacological treatments that have been shown to have concomitant side effects that can limit participants' ability to respond to neurorehabilitation. Spinal cord transcutaneous stimulation (scTS) in addition to activity-based therapy (ABT) have been shown to be effective interventions for neurorehabilitation to improve function for people with SCI. We hypothesize that longitudinal targeted scTS + ABT will also have a beneficial effect on spasticity for SCI. Targeted scTS + ABT incorporated exoskeleton and overground gait training. Specific scTS parameters for training were selected based on mapping sessions that systematically modulated stimulation frequencies, amplitudes, and spinal site locations. Surface Electromyogram (EMG) electrodes (Motion Lab Systems Inc., Baton Rouge, LA) were placed on muscles of the lower extremity before and after completion of the training to analyze muscle activation during overground walking tests performed out of suit. Immediate and long-term substantial reduction in lower limb spasticity was determined from analyses of muscle activation data pre and post intervention protocol. Power spectrum analyses on the EMG collected during walking determined a clear distinction following longitudinal scTS and ABT, showing substantial reduction in peak and average power in the frequency domain for the EMG data. These results show the potential for scTS + ABT as an effective intervention for reducing spasticity while also improving voluntary movement following SCI.

Title: Combining Spinal Cord Transcutaneous Stimulation with Activity-based Training in Inpatient Settings to Improve Upper Extremity Function Following Cervical Spinal Cord Injury

Authors: *F. ZHANG, J. CARNAHAN, A. BHEEMREDDY, M. RAVI, M. ANJARIA, G. FORREST;
Kessler Fndn., West Orange, NJ

Abstract: Initiating rehabilitation at an early stage following spinal cord injury (SCI) is critical and delayed interventions may limit the ultimate functional recovery. Current rehabilitative therapies focus on promoting activity-dependent neuroplasticity by involving functional and task-specific activities with high intensity and high repetition. Spinal cord transcutaneous stimulation (scTS) is a novel, non-invasive technique that can neuro-modulate the excitability of spinal circuits and facilitate the weak or silent drive for restoration of motor and sensor function after SCI. Combining scTS with activity-based training (ABT) as a daily therapy in an inpatient program holds great potential to increase the rate of functional and neurological recovery before the chronicity and emergence of new types of pathology influence long-term recovery. The goal of this study is to assess the safety and preliminary efficacy of the scTS+ABT intervention in an inpatient rehabilitation program, to facilitate upper extremity (UE) functional recovery for individuals with acute to subacute cervical SCI. Individuals with acute to subacute cervical SCI were randomized to receive scTS+ABT, $scTS_{sham}$+ABT, or ABT alone. The interventions were administered over 2 consecutive weeks, for 30mins per session and 5 sessions per week, as a part of the daily 3-hour therapy. ABT focused on activities of grasping, pinching, and gross and fine motor skill. Participants in scTS+ABT received ABT while receiving concomitant, active scTS applied at the cervical and thoracic spinal segments over the dorsal skin with optimized and customized stimulation parameters. The sham-control group went through ABT paired with sham stimulation to control for placebo effects associated with the perception of scTS. The type, frequency, and severity of adverse event reports (related to scTS, ABT, and SCI) during the intervention course were reported to determine whether scTS+ABT is safe and feasible when applied during an inpatient rehabilitation program. In addition, we quantitatively assessed UE motor impairment, maximum voluntary handgrip strength, and functional ability at pre- and post-intervention to evaluate the efficacy of scTS+ABT in promoting UE functional recovery in acute to subacute SCI, as compared to the sham control and ABT only. The research findings could provide evidence for integrating scTS+ABT into inpatient rehabilitation practice, which will significantly accelerate the functional and neurological recovery of acute and subacute SCI in the current clinical care.

Title: Improvement of voluntary movement following task-specific training with subthreshold lumbosacral epidural stimulation in individuals with severe spinal cord injury.

Authors: *C. ANGELI[1,2], E. REJC[1,2], G. FORREST[2], S. HARKEMA[1];
[1]Univ. of Louisville, Louisville, KY; [2]Kessler Fndn., West Orange, NJ

Abstract: Recovery of voluntary motor function several years after clinical diagnosis of motor complete spinal cord injury (SCI) is rare. Subthreshold network targeted lumbosacral epidural stimulation (scES) has been previously shown to restore voluntary movement in individuals with motor complete SCI (Angeli et al. 2014, Grahn et al. 2017, Darrow et al. 2022). The aim of this study is to determine the effects of task-specific training with scES on voluntary movement ability in individuals with severe SCI.Individuals with chronic motor complete SCI (n=27) were implanted at L1-S1 spinal cord level with an electrode array and neurostimulator. These individuals (age: 35.5 ± 10.6 yrs; time post-injury: 10.1 ± 8.1 yrs; 37% female, 15 AIS A, 11 AIS B, 1 AIS C) were unable to move their legs voluntarily or stand independently. Voluntary movement mapping was performed in all participants while asking individuals to attempt flexion movements of the first toe, ankle and hip. Further changes in parameters were dependent on the observed EMG modulation and joint movements. Individuals were randomized to a voluntary training group (Vol-scES) or a cardiovascular group (CV-scES). Individuals used scES for 6 hours a day practicing voluntary movement (Vol-scES) or for blood pressure regulation (CV-scES). We performed torque and EMG assessments in a dynamometer pre and post training with voluntary specific stimulation.All individuals were able to modulate EMG activity in the presence of scES and were able to move at least one joint. There was no difference between groups prior to the start of the training intervention. Individuals randomized to the Vol-scES group showed an improvement in maximum torque generation and ability to perform multiple consecutive repetitions of hip flexion when compared to their baseline (post-implant, pre-intervention values). While individuals randomized to the CV-scES group showed a slight decrease in both outcomes. When asked to perform ankle dorsiflexion the median RMS value of TA showed a slight increase for the VoL-scES group with a decrease for the CV-scES group. Torque generation during dorsiflexion increased in the VoL-scES post training while there was a decrease in the CV-scES. These results provide evidence that task-specific training with scES results in greater voluntary movement ability. Further, scES modulates network excitability of the injured spinal cord to allow for the integration of afferent and supraspinal descending input to generate movement below the injury after severe SCI.

Title: High frequency blood pressure oscillations during orthostasis can occur independently of baroreflex-sympathoneural dysfunction in individuals with cervical spinal cord injury

Authors: *S. WANG[1], H. LEDBETTER[1], S. J. HARKEMA[1,2], D. S. GOLDSTEIN[3];
[1]Kentucky Spinal Cord Injury Res. Center, Dept. of Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [2]Frazier Rehabil. Inst., Louisville, KY; [3]Autonomic Med. Section, Clin. Neurosciences Program, Div. of Intramural Res., Natl. Inst. of Neurological, Disorders and Stroke (NINDS), Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: Introduction: Orthostasis often induces low frequency blood pressure (BP) oscillations (Mayer waves) that are related to altered baroreflex modulation of sympathetic cardiovascular outflow. Orthostasis also increases relatively high frequency (HF) oscillations at the periodicity of breathing. Whether HF oscillations of BP during orthostasis depend on baroreflex-sympathoneural function is poorly understood. Individuals with chronic cervical spinal cord injury (SCI) have orthostatic hypotension (OH) related to baroreflex-sympathoneural failure, providing an opportunity to fill this knowledge gap. **Methods:** Twenty-one participants with chronic cervical SCI and OH underwent 70° head-up tilt for up to 30', with continuous finger BP and electrocardiographic (ECG) monitoring. The respiratory period was estimated from amplitudes of ECG R waves. Power spectral density (PSD) was quantified from systolic BP, RR interval, and R wave amplitude during 5' supine and the first 3' of tilt (shorter if the tilt was tolerated less than 3'), using Welch's modified periodogram. HF spectral power of BP was calculated by integrating PSD in the respiratory frequency range (0.15-0.4 Hz). **Results:** HF spectral power of systolic BP increased in a majority of the participants, but due to individual variability the mean change was not significant ($p=0.1337$). In a subgroup ($n=14$) with a prominent peak in the PSD of respiratory activities, HF spectral power of systolic BP tended to increase from supine to tilt ($p=0.0586$). In the subgroup without a prominent peak in the respiratory PSD, HF spectral power of systolic BP did not change with tilt ($p=0.4820$). **Conclusions:** Individuals with chronic cervical SCI and OH often have tilt-evoked, breathing driven BP oscillations. Such oscillations therefore can occur independently of baroreflex-sympathoneural dysfunction, in contrast with Mayer waves.

Title: Modulation of Spasticity Using Epidural Spinal Cord Stimulation in Chronic Spinal Cord Injury

Authors: *G. FORREST[1], C. A. ANGELI[2], E. REJC[3], S. J. HARKEMA[4];
[1]Kessler Fndn., West Orange, NJ; [3]Neurolog. Surgery, [4]Dept. of Neurosurg., [2]Univ. of Louisville, Louisville, KY

Abstract: The evidence clearly indicates that spasticity is a significant issue for persons with SCI, and has a significant negative impact on the quality of life. Baclofen is a commonly used pharmacological treatment for spasticity. Unfortunately, such pharmacological approaches can produce side effects that include: drowsiness, dizziness, weakness, constipation, sleep disturbances, changes in the muscles innervated, or unintended degradation of voluntary movement. We hypothesized that targeting integrated networks may reduce the spasticity mechanisms, utilizing lumbosacral spinal networks when supraspinal input was chronically compromised. In this study, we neurophysiologically identify specific spinal and peripheral circuitry responsible for using neuromodulation to directly address spasticity in five individuals with chronic cervical SCI, implanted with a Medtronic 5-6-5 electrode array and neurostimulator to apply Epidural Spinal Cord Stimulation (scES). Spasticity was evident and induced in all individuals with SCI without scES when monitored while lying supine. Elicited spasticity induced by a trigger three times sequentially and recorded EMG activity of the hips, knees, and ankles without and with targeted scES. For stimulation, the frequencies ranged from 85 -120 Hz and relied on cathode selection of all but a few electrodes selected as anodes. Muscle activity (as recorded using EMG) was significantly reduced both in the number of bursts and level of activity in all muscles with targeted scES. These results demonstrate that neuromodulation specific to the lumbar spinal cord reduces spasticity in chronic human SCI. Integrated systematic neuromodulation at the lumbosacral spinal, such as scES, now has shown the ability to improve motor function and reduce spasticity, both devastating consequences after severe SCI, using the same epidural implantation method providing a potential multi-modality clinical treatment.

Abstract: Transcutaneous electrical spinal stimulation (TESS) has been used to improve voluntary motor output in humans with spinal cord injury (SCI). However, the effect of TESS on involuntary muscle activation patterns, such as clonus, after SCI remains poorly understood. To address this question, we tested the effect of 20 min of TESS (30Hz pulses with a 5kHz carrier frequency) applied between L1-L2 spinous processes on clonus measured in the soleus muscle using electromyographic (EMG) activity in five individuals with chronic cervical SCI. During testing, participants were seated with their hips at 90° and the knee angle ~110°. Clonus was induced with a rapid dorsiflexion stretch of the ankle plantar flexors by an experimenter. Using EMG burst onsets and offsets, we quantified clonus duration, number of bursts, burst frequency, burst duration, interburst duration (i.e., a period of a decrease or a relative silence following the burst of EMG), and burst amplitude for each individual trial. We found that before TESS the median clonus duration was 26.0 sec (range 4.1-45.7 sec), number of bursts was 130 (range 21-229), burst frequency was 4.9 Hz (range 4.9-6.3 Hz), burst duration was 58.68 ms (range 50.9-86.3 ms), interburst duration was 114.8 ms (range 110.4-142.2 ms), and burst amplitude was 0.2 mV (range 0.2-0.4 mV) (n=5). A Wilcoxon signed-rank test found significant reductions in clonus duration (p=0.04), number of bursts (p=0.04), and burst amplitude (p=0.04) following TESS. In two out of five individuals tested, clonus was completely abolished immediately after TESS and the suppression lasted for several hours. In the other three individuals tested, there was a decrease in the median clonus duration (from 36.0 to 7.4 sec), number of bursts (from 200.3 to 37.3), and burst amplitude (from 0.3 to 0.2 mV) following TESS. These results suggest that TESS can suppress and modulate ankle clonus following chronic SCI.

Title: Intraspinal vs. epidural targeted, activity-dependent spinal stimulation to improve forelimb function after chronic cervical spinal cord injury

Authors: *R. L. MURPHY[1], R. B. ROBINSON[2], R. BOCCAMAZZO[1], U. DEMIRKOL[4], S. I. PERLMUTTER[3];
[1]Physiol. and Biophysics, [2]Dept Physiol. & Biophysics, [3]Dept Physiol. & Biophysics, Washington Natl. Primate Res. Ctr., Univ. of Washington, Seattle, WA; [4]Preclinical Modeling Team, Fred Hutch Cancer Ctr., Seattle, WA

Abstract: Cervical spinal cord injuries (SCI) can damage motor pathways that control movements of the hands and arms and which can have devastating long-term health and financial consequences. We are developing a novel therapy for chronic SCIs that uses targeted activity-dependent electrical spinal stimulation (TADSS) to improve motor recovery. We previously showed that intraspinal TADSS synchronized to volitional contractions of an impaired forelimb muscle improved performances of rats in a reach-and-grasp task. For this study, we wanted to compare intraspinal microstimulation which can precisely target specific motor pools with epidural stimulation in a chronic cervical spinal cord injury model. Epidural stimulation would be easier to implement in humans since it is substantially less invasive and therefore involve less surgical risk to the patient. We also want to understand the mechanisms that drive recovery in animals that receive TADSS therapy by using electrical stimulation of motor cortex and recording evoked potentials in the spinal cord. For these experiments, four week after a moderate-severe cervical SCI, rats were implanted with an array of penetrating platinum iridium microwires in the ventral horn of spinal segments C5-C7 or an epidural array of electrodes, as well as wires in 3 muscles of the impaired forelimb for electromyographic (EMG) recording which were used to trigger spinal stimulation. Animals also had electrodes implanted over motor cortex and the strength of the cortically evoked potentials were assessed during the therapy period. Starting 2 weeks after implantation, male and female rats received therapy for 5 weeks. During the therapy period, TADSS animals received 3-channels of closed-loop spinal stimulation contingent on muscle activity of the impaired forelimb muscles. For 5 hours per day, including during reaching tasks, EMG from each muscle triggered sub-movement-threshold stimulation through a spinal electrode that could elicit contractions of that muscle with higher stimulus currents. Non-stimulated control animals received only behavioral training. Periodically, animals underwent cortical stimulation and evoked potentials were recorded in the spinal cord with the electrodes used for therapy. Epidural and intraspinal stimulation were both effective at restoring reaching performance in females but was not as effective at promoting recovery in males. In animals that received TADSS therapy, there was potentiation of the evoked potentials. These results demonstrate optimizations for long term functional benefits of TADSS and suggest that strengthening descending pathways that survived the injury is driving recovery.

Title: Unveiling the Impact of Spinal Cord Injury on the Pediatric Brain: Neuroimaging and Electrophysiological Findings

Authors: *L. ALVARADO, M. E. KING, B. E. DEPUE, A. L. BEHRMAN;
Univ. of Louisville, Louisville, KY

Abstract: Spinal cord injury (SCI) has far-reaching consequences that extend beyond the spinal cord, impacting supraspinal structures. While previous research has highlighted brain changes in adults with SCI, limited research exists on the effects of SCI on the pediatric brain. To address this gap, our study investigated neural changes in children with SCI using electrophysiology and neuroimaging techniques, aiming to understand the relationship between residual spinal transmission and supraspinal reorganization. The study included children with SCI aged 4 to 12 years who were at least one-year post-injury and in stable medical condition. Electrophysiological examination children with SCI (7 males, 2 females; mean age = 8.8 ± 2.2 years) showed some persistent supraspinal inputs to spinal motor circuitry despite complete SCI, supporting the concept of discomplete injuries and indicating that clinical assessments may underestimate residual sensorimotor function. The neural conduction of the corticospinal tract (CST) mediating volitional motor function was assessed via functional neurophysiological assessment. An acoustic startle response assessment tested the reflexive activity of the reticulospinal tract (RST). Finally, the functional transmission of the dorsal column-medial lemniscus pathway was evaluated by analyzing somatosensory evoked potentials. Neuroimaging showed reduced gray matter morphometry and functional connectivity in cortical and subcortical sensorimotor structures and lower CST microstructural integrity in children with SCI compared to 18 TD controls. There were no significant differences in age, BMI, or gender between the two groups, and neuroimaging quality control analysis indicated no statistically significant differences in motion-related artifacts. Correlation analyses revealed that higher cortical and subcortical measures were positively associated with increased CST activity, while elevated RST activity levels were linked to improved subcortical morphometry and functional connectivity. Our findings provide valuable insights into the quantifiable alterations in the pediatric brain resulting from disrupted neural transmission of spinal pathways. Moreover, our

study highlights the potential of neuroimaging techniques as biomarkers for assessing the progress of recovery and monitoring the effectiveness of interventions that aim to improve spinal translesional connectivity.

Title: Child's Play: Successful Conduct of Neuroscience Focused Research in Children with Spinal Cord Injuries

Authors: *A. L. BEHRMAN, M. E. KING, L. ALVARADO;
Univ. of Louisville, Louisville, KY

Abstract: Conducting research with children can present unique challenges in ensuring valid outcomes. To address these challenges, we developed a child-centric approach building on published guidelines and implementing a three-component strategy: learn, play, practice. Twelve children, including eleven with spinal cord injury (ages 6-15 years) and one typically developing child (age 7), participated in neurophysiology assessments of spinal pathways and magnetic resonance imaging (MRI) of brain morphology and connectivity. Each assessment lasted approximately 1.7 hours on average. To facilitate the learning component, we created a comicbook that provided detailed explanations of each assessment and introduced the participants to the functions of the nervous system. The comicbook was discussed during the consent process, allowing the participant to become familiar with the investigator and to understand their role in the study. Participants were encouraged to engage with the comicbook, ask questions, and familiarize themselves with the assessments. During the play component, children engaged in play-rehearsals using Playmobil® figurines, a mini-MRI scanner replica, and wheelchair toys. This playful simulation allowed them to become acquainted with the MRI protocol and the overall experience. Lastly, the practice component involved children lying in a mock scanner and practicing staying still while becoming accustomed to the typical sounds associated with MRI scans. Our participants exhibited 100% completion rate for all electrophysiology and neuroimaging assessments. Out of a total of 81 assessments, 99% of them yielded valid data. Furthermore, our participants outperformed age-matched typically developing (TD) children from the Child Mind Institute Healthy Brain Network Biobank, with a successful completion rate of 94% for MRI scans compared to 83% in the TD group. The MRI data

obtained from our participants showed significantly lower coefficients of joint variation (CJV) and entropy focus criterion (EFC), indicating reduced motion-related artifacts and improved image quality. Our child-centric approach proved effective in enhancing compliance and creating a positive research experience for children. Furthermore, our approach facilitated their understanding of the assessments, reduced intimidation, and improved familiarity with the research process and personnel. By adopting this approach, we can optimize the quality of data obtained from child participants and contribute to more successful research outcomes in the field of child neuroscience and development.

Title: Feasibility of DeepLabCut technology for posture assessment in children with Spinal Cord Injury

Authors: *P. PARIKH[1], B. CARLSEN[1], A. ADHIKARI[1], G. SINGH[2], K. LUCAS[1], A. L. BEHRMAN[1];
[1]Univ. of Louisville, Louisville, KY; [2]Physical Therapy, Spalding Univ., Louisville, KY

Abstract: Introduction: Markerless motion capture using computer vision techniques is a versatile and cost-effective method for accurate video analysis in research and clinical settings. However, the primary challenge in utilizing machine/deep learning techniques for video analysis lies in optimizing the program and its parameters to minimize errors and maximize efficiency. For custom-trained techniques like DeepLabCut for angle analysis, there are several adjustable parameters during model training for a given video, such as the number of iterations, frames, and train-test split, which significantly affect the accuracy of the results. The primary goal of this study was to investigate the feasibility of training a network on DeepLabCut and evaluate the accuracy of its 2D model compared to existing manual marking technique via MaxTRAQ software. **Methods:** Segmental trunk angles measured via DeepLabCut were compared to MaxTRAQ software. Segmental trunk angles were marked and calculated from trunk posture assessment videos, collected from 4 pediatric participants (6.5 ± 3.7 years old) with spinal cord injury (C2 - T6 range of injury), who completed a training study to improve sitting posture and trunk control. For each participant, trunk segments (Hear-Ear, Head-Shoulder, Head-C7, C7-T8, T8-L1, L1-L5) were identified and marked using retroreflective markers at different anatomical sites. Each participant was asked to maintain an upright sitting posture for 5 seconds for 3 attempts. A high-resolution camera recorded these 3 attempts. The DeepLabCut model was trained using about 35 videos with different iterations, marked frames, and train-test splits. Subsequently, all 35 videos were analyzed using the trained network, and results were compared

with those obtained from MaxTRAQ, where a trained technician manually marked the anatomical sites in the videos for segmental angle analysis. **Results:** Optimal parameters that provided the least train-test pixel error: 125,000 iterations, 15 frames per video, 95:5 train-test split, were identified. Segmental angles obtained from DeepLabCut were compared frame by frame with MaxTRAQ and Root Mean Square Error (RMSE) was calculated. The RMSE values for Head-Ear = 5.03 ± 5.24, Head-Shoulder = 1.1 ± 0.7, Head-C7 = 1.2 ± 0.9, C7-T8 = 1.6 ± 1.7, T8-L1 = 1.6 ± 2.1, L1-L5 = 3.6 ± 7.7, where a lower value translates to better accuracy by the model. **Conclusion:** Thus, preliminary data demonstrates that DeepLabCut is a feasible and accurate method of calculating segmental trunk angles in 2D space using computer vision techniques.

Translation of spinal cord injury (SCI) therapeutics from preclinical animal studies into human studies is limited. To bridge this translation and better assess predictors of functional improvement (neuro-conversion), we compared published data with raw subject-level data. Methods were combined from the Collaborative Approach to Meta Analysis and Review of Animal Experimental Studies (CAMARADES) and individual participant data available in the Open Data Commons for Spinal Cord Injury (odc-sci.org). The systematic review and extraction of data from 32 published papers yielded N=1454 subjects, while individual participant data from these same papers included N=2074 subjects. The N difference may reflect publication bias, with authors frequently publishing only a subset of subjects. Meta-regression models were used to compare neuromotor outcomes in different rodent types, sex, animal strains, sample sizes, injury models, anesthetics, and outcome measures. Strain types, injury severities, behavioral measures, and anesthetic types showed notable differences in effect sizes. Meta-analysis was refined to publications with common injury models (contusive injuries) and the most standardized endpoints (open field assessments). With analysis focused on these parameters, significant differences in effect sizes were observed in strain and rodent types. Lastly, it was found that publications with the smallest sample sizes yielded the largest effect sizes and studies with the largest sample sizes had the smallest effect sizes. This indicates a potential overinflation of effect sizes by inadequately powered small studies, reflecting selection bias. Together the results demonstrate the feasibility and utility of combining individual participant data analysis and traditional literature-sourced meta-analysis to explore effect size reproducibility in SCI.

Abstract: Decubitus ulcers (DUs) pose a significant challenge in the care of spinal cord injury (SCI) patients, often leading to a substantial decrease in their quality of life. Therefore, the development of effective screening methods to identify high-risk individuals for DU onset is of paramount importance. This study investigates the use of machine learning and deep learning techniques to create highly precise predictive models for DU occurrence in SCI patients. We reviewed a total of 539 SCI patients, with a 35% incidence rate of DU (189 subjects) during their hospital stay. We gathered 139 parameters, encompassing baseline characteristics, neurological, functional, and laboratory parameters. For the non-DU group, laboratory data was selected at the initial assessment time, while for the DU group, it was chosen two weeks prior to DU onset. To contrast the machine learning and deep learning models with traditional statistical methods, we employed independent t-tests, Chi-square tests, and logistic regression analysis. Various machine learning and deep learning techniques were utilized, including graph neural networks (GNN), deep neural networks (DNN), linear support vector machines (SVM_linear), support vector machines with radial basis function kernel (SVM_RBF), K-nearest neighbors (KNN), random forests (RF), and logistic regression (LR) models. These models underwent data preprocessing and feature selection, and the data was trained through cross-validation for DU classification. Our statistical analysis revealed significant differences in several neurological and functional parameters between the non-DU and DU groups. In the machine learning approach, the top 20 laboratory parameters were ranked by importance based on the RF outcome. Notably, the DNN model achieved the highest accuracy (0.870) when considering only laboratory parameters. When both laboratory and clinical parameters were combined, logistic regression displayed the highest accuracy (0.877). Decision tree classification models were created for DU prediction using the featured laboratory parameters, with the hematocrit level identified as the primary discriminator for group determination between non-DU and DU groups.In conclusion, our study indicates that ML algorithms, particularly DNN and logistic regression, show excellent performance in predicting DU. Laboratory tests, along with clinical evaluation, are significant factors in these predictions. We propose that artificial intelligence-based prediction model could be a valuable tool for the prevention and early detection of DU in SCI patients in a clinical setting.

Title: Detection of Motor Tract Damage and Dexterity Loss with Magnetization Transfer Ratio in Patients with Degenerative Cervical Myelopathy - a Pilot Study

Authors: *G. HAYNES[1], F. MUHAMMAD[2], L. DING[1,3], Z. A. SMITH[2];
[1]Stephenson Sch. of Biomed. Engin., The Univ. of Oklahoma, Norman, OK; [2]Neurosurg., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK; [3]Inst. for Biomed. Engineering, Sci. and Technol., Norman, OK

Abstract: Degenerative cervical myelopathy (DCM) is a common, non-traumatic degenerative disease in aging adults that can lead to motor and sensory disfunctions. Currently, the standard clinical diagnostic tool for DCM, the modified Japanese Orthopedic Association (mJOA) score, can qualitatively measure DCM severity by assessing peripheral nerve impairment, but cannot provide a quantitative measure. Magnetization transfer ratio (MTR) is an imaging technique that can indirectly measure white matter (WM) volumes within the spinal cord. The objective of this study is to assess MTR's ability to quantify regional and tract-specific WM damage in DCM. Magnetization transfer (MT) imaging was applied to 7 healthy controls (HCs) and 10 DCM patients using a 3T GE MRI scanner. MTR values were extracted from the range of max compression in each region and tract-specific area, identified with the Spinal Cord Toolbox (SCT) PAM50 atlases. Each subject also performed biomechanical measures of dexterity, grip strength, balance, and gait speed using the NIH Toolbox. Differences in DCM and HC MTR values were calculated using a one-tailed Mann-Whitney test. A Spearman's correlation was also applied to tract-specific MTR values and motor testing results. HC and DCM MTR values showed significant differences in the lateral regions ($p = 0.0439$), and the ventral corticospinal ($p = 0.0093$) and tectospinal ($p = 0.0215$) tracts. HC and DCM MTR values failed to show significant difference in the dorsal and ventral regions ($p = 0.1148$, $p = 0.0544$), and the lateral corticospinal ($p = 0.2087$), fasciculus cuneatus ($p = 0.0966$), fasciculus gracilis ($p = 0.1819$), ventral and lateral reticulospinal ($p = 0.0966$, $p = 0.0665$), medial fasciculus ($p = 0.0665$), rubrospinal ($p = 0.1349$), spinal lemniscus ($p = 0.0806$), spino-olivary ($p = 0.1148$), ventral spinocerebellar ($p = 0.4434$), and vestibulospinal ($p = 0.1148$) tracts. Spearman's correlation analysis revealed a significant correlation between dexterity and MTR values within the ventral corticospinal tract ($p = 0.017$, $r = 0.576$). Within the healthy human spinal cord, the corticospinal tract allows for voluntary motor control of peripheral limbs. However, damage to tract WM can result in loss of upper limb dexterity, which is a prevalent symptom within DCM patients. Our results reflect the relationship between MTR values and dexterity measures, and WM changes in corticospinal tracts of DCM patients. In this sense, tract-specific MTR values can become an important clinical diagnostic tool for the identification and treatment of DCM because it can quantitatively reflect key impairments within the WM and establish a specific origin for symptom manifestation.

Abstract: Veterans with chronic spinal cord injury (SCI) are often immunosuppressed and have chronic health conditions associated in the general population with higher risk of complications and more severe symptoms of COVID-19. To our knowledge, there is no public data on antibody responses to SARS-CoV-2 infection or vaccination in Veterans with SCI. In 2021, we surveyed Veterans with SCI who consented for screening in the VA Cooperative Study CS#2003 (NCT02658656) about the COVID-19 pandemic. Standard VA Core Lab assays (Abbott anti-N IgG and anti-S IgG, Beckman anti-Receptor Binding Domain "RBD") and cutoffs determined levels of anti-SARS-CoV-2 antibodies. Systemic inflammatory mediators were measured by ELISA (Bio-Plex Pro Human Cytokine Screening Panel, 48-Plex, IBL International HMGB1 and CRP). Participants reported their clinical and demographic characteristics. There were 70 Veterans with SCI (male=91%; age=56, 11 [median, IQR] years; injury duration=11, 21 [median, IQR] years; paraplegia=76%, motor complete (AIS A or B)=47%) in the study. Few Veterans were positive for anti-N IgG (N=10), of whom most reported exposure (N=6/10) or vaccination (N=7/10). Most Veterans were positive for anti-RBD IgG (N=50/70); of whom a minority reported exposure (N=19/50) and a majority reported vaccination (N=35/50). Of Veterans who were positive for anti-RBD IgG, titers correlated significantly with anti-S and anti-N IgG (Pearson's correlation R=0.92 and 0.59, $P<1.09 \times 10^{-19}$, P<0.0000007 respectively). Most Veterans were positive for anti-S IgG (N=59/70), of whom a minority reported exposure (N=25/59) and a majority reported vaccination (N=41/59). Among Veterans who were positive for anti-S IgG, titers correlated significantly with anti-RBD and anti-N IgG (Pearson's correlation R=0.94 and 0.52, $P<5.16 \times 10^{-27}$ and P<0.00003 respectively). Most participants had a moderate or high risk of cardiovascular disease based on CRP levels (mg/L: high >3: 50%,

moderate 1-2.9: 19%, low risk <1.0: 31%). HMGB1 levels (5.3±0.7 ng/ml, mean± SEM) were in range of reported values for persons with SCI (Papatheodorou et al 2017). Chemokines IP-10, MIP-1a and MIG were elevated in anti-S IgG reactive participants; the cytokine MIF was decreased ($P<0.05$, Mann Whitney). IP-10, MIP-1a and MSCF were lower in anti-N IgG reactive participants ($P<0.05$, Mann Whitney). Veterans with SCI had measurable levels of anti-SARS-CoV-2 antibodies. As in the general population, anti-S and anti-RBD IgG levels correlated significantly. Prospective studies are needed to measure kinetics and levels of COVID-19 antibodies after exposure or vaccination.

Title: Increases in corticospinal excitability after acute intermittent hypoxia is coupled with improvements in sensorimotor adaptation

Authors: A. BOGARD[1], T. HEMBREE[1], A. POLLET[1], L. LATTANZIO[2], I. BUARD[2], A. C. SMITH[3], *A. Q. TAN[1];

Abstract: Restoring voluntary movement after neurological injury hinges on the ability to promote neural plasticity of motor pathways. Promising evidence suggests that breathing mild bouts of low oxygen air (i.e., acute intermittent hypoxia, AIH) enhances corticospinal drive to upper limb muscles in healthy individuals. However, it remains unclear if such changes in excitability are associated with gains in motor control. Notably, mechanistic studies from spinally injured rodents show that AIH may engage brain-derived neurotrophic factor dependent pathways that have been linked with both increases in motoneuron excitably and improvements in motor learning. Accordingly, we examined if AIH-induced gains in corticospinal excitability to the tibialis anterior muscle (TA) would parallel improvements in motor adaptation during a split-belt walking paradigm. All participants received AIH for five consecutive days, in which they breathed 15, 90-second bouts of hypoxic air (9% O2) alternated with 60 seconds of normoxic air (21% O2). We used single-pulse transcranial magnetic stimulation (TMS) to the TA at baseline and after the fifth AIH treatment to construct recruitment curves of the average

motor evoked potential (MEP) amplitude vs. stimulus intensity. Immediately after the post-AIH TMS protocol, we assessed motor learning by quantifying changes in spatiotemporal asymmetry while split-belt walking. Following repetitive AIH, we observed an increase in the maximal TA MEP amplitude, an increase in the recruitment curve slope, and a decrease in the resting motor threshold. Consistent with previous studies, we also found that participants adapted to split-belt walking by reducing step length asymmetry, double support time asymmetry, and net metabolic power. Intriguingly, changes in the maximum TA MEP amplitude and resting motor threshold after AIH were associated with decreases in double support time asymmetry, as well as reductions in metabolic cost. These preliminary results suggest that AIH may increase the gain of lower limb motor neuron excitability, leading to more economical walking coordination strategies. The correlation between excitability and motor adaptation parameters further indicates that AIH-mediated increases in corticospinal excitability may be a potential marker for improvements in motor control. Clarifying how to harness neuromodulation techniques to optimize motor learning is critical to enhance the recovery of walking after neurological injury.

Title: Pelvic floor muscle activation patterns during exoskeleton-assisted walking in people with complete spinal cord injury

Authors: *X. ZHOU[1,2], A. M. WILLIAMS[1,2], J.-S. BLOUIN[1], T. LAM[1,2];
[1]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada

Abstract: The pelvic floor muscles (PFM) are crucial for maintaining continence and a potential therapeutic target for improving urinary control after spinal cord injury (SCI). The PFM can be recruited voluntarily in isolation or co-activated with other abdominopelvic muscles. Previous researchers showed that some people with complete SCI may have preserved corticospinal pathways to the PFM, and can co-activate the PFM during maneuvers that engage the trunk muscles. In this population, trunk muscles are recruited more effectively during walking with overground exoskeletons (e.g., Ekso) than treadmill-based devices (e.g., Lokomat), raising the question of whether such greater trunk muscle activity concomitantly activates the PFM. This within-subject, cross-sectional study aims to (1) characterize the pattern of PFM activity, and (2) explore the co-activation relationship between the PFM and trunk muscles, as well as the effect

of pelvis acceleration on PFM activation, during Lokomat- and Ekso-assisted walking in people with complete SCI. We recorded bilateral surface electromyography (EMG) from the PFM, rectus abdominis (RA), erector spinae (ES), and gluteal muscles, along with pelvis accelerometry data, during walking in the Lokomat and Ekso at 1km/h for >60 strides. Prior to the walking trials, participants performed attempted maximum voluntary contractions of each muscle for EMG normalization. We calculated an average profile of muscle activity and 3D pelvis acceleration magnitude across the gait cycle (defined as time between successive right heel strikes). In controls, PFM EMG amplitude was 88±31% higher during walking in the Ekso than Lokomat. Greater PFM activation was observed alongside higher EMG amplitude from the RA, ES, and gluteal muscles, and positively associated with pelvis acceleration ($r=0.84$, $p<0.05$). We have preliminary data from 3 male SCI participants (41±2 years old, injury level T1-T5, 2 AIS-A and 1 AIS-B) so far. Although the SCI participants could not elicit any PFM activity during attempted maximum voluntary contraction trials, their PFM were recruited during exoskeleton-assisted walking. Compared to the Lokomat, Ekso-assisted walking elicited slightly more (11±4%) PFM activity and higher pelvis acceleration (0.94±0.14g vs. 0.15±0.02g). We also observed bursts of PFM EMG coinciding with single-leg support phase; EMG activation from the other muscles was inconsistent. Results from this study suggest that the PFM can be recruited during exoskeleton-assisted walking, opening the possibility for using this type of gait therapy to recruit the PFM and exploring its potential impact on urinary function in people with SCI.

Title: Acute effects of single session pelvic floor muscle training on somatosensory and corticospinal excitability

Authors: *Y.-H. LIN[1,2], A. M. WILLIAMS[1,2], T. LAM[1,2];
[1]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration on Repair Discoveries (ICORD), Vancouver, BC, Canada

Abstract: The recovery of bladder function is among the top recovery priorities for people with spinal cord injury (SCI). Urogenital dysfunction, including urinary incontinence is a debilitating condition that affects up to 80% of individuals with SCI. The pelvic floor muscles (PFM), the muscles that form the base of our abdominopelvic cavity, play a critical role in urogenital functions, including maintaining urinary continence. Pelvic floor muscle training (PFMT) is commonly prescribed in non-neurological populations as a rehabilitation intervention to manage

urinary incontinence. PFMT involves practicing voluntary PFM contractions of varying intensities and durations. As a non-invasive intervention with few to no side effects, PFMT offers an attractive option for the management of urinary incontinence in neurological populations. However, we still do not have a clear understanding of the underlying neurophysiological effects of PFMT. Therefore, the objective of this study was to investigate the acute neurophysiological changes in sensorimotor pathways following a single session of PFMT, compared to a control intervention (biceps brachii contractions). We randomly assigned participants to either the experimental (PFMT) or control (biceps brachii; BB) group. Participants completed a training program consisting of 55 contractions to different intensities and durations in either their PFM or BB. To examine changes in somatosensory excitability associated with the PFM, we used electroencephalography to record somatosensory evoked potentials in response to pudendal nerve stimulation. To examine changes in corticospinal excitability, we used surface electromyography to record motor evoked potentials from the PFM elicited by transcranial magnetic stimulation over the primary motor cortex. All measures were recorded before and after a single session of training and compared between groups. Preliminary data show a trend of facilitation in somatosensory processing to the cortex following a single session of PFMT and not the control exercise, as indicated by an increase in P40 amplitude. There was no apparent change in corticospinal excitability of the PFM although participants in the PFMT group improved their performance of PFM contractions. These results suggest the acute neurophysiological effects of a short, single session of PFMT are limited to somatosensory pathways. Additional training time may be required to modulate corticospinal excitability. Understanding of the acute neurophysiological effects following a single session of PFMT will support the translation of this intervention to individuals with SCI.

Title: Enhancing rehabilitation effectiveness with coactivation of corticospinal neurons

Authors: *G. SMITH, R. SMIT, T. CAMPION, G. KOMA, M. A. LEMAY, A. SPENCE; Temple Univ., Philadelphia, PA

Abstract: Spinal Cord Injury (SCI) causes interruption of both ascending and descending spinal tracts. Unlike the peripheral nervous system, the central nervous system (CNS) does not

demonstrate significant regeneration. Research in young rodents indicates that the superior recovery, which ceases abruptly beyond postnatal day 10, is owed to the more robust regeneration of corticospinal neurons (CST) across the injury site. Here, we enhanced recovery beyond the critical age using chemogenetic modulation of higher order pathways during unstructured rehabilitation (play). At postnatal day 5 (p5) rats received intracranial (motor cortex) injection of either non-Cre-dependent excitatory DREADD (AAV2-hM3Dq), non-Cre-dependent inhibitory DREADD (AAV2-hM4Di), or control fluorescent (AAV2-GFP). At p14, all animals underwent right C5 hemisections. Subsequently, the activation of either excitatory or inhibitory DREADDs was achieved by treating diet gel with clozapine-N-oxide for 30 days at night during active play (4 randomized juvenile rats housed together). Behavioral assays consisted of IBB, grooming, cylinder touch, and grid walk, starting 10 days after removal of CNO treatment. The excitatory animals performed significantly better on all behavior assessments when compared to both the control and inhibitory cohorts. We also observed a hierarchal recovery in forelimb kinematics and electrophysiological activity where increased activation of cortical motor neurons showed the best recovery. Specifically, we found that activation of corticospinal neurons significantly improved kinematic reach distance, such that it was not significantly different from naïve animals. Due to the size of the injury and histological assessment, recovery was mediated by adaptive sprouting. Interestingly, medullary sections demonstrated significantly more post-synaptic activity in the reticulospinal tracts compared to the other groups. The excitatory group demonstrated robust interhemispheric cortical connectivity to CST neurons and contralateral sprouting of the intact CST distal the spinal cord lesion site when compared to the control and inhibitory groups. We hypothesize that cortical activity modulates axonal sprouting of the CST, while rehabilitation shapes the connects to promote recovery of function.

Title: The Effects of Body Weight Supported Treadmill and Overground Training on the BDNF, TrkB and CREB Pathway in Severely Spinally Contused Rodents.

Authors: *J. ARAIZA[1], O. ZARAGOZA RODRIGUEZ[1], O. M. SURYAVANSHI[1], J. ZHOU[3], S. GUERRA[1], P. SANDOVAL[1], E. ALDANA[1], C. WANG[2], R. DE LEON[3], M. S. JOSEPH[3]; [2]Electrical and Computer Engin., [1]California State University, Los Angeles, Los Angeles, CA; [3]Dept. of Kinesiology, California State Univ. Los Angeles, Los Angeles, CA

Abstract: As a form of rehabilitation, exercise enhances locomotion in spinally contused animals through repeated bouts of training. Exercise strategies such as the body weight supported treadmill trainer (BWSTT) and the overground training system: circular bodyweight-supported ambulatory rodent trainers (cBART), have improved locomotion in rats. The cBART is novel rehabilitation device designed to support a percentage of a rat's body weight on an arm lever hinged on a fulcrum, allowing the animal to step volitionally while the arm rotates around the central axis. However, the molecular plasticity mechanism in the spinal cord after training is not well understood. In this study, we use severe, mid-thoracic (T7-T9) contusion spinal cord injured rodents to investigate the effects of eight weeks of training on CREB, BDNF, and TrkB, markers of plasticity. Preliminary kinematic gait analysis suggests that combined training on contused animals had altered the expression of CREB at the injury site. BDNF expression in the entire lumbar segment below the contusion site was greater in the contused BWSTT group compared to the combined group. Significant differences in TrkB expression between groups for each spinal segment were not observed. These results suggest that in this severe contusion injury model, the combined training modulates the expression of select plasticity markers differently compared to treadmill training alone in severely contused rats, likely from activating both volitional and reflexive pathways. Additional analysis will be required to examine the locomotor behavior to confirm the relation to CREB, BDNF, and TrkB expression in the trained and control groups. Ultimately, a better understanding of training and plasticity will facilitate efforts to restore neuromotor function after a spinal cord injury or in other debilitating conditions.

Abstract: Spinal cord injury (SCI) affects many lives and development of therapeutic strategies is critical to improve patient lives. Exercise training as an intervention for SCI animals and

human patients have shown many gains in locomotor improvement. Exercise training strategies such as the body weight supported treadmill trainer (BWSTT) and the over ground training system, circular bodyweight-supported ambulatory rodent trainers, individually have been shown to improve locomotion in rodents. The mechanism of plasticity is not well understood. Following SCI, the serotonin levels decrease in the spinal cord. Serotonergic activation with exercise has been shown to facilitate locomotor recovery. This study examined the relationship of exercise and the potential plasticity in the *de novo* synthesis in the spinal cord of midthoracic (T7-T9) severe contused rodents. Moreover, cells found around the central channel, C2, T4, L2, and L5 dorsal horn regions of the spinal cord have been associated with synthesizing serotonin. This study examined the exercised mediates plasticity on *de novo* serotonin production in the thoracic injury site, and the lumbar segments of the spinal cord. Brain-derived neurotrophic factor (BDNF) is another marker that plays a significant role in neuronal growth and assists in neuronal plasticity. We investigated expressions of the DDC, 5HT-2a receptor and BDNF spinal cord and how exercises intervention can affect levels of 5-HT 2a receptor, BDNF and DDC. Preliminary analysis suggests the data suggests, in this severe midthoracic contused model the DDC expression increased in the L3-L5 segments in the over ground cBART training when compared to the contused untrained rats. As shown in other studies, 5HT-2a Receptors decreased expression the lumbar segment when compared. We hope to better understand the mechanism of the serotonergic pathway to help potentially develop training and pharmacological strategies to facilitate recovery after spinal cord injury in patients.

Title: Exercise improves cardiac autonomic regulation to alleviate arrhythmias in rats with spinal cord injury

Authors: M. CUSIMANO, E. TAUB, E. OATMAN, A. SINGH, J. HOULE, *S. HOU; Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: High-level spinal cord injuries (SCI) disrupt supraspinal regulation of cardiovascular sympathetic activity, resulting in disordered hemodynamics and cardio-electric conduction. Previous studies have demonstrated that exercise after SCI promotes central neuronal plasticity and prevents peripheral organ atrophy for bodily functional recovery, such as blood pressure and heart rate. Here, we examined whether exercise training following SCI augments the balance of

cardiac autonomic activity to alleviate arrhythmias. Rats received a complete crush at the 2nd/3rd thoracic (T2/3) spinal cord level. Subsequently, passive hindlimb cycling (PHLC) was initiated and continued for 5 or 10 weeks. Rats receiving SCI without exercise and naïve ones served as controls. Afterwards, a telemetric transmitter was implanted into abdominal cavity to record blood pressure and electrocardiography (ECG), including 1) 24-h resting recordings, 2) colorectal distention (CRD)-induced autonomic dysreflexia, 3) dobutamine (DOB) stress tests, and 4) pharmacological interventions for sympathetic and parasympathetic tone. As a result, exercise regardless of duration reduced aberrant high cardiac parasympathetic tone and improved autonomic homeostasis. Though cycling training did not influence resting hemodynamics and the severity of CRD-induced autonomic dysreflexia, it reduced the number of spontaneous autonomic dysreflexia events over a 24-h period. Notably, exercise attenuated, at different extents, the occurrence of arrhythmias triggered by CRD or DOB, which was more prominent in the group with 10-week continuous training, particularly in severe rhythmic problems, e.g., A-V block, premature ventricular contractions, and sinus pause. Together, the results suggest that activity-based training enhances autonomic balance to improve cardiac electrical conduction following SCI.

Title: Impact of activity-based training duration on bowel function in a rat model of spinal cord injury

Authors: *C. HUBSCHER[1,2], J. FELL[1], D. BURKE[2], D. MEDINA AGUINAGA[1];
[1]Univ. of Louisville Anatom. Sci. & Neurobio., Louisville, KY; [2]Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Significant bowel-related issues after spinal cord injury (SCI) that affect morbidity and quality of life include diminished bowel motility, loss of sphincter control, gastric ulcers, autonomic dysreflexia, pain, diarrhea, constipation, and fecal incontinence. Diagnoses and research in humans have largely relied on anorectal manometry (ARM) procedures to increase understanding of the functional effects of SCI on colorectal motility and defecation physiology. Recent pre-clinical rodent studies have also used ARM to further our understanding of bowel-related dysfunctions post-SCI. In the present study, the benefits of different activity-based

training (ABT) regimens on bowel function were examined. Six groups of male rats including two non-trained (uninjured and SCI) and four ABT (quadrupedal stepping on a treadmill) groups. All ABT animals received four weeks of one-hour daily stepping beginning two-weeks post SCI followed by variable amounts for four additional weeks (none; daily; once a week; daily for final 4th week only). Outcome measures included fecal output (home cage; metabolic cage) throughout the study and terminal measurements (post 8-weeks ABT) of external anal sphincter electromyography, resting anorectal pressure, and giant contraction activation under urethane anesthesia. The results indicate that treadmill training normalized defecation amount based on feces weight and food intake, as well as giant contraction frequency, external anal sphincter latency and amplitude during fecal expulsion, and resting pressure in specific areas within the colorectum. The two intermittent training groups consistently showed recorded metrics comparable to the non-injured group. The results demonstrate bowel dysfunction in the rodent SCI contusion model with improvements in functional outcomes following ABT. Importantly, the benefits to bowel-related functions with versus without intermittent ABT illustrates the need for periodic therapy to maintain the functional gains of ABT.

Ctr., [4]Dept. of Neuroscience, Neurology, Col. of Medicine; Ctr. for Adv. Translational Stroke Sci., Univ. of Kentucky, Lexington, KY

Abstract: Introduction: Athletes utilize high-low training (H-L) to maximize athletic performance by exercising under normoxic conditions paired with hypoxic exposure when not exercising. Individually, exercise and hypoxia are beneficial in treating spinal cord injury (SCI) in rodent models. Exercise after SCI increases neurotrophins whose decreased levels are associated with anxiety-like behavior. In humans with SCI, decreased well-being is attributed to increased rates of mental disorders and suicide. Chronic SCI is prevalent as only 0.6 % of patients fully recover and 30% of patients are rehospitalized within any given year due to

diseases of the skin, circulatory, and musculoskeletal systems. Post-SCI inflammation is common and linked with increased anxiety-like behavior. One aspect of this project was to test the hypothesis that H-L training doesn't induce anxiety when implemented chronically after SCI. H-L training was executed in rats with chronic SCI by combining voluntary overnight exercise with repetitive, sustained hypoxia 5 days a week for 8 weeks. **Methods:** Starting with n=62, and final n=49, Sprague Dawley female rats underwent baseline training before receiving a left C2 hemisection (LC2Hx). Subjects were randomly assigned to 4 groups: sedentary control, H-L, exercise-only, or hypoxia-only. At 6-7 weeks post-injury (WPI) treatment was initiated. Voluntary exercise was performed via exercise wheel access overnight and sustained repetitive hypoxia was administered in 4-hour bouts of 11% oxygen exposure. At 5, 9, and 13 WPI, Activity Boxes were used to measure anxiety-like behavior. Following LC2Hx, weights were checked weekly.**Results:** All H-L rats exercised voluntarily. Monitored exercise wheels showed that H-L subjects tend to increase voluntary exercise distance and speed over time. There was an increase in total distance run in the Activity Box for H-L rats before treatment and 8 weeks after starting treatment (p=0.0064). Activity Box data showed that after 4 weeks of treatment, H-L rats had increased (p =0.0126) rearing activity compared to sedentary rats. Sedentary rats increased time spent in the perimeter (open field assay) at each timepoint (p=0.0024), while H-L rats experienced an insignificant negative trend in time spent in perimeter. Weekly weight checks showed an expected decrease in all subjects, but both groups gained weight as the experiment progressed.**Conclusions:** While experiments with the hypoxia-only and exercise-only controls are ongoing, H-L was tolerated by rats with chronic SCI and shows potential as a treatment for humans with SCI without unnecessarily increasing post-SCI anxiety.

Title: High-low training as a rehabilitative therapy for chronic spinal cord injury

Authors: *D. BRITSCH[1], K. COTTER[2], B. ROSE[3], C. STUART[3], M. MALONE[2], T. UJAS[2], J. TURCHAN-CHOLEWO[4], W. ALILAIN[2], A. STOWE[4];

Abstract: Objectives: The technique of "living High, training Low" (H-L) is used by athletes to improve exercise performance. H-L involves repeated cycles of exercise performed at normoxic conditions coupled with hypoxic exposure during periods of rest. Exercise and hypoxia can

individually promote recovery in CNS injury. Rodent models of spinal cord injury (SCI) implementing exercise after injury often show improved recovery of locomotion, while application of hypoxia can induce respiratory motor plasticity to promote recovery. Respiratory disease is a leading cause of rehospitalization and death for people who survive the first 24 hours after SCI. Additionally, less than 1% of human patients regain pre-injury motor function. This project tests the hypothesis that H-L training - initiated as a chronic SCI therapy - is tolerable and improves respiratory, locomotor and sensory function over time. Methods: 62 S.D. rats (F, 3-4 mo.) received a left C2 hemisection, with n=49 surviving to group allocation. Pair-housed cages were randomly assigned to H-L, hypoxia-only, exercise-only, or control group. Treatment began 6-7 weeks post-injury (WPI) and lasted for 8 weeks. H-L treatment was implemented by combining cycles of voluntary exercise with repeated administration of moderate, sustained hypoxia. For 5 days a week, H-L and exercise subjects were housed individually in cages with monitored exercise wheels overnight, and then returned to pair-housed cages in the morning. Sedentary subjects were individually housed overnight on the same schedule as exercise subjects without access to wheels. Immediately following return to pair housing, the H-L and hypoxia groups received 4 hours of 11% O_2. Motor assays (Catwalk, whole body plethysmography, Activity Box) and blood draws were performed at baseline, 5 WPI, 9 WPI and 13 WPI. A sensory assay (Hargreaves) was also performed at 13 WPI. At 14 WPI subjects underwent a terminal, bilateral diaphragm EMG to assess activity. Multiple tissues were collected for histology and cell profiling. Conclusions: 2 cohorts are still ongoing. MATLAB is being optimized for EMG analysis. Most notably, the H-L group experienced decreased frequency (2way RM ANOVA p=0.004) and increased tidal volume (2way RM ANOVA p=0.005) between pre-treatment and 4 weeks later, while control subjects did not, indicating improved respiratory function. H-L group also presented a promising but nonsignificant trend towards reduced hyperalgesia in the contralateral hindpaw compared to control group. Preliminary analysis shows treatment was well-tolerated in chronic SCI rats and has high translational potential.

Title: Gamified Electromyographic Biofeedback with Wearable Sensors is Enjoyable for People with Tetraplegia and Promotes Large Dosages

Authors: *R. COTTON;
Physical Med. and Rehabil., Shirley Ryan Abilitylab / Northwestern Univ., Chicago, IL

Abstract: People with tetraplegia consistently rank recovery of arm function among their highest priorities to improve independence and quality of life. Intensive, repetitive practice can stimulate motor recovery through activity-dependent plasticity and generally produces a greater benefit with greater dosage, but we lack the tools to help patients perform enough high-quality practice at home. To address this gap, we developed a wearable, Bluetooth-connected electromyography (EMG) sensor platform with smartphone games to enable people with spinal cord injury (SCI) to perform EMG biofeedback.

We tested this system on people with acute tetraplegia seen during inpatient rehabilitation. We able to successfully perform EMG biofeedback on numerous paretic muscles, including wrist extensors, wrist pronators, triceps, biceps, and deltoids, although in some cases muscle activity was insufficient for successful control. We assessed engagement with the games using the Physical Activity Enjoyment Scale (PACES). Most participants rated both games as highly enjoyable and on average preferred a game that required more varied muscle activity. However, this game also typically promoted lower maximum intensity muscle activity compared to one that repeatedly requests a maximum activation. In each one-hour treatment sessions, most commonly involving four muscles, participants typically performed hundred to thousands of repetitions.

We also tested this system in multiple sessions over a month on participants with chronic tetraplegia. Like sessions during inpatient, participants continued to perform large repetition dosages throughout the protocol and continued to find the games enjoyable. Participants also gave anecdotal reports of functional improvements. One participant reported improvements in finger extension, one with improvements in triceps activation and wrist pronation, and another with improved ability to reach across the body and perform bilateral tasks.

People with tetraplegia find gamified electromyographic therapy provided via wearable sensors enjoyable and achieved large therapeutic dosages when playing it. Of our two games, the one that participants on average most prefer produces smaller maximal muscle activations, and future work is required to optimize and balance these two tradeoffs. Our initial results also indicate it can produce functional improvements over multiple sessions. Ongoing studies will provide further evidence of efficacy and to test the ability to perform this as home therapy.

Title: Enhancing corticospinal-motoneuronal plasticity by 4-aminopyridine in humans with spinal cord injury: a phase 2b clinical trial

Authors: B. CHEN[1,2], *M. PEREZ[1,3,4,2];
[1]Shirley Ryan Abilitylab, Chicago, IL; [2]Edward Hines Jr. VA Med. Ctr., Chicago, IL; [3]Dept. of Physical Med. and Rehabil., [4]Dept. of Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Paired corticospinal-motoneuronal stimulation (PCMS) has been shown to promote functional recovery in humans with spinal cord injury (SCI). The goal of our study was to assess the effect of 4-aminopyridine (4-AP), a nonselective blocker of voltage-sensitive potassium channels, on PCMS induced plasticity in humans with chronic SCI. Participants with chronic SCI were randomly assigned to receive 40-sessions of PCMS targeting corticospinal-motoneuronal synapses of multiple leg muscles followed by exercise combined with 10 mg of 4-aminopyridine (4-AP, also known as dalfampridine) or 10 mg of a placebo tablet. During PCMS, 180 paired pulses elicited corticospinal action potentials by electrical stimulation (thoracic spine) allowing volleys to arrive at the spinal cord 1-2 milliseconds before motoneurons were activated retrogradely via bilateral electrical stimulation (femoral nerve, common peroneal nerve, and posterior tibial nerve) for quadriceps femoris, tibialis anterior, and soleus muscles. We measured motor evoked potentials (MEPs) and maximal voluntary contractions in all muscles targeted as well as the 10-min and 6-min walk test before and after the repeated sessions in both groups. We found that MEP size and maximal voluntary contractions in all muscles targeted increased after 20 sessions and further increased after 40 sessions but to a larger extent in participants that received 4-AP compared to the group that received placebo. Notably, in people in the 4-AP group, walking speed (measured by the 10-meter walk test) and endurance (measured by the 6-minute walk test) largely enhanced after 20 sessions and further improved after 40 sessions compared with baseline. Our results demonstrate that combinatorial approaches using neurostimulation and 4-AP represent an avenue to further enhance functional restoration following chronic SCI.

Title: Paired corticospinal-motoneuronal plasticity to target respiratory function in humans with spinal cord injury

Authors: *B. CHEN[1,2], M. PEREZ[1,3,4,2];
[1]Shirley Ryan AbilityLab, Chicago, IL; [2]Edward Hines Jr. VA Med. Ctr., Chicago, IL; [3]Dept. of

Physical Med. and Rehabil., [4]Dept. of Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Respiratory function is often impaired in individuals with high cervical spinal cord injury (SCI, C3-C5), leading to reduced quality of life and mortality. Respiratory complications developed in these individuals are largely related to diaphragm impairment. Paired corticospinal-motoneuronal stimulation (PCMS), a noninvasive neurostimulation protocol based on principle of spike-timing dependent plasticity (STDP), effectively promotes recovery in upper- and lower-limb muscles in humans with SCI. Here, we examined the effect of PCMS in the diaphragm muscle in control subjects and in individuals with high cervical chronic SCI. During PCMS, corticospinal volleys evoked by transcranial magnetic stimulation (TMS) over the leg motor cortex were timed to arrive at corticospinal-motoneuronal synapses of the diaphragm muscle 1-2 ms before the arrival of antidromic potentials elicited in motoneurons by electrical stimulation of the phrenic nerve. We tested motor evoked potentials (MEPs) elicited by TMS over the leg motor cortex in the diaphragm muscle before and after 180 paired-pulses. Respiratory function was measured before and after paired-pulses in individuals with SCI. We found that MEP size at rest and electromyograpic activity in the diaphragm during maximal inspiratory effort increased after a single session of PCMS in controls and SCI participants. A ventilator-dependent participant underwent 40 sessions of PCMS combined with standard physical therapy. Notably, we found that vital capacity, forced vital capacity, forced expiratory volume, and maximal voluntary ventilation improved after repeated sessions compared with baseline measures. These results suggest that STDP-like plasticity can represent an avenue to enhance respiratory function following high cervical SCI.

Title: Differential Effect of Corticospinal-Motoneuronal Plasticity in Elbow Flexor and Extensor Muscles in Humans with Spinal Cord Injury

Authors: *C. L. P. BUTLER[1,2,3,4], M. A. PEREZ[1,3,4];
[1]Shirley Ryan AbilityLab, Chicago, IL; [2]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL; [3]Dept. of Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [4]Edward Hines Jr., VA Hosp., Hines, IL

Abstract: Individuals with cervical spinal cord injury (SCI) exhibit limited motor recovery in elbow extensors compared to elbow flexor muscles. The goal of our study was to assess the effect of paired corticospinal-motoneuronal stimulation (PCMS) on corticospinal excitability in elbow flexor and extensor muscles in humans with and without spinal cord injury (SCI). During PCMS, corticospinal volleys evoked by transcranial magnetic stimulation (TMS) were timed precisely to arrive at corticospinal-motoneuronal synapses of the biceps and triceps brachii muscles 1-2 ms prior to the arrival of antidromic potentials elicited through electrical stimulation of the musculocutaneous and radial nerves at the brachial plexus. The interstimulus interval (ISI) between TMS and peripheral nerve stimulation [calculated by using the latency of motor evoked potentials (MEPs), C-roots, and maximal motor responses], was similar between muscles in control (biceps=4.0±1.0ms, triceps=4.1±0.7ms; p=0.8; n=7) and SCI (biceps=4.1±5.1ms, triceps=4.2±5.8ms; p=0.9; n=3) participants. Thus, PCMS was used to target both muscles concurrently using suprathreshold stimulation. We tested the effect of PCMS on MEPs elicited by TMS over the arm representation of the motor cortex in biceps and triceps brachii before and after 180 paired pulses in humans with and without chronic cervical SCI. We found that MEP size increased after PCMS in the biceps brachii to a larger extent than in the triceps brachii in control (biceps=194.4±114.2% of baseline, triceps=124.8±71.4% of baseline) and SCI (biceps=528.0±214.1% of baseline, triceps=137.8±62.2% of baseline) participants. Our findings suggest that in humans spike-timing dependent plasticity mechanisms are easily engaged in elbow flexors compared to elbow extensors muscles. This knowledge might contribute to the design of targeted strategies aiming to enhance upper limb function after SCI.

Abstract: A motor complete spinal cord injury (SCI) results in the loss of voluntary motor control below the point of injury. Some of these patients can regain partial motor function through inpatient rehabilitation; however, there is currently no biomarker to easily identify which patients have this potential. Existing research indicates that spasticity could be that marker. It was found that patients with motor complete SCI who exhibit spasticity show preservation of descending motor pathways, the pathways necessary for motor signals to be carried from the brain to the target muscle. We hypothesized that the presence of spasticity predicts motor recovery after subacute motor complete SCI. Spasticity and descending connectivity were tested in the quadriceps femoris muscle in patients with subacute motor complete (n=36) and motor incomplete (n=30) SCI. Neurological recovery was assessed by using the International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) and the American Spinal Injury Association Impairment Scale (AIS). All measurements were taken at admission and discharge from inpatient rehabilitation. We found that motor complete SCI patients with spasticity improved in motor scores and showed AIS conversion to either motor or sensory incomplete. Conversely, patients without spasticity showed no changes in motor scores and AIS conversion. In incomplete SCI patients, motor scores improved and AIS conversion occurred regardless of spasticity. These findings indicate that spasticity represents an easy-to-use physiological biomarker to predict motor recovery after severe SCI. This knowledge can improve the effectiveness of inpatient rehabilitation for complete SCI patients.

Title: Post-activation depression is attenuated in humans with spinal cord injury with and without spasticity

Authors: *M. NITO[1,2,3], B. CHEN[1,2,4], J. B. NIELSEN[5], M. A. PEREZ[1,2,4];
[1]Shirley Ryan AbilityLab, Chicago, IL; [2]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [3]Occup. Therapy, Yamagata Prefectural Univ. of Hlth. Sci., Yamagata, Japan; [4]Edward Hines Jr., VA Med. Ctr., Chicago, IL; [5]Neurosci., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Post-activation depression (PAD) is thought to be one of the mechanisms altered after spinal cord injury (SCI) that might contribute to spasticity. However, limited information is available on how PAD differs between humans with SCI with and without spasticity. To address this question, we tested the soleus H-reflex at interstimulus intervals of 1, 2, 4, and 10 s using half of the maximal H-reflex (half H-max) and the maximal H-reflex (H-max) size in 34 individuals with chronic (≥6 month) SCI and 17 aged-matched control subjects. Spasticity in the soleus muscle was assessed by the stretch reflex (elicited by rapid >300°/s passive dorsiflexion of the ankle) and the Modified Ashworth Scale (MAS). The presence or absence of spasticity in individuals with SCI was classified based on the highest amplitude of stretch reflex obtained in control subjects. We found that the H-max was similar in individuals with SCI with and without spasticity and control subjects, whereas the M-max was smaller in both groups of individuals with SCI compared with control subjects. PAD was stronger at shorter interstimulus intervals at half H-max compared with H-max in individuals with SCI with and without spasticity and control subjects. Notably, PAD was attenuated to a lesser extent in individuals with SCI compared with control subjects but no differences were found in individuals with SCI with and without spasticity. In addition, the magnitude of PAD was not correlated with the stretch reflex and the MAS. Our findings demonstrate that PAD is attenuated following SCI regardless of the presence of spasticity, suggesting that it is less likely that PAD plays a role in the pathophysiology of spasticity.

Title: Spinal cord injury changes the relationship of ventilatory drive to breathing

Authors: *T. SUTOR[1], M. MIR[2], J. WELCH[5], A. VOSE[2], G. S. MITCHELL[3], E. J. FOX[4]; [1]Univ. of Florida, GAINESVILLE, FL; [3]Univ. of Florida, [2]Univ. of Florida, Gainesville, FL; [4]Brooks Rehabil., Univ. of Florida, Jacksonville, FL; [5]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Spinal cord injury (SCI) disrupts neural pathways necessary to breathe. Resting ventilatory drive measured by mouth pressure 0.1 seconds after an unexpected inspiratory occlusion (P0.1) is elevated in persons with acute (<6 months) SCI who are ventilator dependent. Most persons with chronic SCI breathe independently, and P0.1 is similar to non-injured (NI) persons. However, other breathing impairments persist and vary with injury severity. While P0.1

is a useful index of breathing function, P0.1 associations with injury characteristics and other breathing outcomes have not been established post-SCI. Thus, we quantified relationships between P0.1 and: 1) SCI injury characteristics; and 2) standard clinical breathing outcomes. 22 community-dwelling adults >1-year post- complete or incomplete SCI (C1-T6) enrolled in an ongoing IRB-approved trial to improve breathing were included. Retrospective data from 17 NI controls were used for comparison. P0.1, tidal volume (VT), breathing frequency (Fb) and minute ventilation (VE) at rest were collected. Neurologic level of injury (NLI), ASIA impairment scale (AIS), and time post-injury were recorded in participants. Differences between groups were compared via t-tests. Relationships between P0.1 and other variables were assessed via linear or quadratic univariate or multivariate relationships. P0.1 was not associated with NLI, AIS or time post-injury in participants with SCI, either independently or in multiple regressions. There was no difference between groups in P0.1 (NI: 1.28 cmH2O ± 0.7; SCI: 1.11 ± 0.5, $p>.05$) or Fb (NI: 14 ± 3.5 breaths/minute; SCI 13.4 ± 2.9, $p>.05$). There were significant differences in VT (NI: 0.75 ± 0.2 liters; SCI 0.6 ± 0.13, $p<.01$) and VE (NI: 10 ± 1.5 liters/minute; SCI 7.8 ± 1.4, $p<.001$). VE and P0.1 associations were linear and significant in both groups (NI: $r^2 = .24$, $p<.05$; SCI: $r^2 = .24$, $p<.05$). VT and P0.1 were quadratically associated in NI ($r^2 = .56$, $p<.01$), but unrelated in SCI. Fb and P0.1 associations were quadratic in NI ($r^2 = .69$, $p<.001$) and linear in SCI ($r^2 = .19$, $p<.05$). The lack of association between P0.1 and chosen SCI characteristics is possibly because clinical characteristics commonly used to characterize SCI do not consider ventilatory drive. While P0.1 is associated with VE at rest after SCI, changes in ventilatory drive may more likely manifest as increased Fb since impaired breathing muscle function might impair increases in VT, causing a lack of association between P0.1 and VT. These factors should be considered to provide more comprehensive insight when interpreting changes in P0.1 across time or due to interventions intended to improve breathing in this population.

Abstract: Many preclinical studies in rodents have shown that sensory neurons in the dorsal root ganglia (DRG) exhibit heterogeneity in their intrinsic excitability that parallels their functional diversity. Changes in the intrinsic excitability of rodent DRG neurons, particularly the nociceptor subpopulation, are thought to contribute to pathogenesis and maintenance of pain; however, whether this occurs in the sensory neurons of humans with chronic pain conditions is only beginning to be explored. In this study, we examine whether the intrinsic excitability of human sensory neurons is dynamically modulated by pain history. Using DRG neurons obtained postmortem from organ donors, we have identified at least three physiologically distinct clusters of human DRG neurons that differ in their spike firing patterns, action potential kinetics, and membrane properties. By employing a "Patch-Seq" approach, we map the electrophysiologically-defined clusters to specific, transcriptionally determined subpopulations of sensory neurons. Finally, a comparison of human DRGs from donors with and without pain history reveals cluster-specific, pain history-associated differences in the intrinsic excitability and spike kinetics of human DRG neurons, as well as in the expression of voltage-gated sodium channels. Together, our results are consistent with the notion that sensory neurons from donors with pain history exhibit distinct electrophysiological profiles compared to DRG neurons from donors without pain history.

Title: Peripheral antinociception induced by carvacrol: Activation of the opioid receptor-Nitric Oxide-cGMP-potassium channel pathway

Authors: *M. I. ORTIZ[1], G. CASTAÑEDA-HERNÁNDEZ[2];
[1]Área Académica De Medicina, ICSA, UAEH, Pachuca de Soto, Mexico; [2]Dept. de Farmacología, Ctr. de Investigación y de Estudios Avanzados del Inst. Politécnico Nacional, Cd. México, Mexico

Abstract: The aim of this study was to examine if the local antinociception of carvacrol comprise the participation of a biguanide-dependent mechanism and the nitric oxide (NO)-cyclic guanosine monophosphate (cGMP)-K^+ channel pathway in the 1% formalin test. Male Wistar rats were injected in the dorsal surface of the right hind paw with formalin (1%). Nociception

was quantified as the number of flinches of the injected paw during 1 hour, whereas a reduction of the number of flinches was considered antinociception. Rats received a subcutaneous injection into the dorsal surface of the paw of vehicles or increasing doses of carvacrol (100-300 µg/paw). To determine whether the local antinociception induced by carvacrol was mediated by either the opioid receptors, the NO-cGMP-K^+ channels pathway or a biguanide-dependent mechanism, the effect of pretreatment (10 min before formalin injection) with the appropriate vehicles, naltrexone (opioid receptor antagonist), L-NAME (a NO synthase inhibitor; 100 µg/paw), 1 H-(1,2,4)-oxadiazolo (4,2-a) quinoxalin-1-one (ODQ)(a NO-sensitive soluble guanylyl cyclase inhibitor; 100 µg/paw), glibenclamide or glipizide (both ATP-sensitive K^+ channel blockers; K_{ir}6.1-2; 100 µg/paw), tetraethylammonium chloride (TEA) or 4-aminopyridine (4-AP) (both voltage-gated K^+ channel blockers; K_V; 100 µg/paw), apamin (a small conductance Ca^{2+}-activated K^+ channel blocker; K_{Ca}2.1-3; 2 µg/paw), and charybdotoxin (a big conductance Ca^{2+}-activated K^+ channel blocker; K_{Ca}1.1; 2 µg/paw), or metformin (a biguanide hypoglycemic; 400 µg/paw) on the antinociceptive effects induced by local carvacrol (300 µg/paw) were assessed. Carvacrol produced antinociception during both phases of the formalin test. Carvacrol antinociception was blocked by naltrexone, L-NAME, ODQ, K^+ channels blockers and metformin. In conclusion, local peripheral administration of carvacrol was able to produce significant antinociception and active the opioid receptor-NO-cGMP-K^+ channels pathway and a biguanide-dependent mechanism.

Title: Early life stress modulates neonatal somatosensation and the transcriptional profile of immature sensory neurons

Authors: *K. HARBOUR, M. HAYES, M. BACCEI;
Univ. of Cincinnati, Cincinnati, OH

Abstract: Approximately 9% of infants born every year in the US are admitted to the neonatal intensive care unit (NICU) where lifesaving procedures occur, but also exposure to injury and other chronic stressors. While the long-term consequences of early life stress (ELS) for adult pain sensitivity have been extensively studied, surprisingly little is known about how chronic stress acutely shapes nociceptive processing in neonates. Therefore, we investigated the short-term effects of ELS on both pain sensitivity and the transcriptomic profile of immature dorsal root ganglion (DRG) neurons. ELS was induced in C57Bl/6 mice using a neonatal limited

bedding (NLB) protocol from postnatal day (P)2 to P9, with standard bedding used as a control. Behavioral assays including Von Frey and Hargreaves were performed between P9 and P12 to measure mechanical and thermal sensitivity, respectively. Compared to age-matched control litters, NLB mice exhibited a significant increase in mechanical sensitivity, but not thermal sensitivity, with no differences between sexes detected in either behavioral assay. To identify genes whose expression are significantly altered by ELS, bilateral L3-L5 DRGs were harvested at P9 (n = 6 mice/group; balanced by sex) and bulk RNAseq analysis was conducted. Overall, 132 genes exhibited a ≥ 2-fold increase or decrease in expression after ELS with no significant sex differences observed. The differentially expressed genes were distributed across multiple functional classes including neuropeptides, voltage/ligand-gated ion channels and chemokine/chemokine receptors, including several pain- and itch-related genes such as *Il31ra*, *Trpa1*, and *Chrna6*. Most strikingly, *Sst* and *Nppb*, which are known to be highly co-localized in a subpopulation of DRG neurons implicated in chronic pain and itch, each showed a >16-fold downregulation in NLB mice compared to naïve controls. Collectively, these results yield new insight into the potential mechanisms governing the intersection between chronic stress and pain during the neonatal period.

Title: Involvement of nociceptive TRPA1 channel in the analgesic effects of Lavender essential oil components

Authors: *M. HASHIMOTO, K. TAKAHASHI, T. OHTA;
Dept. of Vet. Pharmacology, Grad. Sch. of Vet. Medicine, Tottori Univ., Tottori, Japan

Abstract: Lavender Essential Oil (LEO) is commonly used in fragrances. It is known that LEO has anxiolytic, sedative, and analgesic actions. However, the mechanism of its analgesic action is not fully clarified. Pain signals elicited by the activation of nociceptors on peripheral neurons are transmitted to the central nervous system. In the present study, we investigated the effects of major LEO components (linalool and its acetic acid ester, linalyl acetate) on transient receptor potential ankyrin 1 (TRPA1) channel, which is important for pain signaling as nociceptors in somatosensory neurons. For detection of channel activity, the intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) was measured using a fura2-based Ca^{2+} imaging system, and membrane currents were recorded by a whole-cell patch-clamp technique. Analgesic actions in individuals were examined in vivo. In mouse sensory neurons, linalool at concentrations without changing the resting

$[Ca^{2+}]_i$, reduced $[Ca^{2+}]_i$ increases induced by allyl isothiocyanate (AITC) and carvacrol, exogenous TRPA1 agonists. Linalool also suppressed Ca^{2+} responses to Prostaglandin J_2 (PGJ_2), an endogenous TRPA1 agonist to the same extent. Similar inhibitory effects of linalool were observed in cells heterologously expressed TRPA1 channel. In wild-type mice an injection of PGJ_2 to the hind paw elicited nociceptive behaviors, which were significantly diminished in TRPA1-gene deficient mice. Linalool dose-dependently reduced the PGJ_2-induced nociceptive behaviors. Similar to linalool, linalyl acetate suppressed $[Ca^{2+}]_i$ and current responses to TRPA1 agonists in cells heterologously expressed TRPA1 channel. However, the inhibitory action of linalyl acetate on AITC was greater than carvacrol. These results suggest that inhibition of nociceptive TRPA1 channel is related to the analgesic actions of linalool and linalyl acetate. Therefore, the components of LEO may be effective as lead compounds for the development of new analgesic drugs.

Title: Decreased AC1 and increased SUR1 spinal cord expression attenuates opioid tolerance and withdrawal in mice

Authors: ***K. M. JOHNSON**, B. A. MEYER, J. MELLANG, A. L. FOWLER, A. H. KLEIN; Univ. of Minnesota, Duluth, MN

Abstract: A recent study found chronic pain has an incidence rate of 52.4 cases per 1,000 person years, which is higher than other known chronic diseases including diabetes and depression, demonstrating the high disease burden of chronic pain (Nahin et al., 2023). Although opioid analgesics are a frequently prescribed drug class, chronic opioid use can lead to abuse, dependence and overdose (Chou et al., 2015). Due to this health burden of opioids, identifying molecular targets which cause opioid tolerance and withdrawal may help chronic pain patients. Under normal physiological conditions, adenylyl cyclases are inhibited upon mu opioid receptor activation (MOR). Under long term opioid exposure and therefore continuing activation of MORs, adenylyl cyclase (AC) activity, and subsequently cAMP activity, increases. Several molecular targets downstream of cAMP, including modulation of ion channels, have been investigated for their role in opioid tolerance. Potassium channel activity, including ATP-sensitive potassium channels (K_{ATP}), are decreased under chronic opioid conditions in the nervous system. Preliminary data from our lab has shown systemic delivery of ST034307 (5mg/kg), an AC1 antagonist, improves morphine tolerance when administered chronically

(15mg/kg, twice daily), but this effect was lost in mice with conditional knock out of sulfonylurea receptor 1 (SUR1), a component of K_{ATP} channels found in the nervous system. In order to further investigate how altered AC1 function affects opioid tolerance and withdrawal via K_{ATP} channels *in vivo,* we used a viral vector strategy to downregulate AC1 (*Adcy1*) in the spinal cord using AAV9-Adcy1-shRNA concurrently with the upregulation of either SUR1 (*Abcc8*) or Kir6.2 (*Kcnj11*) using Ad-m-Abcc8 or Ad-m-Kcnj11, respectfully. Morphine dose responses (1-15 mg/kg) were significantly shifted in control vector mice (AAV9-Scramble-shRNA, Ad-m-Null) after establishment of morphine tolerance compared to dose-response curves obtained before tolerance. The increased expression of K_{ATP} channel subunits combined with the decreased AC1 expression did not significantly shift morphine dose response curves. Mice treated with AAV9-Adcy1-shRNA in conjunction with Ad-m-Abcc8 had the smallest shift in morphine dose responses, indicating both a decrease in AC1 activity paired with an increase in SUR1 can attenuate opioid tolerance and withdrawal.

Title: Functional and anatomical characterization of genetically targeted myelinated nociceptors

Authors: C.-Y. CHEN[1], O. LE MOËNE[1], L. KACZMARCZYK[2], W. JACKSON[2], *M. LARSSON[1];
[2]Wallenberg Ctr. for Mol. Med., [1]Linkoping Univ., Linkoping, Sweden

Abstract: Nociceptive primary afferent fibers that are responsible for detecting different types of noxious stimuli can be broadly divided into unmyelinated C fibers and myelinated A fibers. Whereas some subclasses of C fiber nociceptor have been extensively studied, comparatively less is known about the function of myelinated nociceptors. To enable comprehensive characterization of presumed myelinated nociceptors we generated two mouse lines, Nefh:CreERT2 and NaV1.8:FlpO, that allowed for intersectional Cre- and Flp-dependent genetic targeting of a broad population of such fibers. In the skin, peripheral nerve fibers targeted via this strategy formed free nerve endings as well as circumferential nerve endings around hair follicles. In the spinal cord, a dense plexus of fibers was observed in lamina I, whereas lamina II showed a comparatively low fiber density; a moderate density of fibers was found in laminae III-IV, but lamina V notably exhibited a very low density of fibers. In lamina I, fibers often colocalized with

CGRP but in deeper laminae such colocalization was sparse. Using electron microscopy, both simple dome-shaped terminals and central terminals of synaptic glomeruli were observed to contain peroxidase targeted to these fibers. Cutaneous optogenetic stimulation of the targeted fiber population induced withdrawal reflexes and strong place aversion in a real-time place preference assay. Facial expression analysis during optogenetic stimulation revealed a pattern of facial feature changes that closely resembled those induced by optogenetic stimulation of a population of CGRP-lineage nociceptors. Unexpectedly, whereas facial features recovered to baseline rapidly after cessation of a three-minute optogenetic stimulus of the CGRP-lineage fibers, the pain-related facial expression was retained for at least three minutes after ceasing stimulation of the presumed myelinated nociceptors. These observations suggest that a broad class of myelinated nociceptors target spinal circuits that control reflexive behavior but also relay signals to supraspinal pathways associated with aversive behavior and affective aspects of pain.

Title: Multiple Rab GTPase subtypes are involved in Nav1.7 anterograde transport in sensory axons

Authors: *N. SARVESWARAN[1,4], D. GEBERT[2,4], S. TYAGI[2,3,4], C. BORELLI[2,4], S. LIU[2,4], F. DIB-HAJJ[2,4], S. DIB-HAJJ[2,4], S. WAXMAN[2,4];

Abstract: Nociceptors are specialized somatosensory neurons of the peripheral nervous system that respond to injurious stimuli. Human genetic studies have demonstrated that Nav1.7, a member of the voltage-gated sodium channel family, has a crucial role in fine-tuning the excitability of these cells and subsequent perception of pain - therefore, a highly appealing target for analgesic drug development. Membrane proteins synthesized in the cell body are packaged into vesicles that move anterogradely toward distal axons for insertion along the cell surface. Rab GTPases have been implicated in cargo sorting and directing membrane traffic to specific

neuronal compartments, including several ion channels, surface receptors, and dense core vesicles containing excitatory neuropeptides. Previous work investigating 8 of the ~60 human Rab proteins showed that Nav1.7 was selectively co-transported in Rab6A-positive vesicles. However, an appreciable proportion of Nav1.7-positive vesicles did not contain Rab6A, suggesting additional Rabs could be involved in Nav1.7 anterograde transport. Here we have used the Optical Pulse-Chase Axonal Long-distance (OPAL) imaging assay to investigate Nav1.7 co-transport with three additional Rab proteins that are highly expressed in dorsal root ganglia. Our experiments show that Nav1.7 was also carried in Rab11A- and Rab15-positive vesicles but not in those containing Rab14. Moreover, we observed considerable co-trafficking of Rab6A, Rab11A, and Rab15 in the same vesicles, although they were not always transported together. Finally, we showed a significant reduction in Nav1.7 localization to Rab6A-positive vesicles when Rab6A GTPase activity was inactivated through a point mutation. Further experiments to understand the impact of this change on Nav1.7 surface insertion are ongoing. Our results reveal an association between Nav1.7 and several Rab subtypes within anterograde transport vesicles in sensory axons, and that inactivating GTPase activity of one Rab subtype can partially uncouple its relationship with Nav1.7. Importantly, the co-localization of different Rab subtypes in single transport vesicles offers a layer of redundancy so that functional Rabs can partially stand in for an inactivated isoform in regulating Nav1.7 transport.

Title: Inflammation-induced changes in the functional properties of Aβ-fiber high threshold mechanoreceptors and Aβ-fiber low threshold mechanoreceptors in the hindpaw glabrous skin of mice

Authors: *A. YAMADA[1], A. YAMADA[1], J. LING[1], H. FURUE[2], J. G. GU[1];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Hyogo Med. Univ., Hyogo, Japan

Abstract: Inflammatory conditions often lead to mechanical allodynia, a pain state that can be triggered by a gentle touch. However, the mechanism underlying mechanical allodynia is not fully elucidated. Recently, we have used Nav1.8^{ChR2} transgenic mice and show that Nav1.8^{ChR2}-positive Aβ-fiber mechanoreceptors are mostly high threshold mechanoreceptors (HTMRs) whereas Nav1.8^{ChR2}-negative Aβ-fiber mechanoreceptors are low threshold mechanoreceptors (LTMRs). In the present study, we investigated whether the functional properties of these

HTMRs and LTMRs in the hindpaw glabrous skin of Nav1.8^{ChR2} transgenic mice may be altered following inflammation induced by Complete Freund's Adjuvant (CFA). We used hindpaw glabrous skin-tibial nerve preparations and applied pressure-clamped single fiber recordings to measure mechanical sensitivity on the hindpaw glabrous skin. We found that CFA-induced inflammation impacted functional properties of both Nav1.8^{ChR2}-positive Aβ-fiber HTMRs and Nav1.8^{ChR2}-negative Aβ-fiber LTMRs in the hindpaw glabrous skin. The mechanical threshold of Nav1.8^{ChR2}-positive Aβ-fiber HTMRs was significantly lowered in the CFA group compared to the saline control group. Conversely, for Nav1.8^{ChR2}-negative Aβ-fiber LTMRs, their mechanical threshold significantly increased in the CFA group. Our findings raise the possibility that changes in the mechanical threshold of both Aβ-fiber HTMRs and Aβ-fiber LTMRs may contribute to mechanical allodynia following tissue inflammation, providing a new insight into inflammatory pain. The study is supported by NIH R01 DE023090 to JGG.

Abstract: While genetic mutations leading to pain insensitivity phenotypes are rare, the underlying molecular biology is often used to validate analgesic drug candidates. Pain insensitivity generally results from Mendelian loss-of-function mutations in genes expressed in nociceptive (pain-sensing) dorsal root ganglion (DRG) neurons that connect skin and deep tissues to the spinal cord. Using this peripheral DRG frame of reference, we report on pain

insensitivity in individuals with 7q11.23 duplication syndrome (Dup7) who have three copies of the ~1.5 megabase Williams syndrome (WS) critical region at chromosomal locus 7q11.23, which contains ~26 genes. Our study shows that, based on parental reports, some people with Dup7 are pain insensitive following serious injury to skin, bones, teeth, or viscera. In contrast, their diploid siblings (with two copies of the 7q11.23 WS critical region) and people with WS (having one copy of the same genes) show standard reactions to painful events. Here we use a converging series of human assessments, and cellular, biological, and transcriptomic methodologies that implicate the *STX1A* gene, which codes for the synaptic vesicle fusion protein Syntaxin1A, as the candidate gene in the 7q11.23 copy number variant (CNV) that underlies this phenotype, and the DRG as site mediating the nociceptive dysfunction. First, co-expression profiling showed enrichment of murine *Stx1A* expression in the TRPV1+ population of nociceptive afferents which are critical for cutaneous thermal nociception and deep tissue damage pain. Next, overexpression of *STX1A* by lentiviral transduction of rat primary afferent neurons yielded a reduction in capsaicin-evoked CGRP release, supporting a functional association between STX1A and neuropeptide release from TRPV1+ DRG neurons. Further, anatomical colocalization of *STX1A* with *TRPV1+* neuronal populations was demonstrated by multiplex fluorescent in situ hybridization of human DRG. Finally, in human cell lines from +/-, +/+, and +/+/+ individuals (i.e., WS, diploid, and Dup7, respectively) we observed a clear gene dosage effect with increasing copy number (p-adj=$1.5x10^{-10}$). The progressive increase was specific for STX1A, and expression of none of the 18 other syntaxin analogs was altered (all p-adj's>0.1). The present data suggest *STX1A* overexpression compromises synaptic vesicle fusion and transmitter exocytosis in nociceptive afferent neurons, thereby producing a "genetic analgesia" in affected individuals. As such, this implicates several biochemical pathways as potential targets for pain control.

Title: Understanding the role of prolactin in stress-induced neuronal sensitization and pain outcomes in a preclinical model of post-surgical pain

Authors: *M. DOLATYARI[1], H. J. STRATTON[1], C. KOPRUSZINSKI[1], A. MOUTAL[2], E. NAVRATILOVA[1], F. PORRECA[1,3];

[1]Pharmacol., Univ. of Arizona, Tucson, AZ; [2]St. Louis Univ., St. Louis Univ., St Louis, MO; [3]Neurol., Mayo Clin., Phoenix, AZ

Abstract: Women experience pain more frequently than men, but the biological mechanisms behind these sex differences in pain are not yet fully understood. Post-operative pain (POP) presents a major unmet clinical problem and women frequently report more POP than men – possibly a result of increased or sustained nociceptor sensitization after surgery. Prolactin (PRL), a neurohormone, circulates at higher levels in women and has an established role in driving neuronal sensitization. The existing literature suggests that experiencing stress before a surgical procedure may be associated with poorer POP outcomes. Since stress has been shown to trigger the release of PRL, we hypothesized that presurgical blockade of PRL signaling could improve pain outcomes after surgery. We sought to determine whether stress could prolong the recovery from post-surgical pain in male and female C57Bl6 mice. We utilized restraint stress (RS) to produce sensitization and the plantar incision model (PLI) as a model of postoperative pain. Mechanical hypersensitivity was evaluated using von Frey (VF). In all studies, experimenters were blind to the treatment conditions, animals were randomly assigned to treatment groups, and unblinding was performed after all data were analyzed. We found that stress significantly prolonged the recovery of withdrawal frequency to baseline levels in animals that were stressed compared to unstressed control mice. To investigate the corresponding electrophysiological changes associated with this behavioral hypersensitivity, dorsal root ganglia innervating the paw were dissected and cultured then incubated overnight with a subthreshold dose of PRL. We found that mice exposed to RS had significantly increased excitability compared to non-stressed mice. To determine whether PRL was responsible for prolonging the recovery from post-surgical pain, we used cabergoline to inhibit the release of circulating PRL. Mice received i.p. cabergoline treatments at 1.2 mg/kg 2 hours before RS, PLI, and after von Frey tests on days 4, 6, 8, and 10 after RS and days 2 and 4 after PLI. Controls received the respective vehicles at 10 mL/kg. Treatment with cabergoline blocked stress-induced increase in response frequency and post-surgical hypersensitivity in female mice, but not male mice. DRG neurons were harvested from these animals, and we found that those treated with vehicle had increased excitability in response to low-dose PRL. Still, this effect was blocked in female mice treated with cabergoline. In conclusion, we have found that PRL is involved in stress-induced POP prolongation, suggesting that PRL could be targeted to alleviate pain selectively in female patients.

Title: Lysophosphatidic acid contributes to hyperalgesia in a humanized mouse model of sickle cell disease through direct sensitization of dorsal root ganglia neurons

Abstract: Sickle cell disease (SCD), the most common hemoglobinopathy, is characterized by hemolysis, vaso-occlusion, vasculopathy, ischemia-reperfusion injury, inflammation, and pain. Pain is the dominant clinical symptom of SCD and the most common cause of hospitalization. Transgenic mouse models of SCD recapitulate many disease features, including chronic pain. Homozygous HbSS-BERK mice were used to study the contribution of lysophosphatidic acid (LPA), an endogenous lipid pain mediator, to chronic hyperalgesia in SCD. HbSS mice express >99% human sickle hemoglobin and mirror symptoms of human SCD. HbAA mice expressing normal human hemoglobin were used as a control. Hyperalgesia in HbSS mice was accompanied by increased plasma level of LPA, and administration of LPA produced hyperalgesia in control HbAA mice. Mechanical hyperalgesia was defined by a decrease in paw withdrawal threshold, and heat hyperalgesia was characterized by a reduction in paw withdrawal latency to radiant heat. Considering that LPA exerts its effects by binding to LPA_{1-6} receptors (LPAR), among which DRG neurons widely express $LPAR_1$, qPCR was used to determine the expression of $LPAR_1$ in DRG. Hyperalgesia in HbSS mice was associated with increased expression of $LPAR_1$ mRNA in DRGs. Systemic administration of AM966, an $LPAR_1$ antagonist, attenuated chronic hyperalgesia in HbSS mice. The direct effect of LPA on dissociated DRG neurons was investigated using the patch-clamp recording. Nociceptive neurons were detected by action potential (AP) shape, membrane capacitance, and size (area$\leq$500 μm^2). In contrast to HbAA mice, DRG neurons from HbSS mice exhibited spontaneous APs and increased excitability more than HbAA mice, defined by lower rheobase and depolarized resting membrane potential (RMP). Similar results were observed when DRG neurons from HbAA mice were treated with LPA (10 μM) for 24 hours in vitro. These data suggest that LPA contributes to hyperalgesia in SCD by sensitizing DRG neurons.

Title: Patch clamp profiling the functional properties of human iPSC-derived nociceptors

Authors: *A. E. SNYDER[1], P. J. GANDHI[1], D. LIU[1], C. TIAN[1], C. M. PETROSKI[1], V. TRUONG[2], P. WALSH[2], R. E. PETROSKI[1];

Abstract: According to the National Institute of Neurological Disorders and Stroke, 100 million adults in the United States suffer from chronic pain. One way to study pain is to use human iPSC-derived nociceptors as an in vitro model, but it is important to characterize the cell properties to understand their utility. Here, we profiled the functional properties of human iPSC-derived nociceptors using whole cell patch clamp recordings at different timepoints (1-8 weeks) to determine the time course for the development of a mature neuronal phenotype. Nociceptors were thawed and plated at a low density, with a subset plated on a monolayer of rat astrocytes. Upon establishing the whole cell configuration, we measured the passive membrane properties for every cell including membrane capacitance (Cm), membrane resistance (Rm) and resting membrane potential (RMP). We also recorded spontaneous action potential firing as well as intrinsic excitability using a rheobase protocol. Additionally, we evaluated the expression of voltage-gated sodium and potassium currents. We recorded from over 100 sensory neurons from 1-8 weeks in vitro. Human nociceptors plated at low density on rat astrocytes appeared healthier and were easier to patch compared to neurons plated without astrocytes. Nociceptors grew larger with time in culture as evidenced by an increase in Cm, with decreased Rm. The RMP became more hyperpolarized after three weeks and remained stable thereafter. Little spontaneous activity was observed in cells at every developmental timepoint, as would be expected from sensory neurons. The nociceptors were excitable, however, as action potentials were elicited with depolarizing current injections. Further, the amount of current injection required to elicit the first action potential (rheobase) increased over developmental time, as expected from neurons with lower Rm. Additionally, nociceptors at all developmental timepoints exhibited sodium currents. The voltage-dependent sodium current amplitudes increased with time in culture, while the peak sodium current density (pA/pF) remained stable. We also evaluated the presence of TTX-R sodium currents at 5-8 weeks in vitro and detected their presence at all evaluated time points. The proportion of TTX-R among nociceptors varied. Overall, we determined that these human iPSC-derived nociceptors display a mature developmental phenotype by three weeks in culture, with appropriate RMPs, the ability to evoke activity, and the demonstration of TTX-R and TTX-sensitive Na currents.

Title: Functional Characterization of C-fiber Subtypes in Mouse Skin

Authors: *D. JURCAKOVA[1,2], M. GRENDAR[1,3], B. J. UNDEM[4];
[1]Comenius Univ., Martin, Slovakia; [2]Jessenius Fac. of Med., Dept. of Pathological Physiol., Martin, Slovakia; [3]Biomed. Ctr. Martin, Jessenius Fac. of Med., Martin, Slovakia; [4]Asthma And Allergy Ctr., Johns Hopkins Univ., Baltimore, MD

Abstract: Nociceptive neurons serve as specialized detectors of a plethora of potentially harmful internal and external stimuli and comprise a highly diverse cell population. In the recent years, transcriptional profiling of dorsal root ganglia neurons identified 4 -10 molecularly distinct nociceptive-like subtypes. While these studies inform nerve phenotypes, they are at best cautiously translated to nerve function. Moreover, these studies have focused on the whole ganglia comprising neurons innervating various peripheral tissues. In this study, we focused on functional characterization of C-fiber subtypes based on the responsiveness of nerve terminals innervating the dorsal skin of the mouse. We used *ex vivo* mouse skin-spinal nerve preparation to evaluate responses of 232 individual C-fibers to 15 chemical (chloroquine (CQ), BAM8-22, histamine, bradykinin, ß-alanine, serotonin, ATP, lysophosphatidic acid and TRPV1, V3, V4, A1, C3/6, M2, M8 channel) agonists as well as mechanical stimulation. Based on the mechanical sensitivity, cutaneous C-fibers can be subcategorized into low mechanical threshold (C-LTMs; 8%) and high mechanical threshold (C-HTMs; 92%) C-fibers. C-LTMs were unresponsive to all chemical mediators except the TRPV4 agonist GSK1016790A that discharge C-LTMs with a 3-fold greater potency than other C-fibers (95±24 APs (n=8) vs 32±4 APs (n=36), respectively).The C-HTMs could be, based on the chemical stimulus profile, subdivided broadly into two subgroups, one responding strongly to pruritogens such as chloroquine, histamine or BAM8-22 (n=72, 31%), but not other mediators; the other failing to respond to pruritic stimuli, but respond strongly to ATP or serotonin. Of the latter, about 50% also respond to the MrgprD stimulant ß-alanine; these ß-alanine responsive C-fibres were the only subtype that responded to the TRPV3 channel agonist farnesyl pyrophosphate (10µM). We hypothesize that activating the chloroquine/histamine sensitive C-HTMs likely evokes, relatively selectively, pruritic sensations; the more promiscuous, CQ/histamine insensitive C-fibres likely subserve more varied sensations including cutaneous pain.

Abstract: Targeted gene delivery to nociceptors
Jia Li, X. Jay Luo, Parth Bhatia, Jiaxiang Wang, Eva Semizoglou, Lite Yang, Mengyi Xu, Lorna McElrath, Sinisa Hrvatin, William Renthal
Chronic pain affects over 25 million adults in the United States and is a major cause of disability. Currently available pain treatments such as opioids are often ineffective and associated with unacceptable side effects including respiratory depression and addiction. Viral-based gene therapy offers several attractive advantages in treating refractory pain, as viruses can be engineered to deliver a wide range of molecular cargo capable of regulating neuronal excitability. To develop novel nociceptor-specific viral tools, we performed single-nucleus RNA sequencing and assay for transposase accessible chromatin (ATAC) sequencing on the mouse dorsal root ganglion (DRG) to identify nociceptor-specific molecular features. Specifically, 7,376 epigenomically profiled nuclei from male and female mice were sequenced and analyzed. We identified >10,000 nociceptor-specific regions of chromatin accessibility. Gene regulatory network analyses of these data identified transcription factors that are significantly enriched in DRG nociceptor subtypes, including *EBF1, POU4F3, JUN, MEF2C, NFIA,* and *ISL2*. After prioritization and screening of putative nociceptor-specific enhancers, each was cloned into adeno-associated (AAVs) and delivered to DRGs in mice. *In situ* hybridization of viral GFP and nociceptor markers were used to determine which enhancers drive reporter expression preferentially in nociceptor subtypes. We identified three enhancers that drive expression in DRG nociceptors with significantly more selectivity than control promoters. Ongoing studies are using our lead enhancers to drive the expression of chemogenetic actuators to silence the activity of nociceptors in vitro and in vivo. These nociceptor-selective gene therapy vectors are likely offer significant safety advantages over currently available viral vectors for the treatment of refractory chronic pain.

Title: The MNK-eIF4E Signaling Axis Mediates IL6-Driven Enhancements in Neuronal Protein Synthesis within Human Dorsal Root Ganglion Explants

Authors: *G. TORRIJOS[1], L. F. COOK[1], M. E. MITCHELL[1], L. HE[2], J. M. MWIRIGI[3], S. SHIERS[4], T. PRICE[5];
[1]Univ. of Texas at Dallas, Richardson, TX; [2]Univ. of Texas at Dallas, Dept. of Neurosci., Richardson, TX; [3]Brain and Behavioral Sci., Univ. of Texas At Dallas, Dallas, TX; [4]Cognition and Neurosci., Univ. of Texas At Dallas, Richardson, TX; [5]The Univ. of Texas, Dallas, TX

Abstract: Every day, billions of people throughout the world must endure their debilitating chronic pain symptoms due to the deficit in adequate therapeutic options. Pain symptoms including hypersensitivity and spontaneous pain often severely reduce the daily quality of life for these patients and the ability of these individuals to thrive. A major limitation is the poor success of therapeutics developed in pre-clinical rodent models in clinical settings. Therefore, generating effective treatments requires the study of potential target pathways in living human tissues. Pain symptoms are thought to arise from maladaptive plasticity in pain pathways that drives sustained hyperexcitability in the nociceptor in the dorsal root ganglion (DRG), primary sensory neurons in the PNS that detect and transmit pain-associated activity to the CNS. Cytokine Interleukin 6 (IL-6) is a critical driver of long-term maladaptive nociceptor plasticity in a variety of pain pathologies. In nociceptors, a key long-term plasticity mechanism is the control of gene expression through activity-dependent translation. In rodent models, IL-6 signaling induces protein synthesis in nociceptors by engaging MNK phosphorylation of eIF4E. Engagement of the MNK-eIF4E signaling axis induces polyribosome formation shifting the nociceptor translatome to support long-term hyperexcitability in chronic pain states. Blocking MNK phosphorylation of eIF4E either genetically or pharmacologically with peripheral administration of inhibitors like eFT508 ameliorates hypersensitivity. However, the role of this pathway in human nociceptors is only beginning to be revealed. Here, we tested whether a 20 min pulse with IL-6 (10 ng/mL) increases neuronal protein synthesis via the MNK-eIF4E signaling axis in living human DRG explants. We used Fluorescent Noncanonical Amino Acid Tagging (FUNCAT) to detect nascent proteins and immunofluorescence to detect changes in phosphorylated eIF4E (p-eIF4E). We demonstrate that IL6 induces protein synthesis and enhances p-eIF4E in a subset of neuronal

somata in human DRG explants. Furthermore, we show that a significant proportion of neurons exhibit simultaneous increases in both p-eIF4E and nascent proteins only in IL-6-treated explants. We also found that the addition of the MNK1/2 inhibitor eFT508 (100 nM) blocks this effect, indicating that MNK1/2 is a critical driver of these IL-6-induced increases. Overall, these data suggest that targeting this pathway in the PNS has the potential to inhibit or mitigate IL-6 engagement of maladaptive nociceptor plasticity mechanisms that drive their persistent excitability in chronic pain patients.

Abstract: The question of how tissue responds to injury is fundamental to understanding the initial molecular events in pain, wound healing, and inflammatory processes that contribute to post-operative pain and recovery. Previous work from our lab in a rat incision model used transcriptomics and multiplex labeling to uncover several pathways initiated by surgical incision that signal to DRG neurons and to local tissues, recruiting immune cells, and driving early hyperalgesic pathways. These proof-of-concept rodent studies led to several candidate molecules that may be of interest for pain and wound-healing drug development efforts. However, the degree of overlap between rat and human tissue incision models has not been carefully assessed from a molecular point of view. In this study, we collected tissue from N=12 (5M, 7F) patients undergoing surgeries with a planned duration longer than 4 hours. We sampled tissue from the wound edge serially at staged intervals to capture the time course of induction and assess patterns of gene regulation over time. The longest case finished at 12 hours 44 minutes. We

selected out highly expressed, strongly induced transcripts encoding secreted proteins, and further refined for proteins likely to signal to DRG neurons based on transcriptomic evidence. This strategy highlights gene induction from the damaged tissue whose products can directly signal to the nociceptive afferents, which could be involved in nociceptive transmission, sensitization of the nerve endings, and driving the neuroinflammatory processes arising from tissue injury. Overall, we identified a high degree of correspondence between most of these induction events between rat and human, although the overall pattern of induction in human skin was markedly different from currently used incision protocols in rodents. The major reason for this may be the brief duration of tissue incision used in the rodent incision model, which does not continually traumatize the wound edge, but rather generally assesses longer-term consequences of tissue injury. We found that the most significant genes induced by this paradigm were cytokine signaling pathways including those for interleukins and the pleiotropic cytokine oncostatin M. Additionally, several genes were strongly induced related to innate immune activation, the initiation of wound healing, and neutrophil recruitment. We are investigating the role of these pathways by back-translating the most critical findings into longer-term rodent wound models. This abstract is based on a clinical trial registered at ClinicalTrials.gov (NCT04224870).

Title: Identification of neuronal populations in dorsal root ganglia using spatial transcriptomics: Comparison between pig and human species

Authors: *M. MANCILLA MORENO, D. TAVARES FERREIRA, N. INTURI, S. SHIERS, I. SANKARANARAYANAN, A. ARENDT-TRANHOLM, J. MWIRIGI, T. J. PRICE;
Sch. of Brain and Behavioral Sciences, Ctr. for Advanced Pain Studies, Univ. of Texas at Dallas, Richardson, TX

Abstract: Animal models are used to probe basic pain mechanisms in the dorsal root ganglia (DRG) and to test the efficacy of drugs at the preclinical stage. Although rodent models provide invaluable insight for pain research, they often fail to mirror relevant human conditions, leading to poor translatability of promising therapeutic targets. To address this, pigs are considered an alternative model due to their comparability to humans. Pigs and humans share similar neural

pathways for Aδ- and C-fibers, distribution of free sensory nerve endings, axonal excitability properties, and conduction velocities of nociceptors. Nevertheless, specific neuronal subpopulations in pig DRGs have not been identified. Research studies characterizing the molecular profile of DRGs in rodents yield great insight on the heterogenous neuronal populations. Spatial transcriptomic tools offer an advantage over other next generation sequencing technologies because they capture the physical landscape of cell populations, allowing us to localize RNA transcripts within tissue and enhance our understanding of cell-to-cell interactions. This study seeks to comprehensively characterize neuronal subpopulations in pig DRGs and compare their evolutionary divergence from human DRGs to better assess the translatability of our preclinical pain models. We sectioned and stained 16 fresh frozen pig DRGs (Sus scrofa) with eosin and hematoxylin (H&E) to assess the quality of the tissue and the morphology of the neurons. We used the Visium Spatial Gene Expression kit to generate a near single-neuron spatial resolution. After sequencing, we selected barcodes overlapping neurons using the 10x Loupe Browser platform. Low quality cells with low counts were filtered out during quality control. Finally, we performed computational analysis using Seurat to integrate the datasets and perform neuronal clustering. We used visium spatial transcriptomics and identified 12 distinct clusters corresponding to neuronal populations including nociceptors, proprioceptors, among others. We compared them to those in humans and identified cross-species similarities and differences. We utilized our lab's published spatial transcriptomic dataset on human DRGs from healthy organ donors. Using computational approaches, we characterized neuronal subpopulations in pig DRGs using established markers from the reference human DRG dataset. Different neuronal populations were identified and compared across species. In addition to highlighting evolutionary differences, we also anticipate that this work will allow us to refine pig models, thus increasing translational efficiency of molecular pain research.

Title: Exploring interactions between enteric glia, mast cells, and DRG neurons in a colitis pain model

Authors: *K. MAZHAR[1], B. D. GULBRANSEN[2], A. J. MOESER[2], T. J. PRICE[3]; [1]Neurosci., The Univ. of Texas at Dallas, Richardson, TX; [2]Physiol., Michigan State Univ., East Lansing, MI; [3]Neurosci., The Univ. of Texas At Dallas, Richardson, TX

Abstract: Chronic abdominal pain due to gut inflammation affects several million Americans, especially those with IBS or IBD. However, there is a lack of therapeutics that both effectively treat this pain and avoid severe adverse effects. Here, we aim to study interactions in the colon that promote pain signaling by DRG sensory neurons and have generated a 3-way interactome of potential ligand-receptor interactions between enteric mast cells, enteric glia, and colon-innervating DRG neurons to elucidate how the enteric cells may be signaling to neurons and how they may be activating each other to sensitize nociceptors. Ligands and receptors on glia and mast cells were identified from TRAP-Seq datasets from mice that were handled normally and mice that had developed colonic inflammation after enduring stress due to neonatal maternal separation. This work lays the groundwork for future studies that will validate some of these interactions and identify therapeutic targets for chronic abdominal pain states..

Title: IL-6-Driven MNK-eIF4E signaling drives activity-dependent protein synthesis in human DRG neurons from diabetic organ donors

Authors: *M. E. MITCHELL[1], L. F. COOK[2], G. TORRIJOS[3], L. HE[4], J. M. MWIRIGI[5], S. SHIERS[6], T. PRICE[7];
[1]Neurosci., Univ. of Texas at Dallas, Richardson, TX; [2]Univ. of Texas at Dallas, Dallas, TX; [3]Univ. of Texas at Dallas, Richardson, TX; [4]Univ. of Texas at Dallas, Dept. of Neurosci., Richardson, TX; [5]Brain and Behavioral Sci., Univ. of Texas At Dallas, Dallas, TX; [6]Cognition and Neurosci., Univ. of Texas At Dallas, Richardson, TX; [7]The Univ. of Texas, Dallas, TX

Abstract: Diabetic neuropathic pain is the most common form of neuropathic pain, but no mechanism-based therapeutics have been approved to treat this form of pain. Spontaneous pain is the most destructive aspect of pain in these patients, having a great impact on quality of daily life. A critical origin of this pathology is persistent hyperexcitability of primary nociceptors in the dorsal root ganglion (DRG). This shift in function may arise from damage signal-driven remodeling of translation regulation causing nociceptor spontaneous activity. Cytokine interleukin-6 (IL-6) signaling plays a central role in diverse chronic pain disorders and IL-6 family cytokines are upregulated in the DRG of people with diabetic neuropathic pain. In humans and rodents, IL-6 signaling engages MNK phosphorylation of eIF4E (p-eIF4E) to initiate activity-dependent protein synthesis which increases nociceptor excitability. The resulting hypersensitivity is ameliorated by genetic block of this axis in mice or by MNK1/2 inhibitors like eFT508 in rodents and human neurons. Our work in living human DRG explants demonstrated that in a subset of DRG neurons (68%), IL-6 treatment (20min; 10ng/mL) enhances somatic p-eIF4E and nascent proteins using Fluorescent Non-Canonical Amino Acid Tagging (FUNCAT). MNK-eIF4E signaling is a critical driver of this since MNK1/2 inhibitor eFT508 (100 nM) blocked this effect. Because IL-6 signaling is a central contributor to disease progression in diabetic neuropathy, we asked whether this response is exaggerated in DRG explants from diabetic organ donors. We found that in DRG neurons exhibiting enhanced p-eIF4E, the subset with concomitantly increased nascent proteins was increased in explants from diabetic (~99%) vs non-diabetic (~80%) donors. We also found a smaller number of neurons exhibited increased p-eIF4E without nascent protein increases (diabetic 1.2%; non-diabetic 19%). ROC-AUC analysis showed p-eIF4E is an effective predictor of enhanced nascent proteins in diabetic (~0.99) compared to healthy (~0.61) tissues. This suggests that DRG neurons in diabetic donors exhibit translation regulation remodeling shifting toward MNK-eIF4E-driven

translation. Overall, the work supports the conclusion that MNK inhibitors could be tested for the treatment of diabetic neuropathic pain in clinical trials.

Title: Predictions on human lumbar intervertebral disc to DRG signaling underlying pain production in discogenic low back pain

Authors: ***J. LESNAK**, K. MAZHAR, T. J. PRICE;
Univ. of Texas at Dallas, Richardson, TX

Abstract: Chronic low back pain (LBP) is the leading cause of disability worldwide, however current treatments are inadequate. Intervertebral disc degeneration is the proposed pathophysiology in 40% of LBP cases and is classified as discogenic LBP. Single cell RNA sequencing of intervertebral discs identified 12 unique cell clusters including 7 subsets of nucleus pulposus, 2 subsets of annulus fibrosus, and a subset of fibrochondrocyte cells. Individuals with discogenic LBP have a higher prevalence of a subset of nucleus pulposus cells marked by increased catabolic and pro-inflammatory activity. However, how each of these cell types contributes to discogenic LBP is unknown. Therefore, we used our ligand-receptor interactome to generate hypotheses on how each cell type from degenerating intervertebral discs could be signaling to DRG neurons to drive pain production. Differentially expressed genes between individuals with and without discogenic LBP were determined within each intervertebral disc cell cluster from Gene Expression Omnibus data set GSE222182. Genes that were upregulated in individuals with LBP were inputted into the ligand-receptor interactome which intersects ligand genes with corresponding receptors on DRG neurons. Interactions were filtered to include ligand-receptor interactions that only occurred on nociceptors in DRGs. PANTHER classification was used to categorize the gene function for both the ligand and receptor in the interaction pair. The analysis revealed several ligand-receptor interactions between nucleus pulposus, annulus fibrosus, and fibrochondrocytes with DRGs. Nucleus pulposus cells had upregulation of genes encoding osteopontin (*SPP1*) and inhibin A (*INHBA*), both of which are implicated in pain generation and bind to multiple receptors on DRGs. These nucleus pulposus cell clusters also had upregulation of several genes which were categorized as cytokine, chemokine, and growth factors thus demonstrating a pro-inflammatory profile. Interactions between annulus fibrosus cells and DRGs revealed ligand-receptor pairs whose

function were classified as extracellular matrix producing including collagen (*COL6A, COL9A*) and biglycan (*BGN*). The interactome revealed fibrochondrocytes had upregulation of genes encoding heat shock proteins (*HSP90, HSPA1A*) and alarmins (*S100A10*) which bind to receptors on DRGs. The interactome analysis revealed several ligand-receptor pairs between intervertebral discs and DRGs which could be driving the production of discogenic LBP. Future work will explore these pathways through molecular experiments involving human intervertebral discs and DRGs.

Title: Development of a human sensory neuron multi-electrode array (MEA) assay for phenotypic drug screening

Authors: L. BUTLER[1], D. MAGNANI[1], V. TRUONG[2], P. WALSH[2], J. ANTON[1], C. MANSAT-BHATTACHARYYA[1], ***R. BURLEY**[1], O. FEDORENKO[1], M. IOVINO[1]; [1]Charles River Labs., Little Chesterford, United Kingdom; [2]Anatomic Inc., Anatomic Inc., Minneapolis, MN

Abstract: Multi-electrode arrays (MEA) can be utilised in drug discovery to provide a link from *in vitro* screening to *in vivo* testing, safety assays, or by modelling the functional impacts of disease associated variants. Peripheral sensory neurons are of particular interest in both pain and peripheral neuropathies. Here we functionally characterise human iPSC derived peripheral sensory neuronal cultures using the Maestro Pro (Axion BioSystems). Neuronal activity was measured routinely over prolonged culture where neurons showed a low spontaneous firing rate and burst frequency, consistent with literature data. Time course bulk RNA sequencing data indicates the presence of relevant sensory neuron ion channels, TPRV1, Nav1.7 and Nav1.8, after one week of maturation and comparison with primary DRG shows molecular similarities. We confirmed pharmacological response indicating functional activity of these ion channels at week 3 onwards using MEA. These data show promising results for functional assessment *in vitro* of peripheral neuronal cultures and pathological pain and look suitable for the application of drug discovery and validation.

Abstract: Peripheral sensory neurons in the dorsal root ganglion (DRG) and trigeminal ganglion (TG) are specialized to detect and transduce diverse environmental stimuli including touch, temperature, and pain to the central nervous system. Recent advances in single-cell RNA-sequencing (scRNA-seq) have provided new insights into the diversity of sensory ganglia cell types in rodents, non-human primates, and humans, but it remains difficult to compare transcriptionally defined cell types across studies and species. Here, we built cross-species harmonized atlases of DRG and TG cell types that describe 18 neuronal and 11 non-neuronal cell types across 6 species and 19 studies. We then demonstrate the utility of this harmonized reference atlas by using it to annotate newly profiled DRG nuclei/cells from both human and the highly regenerative axolotl. We observe that the transcriptomic profiles of sensory neuron subtypes are broadly similar across vertebrates, but the expression of functionally important

neuropeptides and channels can vary notably. The new resources and data presented here can guide future studies in comparative transcriptomics, simplify cell type nomenclature differences across studies, and help prioritize targets for future pain therapy development.

Title: Pain persists in mice lacking both Substance P and CGRPα signalling

Authors: ***D. I. MACDONALD**, M. JAYABALAN, J. SEAMAN, A. NICKOLLS, A. T. CHESLER;
NIH, Bethesda, MD

Abstract: Two of the most studied neuropeptides are Substance P and CGRPα. These molecules are highly expressed in pain-responsive neurons throughout the nervous system - both peripherally in nociceptors, and centrally in the spinal cord, brainstem and limbic system. Thus, it is widely held that both peptides must play important roles in modulating pain. Despite intense research over decades, Substance P receptor blockers failed to relieve pain in clinical trials. Although CGRPα monoclonal antibodies have proven effective for subsets of migraine patients,

their usefulness for other types of pain appears limited. We hypothesized that simultaneous inhibition of both Substance P and CGRPα signalling would be a useful strategy for treating pain. To test this, we generated *Tac1* and *Calca* double knockout (DKO) mice, resulting in complete loss of Substance P and CGRPα peptides throughout the nervous system. Behavioural testing revealed that DKO mice displayed largely intact responses to acute noxious stimuli of different modalities. To our surprise, chronic inflammatory and neuropathic pain was also unaffected by loss of the two peptides. Interestingly, and contrary to classical studies, DKO animals developed neurogenic inflammation. Substance P and CGRPα are therefore together not essential for the afferent transmission of pain and their combined inhibition is unlikely to produce analgesia.

Title: Exploring parameter space underlying somatic action potentials in models of small diameter dorsal root ganglion neurons

Authors: A. FELICIANO[1], N. GAMPER[2], ***D. JAFFE**[1];
[1]Univ. of Texas at San Antonio, San Antonio, TX; [2]Nikita Gamper, Univ. Leeds, Leeds, United Kingdom

Abstract: Action potential propagation along unmyelinated, C-fiber neurons may be regulated as they pass through dorsal root ganglia (DRG). The repertoire of axonal voltage-gated channels will be an important determinant of how their modulation will affect excitability and spike throughput. In particular, for spike propagation to be voltage-dependent, the density of high-threshold $Na_V1.8$ channels proximal to the T-junction is likely to be expressed at a lower density (compared with the soma) than TTX-sensitive (TTXs) channels. Here we examine the somatic conductance parameter space for several well-studied voltage-gated channels, to be used as a reference for studying how their differential expression between soma and axon affects spike propagation.
The model contains three groups of voltage-gated Na^+ conductances: TTX-sensitive channels (TTXs) channel and two TTX-resistant (TTXr) channels (1.8 and 1.9), along with two K_V channels (fast and slow). An initial model closely reproducing aspects of the somatic spike waveform and experimentally-measured Na_V currents underlying spikes used densities for TTXs and TTXr ($Na_V1.8$ and 1.9) of 1.4, 4.6, and 0.38 channels/μm^2, respectively. We then included a

high-voltage activated (HVA) voltage-gated Ca^{2+} channel and then systematically varied the 3 Na_V, 2 K_V, and Ca_V conductances 0.1-10X, and across three soma diameters (20, 26, and 32 μm) for a total of 46,872 configurations. Selecting for models based on action potential waveform and TTXs/TTXr current influx during the rising phase of 1/3 reduced the number of acceptable models to 2518. Distributions of TTXs and TTXr rising phase Na_V currents were multimodal and mean currents for higher-order modes were more than 3-fold larger than typically measured for somatic Na channels. Therefore, further selecting for the smaller mode of the TTXr current distribution resulted in 469 models. Finally, for models with 26 μm somatic diameters TTXs, $Na_V1.8$, and 1.9 densities were 0.8 ± 0.5, 4.4 ± 0.6, and 0.6 ± 1.0 channels/μm^2, respectively. The density of HVA Ca_V channels was 0.3 ± 0.2 channels/μm^2, while the total K_V density was 13.6 ± 12.5 channels/μm^2. From these somatic channel densities, we intend to explore how their differential axonal expression affects spike propagation through the DRG.

Title: Apoa-i binding protein (aibp) regulates transient receptor potential vanilloid 1 (trpv1) activity in rat dorsal root ganglion neurons by disrupting the toll-like receptor 4 (tlr4) signaling pathway in cell membrane lipid rafts

Authors: Y. LI[1], ***M. L. UHELSKI**[3], K. E. MCDONOUGH[1], T. L. YAKSH[4], Y. MILLER[5], P. M. DOUGHERTY[2];
[2]Univ. of Texas MD Anderson Cancer Ctr., [1]Univ. of Texas MD Anderson Cancer Ctr., Houston, TX; [3]MD Anderson, Houston, TX; [4]UCSD Anesthesia Lab. 0818, UCSD Anesthesia Lab. 0818, La Jolla, CA; [5]UC San Diego, UC San Diego, La Jolla, CA

Abstract: Paclitaxel is a frontline chemotherapeutic agent used to treat common solid tumors. This aggressive drug causes many side effects, including chemotherapy-induced peripheral neuropathy (CIPN). CIPN is chronic and causes severe neuropathic symptoms which can lead to dose reductions or premature termination of treatment. Neuropathic pain is known to involve pro-inflammatory immune responses, with CIPN exhibiting this same pathophysiological pathway. Toll-like receptors (TLRs) play an important role in the transition between inflammatory and chronic pain. Paclitaxel engages the TLR4 pathway, demonstrating an identical effect to pro-inflammatory agonist LPS. Transient receptor potential vanilloid subtype 1

(TRPV1), like TLR4, is upregulated in the dorsal root ganglia (DRG) of rats treated with paclitaxel, and TLR4 sensitizes TRPV1 in the presence of paclitaxel. Although we believe CIPN is related to the sensitization of peripheral sensory neurons, the cellular signaling pathways and other mediators need further study. Among the potential mediators is the increased presence of lipid rafts that form enhanced TLR4 signaling complexes. Lipid raft function can be explored using Apolipoprotein A-I binding protein (AIBP). AIBP is a protein that reduces lipid rafts, augments cholesterol efflux, and works in part by binding TLR4. Membrane cholesterol has previously been shown to directly influence cell surface expression of TRPV1 in rat DRG neurons, and depletion of cholesterol significantly reduced TRPV1 currents. In this study, TLR4 lipid raft modulation and its influence on nociceptor hyperexcitability and TRPV1 activity was examined in DRG neurons from wild-type and TLR4 knockout rats to determine unexplored mechanisms of CIPN and potential therapeutic pathways. We found that responses to capsaicin were reduced in DRG neurons from TLR4 knockout rats. Further, cholesterol depletion by TLR4-binding AIBP attenuated capsaicin responses in wild-type, but not TLR4 knockout rats. This effect was specific to TLR4, as non-specific cholesterol depletion by methyl-β-cyclodextrin attenuated capsaicin responses in both wild-type and TLR4 knockout rats. In DRG neurons from paclitaxel-treated wild-type rats, treatment with AIBP reduced the rate of spontaneous discharges and decreased responses to capsaicin. These results indicate that TLR4 signaling plays a role in the function of nociceptive properties in DRG neurons and that both TRPV1 and TLR4 signaling are modified in response to paclitaxel treatment. Future studies will explore the exact mechanisms leading to inhibition of action potential firing and capsaicin responses by AIBP.

Title: Intranasal β-endorphin delivery for targeted antinociception in healthy male rats

Authors: *K. A. JONES[1,2], B. SHARMA[1,3], F. S. CURTNER[1,4], R. J. MOORE[1,4], H. C. MCCUBBINS[1,3], C. N. HATCHER-SOLIS[1];

[1]Cogn. Neurosci., Air Force Res. Lab. (AFRL), Dayton, OH; [2]Integrative Hlth. & Performances Div., UES, Inc., Dayton, OH; [3]Oak Ridge Inst. for Sci. and Educ., Oak Ridge, TN; [4]Infocitex, Dayton, OH

Abstract: The passage of molecules from the blood to the brain is restricted by the blood brain barrier (BBB) which regulates brain homeostasis and provides protection from toxic substances and pathogens. While the BBB is critical for neuronal function, it is also a major challenge for the delivery of bioactive molecules to the central nervous system for therapeutic applications. Intranasal administration can address this delivery obstacle as it provides a non-invasive route that bypasses the BBB for direct delivery of molecules to the brain. Here, we investigate the peptide β-endorphin (β-end) for antinociceptive effects and brain distribution after intranasal administration. The tail flick test assessed analgesia after intranasal delivery (n = 11-12) Rats which received intranasal β-end had reduced pain sensitivity as compared to control intranasal saline administration ($p<0.05$) while no significance difference was observed with an insulin control peptide ($p>0.05$). Rats were humanely euthanized immediately after behavior and tissue was collected for peptide detection by enzyme-linked immunosorbent assay (ELISA, n = 11-12). Efficiency of delivery was first confirmed with the control peptide insulin as intranasal insulin administration has been extensively characterized. Insulin significantly increased in all brain regions analyzed after intranasal insulin delivery as compared to intranasal saline administration ($p<0.01$). Intranasal β-end administration also significantly increased β-end concentrations in the brain ($p<0.05$), though there was no significant difference in β-end levels in the hypothalamus or cerebellum ($p>0.05$). While the peptide distribution patterns in the brain varied, the detection of increased β-end in the brain after intranasal administration supports the antinociceptive effects observed in the tail flick test. Future studies are aimed at improving the analgesic effect of intranasal β-end delivery by enhancing peptide bioavailability or targeting delivery to specific brain regions with various synthetic biology and nanotechnology approaches. All animal activities were approved under an IACUC protocol. This study was supported by AFOSR grant 20RHCOR04.

Title: Inhibition of adenylyl cyclase and exchange protein activated by cAMP enhances potassium flux in primary and immortal neuronal cell cultures

Authors: *B. NELSON[1], C. HILL[1], A. H. KLEIN[2];
[2]Univ. of Minnesota Duluth, [1]Univ. of Minnesota, Duluth, MN

Abstract: Understanding the mechanisms of opioid tolerance and withdrawal is critical to creating novel pain treatments. Acute administration of opioids activates *mu*-opioid receptors and decreases both cellular cAMP levels and nociceptor excitability. Yet during chronic opioid exposure, adenylyl cyclase (AC) activity is increased along with downstream targets including protein kinase A and exchange protein activated by cAMP (EPAC). The potential effectors of both AC and EPAC activity that may mediate neuronal activity are ion channels, including the ATP-sensitive potassium channels (K_{ATP}). The possible relationships between K_{ATP} channel function, AC and EPAC activity, and opioid signaling is still unknown. To address this gap in understanding, potassium flux (K flux) was measured in primary cultures of dorsal root ganglia (DRG) and SH-SY5Y neuroblastoma cells after inhibition of AC or EPAC. K flux responses to diazoxide, a K_{ATP} channel agonist, varied in mouse DRG and SH-SY5Y cells, therefore the cells with the highest response rate (100 and 200% from baseline, respectively) were compared amongst treatment groups. DRG were cultured from male and female C57Bl6 mice and DRG exposed to ST034307 (ST0, 2 uM), an AC1 inhibitor. DRG were labeled with Nissl Stain, isolectin B4 (IB4), and cholera B toxin (ChBTx) to categorize these cells. The number of DRG from female mice with a high K flux response after exposure to ST0 was 53% as compared to only 24% of neurons without exposure to ST0. Similarly, in male mice the number of DRG with high K flux increased from 41% for control conditions to 57% when exposed to ST0. Female and male mice have a similar distribution of IB4 and ChBTx labeling. All cell populations indicate an increase in the proportion of cells with high potassium flux after ST0 treatment, with the largest change occurring in unlabeled, or peptidergic C-type neurons with 41% and 19% more cells in the high range of K flux in females and males respectively. Similarly, the incidence of SH-SY5Y cells that with high responsiveness to diazoxide (K flux over 200% change compared to baseline) after morphine treatment and ST0 or HJC 0350 (1uM, 0.5uM), an EPAC2 specific inhibitor, was 31% and 40%, respectively compared to morphine treated cells (18%, 10uM for 72 hrs) and 27% in naive cells. SH-SY5Y cells treated with ST0 (1uM, 1 hour) demonstrated decreased K flux in morphine naive populations and increased K flux in morphine tolerant populations. This research illustrates that AC activity inhibits K flux in neuronal cells. Specifically, AC1 inhibition of K_{ATP} activity may sensitize nociceptive responses during chronic opioid conditions.

Title: Modulation of structural plasticity in mouse sensory neurons by innate immune factors is influences by electrophysiological activity and sex

Authors: T. N. FRIEDMAN[1], S. M. LAMOTHE[2], T. HAMMOND[2], H. T. KURATA[2], ***B. J. KERR**[3];
[1]Neurosci. and Mental Hlth. Inst., [2]Pharmacol., [3]Anesthesiol. and Pain Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Sensory neurons display a remarkable degree of structural plasticity. While most critical during development, this process may also be recapitulated after injury or in the context of diseases that affect the nervous system. Neuronal plasticity is intricately linked to the activity of neuronal membranes. Voltage-gated potassium channels (Kvs) play a critical role in membrane hyperpolarization and repolarization after an action potential. The flow of potassium ions through Kv channels can directly impact the availability of intracellular calcium ions for crucial second messenger systems linked to neural plasticity. Thus, modulation of Kv channels can have profound effects on the plastic properties of neurons. There is strong evidence suggesting a link between sex and clinical neuropathic pain syndromes. Furthermore, studies using painful autoimmune models of inflammation have shown that female mice exhibit heightened immune responses, along with distinct changes in neural structures indicative of neural plasticity. Here, we aimed to investigate sex-specific changes in inflammation-evoked neural plasticity and how neural activity relates to this process.Whole DRG cultures were generated from male and female C57/BL6 mice. Neurons were cultured in the presences of conditioned media from bone marrow derived macrophages (BMDMs) that had been stimulated with either TNFα or IL-4. Neurons were stained with anti-beta III tubulin antibody to assess the extent of neurite outgrowth. In parallel, whole-cell patch clamp recordings were obtained from the neurons at acute (6-hour) and chronic (48-hour) time-points. To investigate the effects of modulating neuronal activity on neurite outgrowth, neurons were incubated with the Kv7 agonist retigabine (RTG) with the different macrophage conditioned media.Macrophage conditioned media (both TNF and IL-4 stimulated) resulted in increased neurite extension in female neurons, while male neurons only exhibited increased neurite outgrowth in response to conditioned media from IL-4 stimulated macrophages. Electrophysiology revealed an inverse correlation between heightened electrical activity and increased neurite extension. Interestingly, there was a dramatic reduction in spontaneous activity associated with the extent of neurite extension rather than the duration of culture. The application of RTG lead to an overall reduction in neurite outgrowth.Our findings suggest that neuronal plasticity is influenced by inflammatory mediators in a sex-specific manner and highlights the potential of using the Kv7 agonist retigabine to prevent aberrant neuronal plasticity under conditions of inflammation.

Title: Regulation of neuronal HMGB1 release via an alpha7 nicotinic acetylcholine receptor-dependent mechanism

Authors: *H. YANG[1], S. PETRUZZELLI[2], A. TYNAN[3], M. BRINES[2], U. ANDERSSON[4], K. J. TRACEY[5], S. S. CHAVAN[5];
[1]Feinstein Inst. for Med. Res., MANHASSET, NY; [2]Feinstein Inst. for Med. Res., Manhasset, NY; [3]The Feinstein Inst. for Med. Res., Manhasset, NY; [4]Karolinska Inst., Stockholm, Sweden; [5]Feinstein Inst. For Med. Res., Manhasset, NY

Abstract: HMGB1 is a critical mediator of sterile injury- and infection-elicited inflammation and immunity. Our recent studies demonstrated that nociceptor HMGB1 is an essential component of the neuroinflammatory response to injury (Yang et al. PNAS 2021). Despite extensive evidence about the role of HMGB1 in inflammatory diseases, almost nothing is known on the regulation of HMGB1 release by neurons. Acetylcholine-mediated signaling via alpha7 nicotinic acetylcholine receptors (alpha7nAChR) inhibits HMGB1 release from immune cells and ameliorate multiple inflammatory conditions. Here, we reasoned that this cholinergic signaling via alpha7nAChR may play a role in regulating HMGB1 release by sensory neurons. To test, we developed an *in vitro* assay where dorsal root ganglion (DRG) sensory neurons expressing channelrhodopsin-2 (ChR2) release HMGB1 upon exposure to blue light (473 nm). Acetylcholine significantly reduces HMGB1 release by DRG nociceptors (HMGB1 levels in unstimulated = 3.4 $\pm$ 0.56 ng/ml; light-stimulated = 30.8 $\pm$ 2.2 ng/ml; light + 10 µM acetylcholine = 9.8 $\pm$ 3.5* ng/ml; *: $p<0.01$ *vs.* light-stimulated; n=5-6/group). Other cholinergic agonists, such as GTS-21 and carbachol, also suppress HMGB1 release by activated nociceptors. Acetylcholine also suppresses release of HMGB1 by pharmacologically activated sensory neurons. Stimulation of nociceptors with a TRPV1 agonist capsaicin resulted in the release of HMGB1 that is inhibited by acetylcholine (HMGB1 levels in capsaicin 5µM group = 20.3 $\pm$ 3.2; capsaicin 5µM + acetylcholine 10 µM = 8.3 $\pm$ 0.7* ng/ml; n=6; *: $p<0.01$). Since DRGs lack cholinergic innervation but express functional alpha7nAChR (Shelukhina et al, Brain Struct Funct, 2015), we reasoned that this receptor system could mediate the signals that inhibit neuronal HMGB1 release. Acetylcholine and GTS-21 fails to inhibit capsaicin-induced HMGB1 from DRGs from alpha7nAChR deficient mice (HMGB1 levels in capsaicin 5 µM group = 21.8 $\pm$ 4.5 ng/ml; capsaicin 5 µM + acetylcholine 10 µM = 23.5 $\pm$ 4.5 ng/ml; n=4; p=not significant). These results suggest that acetylcholine regulates HMGB1 release from nociceptors via alpha7nAChR-dependent cholinergic anti-inflammatory mechanism. Title: Characterization of vagal nerve pathways in visceral pain perception

Authors: *J. R. ROBBINS, Y.-T. CHENG, P. L. KATAYAMA, C. J. WOOLF;
Neurobio., Boston Children's Hosp., Boston, MA

Abstract: Visceral pain (VP) is a prevalent symptom of multiple diseases and among the leading causes for seeking medical help. This referred pain is difficult to localize and even more difficult to treat. VP occurs when nociceptors of internal organs become activated, leading to a sensation of gastrointestinal (GI) discomfort. Current analgesics, particularly opioids, can worsen VP symptoms, especially GI-related symptoms, due to side-effects like constipation. Thus, characterization of the underlying circuitry for VP could inform better treatment strategies, and the vagal nerve (VN) pathway, which delivers parallel ascending signals with spinal projection pathways from the GI tract to the brain, serves as a potential target.
To characterize how ascending pathways encode GI pain, we used a chemogenetic approach to label and contextually activate visceral nociceptive neurons for behavioral paradigms. The parabrachial nucleus (PBN) is a known sensory relay for interoceptive inputs. Thus, we injected Cre-dependent AAV vectors to express activating-DREADDs in the PBN of FosCreERT2 mice. We then subjected the mice to 3% Dextran Sodium Sulfate (DSS) drinking solution to induce colonic inflammation. We injected 4-OHT to induce Cre to express the DREADD actuators. After this, we surgically ablated the VN pathway by a subdiaphragmatic dissection in a group of these mice (VGX). A second group of these mice underwent a SHAM procedure (SHAM), which is the same surgical procedure except the vagus nerve is left intact. As a further control, a third group underwent VN ablation before the DSS trapping. After a CNO injection to recall the visceral-pain associated neurons (VPANs), we performed a von Frey behavioral assay, which assessed the sensory dimension of VP through mechanical sensitivity testing, and a conditioned place aversion (CPA) assay, which assessed the affective and motivational dimension of pain by measuring the changes of their preference for darkness after pairing with VPAN reactivation over a two-day conditioning paradigm.
Our results show a non-significant difference between VGX and SHAM cohorts for the von Frey assay; however, we found a significant difference between the two cohorts for CPA. These findings demonstrate that the VN pathway is likely not directly involved in the sensory processing of GI VP, but rather mediates the affective dimension of VP perception. These findings can inform exploration of circuit-based treatments to modulate those VPANs that specifically govern the affective dimension of VP and direct attention to the spinal cord projection pathway as a potential arbiter of sensory VP perception.

Title: Alpha power is inversely correlated with intensity of pain ratings in healthy subjects

Authors: *S. M. MARGERISON[1], M. L. KEASER[5], B. W. STEWART[6], A. J. FURMAN[2], D. SPEIS[3], A. MAZAHERI[7], J. TEIXEIRA DA SILVA[4], D. A. SEMINOWICZ[8];

Biophysics, Univ. of Western Ontario, London, ON, Canada

Abstract: Alpha oscillations (8-12 hz) are the primary electrical activity recorded from the human brain. Prior studies have shown that contralateral sensory alpha power reduces during exposure to a noxious stimulus relative to baseline. Also, reductions in alpha power during anticipation of a painful stimulus are correlated with subjective pain intensity. However, the relationship between alpha power reductions during a painful stimulus and the subjective intensity of pain related to that stimulus is unknown. EEG data was collected during painful thermal stimulation applied to the left lower extremity in an MR environment. We then analyzed the data to determine the relationship between alpha power and pain intensity, hypothesizing that alpha power would correlate negatively with rated pain. Nine participants each experienced 50 total thermal stimuli over five runs. Participants were instructed to rate their perceived pain on a scale of 0-100 in 10-point increments. EEG data was filtered and re-referenced to the common average then decomposed with independent component analysis. The component displaying a peak in the alpha range and a topography most suggesting a source in the right primary sensory cortex (determined by comparison to a template) was determined for each participant and each run. A timeseries of alpha power values was calculated for each selected component. Average alpha power for each baseline period between thermal stimuli, and for each thermal stimulation was averaged to a single value and inserted into the timeseries. This was compared to pain ratings for individual trials. A negative correlation between alpha power and pain ratings was displayed during at least four of the five runs for seven of the nine participants assessed. Across all participants and runs, the average correlation was r= -0.162. Overall, our hypothesis was supported by this preliminary analysis despite the average correlation strength being low. Further analysis will determine brain regions displaying connectivity associated with both alpha power and pain ratings using fMRI data collected simultaneously with the EEG discussed above.

Title: Discrepant effects of predictive cues on pain-related brain responses and behavior

Authors: *H. JUNG[1], A. YAZDANPANAH[1], M. LINDQUIST[2], A. SOLTANI[1], T. WAGER[1]; [1]Dartmouth Col., Hanover, NH; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Expectations about possible outcomes modulate our everyday experience. Most studies have examined the effects of such expectations in separate domains; thus, it is currently unclear whether expectations in cognitive and affective domains are mediated through separate or shared neural substrates (domain-specific or domain-general). To address this question, we used a factorial design of 2 cue (high/low) x 3 stimulus intensity (high/med/low) across 3 tasks (somatic pain, vicarious pain, and cognitive effort) to investigate cue-expectancy effects across multiple domains. For each trial, participants were presented with a high or low cue ("cue"), subsequently reported their expectations for the upcoming stimulus intensity ("expectation rating") before they were administered blocks of thermal heat stimuli, vicarious videos of patients in pain, cognitive mental rotation images ("stimulus"), and finally reported their subjective ratings of intensity ("outcome rating").
Our behavioral results demonstrated a significant cue-expectancy effect, where higher cues were associated with higher outcome ratings. Surprisingly, we observed an opposite pattern for the neural results in the pain task. Using a multistudy-validated biomarker of pain (Neurological pain signature; NPS), we found that NPS-extracted brain activations were greater for low vs. high cues in the high stimulus intensity condition. Such patterns were indicative of a prediction error-like signal that motivated us to examine behavior using computational modeling. Thus, we fitted a reinforcement learning model of pain expectancy effects to the expectation and outcome ratings and found that despite a good fit of data, there was no significant relationship between the NPS-extracted brain activations and prediction errors. This suggests that the opposite cue-expectancy patterns in the pain-associated brain activation were not a by-product of prediction errors used for adjusting expectations over time.
Based on these results, we conclude that the current models may not be able to capture the interplay between behavioral ratings and stimulus-evoked nociceptive processes. Our next step is

to integrate a neural component into the reinforcement learning model to account for the divergent effects of brain and behavior. This could ultimately allow us to construct a holistic model for expectancy effects across somatic pain, vicarious pain, and cognitive effort and shed light on domain-generality/specificity of expectations.

Title: Individual alpha frequency in individuals with chronic low back pain

Authors: *R. L. M. HO[1], J. PARK[1], W.-E. WANG[1], J. S. THOMAS[2], Y. CRUZ-ALMEIDA[1], S. COOMBES[1];
[1]Univ. of Florida, Gainesville, FL; [2]Virginia Commonwealth Univ., Virginia Commonwealth Univ., Richmond, VA

Abstract: Individual alpha frequency (IAF) derived from resting state electroencephalography (EEG) has potential to become a clinically useful neural biomarker for pain. Data from several studies suggest IAF is lower in individuals with chronic pain when compared to healthy controls, yet a few studies, including one focused on individuals with chronic low back pain (cLBP) have failed to find the same results. While the study on individuals with cLBP found no differences in IAF between groups, psychological variables were correlated with IAF pointing towards psychological factors being a key variable in understanding the relationship between cLBP and IAF. Therefore, the purpose of our study was to investigate how subgrouping based on scores from psychological questionnaires affects measurement of IAF in a group of individuals with cLBP. We collected resting EEG and assessed IAF in a cohort of 70 individuals with cLBP, implemented three different IAF calculations, and separated cLBP subjects based on a psychological variables. We contribute two novel findings to the literature. First, separating our cLBP group based on a median split on Tampa Scale of Kinesiophobia and pain duration leads to a significant difference in all three IAF calculations. However, variables of pain intensity, pain interference, and pain related disability do not lead to differences in IAF. This finding suggests fear of movement and pain duration are keys to understanding differences in neural activity in individuals with cLBP. Second, PCA analysis found a component comprised of pain intensity, disability, and fear of movement and this component was predictive of IAF.

Title: Altered Resting State Functional Connectivity following Oral Morphine: A Functional Near-infrared Spectroscopy Study

Authors: *K. KARUNAKARAN[1], K. PENG[2], M. YUCEL[3], E. A. BITTNER[5], R. EDWARDS[7], L. BECERRA[8], D. A. BOAS[4], D. BORSOOK[6];
[1]Psychiatry, Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [2]l'Université de Montréa, Montreal, QC, Canada; [4]Biomed. Hosp., Boston, MA; [7]Departments of Anesthesiology, Perioperative, and Pain Medicine, and Psychiatry, Brigham and Women's Hosp., Boston, MA; [8]Invicro, Boston, MA

Abstract: The use of brain measures to evaluate therapeutic effects has recently included functional Near Infrared Spectroscopy (fNIRS). Few studies using this domain have included drugs such as analgesics. As such the evolution of the use of fNIRS, because of its portability, cost and potential use in the clinic, has some significant advantages over other modalities such as EEG and fMRI. Here we evaluate the effects of an oral analgesic, immediate release morphine (10mg) tablets, on the resting state functional connectivity (RSFC) of the cortex using fNIRS. The cohort was previously evaluated for the effects of oral morphine on evoked cortical response to noxious stimuli. Each subject acted as their own control in a double blind-placebo controlled study. Peak plasma concentrations after oral immediate release morphine (Tmax) occurs at approximately 1 hour. Based on the onset and offset of morphine (Tmax=60 minutes), the study for drug and placebo each took place on separate sessions for a duration of 90 minutes. Using a repeated measures ANOVA at FDR-$p<0.05$, our results indicate (1) a decrease in the RSFC between right medial frontopolar cortex and right primary somatosensory cortex at both 30-mins and 60-mins after ingestion, recovering to the levels of placebo group at 90-mins; and (2) increase in RSFC within the prefrontal cortex, specifically between lateral and medial frontopolar cortex immediately after morphine ingestion at 30-mins that gradually reduced at 60- and 90-mins post morphine. This study is amongst the first to report that the system can detect alterations in brain functional connectivity in response to a well-known analgesic, morphine. Such evaluations allow for measure of drug effects on brain systems that may in future be used in clinical studies to provide an objective marker.

Title: Assessing sex differences in the neural activity of chronic pain patients practicing emotion regulation techniques while receiving painful thermal stimulation

Authors: *T. DILDINE[1], G. GILAM[2], C. S. LAW[1], J. J. GROSS[3], S. MACKEY[1], K. A. WEBER[1];
[1]Stanford Univ. Sch. of Med., Palo Alto, CA; [2]The Inst. of Biomed. and Oral Research, Fac. of Dent. Med., Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Dept Psychology, Stanford Univ., Stanford, CA

Abstract: Globally, chronic pain is the number one reason individuals seek medical care. However, females are more likely to have chronic pain, more severe pain, and receive less treatment. Many reasons underly sex differences in pain (e.g., hormonal differences), and recent work has identified sex differences in neural activity and network organization of those with chronic pain. Whether these alterations in brain activity impact the effectiveness or how cognitive and top-down processes alter pain perception is still understudied. Here, we tested two emotion regulation (ER) techniques, reappraisal (termed reframing) and acceptance (termed observation) in their effectiveness in decreasing pain during an acute pain paradigm by sex. 172 chronic low back pain participants (94 males) had their brain activity measured during four conditions: no pain, pain with no regulation, pain with observation, and pain with reframing. Each pain stimulus was individually tailored and after each trial, participants rated pain intensity and unpleasantness. We noted no behavioral differences by sex, via two-sample t-tests, in calibrated temperature ($p = .82$), pain intensity ($p > .90$), or unpleasantness ($p > 0.70$). We noted a marginal difference by sex for age ($p = .08$), thus we included age as a covariate in our imaging analysis. For our neuroimaging data, first level images were processed using FEAT 6.0 and submitted for second-level analyses. Our contrasts of interest included No Regulation vs. No Pain, Observe vs. No Pain, and Reframe vs. No Pain separately and for Males vs Females. We looked at active brain regions with a threshold set at $z >= 2.3$ with a corrected cluster significance level of $p < .05$. We noted females had greater neural activity compared to males in the superior temporal gyrus ($z = 4.26$, $p < .001$) and cuneus ($z = 3.36$, $p = 002$) during no regulation vs. no pain, greater anterior cingulate cortex (ACC; $z = 4.71$, $p < .001$) activity during

observation vs. no pain, and greater medial orbitofrontal cortex (mOFC; z = 3.85, p <. 001) activity during reframing vs. no pain. Males had greater neural activity in the precuneus compared to females during both no regulation (z = 4.51, p < .001) and observation (z = 4.36, p = .01) vs. no pain. Our results suggest female chronic pain patients engage greater recruitment of the ACC and mOFC, both implicated in descending pain modulation, during ER. Our behavioral results suggest a significant decrease in pain during both ER conditions (p < .001) for both sexes. Interestingly, our behavioral results do not suggest sex differences in the effectiveness of ER, but neuroimaging reveals potential sex differences in the neural mechanisms underlying pain reduction with ER.

Abstract: The claustrum was recently hypothesized to support the initiation of cognitive control network activity, and multiple studies suggest pain is a cognitive load. We therefore used multiple human fMRI datasets, including data from healthy controls and chronic pain patients, to measure claustrum and cognitive task associated network activity in response to cognitive task, experimental pain, and pain anticipation conditions. Significant signal increases were detected in bilateral claustrum to experimental pain in healthy controls, and the introduction of a pain-predictive cue resulted in a shift of claustrum responses from pain to the preceding cue. Control protocols allowed extraction of claustrum BOLD signal distinct from neighboring structures, with claustrum activation confirmed as significantly different than insular cortex and anterior insula activation in multiple conditions. Significant bilateral claustrum responses to pain were also detected in chronic pain patients, with the right claustrum exhibiting greater activation at pain onset in patients than controls. Significantly different multivariate patterns of cognitive task

associated activity were also detected between groups, with patients exhibiting multiple clusters of greater task associated activity than controls. A region associated with cognitive task processing exclusively in patients was identified as a pain-responsive region in healthy controls, and signal changes in this region and right claustrum were correlated across experimental conditions, suggesting a link between claustrum and cognitive task network alterations in chronic pain.

Title: Functional MRI Assessment of Plasticity within Spinal Cord Circuits in Rats with Neuropathic Pain after Spinal Cord Injury

Authors: *X. ZHANG[1,2], C. MU[1,2], A. MISHRA[1,3], F. WANG[1,3], P.-F. YANG[1,3], J. C. GORE[1,2,3], L. CHEN[1,2,3];
[1]Vanderbilt Univ. Inst. of Imaging Sci., Nashville, TN; [2]Biomed. Engin., Vanderbilt Univ., Nashville, TN; [3]Radiology and Radiological Sci., Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Neuropathic pain is highly prevalent in patients with spinal cord injury (SCI) and is often resistant to treatments. We previously demonstrated that high-resolution fMRI showed localized responses to tactile and heat stimuli in the deeper and superficial laminae of the spinal cord dorsal horn. This study aims to use fMRI to (1) demonstrate nociceptive heat stimulation-evoked activations in spinal grey matter horns/zones, (2) measure resting state functional connectivity (rsFC) within the network of nociceptive-processing horns, and (3) quantify behavioral responses to somatic and thermal pain stimuli in a rat T13 contusion spinal cord injury model. Eight rats were studied longitudinally and were scanned before and after an injury at weeks 1, 4, and 8 under anesthesia. Images were acquired during both a resting state and after the application of 47.5 °C noxious heat stimulation to the left hind paw. FMRI activation patterns within and across segments were mapped and we measured the strength of rsFC between spinal horns. Weekly behavioral tests, including Von Frey tactile filament, hot plate, and Hargreaves tests, were also conducted. All rats exhibited neuropathic pain behavior. Our results revealed widespread heat stimulus-evoked fMRI activation foci in the left dorsal horn across multiple segments above and below the injury level within one week post-injury. Starting from week 4 post-injury, activation location shifted. Following the injury, the rsFC between spinal horns

decreased immediately and began to recover after week 4 post-injury. Parallel behavioral testing revealed that the mechanical detection threshold for the Von Frey test was significantly increased after the injury and gradually returned to baseline starting from week 3 post-injury. The paw withdrawal latency for the Hargreaves test shortened, indicating thermal hyperalgesia post-injury. Our results showed a dynamic shift in activation region to heat stimulus post-injury over time, with horn-to-horn connectivity recovering by week 4 post-injury while the mechanical detection thresholds recovered by week 3. In summary, this study found correlated temporal relationships between plastic changes in segmental-wise gray matter heat responses and inter-horn connectivity and the development of below-level neuropathic pain behavior. These results provide novel insights into spinal circuit contributions to neuropathic pain development, suggesting the dorsal horns play a leading role.

Title: Effects of Environmental Enrichment on Visceral Sensitivity and Brain Connectivity in a Mouse Model of Chronic Overlapping Pain Conditions

Authors: *M. L. KEASER[1], S. HANSON[1], A. J. SCOTT[2], R. J. TRAUB[1,3], J. T. DA SILVA[1,3]; [1]Neural and Pain Sci., [2]Dept. of Microbial Pathogenesis, Univ. of Maryland, Baltimore Sch. of Dent., Baltimore, MD; [3]Ctr. to Advanced Chronic Pain Res., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Temporomandibular disorder (TMD) and irritable bowel syndrome (IBS) are two chronic overlapping pain conditions (COPCs) that present with significant comorbidity. Both conditions are more prevalent in women and are exacerbated by stress. While peripheral mechanisms might contribute to pain hypersensitivity for each individual condition, mechanisms underlying the comorbidity are poorly understood, complicating pain management. It has been suggested that pain amplification in COPCs is the result of dysfunctional CNS pain processing caused by altered connectivity among several brain regions, including the insula. Nonpharmacological therapies such as Environmental Enrichment (EE) have been shown to reduce pain- and anxiety-like behaviors, enhance learning and memory, and induce neural plasticity. We have developed a mouse model of comorbid pain hypersensitivity (CPH: stress during preexisting orofacial pain, Complete Freund's Adjuvant (CFA) induced masseter muscle inflammation) and examined the effects of EE on behavioral and brain connectivity changes

induced by this model. Eighteen female mice underwent resting-state fMRI scans. The 18 mice were divided into 3 groups: 6 CPH + EE, 6 CPH only, and 6 naive mice. Referred pain (visceral pain correlate) was measured as the increase in responsiveness to von Frey stimulation of the lower abdomen above baseline mechanosensitivity following inflammation and stress. A seed-based correlation analysis approach was used to determine changes in insula connectivity to the whole brain in relation to CPH and how EE affects, if at all, this relationship. CPH increased referred pain in female mice for at least 4 weeks. EE blocked the referred pain development. Contrast map results ($p < 0.05$) show mice placed in an enriched environment exhibited significantly lower insula connectivity to the following regions compared to CPH mice without EE: Claustrum, Caudoputamen, Central medial nucleus of the thalamus, Central amygdalar nucleus, medial part (Allen Brain Atlas nomenclature). In addition, CPH mice with EE show a trend of increased connectivity between insula and periaqueductal gray, which is similarly seen in naive mice compared to CPH group. These results demonstrate that EE can reduce referred pain and functional connectivity of areas involved in pain and stress processing, and may be strengthening the impaired endogenous pain inhibitory system seen in comorbid pain conditions. Further experiments are currently being done to fully investigate the effects of EE on comorbid pain conditions and potential sex differences.

Title: Intrinsic anterior insula activity distinguishes individuals with rotator cuff tendinopathy from healthy, matched controls

Authors: *M. HEINDEL[1], J. J. KUTCH[2], L. A. MICHENER[2];
[1]Biokinesiology and Physical Therapy, [2]USC, Los Angeles, CA

Abstract: Title: Intrinsic Anterior Insula Activity Distinguishes Individuals with Rotator Cuff Tendinopathy from Healthy Controls
Authors: Heindel MD, Kutch JJ, Michener LA; Biokinesiology, University of Southern California
Disclosures: None
Motivation/problem statement: Shoulder pain affects up to 25% of the general population, and rotator cuff tendinopathy (RCtend) is the most common diagnosis. Unfortunately, 40-50% of those with RCtend develop recurrent or chronic pain. Nociceptive input from the tendon to the central nervous system has been considered the primary mechanism of pain. However, recent evidence suggests central nervous system dysfunction underlies the development and progression

of RCtend, specifically increased centrally-defined pain sensitivity. However, identified central mechanisms of RC tendinopathy are sparse, and there have been no direct measures of intrinsic brain activity. Therefore, we hypothesized intrinsic brain activity would differentiate those with RCtend from healthy controls (HC).
Methods/Approach: Cohort of 19 individuals with right-sided RCtend and 19 HC, matched for age, sex, and body mass index, underwent resting-state fMRI. Preprocessing was completed with *fMRIPrep v 20.0.7.* Images were smoothed, bandpass filtered for fractionated amplitude of low frequency fluctuation content (fALFF) in the slow-5 band (0.01 to 0.027), and 6 acompcor confounds of no interest were removed using *Analysis of Functional Neuroimages 3dTProject.* A whole-brain group-level analysis was performed with a cluster-wise threshold of $z > 2.3$ and cluster significance threshold of $p < 0.05$ with *Functional MRI of the Brain Software Library* (FSL) v.6. An independent t-test was used to compare groups (RCtend, HC) with pain in the scanner as a demeaned covariate.
Results: The group with RCtend had greater activity than HC in the right anterior insula (406 voxels, $p < 0.001$).
Conclusion: There was greater resting-state activity in those with RCtend than HC. Therefore, intrinsic anterior insula activity may be useful to distinguish those with RCtend from HC. The anterior insula is involved in both pain processing and the unpleasant experience associated with pain. Therefore, the centrally-defined pain sensitivity may relate to dysfunction of the anterior insula. Longitudinal research and validation on larger datasets is needed to characterize the relationship of anterior insula activity and centrally-defined pain sensitivity.

Title: A resting state connectivity functional alignment model for pain prediction

Authors: *B. PETRE[1], M. CEKO[3], N. P. FRIEDMAN[4], M. C. KELLER[4], M. A. LINDQUIST[5], T. D. WAGER[2];
[2]Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH; [3]Univ. of Colorado, Boulder, Boulder, CO; [4]Univ. of Colorado Boulder, Boulder, CO; [5]Johns Hopkins Univ., Baltimore, MD

Abstract: Anatomical landmarks are used to establish functional correspondences for population level studies of the brain, but interindividual functional variability is not fully captured by

anatomical alignment. To resolve potential idiosyncratic functional topographies and tuning profiles we develop and compare two high quality templates of a functional connectome using resting state data from the human connectome project (HCP, N=333, 1 hour/participant). HCP participants are prealigned using multimodal surface matching (MSM) warps, but we further refine this. First we generate a diffeomorphic reference template by averaging MSM aligned connectomes across participants. Second we hyperalign individuals' voxel-level tuning curves to the common template using high dimensional orthogonal transformations. Two constraints regularize the latter. We perform alignment within coarse scale regional parcellations of the cortical surface or volumetric structures, and also incorporate a novel subspace projection to ensure regional mean invariance. These templates represent different hypotheses of interindividual functional correspondence, either a common coarse topography or a shared set of higher-dimensional finer-grained tuning profiles, respectively. We test these templates using data from a separate study of multimodal pain behavior (N=150). Using five minutes of resting state data we compute diffeomorphic alignments of connectomes to the first template and fit a shared response model to project tuning curves to the second template. We then compare between subject correlations (BSC) in pain evoked topographies, and out-of-subject discrimination of experimental conditions and pain prediction. Diffeomorphic alignment significantly increases BSCs when considering the entire brain ($t=121.8$, $p < 10e-5$, ~5% increase in variance explained), or only considering within region BSC ($t = 98.8$, $p < 10e-5$, 23.2% increase). Subsequent shared response model hyperalignment decreases overall BSC, especially in areas along the somatosensory strip (FDR $q=0.05$) and cerebellum. Paradoxically, out of participant decoding of pain intensity and modality improves after hyperalignment (Mean accuracy heat vs. pressure = 0.766 vs. 0.789, mean predicted pain vs. observed pain within participant $r2 = 0.218$ vs. 0.247). These preliminary results suggest different models of functional correspondence may be appropriate for different brain areas, and establish a first benchmark for interpretable functional template construction and implementation.

Title: Contactless cutaneous Laser reliably induced Temporal Summation of Pain - a Comparison between Body Sites and Sex

Authors: *X. ZHANG, D. WANG, W. CARTER, A. TRINH, S. MOOSA, W. J. ELIAS, C.-C. LIU;
Neurosurg., Univ. of Virginia Sch. of Med., Charlottesville, VA

Abstract: Temporal summation of pain (TSP) is an endogenous pain facilitation phenomenon characterized by elevated pain intensity to a series of identical painful stimuli. Greater TSP has been linked to central sensitization and higher risks for chronic pain development. However, current literature reported inconsistent results for sex and body site differences on TSP responses. One possible limitation in previous studies was the use of contact thermode which inevitably activate low-threshold mechanoreceptors that may reduce mask painful sensation during heat pain delivery. In the present study, we used contactless painful laser stimulation for heat pain delivery to test the hypothesis that no significant difference in TSP responses between female and male subjects across body sites in healthy subjects. A Nd:YAP laser stimulator (wavelength 1.34μm, beam diameter 8mm, pulse duration 4ms) was used for contactless heat pain delivery. During TSP induction, painful laser stimulations were delivered in triplet fashion (i.e. S1, S2, S3 with a fixed inter-stimulus interval of 1.5s) with a constant stimulus intensity (40-50/100 pain intensity adjusted at the baseline), and a random inter-triplet interval between 10-30s. Stimulus related EEG recordings (1000Hz sampling rate, 0.1-25Hz bandpass) were extracted into -0.1 to 1.4s for laser evoked potentials (LEPs) analysis. Twenty-six healthy subjects were enrolled (25.5 ± 2.3 yrs, 11 female) to the present study. Subjects were instructed to attend to the laser stimulations and report pain intensity for each stimulus using a 0-100 visual analogue scale. TSP responses were quantified as the increased pain from S1 to S3, and normalized by the S1 (i.e. TSP = (S3-S1)/S1). We found that the TSP were induced in all subjects ($p < 0.01$). No significant TSP difference was found across body sites (hand, leg, and back), indicating that TSP is a centrally mediated phenomenon. Female subjects showed greater TSP than male subjects ($p < 0.05$). Furthermore, significant correlations were found between LEP amplitudes and TSP responses ($p<0.01$, Spearman rank correlation). In conclusion, our preliminary findings demonstrated comparable TSP across body sites, and stronger TSP responses were found in female subjects.

Title: Functionally mapping the transition from acute to chronic pain using awake rs-fMRI & Next-Generation Behavioral Sequencing

Authors: *A. Z. JHUMKA, D. LICHTMAN, A. A. LAWEN, I. KAHN, I. ABDUS-SABOOR; Columbia Univ., New-York, NY

Abstract: Chronic pain is a heavily debilitating disease affecting more than 1.5 billion people worldwide. Epidemiological and functional imaging studies suggest a bidirectional relationship between chronic pain and mental health disorders, which can partially be explained by shared neural mechanisms. Current pain neuroimaging studies present tremendous potential in terms of translational diagnostic, prognostic and or treatment-response tools. However, many technical obstacles persist. Indeed, the variability across chronic pain patients and conditions makes it challenging to understand functional brain dynamic alterations supporting pain chronification. While pain duration varies according to the initial cause of tissue injury, there is no rigorously controlled study establishing both semiology- and etiology-specific dynamic brain signatures for the transition from acute to chronic pain. In other words, can we functionally map the transition from acute to chronic pain and can we target such alterations to abort or reverse pain chronification mechanisms? In line with this, most preclinical pain neuroimaging studies are performed on anesthetized laboratory animals, which is a confound considering the analgesic effect of anesthetics. Furthermore, pain, *stricto sensu*, is challenging to measure in animals because they cannot verbally communicate with experimenters. In line with this, indirect measurements of pain in animals have long relied on the quantification of spontaneous nocifensive behavioral bouts, evoked withdrawal reflexes, touch or temperature avoidance, etc. While these readouts are informative on animals' sensitivity, such assays bear a number of caveats such as experimenter-induced variations and or bias, sensitization or habituation of animals to given stimuli, etc. Such caveats render correlations between chronic pain behavior and real-time brain activity challenging. Here we present a unique and unprecedented pipeline based on next-generation behavioral sequencing and awake resting-state fMRI in head-fixed mice, to functionally map the transition from acute to chronic pain in real time by correlating functional brain and behavioral signatures according to the etiology of the pain.

Title: The impact of trigeminal neuralgia pain on the hippocampus and its major efferent pathway

Authors: *P. SRISAIKAEW[1], T. LATYPOV[3], D. JOERGENS[1], W. WANG[1], A. NOORANI[3], S. HANYCZ[5], M. WALKER[2], M. HODAIE[4,1];

Abstract: Trigeminal neuralgia (TN) is a severe chronic neuropathic pain disorder with intense shock-like pain in distributions of the trigeminal nerve branches and over 70% of patients experienced memory difficulties. Evidence suggests the hippocampus (HPC) and its major efferent pathway, fornix (Fx), are not only involved in memory but also involved in pain processing and pain modulation. Abnormalities of the HPC and the Fx have been reported in chronic pain patients. However, how these structural abnormalities change before and after surgery in TN patients remains poorly understood. We aimed to investigate the changes in the HPC and Fx and their potential resolution following TN pain relief. 3T T1w and DWI images from 54 TN participants (pre-/6 months postsurgical) and 54 age-/sex-matched healthy controls were recruited and analyzed. FreesSurfer was used to perform HPC subfields volumetric segmentation using T1w data. DWI data were pre-processed and all DTI values (fractional anisotropy, FA; and axial, mean, and radial diffusivities, AD, MD, and RD) of the Fx were obtained. All statistical analysis was performed using Python. A significant statistical level was set at $p<0.05$ and multiple comparisons correlation was done. The reduction of the HPC volume and Fx integrity was found in TN patients at both time points compared to controls ($p<0.001$), over and above the influence of age and sex. HPC subfields volumes (CA4 and dentate gyrus) were significantly increased following the pain relief, however, abnormalities found in the Fx did not normalize after surgery. Pain-related functional hemispheric asymmetry was found in the HPC normalization pattern toward the right hemisphere - this effect was more robust in patients who experienced pain relief after surgery. A significant sex difference was found only in the Fx at the postsurgical timepoint. This suggests that males and females TN may be responding to the treatment differently. Our findings revealed a significant impact of pain on both macro- (HPC volume) and micro-structural (Fx integrity) levels in the limbic circuitry. However, a discordant normalization is observed only in the macrostructure (HPC volume) and the functional asymmetry was found toward the right hippocampus. These findings advance our understanding of CNS-related dynamic abnormalities in chronic neuropathic pain, particularly in the limbic structures.

Title: Pain embodiment measures and related disruptions in the anterior cingulate cortex are associated with increased risk for aberrant opioid-related behavior in chronic pain patients

Authors: *K. SHAH, J. MA, *J. ROGOWSKA, M. LEGARRETA, E. MCGLADE, P. RENSHAW, D. YURGELUN-TODD;
Psychiatry, Univ. of Utah, Salt Lake City, UT

Abstract: Pain embodiment is a form of maladaptive body awareness whereby dysfunctional integration of painful sensations into the assessment of bodily states, such as the tendency to apprise sensations as a threat to bodily integrity, changes the way the body experiences pain. This study examines how chronic pain embodiment and associated changes within the anterior cingulate cortex (ACC) relate to the risk for aberrant opioid-related behaviors (AORB). Participants were 23 adults (13M/10F) with chronic musculoskeletal or primary pain for >3 months and free from substance abuse for >60 days (mean age: 34.9 years, sd 6.0; mean duration of pain: 11.0 years, sd: 6.6). The Multidimensional Assessment of Interoceptive Awareness evaluated pain embodiment. The Current Opioid Misuse Measure (COMM) quantified current AORB risk. Low-and high-risk stratification for the COMM was determined using the clinical cutoff of ≥9. Neuroimaging consisted of a resting-state BOLD MRI scan and ^{1}H magnetic resonance spectroscopic data acquired in the ACC. T-tests were used to measure differences in pain embodiment measures and ACC metabolite concentrations between low- and high-risk COMM groups. Multiple regression was performed with pain embodiment measures against the default mode network (DMN) using a seed in the posterior cingulate cortex (FWE-corrected, $p<0.005$, $k>20$). Pearson correlations were used to examine the relationships between embodiment measures and ACC metabolite concentrations. Participants with high-risk COMM scores report a higher tendency to distract from painful sensations, a higher tendency to worry about painful sensations, and a decreased ability to regulate pain-related distress. Worrying about painful sensations associated with increased DMN connectivity with the right ACC and left frontal superior cortex ($p=0.007$). ACC Glx (combined glutamate and glutamine) negatively correlates with the tendency not to distract from painful sensations ($r=-.55$), the tendency not to worry about painful sensations ($r=-.46$), and the ability to regulate attention to body sensations ($r=-0.49$). Participants with high-risk COMM scores exhibit higher concentrations of ACC Glx. Overall, increased pain embodiment in chronic pain patients is associated with increased ACC Glx, increased DMN connectivity to the ACC, and increased risk of AORB. The ability to self-regulate distress and attention to bodily sensations may be protective factors against developing opioid misuse behaviors. This study highlights the importance of pain embodiment as it relates to changes in the ACC and chronic pain behaviors such as risk for aberrant opioid-related drug misuse.

Title: Structural sensorimotor adaptations in young adults with low back pain.

Authors: *J. ARMOUR SMITH[1], **I. CHRISMAN**[2], R. TAIN[3], K. G. SHARP[4], L. M. GLYNN[2], L. R. VAN DILLEN[5], J. V. JACOBS[6], S. C. CRAMER[7];

Abstract: Background. Chronic low back pain (CLBP) is now the largest cause of disability worldwide. There is increasing evidence for region-specific patterns of structural brain adaptation in individuals with CLBP. Most studies have investigated middle-aged adults and typically demonstrate decreased grey matter density in regions associated with pain processing. It is not clear if structural adaptations are evident early in the lifespan in individuals with CLBP in regions associated with sensorimotor function. The purpose of the study was to compare sensorimotor gray matter density in young adults with a history of CLBP compared with back-healthy controls. Methods. Fifty-three young adults with a greater than 1-year history of CLBP (average age 21.9 ± 3.1 years) and 29 young adults with no history of LBP (average age 23.7 ± 4.0 years) participated. Clinical characteristics of the LBP group were quantified with measures of pain duration, intensity, and impact as well as pain-related fear, disability and typical physical activity. Gray matter density was quantified using voxel-based morphometry. Whole brain and sensorimotor region of interest (ROI) comparisons between groups were made after covarying for age and total intracranial volume. ROIs were determined *a priori.* The association between clinical characteristics and average gray matter density in sensorimotor ROIs were explored using Pearson's correlation coefficients. Results. Individuals with LBP reported an average duration of pain of 4.8 (± 2.2) years and average pain intensity of 5.0/10. Whole brain analyses indicated significantly greater gray matter density in the LBP group in the right primary somatosensory cortex, right superior parietal lobule, and right/left inferior parietal lobule (all comparisons $p < 0.001$ uncorrected). The LBP group had less gray matter density in the right caudate nucleus ($p < 0.001$ uncorrected). ROI analysis showed that the LBP group had greater gray matter density in the right primary somatosensory cortex and right primary motor cortex ($p < 0.05$ FWE corrected for both comparisons). No areas of decreased gray matter density in the LBP group survived FWE correction. There were no significant linear associations between clinical characteristics and average gray matter density in the selected ROIs.Conclusion.We demonstrate that in young adults, persistent musculoskeletal pain is linked with structural neuroplasticity in regions associated with sensory processing and motor control. Increased grey matter density early in the lifespan of individuals with CLBP may reflect an adaptation to ongoing nociceptive input.

Title: Nucleus Accumbens Valence Processing During Offset Analgesia

Authors: *A. D. VIGOTSKY[1], R. JABAKHANJI[1], L. HUANG[2], P. BRANCO[3], M. BALIKI[1], A. APKARIAN[1];
[2]Northwestern Univ., [3]Neurosci., [1]Northwestern Univ., Chicago, IL

Abstract: Pain is not a static function of a noxious stimulus; rather, it is a time-evolving experience whose history-dependence arises from the complex interaction of multiple circuits. This is especially apparent in offset analgesia, a pain psychophysical phenomenon characterized by disproportionately large decreases in pain following a small decrease in the intensity of a noxious stimulus. Offset analgesia's dynamic uncoupling of the stimulus from the sensation has intrigued the field of pain research since its discovery over a decade ago, but its mechanisms have remained elusive. Pharmacological studies have ruled out opioidergic (e.g., descending inhibitory circuits) and NMDAergic circuits (e.g., diffuse noxious inhibitory control circuits). In this work, we build on our previous work proposing that offset analgesia may arise from mesolimbic dopamine circuits. We combined psychophysics, modeling, and functional magnetic resonance imaging (fMRI) to study how local dopamine circuit dynamics (nucleus accumbens, NAc) relate to offset analgesia. Specifically, we investigated how latent dopamine neuron dynamics, which capture the time course of offset analgesia, map onto NAc activity. We recruited fourteen healthy individuals (10 M, 4 F) to participate in this study. We collected fMRI (3T, 2×2×2 mm^2, multiband 4, multi-echo 4, 64-channel head/neck coil) while applying an offset analgesia stimulus train to the participants' volar forearms. We fit a mesolimbic valence competition model to the participants' pain ratings. Our model uses coupled first-order differential equations and posits that rewarding and aversive dopamine neuron subpopulations compete with one another, such that decreases in the intensity of the noxious stimulus activate reward circuits, which inhibit aversion circuits, thereby promoting algesia. We then used the latent reward and aversion time series from the model in a general linear model of NAc activity. Preliminary results indicated disparate positive and negative valence-related NAc activity, which was spatially heterogeneous. These preliminary findings are consistent with the dopaminergic hypothesis of offset analgesia and the spatial arrangement of dopamine neuron subtypes.

Title: Domain-general and domain-specific activations of expectancy-based pain modulation as compared to aversive and pleasant tastes

Authors: Y. ZHAO[1], I.-S. LEE[4], Q. YU[1], M. ROSE-MCCANDLISH[1], D. MISCHKOWSKI[5], J. AVERY[2], J. INGEHOLM[2], *L. ATLAS[3];
[1]NCCIH, [2]NIMH, [3]NIH, Bethesda, MD; [4]Dept. of Sci. in Korean Med., Kyung Hee Univ., Seoul, Korea, Republic of; [5]Psychology, Ohio Univ., Athens, OH

Abstract: The specificity of pain perception remains controversial. Previous studies have proposed a pain-specific brain matrix and specific neural patterns, such as the neurologic pain signature (NPS; Wager et al., 2013) and the stimulus intensity independent pain signature (SIIPS; Woo et al., 2017). However, activation in these brain networks has been found to overlap with other salient experiences and a general negative affect pattern (Čeko et al., 2022). The orbitofrontal cortex (OFC) has been implicated in value-based learning across various domains, including pain. The anterior insula has been found to play a role in expectation modulation, with a particular subregion exclusively influenced by expectancy of pain rather than other aversive events (Sharvit et al., 2019). However, the expectation effect and underlying neural mechanisms across pain and both aversive and pleasant sensations have not yet been directly investigated. In this study, we compared pain perception with perception of both unpleasant and pleasant tastes (i.e., salt and sugar), to isolate the distinctive and common modulatory effects of expectation on pain and tastes. We randomly assigned sixty participants to receive either heat stimulation, liquid salt, or liquid sugar during fMRI scanning (n = 20 per group). During conditioning, visual cues were paired with high-intensity (high cue) or low-intensity (low cue) stimulation. Each cue was then equally likely to be followed by its conditioned intensity or a medium intensity stimulus. Intensity and valence were rated after each stimulus. Participants rated higher intensity when medium stimuli were preceded by the high cue compared to the low cue ($p < 0.001$). These effects did not differ among the groups. During anticipation, we observed cue-related activation (High cue > Low cue) in the OFC across all groups. Cue effects on intensity ratings on medium trials were mediated by the anterior insula across all groups. However, when we examined whether OFC anticipatory activation moderated responses to cues during medium trials, we observed different networks of activation across modalities, consistent with domain-specific effects. Furthermore, when we compared high and low intensity stimuli within each group, we found differences in neural patterns. Specifically, the NPS and SIIPS showed larger differences for the heat group compared to the salt and sugar groups, while the affect pattern did not differ between the heat and salt groups. In conclusion, our findings suggest that predictive cues engage both domain-general mechanisms (such as the OFC and insula) and domain-specific processes in the context of heat compared to aversive and pleasant tastes.

Title: Morphological and transcriptomic decoding of accelerated brain aging in chronic pain

Authors: L. ZHAO, W. ZHAO, ***Y. TU**;
Inst. of Psychology Chinese Acad. of Sci., Beijing, China

Abstract: Patients with chronic pain (CP) are at a higher risk of dementia, but the mechanism remains unclear. Dementia-risk-related biological impairments in the brain accumulate with age but vary in velocity across different conditions, suggesting the implication to decode the neurobiological mechanisms between CP and dementia via characterizing brain aging. Considering CP is a unifying symptom in a series of highly heterogeneous conditions, whether common CP types present a general or distinct brain aging patterns that are associated with patients' cognitive functions, dementia risks, and genetic predisposition, are still unknown.
To decode accelerated brain aging in CP, we developed an MRI-based brain age model in healthy adults (N = 6,725) and applied it to examine the brain aging acceleration (quantified by the predicted age difference [PAD]) in five common types of CP (Dataset 1; N = 2734) including knee pain, back pain, headache, neck pain, and hip pain. The findings of brain aging acceleration were further validated in an independent dataset (Dataset 2; N = 192) that had baseline and 5-year follow-up sessions. The associations between brain aging acceleration and pain symptoms, cognitive function, and dementia risks were assessed cross-sectionally and longitudinally. We also employed genetically pleiotropic, imaging-transcriptomic and enrichment analyses to identify the molecular genetic basis of brain aging acceleration in CP.
Compared to healthy controls, a significantly increased PAD was only observed in chronic knee pain cohort (Cohen's d = 0.130). In the subgroups of chronic knee pain, a significant increase in PAD was found in the knee osteoarthritis (KOA) cohort (d = 0.437) but not in the subgroup without KOA. The increased PAD in KOA was replicated in Dataset 2 (d = 0.454) and was

associated with memory decline (r = 0.348) and dementia risk (Spearman's rho = 0.278). The gene SLC39A8 showed pleiotropy between brain aging acceleration and KOA, as well as transcriptional associations with KOA neuroimaging phenotypes across both datasets. The genes exhibiting transcriptional associations with KOA neuroimaging phenotypes were highly expressed in microglial cells and astrocytes, and primarily enriched in synaptic structure and neurodevelopment.
In summary, our study demonstrates the heterogeneity of brain aging in CP and unfolded a distinct heritable pattern that links KOA to dementia by providing an integrative biological profile that connects specific genes, molecular processes, and cell classes with morphological brain aging.

Title: Cortical oscillations of the sensory-discriminative and affective-motivational dimensions of pain using the electroencephalogram

Authors: I. CASMEDES, N. CIVITELLO, S. LOVE, ***A. HARRIS BOZER**;
Psychological Sci., Tarleton State Univ., Stephenville, TX

Abstract: Pain is a complex, multidimensional phenomenon and consists of three dimensions: sensory-discriminative, affective-motivational, and cognitive-evaluative. Pain questionnaires such as the widely used McGill Pain Questionnaire contain sections that assess both the sensory and affective dimensions of pain. It is well documented that the pain dimensions are associated with activity in select cortical areas (e.g. primary somatosensory cortex for the sensory dimension and anterior cingulate cortex for the affective dimension), yet the EEG profile of the cortical activity that underlies the pain dimensions is not comprehensively known. Right-handed participants (18-30 years old) were placed into two groups: chronic pain reported (n=3) vs. no chronic pain (n=6). After an impedance check, cortical activity was recorded using an ABM B-Alert 24 electrode EEG and iMotions software (referenced to mastoids) in a double-walled and foam insulated sound attenuating chamber (Whisper Room) during presentation of previously validated sensory-discriminative and affective dimension questions from the McGill Pain Questionnaire. Frequency band data were extracted in Cartool software (fast fourier transform) after Matlab was used to filter (.05-50Hz) data and reject artifacts. ANOVAs were run to compare EEG oscillations within the frequency bands (delta .05-3 Hz; theta 4-7 Hz; alpha 8-13 Hz; beta 14-30 Hz; and gamma 31-50 Hz) by group (chronic pain vs. no pain) and dimension (sensory vs. affective dimension questions). There were no significant differences by dimension or pain group, $p>.05$. These preliminary data were collected to expand the literature by

investigating the cortical (EEG) response during the sensory- discriminative and affective dimensions using questions from the McGill Pain Questionnaire.

Title: Distinct ascending light touch pathways differentially encode vibratory stimuli

Authors: *E. HUEY, J. TURECEK, M. M. DELISLE, M. DUA, D. D. GINTY;
Harvard Med. Sch., Boston, MA

Abstract: A physiologically diverse group of mechanosensory neurons that innervate the skin underlies our abilityto perceive a remarkable range of tactile stimuli and provide us with the capacity to manipulate objects,detect threats, and navigate our environment. Despite the fundamental importance of our sense of touch,relatively little is known about how distinct ascending pathways organize and represent touch information.The dorsal column nuclei (DCN) of the brainstem, along with the spinal cord, are early sites of tactileinformation processing. Non-overlapping populations of DCN projection neurons target the ventralposterolateral nucleus of the thalamus (VPL) and the external nucleus of the inferior colliculus (ICX). Wehypothesized that these ascending light touch pathways serve distinct functional roles: the thalamicpathway may be important for fine tactile discrimination and acuity, while the collicular pathway maycontribute to innate behaviors, such as orienting in relation to salient tactile stimuli. Previous work in thelab supports this hypothesis, demonstrating that DCN neurons projecting to ICX are able to phase lockto high frequency vibratory stimuli (>250hz) while DCN neurons projecting to VPL rarely can. In order tounderstand how this dichotomy in DCN projection neuron response properties is represented indownstream brain targets, we performed *in vivo* extracellular recordings of neurons in VPL and ICX. Wefound that the VPL and ICX inversely represent vibratory stimuli, where ICX neurons are most sensitiveto vibrational stimuli between 200-500hz and VPL neurons optimally respond to low frequency stimuli inbetween 10-200hz. We hypothesized that Pacinian afferents, which are unique in their ability to encodehigh frequency vibratory stimuli, have an outsized role in shaping ICX response properties in comparisonto other primary afferent types. ICX responses to vibration were greatly attenuated in a genetic mousemodel lacking Pacinian corpuscles, whereas VPL responses were largely normal in the same model. Ourfindings demonstrate that the ascending touch pathway to the ICX is uniquely tuned to high frequencyvibratory stimuli mediated by Pacinian afferents. Ongoing experiments are determining the functionalsignificance of this high frequency bias in the context of animal

behavior. Preliminary results reveal thatsilencing the ICX reduces avoidance of a 500hz vibratory stimulus in a preference assay, suggesting thatcertain somatosensory behaviors are selectively mediated by the ICX pathway.

Title: 3-d reconstruction of the fingertip during tactile interactions

Authors: *D. DOUMONT[1], A. R. KAO[2], G. J. GERLING[2], A. BROWET[1], B. P. DELHAYE[1], P. LEFEVRE[1];

Abstract: Tactile signals underlying our perception of touch originate from the mechanotransduction of skin deformation. Quantification of such deformation during interactions between the fingertips and objects can provide new insights into the tactile information provided to the brain. Measuring skin deformation without affecting its behavior is challenging, and studies have successfully used optical imaging and digital image correlation (DIC) to reconstruct deformations at the contact interface, using a glass surface. Here, we aimed to extend those efforts and develop a method to reconstruct the 3-D deformation of the skin inside (planar) and outside (non-planar) the contact resulting from the normal and tangential loading of the fingertip over a flat surface. Using a robotic platform, the index fingertip of participants is passively pressed against a flat transparent surface (loading). Then, while maintaining the normal force constant, the surface was moved laterally at a set velocity until full slippage occurred (Fig 1A). The fingerpad is imaged by two pairs of high-resolution [2MP, 50fps] industrial cameras. A speckle pattern was drawn on the fingerpad using black ink to create a unique pattern for the DIC tracking (Fig 1B). Finally, we performed stereovision calibration and used DIC on each stereo-pair to reconstruct the skin surface in 3-D. During loading, we observed that the contact area is subjected to a radial compressive field of deformation of more than 5% at 5N, whereas the outside of the contact area expands to a similar magnitude (Fig 1C). During slip onset, deformations outside the contact are significantly larger and less homogeneous compared to the loading phase (Fig 1D). This heterogeneity could potentially be attributed to the geometry or the fingerprint of the fingertip. Those 3-D measurements will help to develop more accurate mechanical models of the fingertip and could be used concurrently with neurophysiological recordings to improve existing tactile afferent models.

Title: Adaptation in low-threshold mechanoreceptors improves encoding of stimulus amplitude and frequency

Authors: A. HALAWA[1,2], L. MEDLOCK[1,2], D. AL-BASHA[1,2], C. DEDEK[1,2], S. RATTÉ[2], S. PRESCOTT[2,1];

Abstract: Primary sensory neurons transduce and transmit all the information about the external world that the brain has access to. When presented with prolonged stimulation, sensory neurons must maintain effective information transfer despite bioenergetic constraints. We investigated spike-rate adaptation in rat hind paw low-threshold mechanoreceptors (LTMRs) recorded in vivo during 30 seconds of vibrotactile stimulation with sine waves of varying frequencies (2-300Hz) and amplitudes (150-225mN). Our goal was to explore how prolonged stimulus exposure affects not just firing rate, but also spike-timing precision. What is the basis for this adaptation, and how does it affect the mutual information between neuronal response and stimulus? Whereas spike rate quickly decreased during prolonged stimulation, spike-timing precision rapidly improved (i.e. jitter decreased), and stayed high throughout the trial. To examine how this happens, we fit neurons with general linear models (GLMs) during both early and late phases of the response. Adaptation was accounted for by changes in the refractoriness (h filter) and passive current (u) with minimal concomitant changes in the stimulus (k) filter. Stability of the stimulus filter suggests that neurons maintain the same frequency preference despite adaptation. Increased refractoriness (greater afterhyperpolarizing current) might regularize the spike train, which can decrease entrainment by increasing cycle skipping, but also improve spike-timing precision. To study the effect on coding, we calculated information gain between stimulus and neural response. We found that information per spike rapidly increases in the first second, similar to the improved precision. Despite the increase in information per spike, the decrease in spike rate late in the stimulus presentation resulted in less total information gained from the response of a single neuron. However, when we trained a discriminator to classify the stimulus parameters (frequency & amplitude) based on population-level spiking, we found that the decrease in spike rate did not limit information transfer; instead, information was lowest in the first second, after which it rapidly increased and stayed high. This followed a timeline similar to the improved information per spike, the change in linear filters, and the improved spike-timing precision. All in all, our work shows that adaptation is beneficial for coding vibrotactile input by an ensemble of LTMRs, improving the temporal coding of stimulus frequency and the rate coding of stimulus amplitude.

Title: Impact of moisture on the biomechanical response of finger pad skin

Authors: *B. DELHAYE[1], S. LALLEMAND[1], D. DOUMONT[2], P. LEFEVRE[3];
[1]Univ. catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Univ. Catholique de Louvain, Louvain-la-Neuve, Belgium; [3]ICTEAM and Inst. of Neuroscience, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium

Abstract: The human fingerpad skin contains sweat glands and sweat pores that actively regulate fingerpad moisture content. It has been observed that moisture content can have a strong impact on friction and gripping behavior during active manipulation of objects with the fingertips. It has also been hypothesized that sweat softens the skin tissues, thereby influencing fingerpad-object contact. If the mechanical stiffness of the skin is impacted by moisture content, similar mechanical constraints should lead to different deformations at different levels of moisture. Given that the tactile mechanoreceptors encode skin deformations, fingertip moisture might therefore tune the neural response of those receptors.
To test this idea, we developed and calibrated a transparent moisture sensor to make possible a continuous measure of fingertip moisture while measuring at the same time the skin mechanical deformation resulting from the loading and sliding of a transparent surface, using optical imaging. In an experiment involving 16 subjects, the index finger pad was passively contacted with a flat transparent surface at 1,2 or 5N normal force. The surface was then moved laterally at a constant speed (5mm/s) in the ulnar direction until a full slip, thereby generating substantial surface deformation in the skin. The fingertip skin moisture content was varied naturally, by using the occlusion phenomenon, or artificially by adding water or drying the skin using ether. In the occluded condition, a 30-second break was observed between the contact and the onset of slip to allow for the natural increase of moisture at the contact interface. We observed the moisture level at the contact interface, varied naturally or artificially, had a significant impact on several biomechanical parameters.
We confirmed that friction was directly impacted by moisture and reproduced previous results showing that an intermediate level of moisture maximizes friction. Moreover, while the gross contact area was mostly unaffected, real contact strongly increased with the moisture content. Finally, preliminary analyses on one subject show a significant impact of moisture on fingertip skin deformation.

Title: Innervation of Meissner corpuscles in the glabrous skin of the marmoset hand

Authors: *V. SUKUMAR[1], M. FEYERABEND[2], S. EVERLING[3], J. MARTINEZ-TRUJILLO[4], W. INOUE[2], A. PRUSZYNSKI[2];
[1]UNIVERSITY OF WESTERN ONTARIO, LONDON, ON, Canada; [2]Univ. of Western Ontario, London, ON, Canada; [3]Univ. Western Ontario, London, ON, Canada; [4]Schulich Sch. of Med. and Dentistry, Robarts Institute, Western Univ., London, ON, Canada

Abstract: Cutaneous mechanoreceptors are specialized structures that respond to the stresses and strains arising from skin deformation. Meissner corpuscles (MCs) are low threshold cutaneous mechanoreceptors found in the dermal papillae of the glabrous (i.e. hairless) skin. MCs are crucial for fine, discriminative touch and vibration. Recent studies have shown that the Aβ afferent neurons innervating primate MCs signal the geometric features of touched objects [Pruszynski et al., 2014; Sukumar et al., 2022; Suresh et al., 2016]. We have suggested that this functional capacity arises because of the dendritic-like branching of Aβ afferent neurons in the skin and the spatial arrangement of the many MCs they innervate. However, beyond their existence, relatively little is known about these branching patterns in primates. Here we provide a comprehensive account of the anatomy of MCs in the glabrous skin of the marmoset hand and the neurons innervating them, including the first detailed characterization of the branching patterns. We used immunofluorescence confocal microscopy to image the marmoset glabrous skin (n=8; 4 adult male/female, 2-5 years old), including the fingertips, the intermediate phalanges, the first interphalangeal joint, and the palmar surface of the hand. We visualized MCs and their myelinated innervation, especially Aβ fibers, as well as their non-myelinated innervation. We also visualized peptidergic and non-peptidergic neurons innervating MCs. We report the following preliminary findings. MCs are located throughout the marmoset hand, at a depth of ~140μm from the surface of the skin. MCs are approximately 21μm in diameter and 35μm in length. MC density appears similar across fingertips but varies along the distal-proximal axis of the hand, with highest density in the fingertips. Each MC is innervated by at least one myelinated Aβ afferent fiber (~4μm diameter), which wraps around the lamellae in the MC. Many of the MCs in the fingertips are innervated by multiple branches of the Aβ afferent fibers, some of which arise from distinct neurons. MCs also receive non-Aβ innervations (~1μm diameter). Finally, similar to macaques and humans, Aβ neurons branch extensively, each innervating many MCs both within and across dermal ridges. Preliminary neuronal tracing indicates that, at least in the fingertip, MCs innervated by different Aβ neurons interdigitate with each other. Taken with the finding that MCs receive multiple distinct Aβ innervations, this suggests that the receptive fields of these neurons overlap substantially.

Title: Electrophysiological analysis of the peripheral sensory pathway related to clitoral sheath mechanoreceptors of the rat

Authors: *M. SERRANO[1], O. LARA-GARCÍA[3], M. OLOARTE FLORES[3], B. MOLINA[4], M. LARA GARCIA[2], P. PACHECO[5];

Abstract: Clitoral sheath mechanical stimulation such as pressure, reflexively activates pubococcygeus muscle (Pcm) motoneurons which response differs according to gonadal hormone *milieu*. In diestrus phase, Pcm reflex activity evoked by clitoral pressure was only noticed during stimulation period, while in proestrous phase, this electromyographical activity was not only present during stimulation, but displayed a long-lasting post-stimulation activity namely afterdischarges. Moreover, in ovariectomized rats these afterdischarges were absent, but if a subcutaneous injection of estradiol is applied; then, these afterdischarges became restituted. Estradiol receptors (ER´s) are present not only in efferent pathways but in afferent as well, from which it is known that sensory neurons from most dorsal root ganglia posses ER´s. Thus, it is likely that these afterdischarges activity may merely be reflecting a sensory neuron hypersensitivity induced by a high estradiol milieu. Here, we explored a sensory pathway that carries peripheral information evoked by mechanoreceptors within clitoral sheath. Pre and post L_6 dorsal root ganglion electrophysiological recordings were taken from adult female Wistar rats, in diestrus and proestrous phase, ovariectomized and ovariectomized plus a single subcutaneous injection of estradiol benzoate. Pre and post ganglionic repetitive activity was present during and after mechanical stimulation in all studied groups. Post-stimulation activity duration was proportional to stimulus duration. Interestingly enough was that clitoral receptors together with its corresponding sensory axon produced afterdischarges which persist during its pass through the dorsal roots.

Title: Glans penis sensory receptors activity by rubbing is sensitive to gonadal hormones in the rat

Authors: *M. OLOARTE FLORES[1], B. MOLINA[2], O. LARA-GARCÍA[1], Y. CRUZ[3], K. YAMADA[4], M. LARA GARCIA[5], P. PACHECO[6];

Abstract: Sensory stimulation induces spinal reflex activity, which may last even after stimulus cessation. This post-stimulation activity may be due to bistability in spinal motoneurons. Nociceptors and thermoreceptors are sensitive to estradiol. Ganglionic cells possess estradiol receptors and respond to testosterone, at least in *in vitro* preparations. Neither sex difference nor differences in gonadal hormones effects are usually considered in *in vivo* preparations focused on sensory receptors physiology or their afferent pathways. It is known that penis afferent input is through pudendal nerve, which originates from L_6 and S_1 spinal nerves; and that testosterone is necessary to maintain histological and physiological characteristics of the penis. We have described that glans penis sensory receptors activity rely on the type of mechanical stimulation applied, from which rubbing was the only stimulus that never induced dorsal root post-stimulation activity from L_1 to S_1. Nonetheless, there is no information regarding gonadal hormone sensitivity of afferent activity originated from sensory receptors within the glans penis; then, in the present study, we recorded glans penis electrophysiological activity evoked by rubbing stimulation in L_6 and S_1 dorsal roots of adult Wistar rats gonadally intact, gonadectomized (Gdx) and Gdx with a single subcutaneous injection of testosterone propionate or estradiol benzoate. In intact animals, only phasic and tonic “on” responses were noticed. In Gdx animals, besides phasic and tonic “on” responses, there were long-lasting tonic “off” responses (afterdischarges). In Gdx rats with acute testosterone administration, only phasic and tonic “on” responses were recorded, no afterdischarges were noticed in either dorsal root following testosterone administration. Gdx rats with acute estradiol administration, did not modify afterdischarge activity. Results suggest that testosterone nor estradiol, is actively regulating sensory information arising from glans penis rubbing-related sensory receptors. This is supported by the hypersensitivity noticed in Gdx rats whose sensory receptors and/or ganglionic cells related to rubbing stimulation returned to intact-like characteristics following testosterone administration but estradiol. Thus, sensory activity in L_6 and S_1 dorsal roots ganglions possess a repetitive-like behavior that is modulated by testosterone in male rat.

Title: Krause corpuscles of the genitalia are vibrotactile sensors required for normal sexual behavior

Authors: *L. QI, M. ISKOLS, A. HANDLER, D. GINTY;
Harvard Med. Sch., BOSTON, MA

Abstract: Krause corpuscles, first discovered in the 1850s, are enigmatic sensory structures with unknown physiological properties and functions found within the genitalia and other mucocutaneous tissues. Here, we identified two distinct somatosensory neuron subtypes that innervate Krause corpuscles of the mouse penis and clitoris and project to a unique sensory terminal region of the spinal cord. Using *in vivo* electrophysiology and calcium imaging, we found that both Krause corpuscle afferent types are A-fiber rapid-adapting low-threshold mechanoreceptors, optimally tuned to dynamic, light touch and mechanical vibrations (40-80 Hz) applied to the clitoris or penis. Optogenetic activation of male Krause corpuscle afferent terminals evoked penile erection, while genetic ablation of Krause corpuscles impaired intromission and ejaculation of males and reduced sexual receptivity of females. Thus, Krause corpuscles, which are particularly dense in the clitoris, are vibrotactile sensors crucial for normal sexual behavior.

Sch., Seoul, Korea, Republic of

Abstract: To develop realistic metaverse systems such as virtual reality (VR), augmented reality (AR), and mixed reality (MR), it is important to implement virtual tactile technology on wearable devices such as lightweight and thin gloves and thimbles. This is because a large and heavy mechanical device is needed to generate a natural pressure stimulation. Therefore, techniques for encoding inter-spike-interval (ISI) patterns that allow tactile nerves to feel virtual pressure using electrical or micrometer-scale vibrational stimuli is necessary core technology. We first performed a study to apply pressure stimulation to the skin of mice in Ex-Vivo state and measured the spike firing pattern of slowly adapted (SA) neurons isolated from peripheral nerve bundles to decode the neuron spike pattern corresponding to pressure stimulation. More specifically, the skin and nerves (C57bl/6, 8-10 weeks) of mice were extracted, and spike signals generated by slow-adapting (SA) neurons isolated from afferent nerves were recorded by Au electrodes in paraffin oil chambers electrochemically separated from the synthetic interstitial fluid chamber, at a pH of 7.4 and temperatures 29-30℃. A neural spike response was obtained by applying a force of 10 to 100 mN for 6 seconds using a stimulus rod. When pressure stimulation is applied, the spike fires rapidly, and the firing rate decreases within 0.1 to 0.2 seconds and then randomly distributed within a certain range. And the initial firing rate is proportional to the strength of the pressure. To fit the exponentially decreasing firing rate curve, we performed the least square regression analysis using the exponentially attenuated curve. In this work, we propose an decoding method that uses random functions to add random deviations within a certain value to the exponential attenuation curve when generating neural spike patterns. By introducing random deviation components, the similarity between the experimental and simulated ISI patterns linked to the firing rate curve is greatly improved, and a quantitative evaluation index based on correlation coefficient of time and frequency dimensions about the similarity of ISI patterns is newly proposed and studied. When the random function was introduced, the correlation coefficients between the experimental and simulated ISI patterns were improved by more than 50%. Applying electrical stimulation or micrometer-scale vibration stimulation to finger with the encoded signals obtained based on the reverse direction of the decoding model derived using this newly proposed method can provides a more natural pressure sensation to human.

Title: The mechanosensation of active movement

Authors: *J. TURECEK, D. D. GINTY;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Pacinian corpuscles are exquisitely sensitive to high-frequency mechanical vibrations from 50-1000 Hz. However, it is unclear how vibration is encountered and detected during unconstrained behavior. Here, we record from Pacinian corpuscles in awake, freely moving mice. In awake animals, Pacinians can reliably encode subtle surface vibrations, and when standing on certain substrates, can easily detect mechanical activity from over a meter away. During movement, the firing rate of most Pacinians is higher than any other low-threshold mechanoreceptor or proprioceptor. The firing of Pacinians can encode information about the type of material making contact with the limb, as well as the nature of self-contact. In addition to surface vibrations and locomotion, we find that Pacinians are also robustly activated during a wide variety of natural behavior, including grooming, digging, climbing and interactions with other animals. Pacinians in the hindlimb are sensitive enough to be activated by forelimb- or upper-body-dominant behaviors. Finally, we find that their responsiveness during awake behavior is strongly dependent on their sensitivity and frequency tuning. Thus, natural behavior generates a wealth of mechanical vibrations that can be encoded by Pacinian corpuscles, detecting both self-generated movement and externally generated vibrations within the environment. The diverse tuning of Pacinians enables rich sensory coding across a wide variety of behaviors, even those that are not typically associated with vibration.

Title: Biomechanical filtering diversifies tactile encoding in whole-hand Pacinian corpuscle neuron populations

Authors: *N. TUMMALA[1], G. REARDON[2], B. DANDU[1], Y. SHAO[5], H. P. SAAL[6], Y. VISELL[3,4,1,2];
[1]Electrical and Computer Engin., [2]Media Arts and Technol., [3]Biol. Engin., [4]Mechanical Engin., Univ. of California, Santa Barbara, Santa Barbara, CA; [5]Ctr. for Tactile Internet with Human-in-the-Loop (CeTI), Technische Univ. Dresden, Dresden, Germany; [6]Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: The human hand contains hundreds or more exquisitely sensitive Pacinian corpuscle neurons (PCs) that encode vibrotactile information during manual touch interactions. When directly stimulated, PCs exhibit highly similar response characteristics, with the highest sensitivity to frequency components near 250 Hz. Given that touch-elicited skin oscillations travel readily across the whole hand and excite large numbers of widespread PCs, the relative homogeneity of PC response characteristics suggests a degree of redundancy that is difficult to reconcile with principles of efficient neural encoding. Here, we show that biomechanical filtering reduces redundancy and promotes heterogeneity in PC population responses by modifying signal transmission across the hand. We characterized the biomechanical transmission of touch-elicited skin oscillations by collecting spatiotemporally resolved optical vibrometry measurements across the glabrous skin of human hands (N=7) for each of four stimulus contact locations. The vibrometry data revealed hand biomechanics to impart complex frequency-dependent patterns of attenuation due to the soft tissue mechanics and morphology of the hand. To investigate the implications of these findings for tactile encoding in the PC system, we used the collected vibrometry measurements to drive whole-hand populations of simulated PC neurons. We found that biomechanical filtering diversified response characteristics across PC populations by modifying the frequency content in skin oscillations transmitted to PC locations prior to mechanotransduction. As a result, correlations between the response characteristics of PCs near the contact location and those of PCs outside the contact region decreased with increasing distance. Moreover, PCs across the hand exhibited a range of peak sensitivities (25-500 Hz) significantly wider than is observed when PCs are directly stimulated (200-300 Hz). Biomechanical filtering also reduced redundancy in PC firing rates and spike timing, as determined through principal component analysis and interspike interval information entropy. Our findings show how biomechanical filtering serves as a pre-neuronal mechanism for diversifying PC population responses, thereby supporting encoding efficiency in the PC channel. Our vibrometry-driven computational model of PC population responses also supplies a valuable tool for investigating the neuromechanical basis of tactile encoding in the periphery.

Abstract: Despite the potential importance of genital mechanosensation for sexual reproduction little is known about how perineal touch influences mating. Here we explored how mechanosensation affords exquisite awareness of the genitals and controls reproduction in mice and humans. Using genetic strategies and in vivo functional imaging, we demonstrated that the mechanosensitive ion channel Piezo2 is necessary for behavioral sensitivity to perineal touch. Notably Piezo2-function is needed for triggering a touch evoked erection reflex and successful mating in both male and 25 female mice. Humans with complete loss of PIEZO2 function have genital hyposensitivity and experience no direct pleasure from gentle touch or vibration. Together, our results explain how perineal mechanoreceptors detect the gentlest of stimuli, trigger physiologically important sexual responses, providing a platform for exploring the sensory basis of sexual pleasure and its relationship to affective touch.

Abstract: Our external senses of sight, smell, sound, touch, and taste enable us to perceive the external world. In addition, our internal sensory system monitors the physiological states of peripheral organs, such as mechanical and chemical cues from ingested food, irritants in the airway that induce cough, and inflammatory cues that signal tissue damage. In comparison to external sensory systems, the principles that define visceral sensory processing remain poorly defined. Here, we developed an *in vivo* two-photon calcium imaging preparation to understand internal organ representations in the nucleus of the solitary tract (NTS), a sensory gateway in the brainstem that receives vagus and other inputs from the body. Combining the imaging platform with stimulation of visceral organs, we uncover diverse neuronal responses to internal stimuli, while functionally defined cell types are highly organized within the NTS. Combining functional imaging with pharmacogenetic manipulations and viral tracing from genetically defined vagal sensory cell types, we show that the highly organized representations of internal senses are generated by vagal axon sorting and higher-order sensory processing within the NTS. Ongoing work will connect the response profiles of NTS neurons to the connectivity to downstream target areas. Together, our study reveals basic coding principles used by the brain to process visceral inputs and may shed light on the treatment of viscerosensory and autonomic dysfunctions.

Ctr. for Complementary and Integrative Hlth., Bethesda, MD; [6]NCCIH/NINDS, NIH/NCCIH, Bethesda, MD

Abstract: The mammalian tongue is richly innervated with somatosensory, gustatory and motor fibers. These form the basis of sophisticated sensorimotor functions such as the determination of

object shape and texture during active touch. Despite high tactile acuity and sensitivity revealed by human behavioral and microneurography studies, the neural basis of tongue mechanosensation remains largely mysterious. In particular, the relationship between electrophysiological responses and anatomical innervation patterns of distinct sensory neuron types remains unclear. Here we found that sensory neurons in the trigeminal ganglion (TG) innervated both fungiform papillae and filiform papillae of the tongue, unlike gustatory afferents from the geniculate ganglion which innervate only the fungiform papillae that contain taste buds. Trigeminal afferents were the main source of Piezo2+ afferents in the fungiform papillae, which terminated at the extragemmal region and exhibited a ring-like terminal pattern surrounding the taste pore. Myelinated lingual afferents in the mouse fungiform and filiform papillae did not form corpuscular sensory end organs but rather had only free nerve endings. In contrast, in the ferret tongue we found sensory end organs in filiform papillae with shapes that resembled Krause end bulbs. Single-unit recordings from TG in anesthetized mice revealed two types of lingual low-threshold mechanoreceptors (LTMRs) with conduction velocities in the Aδ range or above and distinct response properties: intermediately adapting (IA) units and rapidly adapting (RA) units. IA units were sensitive to static indentation and stroking, while RA units had a preference for tangential forces applied by stroking. Lingual LTMRs were not directly responsive to rapid cooling or chemicals that can induce astringent or numbing sensations. Genetic labeling of lingual afferents in the tongue revealed at least two types of nerve terminal patterns, involving dense innervation of individual fungiform papillae by multiple putatively distinct afferents, and relatively sparse innervation of filiform papillae. Together, our results suggest a simple model that links the functional and anatomical properties of tactile sensory neurons in the tongue.

Title: Default mode network function, neural oscillatory modulation, and autistic characteristics in individuals with misophonia

Authors: *M. M. MORGAN[1], J. E. NORRIS[2], L. E. ETHRIDGE[2];
[2]Dept. of Psychology, [1]Univ. of Oklahoma, Norman, OK

Abstract: Misophonia is characterized by intense emotional and physiological reactions to specific auditory stimuli. People with misophonia exhibit differences in brain activity in the auditory cortex and salience networks during auditory tasks. Because individuals with autism

spectrum disorder (ASD) often experience similar sensory hypersensitivities, similarities in brain activity between the two groups may suggest shared neurobiological pathways. To better understand the neural underpinnings of misophonia and its potential relationship with ASD, this study examines potential deviations in neural oscillations related to the default mode network that may contribute to the overall phenotype of individuals with misophonia. Participants (16 individuals with misophonia and 17 non-misophonic controls) ages 18-22 (M = 18.91, SD = 1.01, 88% female) completed the Broad Autism Phenotype Questionnaire (BAPQ) and an eyes open/eyes closed resting electroencephalography (EEG) task. Compared to controls, individuals with misophonia exhibited increased BAPQ rigidity scores and trended towards increased aloofness and pragmatic language scores, (Rigid: $t(31) = -2.34$, $p = .026$, $d = -.81$; Aloof: $t(31) = -1.71$, $p = .097$, $d = -.59$; Pragmatic Language: $t(31) = -1.92$, $p = .064$, $d = -.67$). Individuals with misophonia trended towards decreased alpha reactivity (ratio of eyes open to eyes closed) relative to controls $t(29) = 1.75$, $p = .091$, $d = .63$. Correlations across both groups were found between increased eye closed occipital peak alpha frequency (PAF) and increases in both BAPQ pragmatic language ($r = .355$, $p = .042$) and rigidity ($r = .387$, $p = .026$) scores. When limiting correlations to misophonia only, correlations emerged between both frontal and occipital PAF during the eyes closed condition and the BAPQ rigidity subscale score (frontal PAF: $r = .496$, $p = .043$, occipital PAF: $r = .487$, $p = .048$) but not pragmatic language scores. Individuals with misophonia exhibited decreased occipital theta-gamma phase-amplitude coupling (PAC) compared to controls, $t(28) = 2.57$, $p = .016$, $d = -.39$, and also trended toward decreased frontal theta-gamma PAC compared to controls, $t(31) = 1.92$, $p = .064$, $d = -.53$. However, individuals with misophonia did not significantly differ from controls on alpha-gamma PAC. Theta-gamma PAC has been related to network switching during shifts in cognitive load, while alpha reactivity is associated with modulation of the default mode network; these results may provide some preliminary support for the notion that misophonia involves deviations in default brain state functioning and that these differences may be related to subthreshold ASD-like characteristics.

Title: Population coding of time-varying sounds in the non-lemniscal Inferior Colliculus

Authors: K. SHI[1], G. QUASS[1], M. M. ROGALLA[1], A. FORD[1], J. E. CZARNY[1], *P. APOSTOLIDES[2];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: The inferior colliculus (IC) is an evolutionarily conserved midbrain structure playing pivotal role in processing amplitude modulation (AM) of sound envelope, a key feature in conspecific vocalizations and human speech. The IC is comprised of several sub-regions: A primary central region receives ascending auditory inputs from the brainstem and projects to primary auditory thalamus, while non-primary "shell" regions integrate intra-collicular inputs and project to behaviorally relevant, higher-order thalamic regions interfacing with the amygdala, striatum and non-primary auditory cortex. While decades of studies on AM coding have focused on central IC neurons, whether and how AM sounds are encoded in shell IC neurons are underexplored, owing to the challenges of recording from these neurons located near the tectal surface. Here, we used 2-photon calcium imaging to study how shell IC neurons of awake, head-fixed mice respond to sinusoidal amplitude modulated (sAM) narrow-band noise (65-70 dB SPL, 5-200 Hz modulation rate, 0-100% modulation depth, carrier bandwidth: 16 ± 2 kHz). The calcium indicator GCaMP6f/6s/8s was expressed in shell IC neurons of 5-8 weeks old mice; 2-photon microscopy was used to record neural activity in the shell IC as the mice were passively listening to sAM stimuli of varying modulation depths and rates. We analyzed responses from 1213 sound-responsive neurons recorded from 13 mice. We find that all the major sAM tuning properties previously described in the central IC — low-pass, high-pass, band-pass, and band-reject — are similarly identified in both excitatory and inhibitory shell IC neurons. Overwhelmingly, increasing modulation depth of sAM sound enhanced shell IC neuron responses to preferred and non-preferred modulation rates, indicating a monotonic encoding of modulation depth and limited mixed selectivity to specific combinations of modulation rate and depth. Although most individual shell IC neurons display low neurometric discriminability and selectivity for sAM signals we find that sAM information is accurately represented in the shell IC based on a neural population code. Specifically, modulation rate is well-represented in the shell IC and such representation is heavily dependent on the modulation depth. Altogether our data uncovers a substantial population level AM representation in the non-lemniscal regions of the IC, thus shedding light on the building blocks of complex sound perception.

Title: Phase coding in phoneme processing slows with age

Authors: *K. DAPPER, 1995[1,2,5], J. SCHIRMER[2], L. RÜTTIGER[2], E. GOUDRAIN[6], S. VERHULST[7], C. BRAUN[3], E. DALHOFF[2], M. KNIPPER[2], M. H. MUNK[5,4];

Abstract: Age-related hearing loss is a growing problem in aging societies. Listening difficulties occur even if audiometric thresholds indicate normal hearing, a feature possibly linked to cochlear synaptopathy. We tested passive electrical brain responses to syllables (/du/, /bu/, /di/, /bi/, /o/, and /y/), while 80 participants (55f, 25m) watched a silent movie. Measuring phase and amplitude of the most prominent entrained EEG response at 116 Hz based on continuous wavelet transformation revealed a relation to age-dependent hearing loss. EEG amplitude and phase were correlated with PTA4, PTA-EHF (10-16 kHz), broadband OLSA (with and without noise) and age. Specifically, an increase in speech processing delay was linked to a speech comprehension deficit (OLSA) as well as with hearing loss in extended high-frequencies. As the absolute temporal delays were in the order of 1-2ms, which is beyond expected values for brainstem delays, we reason that thalamic and cortical processing is mainly responsible for this age-related slowing. We conclude that a decrease in temporal coding is related to a decrease in phoneme discrimination and hearing threshold in particular at high frequencies.

Title: Inferior colliculus neurons are sensitive to sub-millisecond variations in sound onset duration

Authors: *M. RYAN, S. JOSHI, H. SRIVASTAVA, H. JIANG, M. MCGINLEY;
Baylor Col. of Med., Houston, TX

Abstract: Rapid acoustic onsets are prominent in natural sounds, including in speech, such as after gaps, and in adventitious sounds, such as rustling noises. Octopus cells (OCs) in the cochlear nucleus are highly responsive to these rapid onsets and drive precisely timed inhibition in the inferior colliculus (IC) via the ventral nucleus of the lateral lemniscus[1]. However, the function of OC-driven onset inhibition in the IC remains unknown. There are several divergent models for the role of this onset inhibition in the circuit function of the IC, including: suppressing spectral splatter; preserving excitatory/inhibitory balance during onsets; and facilitating feature binding. [2,3]. To begin to arbitrate between these models, we examined the impact of onset gate duration on computational models and Neuropixel recordings of neural responses to single tones in IC of mice. We have characterized the theoretical limit, and simulated cochlear extent, of spectral splatter in natural sounds, and tones with varying onset gate durations, and find that changes in spectral splatter due to sub-millisecond differences in onset gate duration are recapitulated by the cochlea. During presentation of single tones with manipulated onset gate durations, we record neural response properties in the IC of head-fixed, awake mice. We find that sub-millisecond gate duration affects tone-evoked firing by up to 2-fold (N=3) particularly at tone carrier frequencies away from best frequencies, indicating that population responses in IC are strongly impacted by spectral splatter. Future optogenetic work will test the potential role of OCs in spectral splatter suppression. Ongoing analyses are determining the implications of our results for models of the function of rapid onset inhibition in IC.

Title: Age-induced modulation in sound-evoked local field potentials in the inferior colliculus of CBA/CaJ mice

Authors: *D. L. BRUNELLE[1], T. J. FAWCETT[2], J. P. WALTON[3];
[1]Communication Sci. and Disorders, [2]Res. Computing, Med. Engineering, Chemical, Biological, and Materials Engin., [3]Communication Sci. and Disorders, Med. Engin., Univ. of South Florida, Tampa, FL

Abstract: The inferior colliculus (IC) is a major midbrain convergence site critical for processing complex sounds such as speech and undergoes fundamental changes with age-related hearing loss (ARHL). The loss of peripheral inputs and senescence-related alterations in neurotransmission lead to decreased activity driving neurons in the IC, causing spectral-temporal auditory processing deficits. Local field potentials (LFPs) represent the electrical potential surrounding neurons in the extracellular space, reflecting pre-synaptic activity and the integration of excitatory and inhibitory signals from neuronal inputs generating action potentials. In the current study, age-related changes in sound-evoked LFPs were assessed in the CBA/CaJ mouse model of ARHL via deconstructing various LFP components evoked by wideband noise bursts. To assess the effects of age on pre-synaptic sound-evoked activity in the IC, multi-channel arrays were placed in the IC central nucleus and neural activity was acquired from 11 young (4-6 mo.), 10 middle-aged (8-14 mo.), 20 old (24-25 mo.), and 6 very old (27-30 mo.) mice. Only one session and recording location was selected per animal as not to bias further analyses by over representing data from any single animal. LFPs were recorded from linear 16-channel NeuroNexus probes sampled at 1017 Hz and down-sampled to 2-300 Hz. 589 recording sites were characterized into low, mid, or high frequency regions based off the tonotopic arrangement of the IC. LFPs were temporally decomposed into several regions, based on the amplitude and time of the component of interest.Statistically significant age effects at 80 dB SPL stimuli were found in both the magnitude and latency of temporal LFP components across all frequency regions. Old mice exhibited significantly larger N1 peaks than young in the low (130uV) and mid (98uV) frequency regions. Young mice exhibited the highest P1 peak magnitudes to mid and high frequencies with a 27uV higher P1 versus middle-aged animals at mid and 22-30uV higher P1 amplitudes than older mice at high frequencies. The magnitude of the N2 was 51.6 to 54.3uV deeper for young compared to both old and very old animals at low frequencies while only 41.8uV deeper at mid frequencies. Statistically significant changes in latency of temporal features of the LFP were also observed. The results of this study indicate a significant age-related modulation of both excitatory and inhibitory components of the LFP in aged auditory midbrain neurons. These changes vary as a function of tonotopy and may be related to known age-related alterations in auditory midbrain neurochemistry.

Title: Connectivity and electrophysiology in binaural and asymmetric integration of temporal information

Authors: *T. M. D. AUGEREAU[1], S. CORMIER[1], F. CHAMPOUX[2], V. DUDA[1];
[1]Univ. de Montréal, Montréal, QC, Canada; [2]Univ. of Montreal, Univ. de Montréal, Montreal, QC, Canada

Abstract: Frequency is differentially perceived depending on laterality of the stimulated ear, suggesting a hemispheric lateralization of auditory processes. Few studies have examined the extent of lateralization of auditory temporal processes. For instance, behavioral studies either suggested a lateralization of temporal resolution functions in normal hearing subjects (Brown & Nicholls, 1997; Sulakhe et al., 2003) or no lateralization at all (Baker et al., 2008; Efron et al., 1985). Moreover, it is still unknown whether binaural integration of temporal information can enhance its perception as it has already been demonstrated with intensity summation. A binaural effect on temporal resolution was suggested by Baker et al. (2008) data but no conclusions could definitely be drawn from the study. Our work aims to explore electrophysiological correlates of temporal resolution asymmetry and binaural summation in normal hearing subjects using both behavioral and electrophysiological tasks. Asymmetry will be explored using the left/right lateralization but also using the observed behavioral ear advantage lateralization. 30 subjects aged 18 to 40 with verified normal hearing were recruited. All tasks were presented in 3 conditions : left, right and binaural stimulation. Stimuli used in the study were 200 ms broadband pink noises and presented through ER-2 earphones. Hearing thresholds were determined using a 3 alternative forced choice 1up-3down psychometric staircase procedure. Then, all stimuli were sent at a comfortable intensity level of 40dBSL, thus with adapted intensities for each of the left, right and binaural conditions. A gap detection task was then performed using the same psychometric staircase procedure. The electrophysiological tasks were performed using the optimal multideviant paradigm (Duda-Milloy et al., 2019; Näätänen et al., 2004) with gap deviants stimuli of 2 ms, 5 ms, 7 ms, 15 ms and 30 ms. All deviants were pseudo-randomized and had a 10% chance of being presented. The EEG was recorded using the BrainVision 64 active electrode cap with ActiChamp and Neuroscan SynAmps 2 amplifiers. The Mismatch Negativity was used as an index of electrophysiological temporal resolution thresholds. EEG data were analyzed through Brainstorm and connectivity was measured through bivariate Granger causality using the ICBM152 2023b head model. Preliminary results suggest an ear advantage as well as a binaural summation in temporal resolution processes. These results indicate a lateralization of temporal resolution in the brain, not constrained to the right or left hemisphere, as well as a binaural central integration of such an early process.

Title: Arousal-driven modulation of cell-type specific sensory processing in the auditory cortex

Authors: *K. J. KAUFMAN[1], R. F. KRALL[1], M. P. ARNOLD[1], R. S. WILLIAMSON[2];
[2]Otolaryngology, [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The interplay between external inputs and internal states, such as arousal, shapes the neural basis of perception. Arousal states, reflected by pupil diameter, exert continuous influence on the neocortex, impacting membrane potentials, cortical state, neuronal gain, and sensory processing. We hypothesized that pupil-linked arousal states would have a diverse influence on the cortex as stimulus encoding recruits an array of distinct cell types that span the cortical lamina (i.e., intratelencephalic (IT), extratelencephalic (ET), and corticothalamic (CT) cells). To decipher the role of arousal on sensory coding, we investigated the response properties of these populations in the auditory cortex (ACtx) using two-photon calcium imaging and full-face videography in awake mice. We first inspected the response strength to pure tone stimuli of layer (L) 2/3, L5 IT, ET, and CT cells. Increases in arousal enhanced the activity in all cell populations except L5 IT cells. Reliability analysis revealed that ET and CT activity is most reliable (less variable) when pupil is large, while L2/3 and L5 IT cells exhibited consistent reliability across arousal states. To compare excitability at high and low states, we calculated a modulation index for every cell. Values of this index closer to -1 implies higher responses at low states respective to high states, whereas values closer to +1 indicates the opposite effect. L5 IT cells had the highest variability and lowest mean modulation index, whereas ET cells displayed the lowest variability and highest mean modulation index. These findings illustrate a modulation motif in ET cells whereby an increase in activity coincide with heightened alertness. To explore the effects of arousal on spontaneous and evoked activity, we employed a multivariate regression model to predict a cell's activity on a given trial based on pupil diameter and its neural response (Schwartz et al., 2020). Our analysis revealed heterogeneity in how pupil size correlates with baseline and sound-evoked activity, encompassing both suppression and enhancement effects. Notably, L5 IT cells demonstrated a more uniform distribution of pupil effects compared to other populations. We also presented broadband noise to examine shared trial-to-trial response variability and found that higher states coincided with a decrease in shared variability in these cell types. This suggests that wakefulness alters correlated neural activity uniformly, highlighting the role of arousal in shaping functional connectivity. Collectively, our findings provide key

insights into the intricate relationship between arousal and cell-type-specific activity during sensory coding.

Title: The dorsal cortex of the mouse inferior colliculus processes the Spectrotemporal features of sound through novel cellular organizations that are dynamically modulated by sound intensity.

Authors: *B. A. IBRAHIM, Y. SHINAGAWA, A. DOUGLAS, G. XIAO, A. R. ASILADOR, D. A. LLANO;
Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: The inferior colliculus (IC) is an information processing hub that receives widespread convergent auditory projections. While the dorsal cortex (DC) - the non-lemniscal division of the IC- receives major auditory cortical projections, some reports showed that the DC is a tonotopic structure, which indicates the structure's ability to integrate the basic spectral features of sound to process the complex auditory information. However, it is unclear if the DC has another level of mapping to integrate the different spectral and temporal features of complex sounds across different sound levels. Therefore, the two-photon imaging of the calcium signals was used to track the neuronal response of the DC to sounds of different degrees of spectral and temporal complexity such as pure tones (PT), amplitude unmodulated (UN), and modulated (MN) broadband noise. In addition to the tonotopic map, the DC showed a periodtopic organization where the cells of a medial rostrocaudal area were best tuned to UN separating medial and lateral regions where the cells were best tuned to MN. Analyzing the neuronal response to each tested sound was used to generate spectral and temporal indices for each neuron, which were then used to map the DC based on the dynamics of the neuronal responses across different sound amplitudes. The DC showed a cellular organization that mapped the DC surface into two main regions: dorsomedial (DMC) and dorsolateral (DLC) cortices. At the lowest tested sound level (40 dB SPL), the DMC was more responsive to simple tones (i.e. PT) and less responsive to complex sounds (i.e. UN and MN) compared to the DLC. Although increasing the sound level increased the percentage of responsive cells in both DMC and DLC, it dynamically modulated the cells of the DMC to be more responsive mostly to UN without changing the response profile of the DLC. These data suggest that the DC is mapped to process the different spectrotemporal

features of sound based on the sound intensity to probably enhance the segregation of different sound sources.

Title: Neural correlates of auditory category learning of FM sweeps in the mouse auditory cortex

Authors: *O. YUDCO[1], L. FEIGIN[2], I. MAOR[2], A. MIZRAHI[2];
[1]Life science, [2]ELSC, Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Category learning is a fundamental brain process that enables quick and accurate response to novel stimuli in complex sensory scenes. In the auditory modality, category learning underlies many processes of sound perception, such as understanding of language in humans. While the learning process has been shown to be accompanied by changes in neuronal representation, its underlying mechanisms are not yet clear. Using an automated learning platform, we trained female mice (n = 22) to discriminate between two categories: rising frequency modulated (FM) sweeps and falling FM sweeps. At the end of training, we presented mice with novel stimuli in order to decipher the learned categorization rule and found that they the used frequency content of the sweep as the categorical boundary cue, rather than the slope of the sweep. Using the multiarray silicon probe, Neuropixels, we performed electrophysiological recordings from the auditory cortex of awake mice (n = 9 experts, n = 4 naïve) while listening passively to FM sweeps and pure tones. We acquired data from primary auditory cortex (AUDp, n = 389 neurons) and the auditory temporal association cortex (TeA, n = 91 neurons) and found that more neurons of expert mice prefer the frequency of the category boundary as compared to naïve mice. Furthermore, neurons of expert mice as well their population activity have higher discriminability between sets of both FM sweeps and pure tones. Our results show that the plastic changes in neuronal discriminability of sounds by neurons in the auditory cortex correspond to the behavioural strategy used by the mice to categorize sounds.

Title: Exogenous BDNF application alters ionic currents in a spatial and temporal manner in the avian auditory brainstem

Authors: *K. MCLELLAN[1], M. TAKAHASHI[1], H. HONG[2], G. ORDIWAY[1], J. T. SANCHEZ[1];

Abstract: Neurotrophins are growth factor proteins that mediate normal neuronal development by using spatial and temporal signaling gradients. While neurotrophins are critical for peripheral auditory development, it is unknown how they affect the functionality of central auditory structures. The chicken nucleus magnocellularis (NM), an analogous brainstem structure to the mammalian anteroventral cochlear nucleus, provides a model system where neurotrophin signaling between brain-derived neurotrophic factor (BDNF) and its high-affinity tyrosine receptor kinase B (TrkB) is temporally and spatially regulated. Not only is it unknown how auditory brainstem neurons within NM respond to BDNF-TrkB signaling, but it is unclear whether neurotrophins affect NM in a tonotopically or developmentally distinct manner. To investigate this, we exogenously applied BDNF on NM neurons *ex vivo* and studied the neurons' intrinsic properties using whole-cell patch clamp electrophysiology. BDNF application significantly reduced outward potassium currents and increased aberrant neuronal excitability for NM neurons earlier in development, when TrkB expression is relatively high. Additionally, high frequency NM neurons at this early developmental stage exhibited stronger changes to their intrinsic properties compared to low-frequency neurons. Little to no changes were seen to mature NM neurons, which express virtually no TrkB receptor at this stage in development. This demonstrates that BDNF-TrkB signaling causes neuronal alterations within the auditory brainstem that likely promote the normal development of a mature auditory system. Elucidating the effects of exogenous neurotrophins on the auditory system is not only an essential step to infer the effects of neurotrophins *in vivo*, but it has vital consequences for the use of neurotrophins as therapeutics for auditory-related disorders.

Title: Investigating how neurons invariantly encode pitch derived from two types of acoustic cues

Authors: *V. TARKA[1], Q. GAUCHER[2], K. WALKER[3];
[1]Physiology, Anat. and Genet., Oxford Univ., Oxford, United Kingdom; [2]CNRS, UMR CNPS 8195, CNRS, UMR CNPS 8195, Orsay, France; [3]Univ. of Oxford, Oxford, United Kingdom

Abstract: Pitch is our perception of the tonal quality of sound. It is the basis of musical melody and plays a key role in communication and sound segmentation. The pitch is perceived at a single fundamental frequency (F0), which can be derived for a complex sound from either the regular spacing of harmonics in the frequency domain, the repetition rate of the sound's waveform in time, or a combination of these features. Studies in marmosets have described specialized neurons located within a "pitch centre" in auditory cortex that encode F0 invariantly to other spectral changes, but there has not been clear evidence for such specialized pitch neurons in other species. We performed Neuropixels recordings of single neurons in the auditory cortex of 4 anaesthetized ferrets while presenting a variety of pitch-evoking sounds across a range of F0s (0.25-4 kHz). We found that some neurons derived F0 exclusively from resolved harmonics, while others from temporal periodicity. A further subset of neurons encoded F0 invariantly across both classes of pitch cues, which may be the first evidence for specialized "pitch neurons" in non-primates. These neurons were not confined to a localized pitch centre, as in the marmoset, but were instead distributed throughout primary auditory cortex (A1 and AAF). F0 tuning in these neurons was robust across many complex sounds but usually failed to extend to the frequency of pure tones. This suggests some auditory cortical neurons may be specialized to represent the pitch of complex sounds, and these may differ from neurons that represent the frequency of pure tones.

Title: Contextual modulation is a stable feature of the neural code in auditory cortex of awake mice

Authors: M. AKRITAS[1], A. G. ARMSTRONG[1], J. M. LEBERT[1], A. F. MEYER[2], M. SAHANI[3], *J. F. LINDEN[1,4];
[1]Ear Inst., [2]Sainsbury Wellcome Ctr., [3]Gatsby Computat. Neurosci. Unit, [4]Dept. of Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: The perceptual salience of a sound depends on the acoustic context in which it appears. Single-neuron correlates of this contextual sensitivity can be estimated from neuronal responses to complex sounds using the nonlinear-linear "context model" (Williamson et al. 2016 Neuron). Context models provide estimates of both the principal (spectrotemporal) receptive field of a neuron and a "contextual gain field" describing its nonlinear sensitivity to combinations of sound input. Previous studies of contextual gain fields in auditory cortex of anesthetized mice revealed strong neuron-specific patterns of nonlinear sensitivity to sound combinations. However, the stability of these patterns over time, especially in awake animals, is unknown. We recorded electrophysiological activity of neurons in auditory cortex of awake mice over many days using chronically implanted tetrode arrays. Concurrently we recorded locomotor activity and pupil diameter to measure behavioural state. Repeated recordings were made at each recording site across at least five days, during presentations of prolonged complex sounds (dynamic random chord stimuli). We used spike-waveform matching to identify the same units recorded on different days, and the context model to estimate principal receptive fields and contextual gain fields for each neuron in each recording session. We then quantified the stability of these fields both within and across days. We also examined the dependence of context model fits on measures of behavioral state. Contextual gain fields of auditory cortical neurons in awake mice were remarkably stable across many days of recording. In more than 90% of the 69 neurons tracked for multiple days, neuron-specific patterns of sound combination sensitivity (and spectrotemporal sensitivity) remained stable on a timescale that matched or substantially exceeded the typical five-day range of our measurements. Interestingly, there were small but significant effects of changes in locomotion or pupil size on the ability of the context model to fit temporal fluctuations in the neuronal response. We conclude that contextual sensitivity is an integral and stable feature of the neural code in the awake auditory cortex, which may be modulated by behavioral state.

Title: Early acoustic experience degrades rhythm perception of rats

Authors: Y. SUN, ***Y. ZHANG**;
East China Normal Univ., Shanghai, China

Abstract: Objective The early postnatal brain exhibits a high degree of plasticity, which facilitates its rapid structural and functional development in responding to multimodal sensory inputs. However, this plasticity also makes the developing brain vulnerable to atypical sensory experiences during early postnatal stages, leading to more pronounced degradation of higher-order brain functions such as learning & memory, reading comprehension, and social interaction in adulthood. How these atypical early sensory experiences might affect the communication-related function remains largely unstudied. **Methods** Our previous work has revealed the synaptic plasticity mechanism underlying the impact of early sensory experiences on spatial learning and memory (Proc Natl Acad Sci U S A. 2021 Jan 7;118(1):e2017841117. doi: 10.1073/pnas.2017841117.). In the present study, we investigated the impact of early acoustic experience on rhythmic perception, which plays a crucial role in vocal communication and speech, by using rat as a research model. In vivo whole-cell patch-clamp was used to investigate millisecond level changes in post-synaptic currents in auditory cortex neurons during rhythm perception. **Results** Early acoustic stimulation interfered with the development of inhibitory interneurons in the microcircuit of the rat auditory cortex, which in turn disrupted the temporal balance of excitatory-inhibitory postsynaptic currents induced in cortical pyramidal neurons, leading to degradation of the phase-locking ability of pyramidal neurons in responding to repetitive stimuli and ultimately to degradation of rhythm perception in behavior. **Conclusion** These results in rodent model provide evidence that tiny millisecond-level changes in excitatory-inhibitory integration of cortical synaptic networks caused by early acoustic experiences are sufficient to degrade the rhythm perception in adult individuals.

Title: Investigating the neuronal response of the auditory thalamus

Authors: *B. KIM, H. JEONG, E. CHEONG;
Dept. of biotechnology, Yonsei Univ., Seoul, Korea, Republic of

Abstract: The ability to process a wide array of auditory information is crucial for the animals as it directly relates to survival in an environment filled with diverse sound stimuli. One of the main components of the auditory pathway is the lemniscal pathway, which transmits sound information originating from the cochlear to the primary auditory cortex (A1). This transfer of sound stimuli involves sequential passage through various structures including the cochlear nucleus, superior olivary complex, inferior colliculus (IC), and medial geniculate nucleus of the thalamus (MGN). Neurons within these structures are known to display a tonotopic arrangement, where their spatial distribution correlates with responsiveness to specific frequencies. Interestingly, some of the A1 neurons also demonstrate response towards diverse characteristics of sound, such as timing and frequency change gradients. Ventral MGN, one of the components of the lemniscal pathway, receives inputs from central nucleus of IC, both of which exhibit this tonotopic arrangement. However, our understanding of the neuronal responsiveness of auditory thalamus in living animals remains incomplete. In this study, we fill this gap by presenting the activity of MGv neurons of living mice by the extracellular single-unit recordings *in vivo* using Neuropixels probes.

Abstract: Temporal dynamics of functional brain activity during processing of different auditory and linguistic components are not well characterized. To better understand the neural language processing, it is important to investigate the effect of different types of auditory stimuli on the patterns of propagation of cortical activations. We studied ECoG gamma-band modulations induced by different auditory tasks. Five subjects (two females and three males, age 34~64 years) with left temporal lobe glioma underwent resection involving awake language mapping, using a 4x8 ECoG electrode grid with 1cm pitch. Tasks included verbally responding to single word vs tone categorization (stimulus duration 300~500ms), and sentence level auditory naming

(AN) task (stimulus duration > 1s). High gamma-band (50~300Hz) modulations in superior and middle temporal gyri (STG, MTG) were induced by words and tones across all subjects, with distinct spatio-temporal patterns for each stimuli type. Both types of stimuli induced modulations as early as 100~200ms post stimuli-onset, word-induced modulations lasted longer (> 500ms) compared to tone. Word-induced modulations propagated from posterior to anterior temporal lobe, had larger spatial spread and late (> 200ms post onset) activated regions in the posterior MTG, compared to tone-induced posterior modulations. This indicates the association of anterior temporal regions with semantic processing. Spatio-temporal pattern of cortical modulations by word stimuli and the AN task were similar. This study shows that neural processing of auditory stimuli with and without linguistic components differs in activated cortical regions as well as in temporal dynamics.

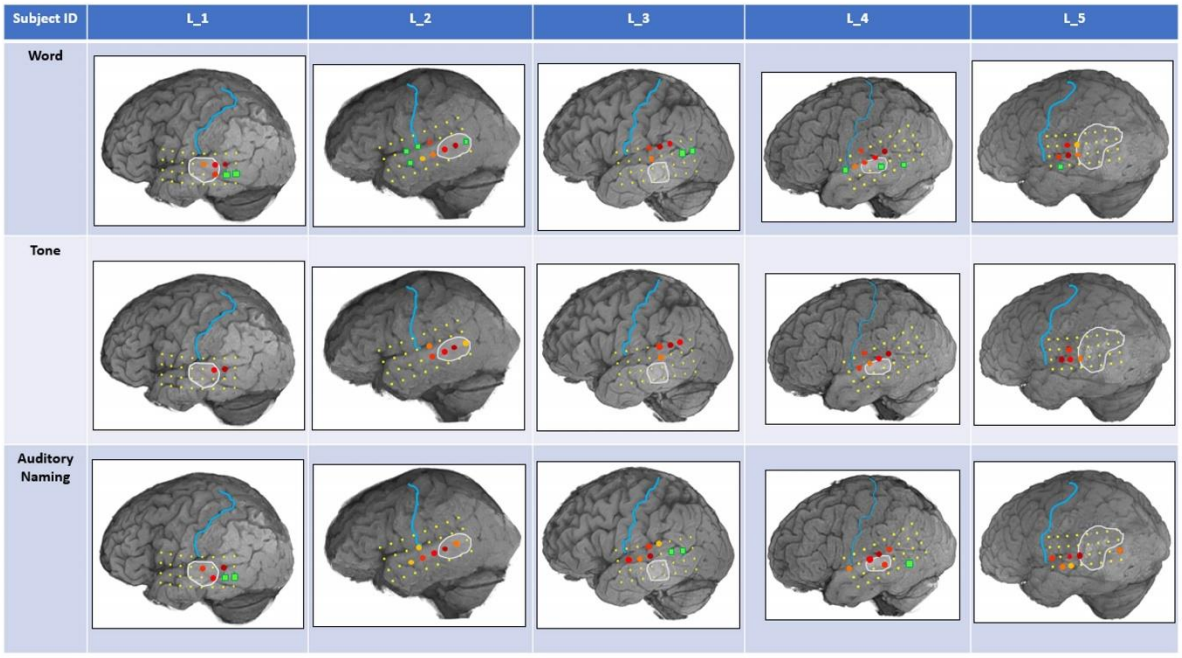

Figure: ECoG high-gamma band (50~300Hz) activation profile induced during different auditory processing tasks, across five subjects. 3D cortical brain mesh from patient-specific pre-operative MRI scans, tumor regions (grey curve) and central sulcus (cyan) are marked. Electrode contacts (small yellow dots), task-specific high-gamma modulated contacts (larger circles; signal propagation denoted by color gradient: from red to orange) and late activated contacts (green squares) are also marked.

Title: Evidence for parallel processing of temporal and spatial information in the primate auditory cortex at single neuron resolution in a behaving macaque monkey

Authors: *D. LU, J. S. JOHNSON, K. L. SISSON, M. STROUD, K. NEVERKOVEC, K. STEWART, J. ROBERTS, G. H. RECANZONE;
Univ. of California, Davis, Davis, CA

Abstract: Auditory cortical processing in primates has been proposed to be divided into at least two parallel processing streams, a caudal spatial stream and a rostral non-spatial stream. Whereas functional imaging studies in humans have supported this hypothesis, few studies have investigated neural processing at the single-cell level in the auditory cortex of nonhuman primates. Therefore, we recorded single neurons from auditory cortex while an adult male macaque monkey was performing a two-alternative forced choice task to discriminate either the modulation frequency or the spatial location of a broadband amplitude-modulated noise on alternating blocks of trials. Stimuli were 500ms duration, 65 dB SPL, 100% modulation depth broadband noise presented from 90 - 170 degrees approximately 1 m from the center of the monkey's head. The macaque was trained to initiate a trial by moving a joystick to the left. The first stimulus (S1) was modulated at either 17 or 34 Hz, presented from 130 degrees, followed by the second stimulus (S2) 500 ms after the offset of the S1. In the temporal task, the modulation frequency of the S2 varied from the S1 by +/- 1 octave in 7 equal octave steps, and it was presented from the same speaker as S1. For the spatial task, the same stimulus as the S1 was presented from +/- 40 degrees in 8 degree steps. The monkey was required to move the joystick in one of two directions to indicate that it perceived the S2 as either at a higher or lower rate than the S1 in the temporal task, or to the left or right of the S1 in the spatial task. We recorded single neuron activity from the contralateral primary auditory cortex (A1; n = 113), the caudolateral field (CL; n = 19), the caudomedial field (CM; n = 49) and the rostral field (R; n = 113). We calculated the firing rate (FR) and the vector strength (VS) of each neuron from 70-500 ms from each S2 onset. We also calculated the linear regression of each neuron across S2 stimuli for both the temporal and spatial tasks for both FR and VS. Finally, we calculated the dynamic range, defined as: (max-min)/(max+min) across S2 stimuli in each task. In the temporal task, we found that neurons in all four areas had equivalent FR tuning. However, based on the VS, neurons in area R had the best tuning and those of CL the worst. In the spatial task, neurons in area CL had the best FR tuning with the other three areas having equivalently worse tuning. Tuning based on the VS was equivalent across neurons in all four areas. These results provide good evidence in support of parallel processing of temporal and spatial information in the primate auditory cortex at the single neuron level.

Title: Flexible tracking of rhythmic acoustic streams in parallel thalamocortical circuits

Authors: C. A. MACKEY[1], A. BARCZAK[1], S. NEYMOTIN[1], K. MACKIN[1], T. M. MCGINNIS[1], T. A. HACKETT[2], P. LAKATOS[1], C. E. SCHROEDER[3], *M. O'CONNELL[4,1]; [1]Nathan Kline Inst., Orangeburg, NY; [2]Hearing & Speech Sciences, Psychology, Vanderbilt Univ., NASHVILLE, TN; [3]Nathan Kline Inst. - Translational Neurosci. Div., Columbia Univ. Col. of Physicians and Surgeons, Orangeburg, NY; [4]Nathan S Kline Inst., Orangeburg, NY

Abstract: The natural world is replete with acoustic signals displaying varying degrees of periodicity, such as speech. The auditory system's ability to track periodicity via oscillatory entrainment of the local field potential (LFP) has been well documented in humans and nonhuman animals, with animal models providing critical insight into the laminar circuitry involved. However, animal studies typically use periodic stimuli, while natural stimuli such as speech are "quasi"-periodic; and humans readily comprehend time-compressed speech. Tolerance for quasi-periodicity and time compression suggest speech processing is highly flexible, however, much remains to be discovered about the underlying circuitry. Our previous work suggests that distinct cortical layers, and their thalamic inputs, play different roles in the entrainment process. "Matrix" (nonlemniscal) thalamic inputs targeting supragranular layers provide a modulatory influence on the processing of narrowly tuned information that is conveyed to the granular layer from the "core" (lemniscal) thalamus. This leads us to hypothesize that tracking of more naturalistic, quasi-rhythmic auditory stimulus streams may differ across core and matrix thalamocortical circuits. To test this hypothesis, we evaluated the degree to which neuronal activity in macaque primary auditory cortex (A1) and medial geniculate body (MGB) tracks or entrains to 40 dB SPL band-pass noise that was progressively jittered around presentation rates (1.6 Hz, Delta; 6 Hz, Theta; 11 Hz, Alpha). We analyzed LFPs (via current source density for cortex, and bipolar field potential for thalamus) and multi-unit activity. Entrainment was quantified using intertrial coherence (ITC), measuring the consistency of LFP phase across trials. For each recording site, ITC was used to estimate entrainment's "tolerance for" or robustness to jitter and its flexibility across different repetition rates. Across core and matrix circuits, entrainment decreased as jitter increased, and the tolerance for jitter decreased as presentation rate increased. The supragranular layers of A1 exhibited greater flexibility than the granular and infragranular layers in that their entrainment suffered less from increasing presentation rate. Consistent with this, at the highest presentation rate (11 Hz), matrix MGB exhibited greater tolerance for jitter than core MGB. These results suggest that parallel core and matrix thalamocortical circuits may have different roles in tracking patterns present in natural sounds. Future analyses will incorporate spiking activity and modulatory influences, like attention and eye movements.

Title: Orbitofrontal cortex shapes auditory cortical and perceptual sensitivity

Authors: *M. MACEDO-LIMA, L. S. HAMLETTE, M. L. CARAS;
Biol., Univ. of Maryland Col. Park, College Park, MD

Abstract: Sensory acuity can benefit from practice, through which we can improve our ability to see, hear, smell, and taste - a process termed perceptual learning. In the auditory system, perceptual learning supports the development of speech and musicality and improves speech recognition in the hearing-impaired. Non-sensory processes, like attention or reward, make critical contributions to perceptual learning, but the neural circuits and mechanisms that mediate their involvement are poorly understood. The orbitofrontal cortex (OFC) has well-established roles in signaling reinforcement and in transmitting state-dependent feedback via direct projections to auditory cortex. We hypothesized that OFC neurons provide non-sensory input to the auditory cortex that supports auditory perception and perceptual learning. If OFC transmits a non-sensory signal to the auditory cortex that shapes auditory cortical sensitivity and perception, then silencing OFC activity should disrupt auditory cortical sensitivity and impair behavioral sound detection. To test this prediction, we used muscimol (a GABAa agonist) to inactivate bilateral OFC, and simultaneously recorded extracellular responses from auditory cortical neurons in freely moving Mongolian gerbils of both sexes as they performed an amplitude modulation (AM) detection task. We found that inactivation of bilateral OFC significantly impaired both behavioral and neural AM detection. Next, we asked whether OFC neurons exhibited learning-related changes in activity by using chronically implanted electrode arrays to record from OFC neurons as gerbils trained on an auditory perceptual learning task with progressively more challenging AM stimuli. We found that the firing rates of OFC neurons gradually increased and correlated with the degree to which perceptual thresholds improved. To determine whether learning affected the specific subpopulation of OFC neurons that innervate the auditory cortex, we used fiber photometry to record calcium signals from just the OFC neurons that project to the auditory cortex as gerbils underwent auditory perceptual learning on the same task. We found that calcium signals in these cells grew larger as perceptual thresholds improved, suggesting that OFC neurons send progressively stronger signals to auditory cortex

over the course of perceptual learning. Our results support the hypothesis that the OFC facilitates practice-dependent improvements in perceptual and auditory cortical sensitivity via a direct projection to auditory cortex.

Title: Neural representation of auditory stimuli in misophonia tracks with subthreshold autistic phenotype

Authors: *A. AK[1], J. E. NORRIS[1], S. H. KIMBALL[2], L. E. ETHRIDGE[1,3];
[1]Dept. of Psychology, Univ. of Oklahoma, Norman, OK; [2]Dept. of Communication Sci. and Disorders, [3]Dept. of Pediatrics, Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Misophonia is a disorder in which one or more specific auditory stimuli cause an extreme emotional response. Individuals with misophonia may present with sensory symptoms similar to those below the threshold for autism spectrum disorder (ASD), where symptom severity of ASD-like symptoms may track across the entire spectrum. Thirty-seven undergraduate students (18-22; M age = 18.89, SD = 0.99, 19 individuals with misophonia, 18 individuals without misophonia) from the University of Oklahoma completed a self-report spectrum characteristics survey indexing misophonia and the broad autism phenotype questionnaire (BAPQ). They also completed an audiology workup and participated in five tasks while undergoing 128 channel electroencephalography (EEG). The current study reports on results from the auditory chirp (white noise amplitude modulated by a sinusoid linearly increasing in frequency from 0 to 100 Hz over 2000ms) EEG task. Changes in neural responses to the chirp stimulus have been found in individuals with ASD and related developmental disorders. Misophonic individuals self-reported significantly increased autistic traits across all BAPQ sub-scales compared to controls: aloof: $t(34) = -2.23$, $p = .033$, d = -.74; pragmatic language: $t(34) = -2.25$, $p = .031$, d = -.75; rigid: $t(34) = -2.90$, $p = .007$, d = -.97. Additionally, a significant correlation was found between misophonia symptoms severity from audiology and the rigid subscale score (r = .33, $p = .048$). Log transformed phase-locking in the low gamma frequency range to the chirp stimulus was marginally lower for the misophonia group compared to controls, t(34)= 1.97, p=.058, d=.66. Log-transformed phase locking in the high gamma frequency range was significantly correlated across groups with increased autistic traits for both pragmatic language (r = .35, $p = .045$) and aloof (r = .36, $p = .035$) subscale scores. Individuals with misophonia exhibit a subthreshold autistic phenotype which shares a complex relationship with sensory processing-related neural activity in the gamma range. Reductions in

low gamma phase-locking to the chirp stimulus reflect an auditory phenotype similar to that found in ASD and related developmental disorders, which may reflect shared biology.

Title: Increased interactions between harmonic-neurons & broadly-tuned neurons contributes to the increased selectivity to more spectrally complex stimuli in L2/3 of mouse secondary auditory cortex

Authors: *Y. CHEN, P. O. KANOLD;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Harmonics, universally found in vocalization, plays a vital role in daily life of human and other species to perceive their surroundings. Harmonics can be composed of one or more frequencies that are integer multiples of a fundamental frequency. Higher order auditory cortical areas such as L2/3 of secondary auditory cortex (A2) are thought to be preferentially activated by vocalizations and artificial harmonics complexes. Sound evoked responses emerge in the primary auditory cortex (A1) and A1 L2/3 neurons can already be highly selective to features of vocalizations. Since a transformation of the neural representation of sound features occurs between A1 L4 and A1 L2/3, the selectivity for vocalization features might emerge in a hierarchical manner between A1 L4 and A2. Here we use in vivo two photon calcium imaging to image L2/3 and L4 of A1 and L2/3 A2 of CBA;thy1GCaMP6s transgenic mice to study the neural representation of simple and complex harmonics in terms of number of components, and to identify differences of neural representations in A1 L4, A1 L2/3, and A2 L2/3. We find that neurons responding to only harmonics are present in both A1 and A2. However, while A1 shows a similar fraction of neurons responding to harmonic sounds with one or more components, A2 shows higher fraction of responding neurons when more complex harmonics are presented. These results indicate a progressively increasing selectivity for more spectrally complex stimuli from A1 to A2. Imaged neurons are grouped based on their response to sounds into: HN (only harmonics), PTN (only pure tones), and HPTN (harmonics and pure tone components). Most of HPTNs respond to multiple harmonic sounds and their pure tone components, which indicates HPTNs are more broadly tuned. We found neurons of all categories in A1 and A2. To identify differences in functional connectivity between cell categories between areas, we calculated noise correlations. Noise correlations in HN-HN neuron pairs between harmonic and pure tone conditions in A1 and A2 are similar, indicating that intra-group communication among HNs

might not be necessary for A2 to construct its selectivity. In contrast, inter-group interaction of HN-HPTN in A2 L2/3 has significantly increased noise correlation to two-tone harmonic which is sustained in ten-tone harmonic compared to pure tone. A1 L2/3 shows significantly decreased HN-HPTN noise correlation only to ten-tone harmonic but not to two-tone harmonic. A1 L4 shows no significant difference in all three conditions mentioned above. These results suggest that A2 contains specific functional connectivity that might contribute to the high selectivity to more spectrally complex auditory stimuli.

Title: Specializations of bat auditory cortex for processing echoes arriving at different delays.

Authors: *S. MACIAS HERRERA[1], M. SMOTHERMAN[2];
[1]Virginia Tech., Blacksburg, VA; [2]Texas A&M Univ., College Station, TX

Abstract: The bat auditory system follows the standard mammalian plan, but many specializations have been uncovered that appear uniquely tailored to support echolocation. However, it still remains uncertain which, if any, neurophysiological specializations are truly unique to echolocation. The question is important because it defines the extent to which bats may serve as general models of auditory processing, and it points toward which elements are critical for biosonar processing. One of their most unique neurophysiological features is the presence of neurons sensitive to the time delay between the outgoing pulse and returning echo. These delay-tuned neurons are found in the auditory cortex of all bats, but their neuroanatomical distribution is distinctly different in FM-type bats compared to CF-type and neotropical fruit bats. In FM bats, delay-tuned neurons are sprinkled throughout the primary auditory cortex rather than comprising their own auditory subfield, suggesting they might do more than just target ranging. We hypothesized that delay-tuned neurons might dynamically modulate the neural substrate to match changing pulse acoustics for targets at different distances. Results supported the hypothesis by showing that activation of delay-tuned neurons was directly correlated with concomitant changes in the frequency-tuning properties of nearby neighboring neurons.

Title: Encoding of musical features during naturalistic listening: an intracranial EEG study

Authors: *A. J. BILLIG[1], A. E. RHONE[2], K. V. NOURSKI[2], D. GRAY[1], J. I. BERGER[2], C. M. GARCIA[2], C. K. KOVACH[2], C. I. PETKOV[2], B. J. DLOUHY[2], H. KAWASAKI[2], M. A. HOWARD III[2], T. D. GRIFFITHS[3], M. STEINSCHNEIDER[4];

Abstract: Music is present in all human cultures, can evoke powerful emotional responses, and has potential in a range of therapeutic settings. Neural transformations from acoustic to higher-order representations possibly underlying these effects during naturalistic listening have rarely been studied with high spatiotemporal resolution. We used techniques from continuous speech modelling (Broderick et al, J Neurosci 2019 39:7564-75) to examine the contribution of different acoustic and musical features to responses throughout the human brain. Participants were 55 patients undergoing pre-surgical intracranial electroencephalography (iEEG) monitoring for epilepsy using cortical grids and depth electrodes. They listened passively to at least three pieces of Western classical and popular music. Following a study in mice (Martorell et al, Cell 2019 177:256-271), which found that 40 Hz click trains entrained hippocampal unit firing and reduced Alzheimer's disease-like pathology, we also presented a subset of participants with a 40 Hz sinusoidally amplitude-modulated version of one musical piece. Multivariate temporal response functions were derived from the iEEG data, relating the 1-8 Hz bandpass-filtered neural signal at lags of 0-600 ms to acoustic and musical stimulus features (envelope, rectified envelope derivative, spectrogram, key clarity and stability). Cross-validated prediction accuracies were tested against results from a null distribution obtained by permuting stimulus information. Stimulus envelope most strongly predicted responses in core auditory cortex within posteromedial Heschl's gyrus, with peaks in the temporal response function within 100 ms. In a subset of envelope-following sites at mostly superior temporal locations, the inclusion of onset and spectral information in the model explained additional response variance. Higher-level musical features (key clarity and stability) were most strongly represented at more anterior and medial temporal sites, including temporal pole, parahippocampal gyrus, and hippocampus. Encoding of these features was maximal at lags greater than 300 ms. For amplitude-modulated stimuli, 40 Hz iEEG power increased at widely distributed sites, and in the small number of participants with single unit data, firing in auditory cortex but not hippocampus aligned to particular phases of the 40 Hz cycle. Further unit data are being collected, while ongoing analysis extends the modelling to other neural frequency bands and examines effects of musical familiarity on response latency and connectivity between auditory and memory circuits.

Title: Neural tracking of speech and song is predicted by subjective ratings of rhythmic regularity

Authors: *C. M. V. B. DER NEDERLANDEN;
Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Rhythm is a key feature in communicative interactions, especially for vocal communication through speech and song. However, the way that rhythm unfolds in speech and song differs, where onsets in song occur on the beat and at integer multiples of the beat but not in speech. A large body of work characterizes how the brain tracks speech rhythms at the syllable rate (theta, 4-8 Hz), but how do the regular rhythms of song affect neural tracking of syllables when they are sung and spoken? In this jack-knifed reanalysis of MEG neural tracking data for speech and song (32 participants, 384 trials), independent subjective ratings of rhythmic regularity (51 participants, 96 trials) for each stimulus predict the degree of neural tracking (cerebro-acoustic phase coherence). Rhythmic regularity and pulse clarity predict unique variance in neural tracking, even when stimulus type (speech or song) is included in the model, suggesting that rhythmic regularity for speech and song drives neural tracking. Results will be discussed in the context of how the regular rhythmic features of song could be used to facilitate learning and memory.

Abstract: Individual differences in behavior and cognition have been shown to be reflected in variability of functional connectivity. High individual variability may be one of the major factors why a widely accepted model of the human auditory cortex (AC), analogous to that in non-human primates, is still lacking. Due to the lack of a robust strategy for individual-level analysis, most neuroimaging studies on human AC have focused on group-level analyses to identify central tendencies that represent the typical brain. Another major challenge has been that the spatial resolution of the noninvasive neuroimaging methods is insufficient to localize small subareas of AC, many of which encompass only a few conventionally sized functional magnetic resonance imaging (fMRI) voxels. To overcome these challenges, we applied a novel highly reliable functional network parcellation strategy to localize fine-grained functional subareas of AC in individuals based on ultra-high-resolution data acquired by 7T MRI (1 mm^2 voxel size, N =30). All participants took part in at least three two-hour sessions on different days. Two of the sessions included resting state measurements and the remaining sessions auditory and audiovisual localizer tasks. The subareas of superior temporal cortex (STC) in or near auditory areas showed high within-subject reproducibility between the resting state measurements (Dice's coefficient: left: 0.78, right: 0.78). At the same time, these STC subareas revealed substantial inter-subject variability (Dice's coefficient: left: 0.68, right: 0.69). As expected, the intrasubject similarity was significantly higher than the inter-subject similarity ($p<0.001$), demonstrating that our approach is not only highly reproducible within individuals but also reliably and robustly captures meaningful individual variability. The inter-subject variability was also larger in AC than in the rest of the brain (Dice's coefficient: left: 0.81, right: 0.81, $p<0.001$). The parcellation results were consistent with a tonotopy map and an audiovisual interaction map determined using a general linear model analysis from task-based localizer data. Our results demonstrate that AC can be reliably segmented into functional subareas that substantially vary across individuals.

Title: Effects of vesicular zinc signaling on parvalbumin interneurons in the mouse auditory cortex

Authors: *H. A. BOYD-PRATT[1], P. T. R. BENDER[2], C. T. ANDERSON[3];
[2]West Virginia Univ. - Neurosci. Grad. Program, [1]West Virginia Univ., Morgantown, WV;
[3]WVU Sch. of Med., Morgantown, WV

Abstract: Auditory processing in the auditory cortex relies on precisely organized circuits consisting of discrete inhibitory and excitatory neurons in different cortical layers. Parvalbumin (PV)-positive interneurons, the most common type of inhibitory neuron in the sensory cortex, provide inhibitory control of cortical function through their synaptic connections with local excitatory neurons.
ZnT3 is a zinc transporter protein that loads free zinc into glutamatergic vesicles where it is coreleased with glutamate and shapes the function of NMDA and AMPA receptors. This synaptic zinc is a powerful modulator of synaptic signaling and supports the processing of acoustic stimuli. Recently, research has uncovered cell-type and synapse-specific roles of synaptic zinc signaling, but the synaptic mechanisms by which vesicular zinc shapes the activity of inhibitory interneurons is not well understood.
Understanding the role of synaptic zinc and ZnT3 in specific excitatory-inhibitory circuits addresses a significant gap in our understanding of the mechanisms underlying the synaptic basis of inhibitory control crucial for precise acoustic encoding. We used optogenetic activation and simultaneous paired whole-cell patch-clamp electrophysiological recordings in acute brain slices from PV-Cre mice to determine the synapse-specific effects of synaptic zinc on excitatory-inhibitory microcircuits in the auditory cortex of mice.

Title: Trans-synaptic relationship between vesicular zinc and Shank3 supports dendritic spine structure and function

Authors: *A. MANNING, P. T. R. BENDER, H. BOYD-PRATT, M. HRUSKA, C. T. ANDERSON;
Neurosci., West Virginia Univ., Morgantown, WV

Abstract: Mutations in the gene that encodes for Src homology 3 and multiple ankyrin repeat domains protein 3 (Shank3) result in altered synaptic function and morphology. Shank3 is a synaptic scaffolding protein that assists in tethering and organizing proteins and glutamatergic receptors in the postsynaptic density of excitatory synapses, thereby supporting normal synaptic function. The localization of Shank3 to excitatory synapses and the formation of stable Shank3 sheets is regulated by the binding of zinc to the C-terminal sterile-alpha-motif (SAM) domain of Shank3. Disruptions of zinc in synapses that are enriched with Shank3 leads to a loss of postsynaptic proteins important for synaptic transmission, suggesting that zinc supports the localization of postsynaptic proteins via Shank3. The brain is highly enriched with free zinc inside glutamatergic vesicles at presynaptic terminals. Zinc transporter 3 (ZnT3) moves zinc into vesicles where it is co-released with glutamate. Alterations in ZnT3 are implicated in multiple neurodevelopmental disorders, and ZnT3 knock-out (KO) mice - which lack synaptic zinc - show behavioral deficits associated with autism spectrum disorder and schizophrenia. Here we show that ZnT3 KO mice have smaller dendritic spines and mini excitatory postsynaptic current amplitudes than WT mice. Additionally, spines with Shank3 are smaller in ZnT3 KO mice compared to WT mice, and synapses with both Shank3 and ZnT3 have larger spines in WT mice compared to synapses with only Shank3. Together these findings suggest a mechanism whereby presynaptic zinc supports normal postsynaptic structure and function via Shank3.

Title: Synaptic zinc potentiates AMPA receptor function in mouse auditory cortex

Authors: *P. T. R. BENDER, M. MCCOLLUM, H. BOYD-PRATT, B. Z. MENDELSON, C. T. ANDERSON;
Neurosci., West Virginia Univ., Morgantown, WV

Abstract: Synaptic zinc signaling modulates synaptic activity and is present in specific populations of cortical neurons, suggesting that synaptic zinc contributes to the diversity of intracortical synaptic microcircuits and their functional specificity. To understand the role of zinc signaling in the cortex, we performed whole-cell patch-clamp recordings from intratelencephalic (IT)-type neurons and pyramidal tract (PT)-type neurons in layer 5 of the mouse auditory cortex during optogenetic stimulation of specific classes of presynaptic neurons. Our results reveal that synaptic zinc potentiates AMPAR function in a synapse-specific manner. We performed in vivo 2-photon calcium imaging of the same classes of neurons in awake mice and found that changes in synaptic zinc can widen or narrow the sound-frequency tuning bandwidth of IT-type neurons, but only widen the tuning bandwidth of PT-type neurons. These results expand the known functions of synaptic zinc and reveal synapse- and cell-type specific actions of synaptic zinc in the cortex.

Title: Cell-type specific enhancement of deviance detection by synaptic zinc in mouse auditory cortex

Authors: *M. MCCOLLUM[1], A. MANNING[2], C. T. ANDERSON[3];
[1]West Virginia Univ., Morgantown, WV; [2]West Virginia Univ. Neurosci. Grad. Program, West Virginia Univ. - PhD in Neurosci., Morgantown, WV; [3]WVU Sch. of Med., Morgantown, WV

Abstract: A fundamental feature of sensory processing is the ability of animals to adapt to the current conditions in their environment yet maintain their ability to detect novelty in the same environment. A correlate of this ability is a robust neuronal phenomenon called stimulus-specific adaptation, in which a repeated stimulus will result in adaptation with smaller and smaller neuronal responses over time, but a deviant stimulus will still elicit larger robust responses from the same neurons. Recent work has established that synaptically released zinc is an endogenous mechanism that shapes neuronal responses to sounds in the auditory cortex. Here, to understand the contributions of cortical synaptic zinc to deviance detection of specific cortical neurons we performed wide field and 2-photon calcium imaging of multiple classes of cortical glutamatergic neurons. We find that intratelencephalic (IT) neurons in both layer 2/3 and layer 5 as well as extratelencephalic (ET) neurons in layer 5 all demonstrate deviance detection, however, we find a specific enhancement of this deviance detection in ET neurons that arises from ZnT3-dependent synaptic zinc from layer 2/3 IT neurons. Genetic deletion of ZnT3 from layer 2/3 IT neurons removes the enhancing effects of synaptic zinc on ET neuron deviance detection and also results in poorer acuity of detecting deviant sounds by behaving mice.

Title: Exploring the Role of Tonic GABA in Mouse Auditory Thalamus

Authors: *Y. CHO, E. CHEONG;
Yonsei Univ., 50, Yonsei-ro, Seodaemun-gu, Seoul, Korea, Republic of

Abstract: Sound perception is crucial for animals' survival, enabling them to localate and identify sound sources. The auditory pathway, beginning at the ear, culminating at the cortex, involves several critical stages. One of these stages includes the transmission of auditory signals through medial geniculate nucleus (MGN) in the thalamus, an important sensory relay station within the auditory thalamus, forwarding it to auditory cortex. The MGN itself is divided to three different subdivisions based on their anatomical location, MGv (ventral), MGd (dorsal), and MGm (medial). These subdivisions have unique connective inputs from inferior colliculus (IC), and each of the pathway reflects subdivision-specific connections from IC to MGN, and thus has different roles in auditory processing. MGv is responsible for primary sound representation, MGd is associated with secondary and more complex sound representation, and MGm is

responsible for multi-modal sensory processing. We previously reported that tonic GABA current in the thalamus plays a critical role in modulating sensory processing. However, the function of tonic inhibition in auditory processing, particularly within the MGN subdivisions, has not been fully understood yet. Thus we explore tonic GABA current in various MGN subdivisions via *ex vivo* electrophysiology.

Abstract: Identifying neural targets that control central auditory plasticity will have far-reaching impact, offering potential ways to restructure neural circuitry. Work from our lab and others have demonstrated that a group of cortical GABAergic neurons expressing vasoactive intestinal peptide (VIP) is important for sensory plasticity. Although many studies have leveraged the expression of VIP to genetically target this specific interneuron population, few have evaluated the function of the non-classical signaling molecule VIP in sensory processing and plasticity. We used a GPCR-Activation-Based (GRAB) peptide sensor and *in vivo* fiber photometry to study the release of VIP in mouse auditory cortex (ACtx) during passive sound presentation and associative auditory learning. Sound stimuli elicited VIP sensor responses in ACtx from a subset of mice. Furthermore, as mice learn to associate specific sounds with reward, VIP release may be modulated by the behavioral relevance of the sound stimuli. These experiments represent the first effort to study the *in vivo* release of VIP within sensory cortices. Parallel experiments are evaluating the postsynaptic effects of VIP release in ACtx. We first used *in situ* hybridization to quantify the expression levels of mRNA encoding the VIP receptor 1, *Vipr1*, across ACtx. Consistent with previous studies in other sensory cortices, we found that *Vipr1* is expressed

within 77% of excitatory pyramidal cells, marked by expression of vesicular glutamate transporter 1 (*Slc17a7*) and 18% of GABAergic neurons, marked by expression of the GABA synthesizing enzymes *Gad1* and *Gad2*. Ongoing studies are using *in vitro* electrophysiology to determine the functional postsynaptic effects of VIP receptor 1 activation. Together, these results may elucidate the effects of VIP within auditory cortical circuits, laying the necessary foundation for future loss- and gain-of-function experiments to evaluate the function of VIP release in auditory perception and learning.

Title: The two-pore potassium channel subunit Task5 regulates central auditory processing

Authors: *C. KÖRBER[1], H. SABER[2], M. KAISER[2], L. RÜTTIGER[3];
[1]Functional Neuroanatomy, Univ. Heidelberg, Heidelberg, Germany; [2]Heidelberg Univ., Heidelberg, Germany; [3]Univ. of Tübingen, Tübingen, Germany

Abstract: Processing of precisely timed auditory signals critically depends on the neuron's ability to fire brief action potentials (APs) at high frequencies and high fidelity for prolonged times. Many neurons perceiving information about the timing of signals fire a single AP at the be-ginning of the stimulus (onset firing), when stimulated in vitro. This firing pattern depends on brief APs as well as on the tight regulation of the neuronal excitability, which in turn de-pends on the expressed set of ion channels as well as the resting membrane potential (RMP). The RMP is determined by the ion channels open in the absence of an AP. Among these channels, two-pore potassium channels (K2P channels) play a key role as they contribute a large part of the potassium conductance at rest. The K2P subunit Task5 is expressed almost exclusively in the auditory brainstem nuclei. However, since it failed to form functional ion channels in heterologous expression systems, its function remined elusive. Here we show, using shRNA-mediated knock-down (KD) of Task5, that Task5 takes part in regulation of establishment of precisely timed, brief APs and onset firing pattern. Moreover, we demonstrate that Task5 knock-out (KO) mice show deficits in high frequency, high fidelity synaptic transmission at the endbulb of Held synapse in the cochlear nucleus of the auditory brainstem and in the processing of loud sounds.

Title: GluN2D-containing NMDA receptors enhance temporal integration in VIP neurons in the inferior colliculus

Authors: *A. C. DROTOS, Y. N. HERRERA, R. L. ZARB, M. T. ROBERTS;
Dept. of Otolaryngology, Univ. of Michigan, Ann Arbor, MI

Abstract: Along the ascending auditory pathway, there is a broad shift from temporal coding, which is common in the lower auditory brainstem, to rate coding, which predominates in auditory cortex. This temporal-to-rate transition is particularly prominent in the inferior colliculus (IC), the midbrain hub of the auditory system, but the mechanisms that govern how individual IC neurons integrate information across time remain largely unknown. However, previous work has suggested that NMDA receptors (NMDARs) may play a role in this transition. NMDA receptors are critical components of most glutamatergic circuits in the brain, and the diversity of NMDA receptor subtypes yields receptors with a variety of functions. Here, we report that mRNA for the *GluN2D* NMDAR subunit is widely expressed in the IC, which is unusual as this subunit is typically expressed only early in development. Additionally, GluN2D-containing NMDARs are relatively insensitive to voltage-dependent Mg^{2+} block, and thus can activate at resting membrane potential in the absence of AMPA receptor activation. By using whole-cell electrophysiology combined with optogenetics and pharmacology, we show that GluN2D-containing NMDARs are activated at resting membrane potential in some IC neurons via inputs from the anteroventral cochlear nucleus (AVCN) and via inputs from the contralateral IC through the IC commissure. GluN2D-containing NMDARs also have much slower kinetics than other NMDARs, and we found that GluN2D-containing NMDARs facilitate temporal summation for trains of optogenetic stimuli in IC neurons by prolonging the time window for synaptic integration. Currently, we are using a dynamic clamp to investigate how expression of different NMDAR subunits alters temporal summation. Our results suggest that GluN2C/D-containing NMDARs support the shift from temporal to rate coding in the auditory system by facilitating the integration of ascending inputs.

Title: Expression of Neurotrophins (BDNF and NT-3) and their Receptors Across Ageing Adult Human Cochleae

Authors: *A. MISHRA[1], T. G. JACOB[1], T. C. NAG[1], A. YADAV[2], T. S. ROY[3];
[1]Anat., [2]Forensic Med. and Toxicology, AIIMS New Delhi, New Delhi, India; [3]Anat., North DMC Med. Col. and Hindurao Hosp., New Delhi, India

Abstract: Background:
Over 5% of the world requires rehabilitation for sensorineural hearing loss. It encompasses pathologies of the inner ear and auditory nerve. SNHL's definitive management is cochlear implantation, contingent on the presence of an adequate number of spiral ganglion neurons (SGNs) and hair cells. Age-related degeneration of these cells is a limiting factor in cochlear implant efficacy. Neurotrophins are keystones for the development and differentiation of SGNs, alongside maintaining synapses with the organ of Corti. BDNF and NT-3 are expressed in mice, rats, and chick cochleae at different stages of life, the experimental absence of which leads to deafness. Exogenous delivery of neurotrophins promotes SGN survival in deafened animals, indicating their probable therapeutic use for increasing the efficacy of cochlear implants. Studies on neurotrophin expression in adult human cochleae are lacking.
Methods:
Post ethical clearance, twelve human temporal bones containing cochlea and auditory nerve were derived within 24 hours of death. Bones were fixed in 4% paraformaldehyde, decalcified with 10% EDTA for twelve weeks, cryoprotected, mounted, and sectioned at 40µm on a cryotome to obtain coronal sections of the cochlea. Cryosections were used for studying the expression of BDNF, NT-3, and their receptors using immunohistochemistry. Antigens were retrieved using heat shock in citrate buffer (0.01M, pH 6), blocked in normal serum, quenched in 5% hydrogen peroxide, and incubated in primary antisera followed by species-specific secondary antibodies. The avidin-biotin-peroxidase complex is used to amplify the signal. Antigen-antibody binding sites were visualized using 3,3-diaminobenzidine tetrahydrochloride.
Results:
BDNF and NT-3 expressed in SGNs and neuropil, showing membranous and cytoplasmic positivity. The apical layer of stria vascularis (SV) expressed distinct positivity among the three layers. SGNs expressed bipolar positivity for TrkB and TrkC. Entire SV stained positive for receptor proteins.
Conclusion:
It can be extrapolated that the apical layer of SV produces neurotrophins which act on cells

expressing TrkB/TrkC. Age-related changes concluded a random decline in older groups in this qualitative observational study.

Title: Transcriptomic and morphological markers of functional specialization in statoacoustic ganglion neurons of larval zebrafish

Authors: *S. SEMENOVA, G. MARGOLIN, H. BURGESS;
NICHD/Eunice Kennedy Shriver Nat'l Inst. of Child H, Rockville, MD

Abstract: Sensory neurons associated with the inner ear of zebrafish receive multiple types of acoustic and vestibular input. Precise transgenic targeting of subpopulations of statoacoustic ganglion (SAG) neurons will facilitate functional decoding of central pathways for auditory processing. Therefore, we analyzed morphological and transcriptomic diversity of statoacoustic ganglion neurons in 6-day post-fertilization (dpf) larval zebrafish with the goal of identifying transcriptomic markers of structurally and/or functionally distinct groups of sensory neurons. Sparse transgenic labeling and morphological reconstruction of 228 SAG neurons revealed a topographic arrangement of cell bodies, where anteroposterior positioning of the neurons in the SAG reproduced the positioning of target hair cell patches, the sources of sensory input in the inner ear. Clustering of neuron traces based solely on central axon morphology showed that neurons that received peripheral input of the same type also projected to similar central targets. For example, axons of neurons that receive input from hair cell patches of the cristae associated with the semicircular canals were morphologically distinct from axons of utricle- and saccule-projecting neurons. Neurons that received input from the saccule were divided into four morphological subtypes based on axon branch length and symmetry. Three of these subtypes targeted restricted areas of the hair cell patch and thus may be selective for specific types of saccular input. As we observed neuron subpopulations forming “tracts” to connect specific hair cell groups to distinct brainstem targets, we set the goal to identify transcriptomic markers of these subpopulations. Using SmartSeq, we performed deep single cell RNAseq from 226 manually isolated 6 dpf SAG neurons. As expected, when merged with transcriptomic data from mouse sensory neurons, SAG neurons co-clustered with vestibular ganglion rather than spiral ganglion neurons. The degree of developmental maturity was the major factor that shaped SAG neuron transcriptomes: neurons from a population enriched in cristae-projecting cells were assigned to a cluster with high expression of developmentally regulated transcription factor genes (such as isl1 and tlx2) at 6 dpf, consistent with the idea that cristae-projecting neurons

become fully functional at late larval stages. Transcriptomic data also established differences in calcium handling and radial axon growth in neuron subgroups. Thus, SAG neuron subpopulations with distinct central and peripheral targets express unique molecular markers, paving the way for functional analysis through targeted transgenic lines.

Title: Assessing Auditory Neural Responses in the Rett Syndrome Rat Model: A Comparative Analysis of Pre- and Post-Regression Responses

Authors: *Y. TAMAOKI, S. KROON, J. R. RILEY, C. T. ENGINEER;
Univ. of Texas at Dallas, Richardson, TX

Abstract: Title: Assessing Auditory Neural Responses in the Rett Syndrome Rat Model: A Comparative Analysis of Pre- and Post-Regression Responses**Authors**: Y. Tamaoki, S.L. Kroon, J.R. Riley, C.T. Engineer **Abstract**:Rett syndrome is a genetic disorder that is caused by a mutation in X-chromosome linked *Mecp2* gene. Individuals with Rett syndrome often exhibit seizures, impaired sociability, and difficulty in cognition, motor movements, and speech-language perception and production. These children initially develop seemingly typically, and regression symptoms occur at the age of 6 to 18 months. In the rodent model of Rett syndrome, similar regression symptoms, including impairments in sensory processing, become apparent starting from 4 months of age. Behaviorally, these heterozygous *Mecp2* rodents perform poorly on auditory discrimination tasks when background noise of varying intensities were present. These behavioral impairments are accompanied by degraded cortical activity patterns.. In the primary auditory cortex (A1), the tonotopic map that is normally organized from low to high frequencies are disrupted in *Mecp2* heterozygous rats. There is a shift in the tonotopic organization in which a greater representation of higher frequencies are observed. These findings have been documented in post-regression animals and nothing is known about auditory processing in pre-regression animals. Additionally, no studies have documented subcortical physiology in *Mecp2* animals. Therefore, the aims of this study are to 1) document multi-unit primary auditory cortex responses to sounds in heterozygous *Mecp2* rats before and after signs of regression are apparent and 2) investigate responses from the inferior colliculus in both pre-regression and post-regression rats. Neural responses evoked by tones, speech sounds, and click sounds were recorded from the primary auditory cortex and the inferior colliculus in heterozygous *Mecp2* rats and age-matched littermate control wild-type rats. Our preliminary

results suggest that responses to sounds in the inferior colliculus are also degraded in post-regression *Mecp2* rats. Surprisingly, pre-regression *Mecp2* rats also exhibit degraded responses to sounds in the primary auditory cortex. Insights derived from this study may expand the current understanding of auditory processing in Rett syndrome and other neurodevelopmental disorders.

Title: Investigating histological changes in startle-mediating neurons in the brainstem of Cntnap2 knock-out rats

Authors: *A. ZHENG[1], C. DE OLIVEIRA[2], B. L. ALLMAN[2], S. SCHMID[1];
[2]Anat. and Cell Biol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Mutations in the contactin-associated protein-like 2 gene (*CNTNAP2*) are associated with various neurodevelopmental disorders in humans, most notably autism spectrum disorder (ASD). Previous studies from our lab have consistently found that *Cntnap2* knock-out (KO) rats, a genetic animal model of ASD, have increased auditory reactivity as measured through the acoustic startle response (ASR), paralleling auditory hypersensitivity observed in ASD. Gaining a better insight into the neural basis underlying increased acoustic startle in *Cntnap2* KO rats will allow us to better understand auditory hypersensitivity in autistic individuals. The brain region that mediates the ASR is the caudal pontine reticular nucleus (PnC). Through conducting extracellular *in vivo* electrophysiological recordings in the PnC, we previously found increased firing rates in response to startling sounds in *Cntnap2* KO rats compared with wildtype littermates. However, these PnC firing rate differences were more drastic between female wildtype and female *Cntnap2* KO rats, whereas increased behavioural ASR does not show sex-dependent effects. Thus, having increased PnC firing rates does not fully explain increased ASR in *Cntnap2* KO rats. We therefore investigated morphological and histological properties of startle-mediating neurons in the PnC, which are known as “giant neurons”. Through immunohistochemical labelling of cells, we found that the total number of PnC giant neurons was not different between wildtype (n = 8) and *Cntnap2* KO (n = 8) rats. Next, we activated PnC giant neurons by presenting the rats with 30 pulses of startling stimuli (20-ms pulses at 95 dB,

white noise, 5 minutes prior to perfusing). Brain sections were labelled with an antibody against phosphorylated cAMP response element binding protein (pCREB) to visualize which neurons were activated. *Cntnap2* KO rats had increased expression of pCREB in PnC giant neurons compared with wildtype littermates. Additionally, male rats had increased pCREB expression compared with female rats. The PnC giant neurons that expressed pCREB were larger in terms of soma area in *Cntnap2* KO rats compared with wildtype littermates. However, pCREB was also seen in PnC giant neurons from a few control rats that were not presented with startling stimuli. Future studies will investigate whether increased ASR in *Cntnap2* KO rats is indeed due to increased pCREB expression in giant neurons in response to startling stimuli or due to increased pCREB expression in giant neurons at rest. Overall, our findings indicate that electrophysiological and histological changes in the PnC contribute to increased acoustic startle in *Cntnap2* KO rats.

Title: Code of silence: Encoding Information in neural activity and silence along auditory pathways

Authors: *A. BUCK[1], T. DUPONT[1,2], R. ANDREWS[1], O. POSTAL[1,3], J. BOURIEN[4], N. MICHALSKI[1,5], B. GOUREVITCH[1];

Abstract: There has been a long debate as to whether the auditory system uses a rate or temporal code. But what if this problem has been ill-defined as an 'either or' rather than as combinatorial? Here we recorded responses to long random dynamic complex sounds from a large sample of neurons in the inferior colliculus (IC), auditory thalamus (MGB) and auditory cortex (AC) of awake mice in addition to simulating responses in a biophysical model of the auditory nerve. We then quantified the amount of stimulus information carried by the firing rate, temporal patterns and neural silence (resting state of the neuron). We confirmed that stimulus information carried by individual neurons as well as information redundancy within populations of neurons decreases along ascending auditory pathways regardless of the encoding strategy used. We observed that maximum information reached by neurons was progressively transitioning from temporal encoding to encoding in the firing rate along the ascending auditory pathway. We

showed that periods of neural silence contain a significant amount of stimulus information, especially in subcortical areas, and therefore should be considered as part of neural encoding. Importantly, our observations from all auditory areas show the amount of information carried by a given code heavily depends on a given neuron's firing characteristics. These results suggest that both silent and active patterns of neural responses are relevant for information encoding further implying a multitude of encoding strategies co-existing at each level of the auditory system.

Title: Neural entrainment myth: Is 40 Hz special in mice?

Authors: *B. GOURÉVITCH, N. GONÇALVES, A. BUCK, C. DE CAMPOS PINA, T. DUPONT, N. MICHALSKI, L. ARNAL;
Inst. Pasteur, Paris, France

Abstract: Brain activity synchronizes with sensory input rhythms through neural entrainment. This seems to be particularly important for auditory perception and can even be enhanced when the stimulus amplitude modulation rate corresponds to the time constant of activated neural circuits. For nearly half a century we have known that there is an increased response in the human EEG and MEG response to a stimulation rate of 40Hz in the auditory system, a phenomenon dubbed as the 40Hz auditory steady state response (ASSR) in the literature. Mechanisms remain unclear and would involve Parvalbumin positive interneurons. Importantly, the 40Hz ASSR has been identified as a marker of neurological health with multiple studies demonstrating its decreased prevalence in many neurological disorders. Thus, the 40Hz ASSR gained importance and was quickly adopted in rodents and especially mice models as a functional marker for brain disorders. However, does the enhanced neural entrainment at 40Hz even exist in mice? To answer this we went back to the compound and local neural activity in anesthetized and awake mice that we've recorded for years in the auditory pathways. We show that there is only a small enhancement of response amplitudes at 40Hz rhythms in the inferior colliculus, auditory thalamus (MGB) and auditory cortices of mice. This enhancement is robust to anaesthesia, but is more prevalent at the subcortical levels. These results bring into question

the specific role this frequency plays in the brain, and whether mouse is a valuable animal model for relating the 40Hz ASSR to the presence of neurological pathologies.

Title: A spatial code for temporal information is necessary for auditory learning

Authors: *S. BAGUR[1], J. BOURG[1], A. KEMPF[1], T. TARPIN[1], K. BERGAOUI[1], Y. GUO[1], S. CEBALLO[1], J. SCHWENKGRUB[1], A. VERDIER[1], J.-L. PUEL[2], J. BOURIEN[2], B. BATHELLIER[1];
[1]Inst. Pasteur, Paris, France; [2]Inst. des Neurosciences de Montpellier, Univ. de Montpellier, Montpellier, France

Abstract: The temporal structure of sensory inputs contains essential information for their interpretation. Sensory cortex represents these temporal cues through two codes: the temporal sequences of neuronal activity and the spatial patterns of neuronal firing rate. However, it is unknown which of these coexisting codes causally drives sensory decisions. To separate their contributions, we generated in the mouse auditory cortex optogenetically-driven activity patterns differing exclusively along their temporal or spatial dimensions. Mice could learn to behaviorally discriminate spatial but not temporal patterns. Moreover, large-scale neuronal recordings across the auditory system indicated that the auditory cortex is the first region in which spatial patterns efficiently represent temporal cues on the time scale of several hundred milliseconds. This feature is shared by the deep layers of neural networks categorising time-varying sounds. Therefore, the emergence of a spatial code for temporal sensory cues is a necessary condition to

associate temporally structured stimuli with decisions. We expect this constraint to be crucial for re-engineering perception by cortical stimulation.

Title: Cortical PV neurons shape the neural code for loudness perception and are a critical point of failure in auditory hypersensitivity disorders

Authors: *K. K. CLAYTON[1,2], M. MCGILL[1], B. AWWAD[1,2], K. STECYK[1], D. NARAYANAN[1], C. KREMER[1], Y. WATANABE[1], K. HANCOCK[1], E. KOZIN[1,2], D. B. POLLEY[1,2];
[1]Eaton-Peabody Labs, Massachusetts Eye and Ear, Boston, MA; [2]Dept. of Otolaryngology-Head and Neck Surgery, Harvard Med. Sch., Boston, MA

Abstract: The auditory periphery converts a million-million-fold change in acoustic signal energy (120 dB) into an electrochemical code for sound intensity. The central auditory pathway, in turn, converts this sound intensity code into the perception of loudness. The essential circuitry for intensity-to-loudness transformation has not been identified, though there is reason to believe that dysfunction in these circuits could produce hypersensitivity to sound. Here, we tested the hypothesis that local circuits formed between parvalbumin-expressing (PV) GABA neurons and excitatory (RS) neurons in the mouse primary auditory cortex (A1) mediate loudness perception and are a critical failure point in hyperacusis.
A1 single unit recordings revealed heterogeneous intensity tuning that was aggregated at the level of the cortical column into a linear readout of sound level that could be decoded with high accuracy. Optogenetic inactivation or activation of A1 PV neurons imposed opposite shifts in sound intensity coding towards temporary neural hyperacusis or hypoacusis, respectively (n = 6 mice/177 units). To directly relate PV activity to loudness perception, head-fixed mice were trained in a two-alternative forced choice categorization task. Bilateral optogenetic inactivation or activation of A1 PV neurons immediately and reversibly shifted the perceptual boundary between soft and loud sound reporting, respectively, suggesting that A1 PV neurons function as a volume knob for loudness perception (N=12).
To test whether reduced PV-mediated inhibition is an underlying cause of hyperacusis, we induced hearing loss in the high-frequency base of the cochlea with noise. After cochlear injury,

A1 RS units were hyper-responsive to spared mid-frequency tones and were less suppressed by optogenetic PV activation (N = 6/484 units). Noise-exposed mice also exhibited hyperacusis in loudness categorization compared to sham-exposed controls (N = 10). Importantly, optogenetic activation of PV neurons in hyperacusic mice (N = 5) transiently shifted loudness categorization back to pre-exposure levels.
Finally, we asked if high-frequency stimulation of PV neurons could reinvigorate PV-mediated inhibition and stably reverse hyperacusis. We found that activating PV neurons for 15 minutes at 40 Hz - but not 1Hz - reduced sound-evoked spiking in A1 RS units up to 60 minutes later (N = 13/242 units) and shifted behavioral loudness categorization towards softer sounds for up to 1 week (N = 4). These findings identify new therapeutic targets for hyperacusis, a common sensory component in neurodevelopmental disorders, aging, and sensorineural hearing loss.

Title: Cortical subpopulations perform computations to produce noise invariant representations of frequency embedded in noise

Authors: *T. SUAREZ OMEDAS[1], R. S. WILLIAMSON[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Discriminating relevant auditory signals from background noise poses a fundamental challenge to sensory systems. In rodents, the auditory cortex (ACtx) is known to play a key role in disentangling auditory signals from background noise; however, the specific contributions of distinct cortical subpopulations remain elusive. We investigated how subsets of excitatory neurons in ACtx layer (L) 2/3 and 5 process sensory signals in the presence and absence of noise. We focused on intratelencephalic (IT) neurons in L2/3 and both IT and extratelencephalic (ET) neurons in L5, each distinct excitatory subset characterized by distinct functional, synaptic, and anatomical properties. Our objective was to elucidate the functional mechanisms these subpopulations use to disentangle signal from noise. Using genetically modified mouse lines and viral techniques, we conducted *in-vivo* two-photon calcium imaging of L2/3 and L5 (IT and ET) neurons while presenting pure tones varying in frequency and intensity in the presence or absence of broadband white noise (50 dB SPL). At the single neuron level, L2/3 neurons exhibited a prominent reduction in responses relative to their preferred frequency. This reduction was both subtractive and divisive, determined through regression analysis, consistent with previous work. In contrast, L5 IT and ET neurons exhibited similar responses for both

conditions. We analyzed the stimulus information content and complexity of cortical communications through binary decoding and population dimensionality, respectively. Population dimensionality analysis demonstrated that the number of dimensions used by L2/3 and L5 neurons for inter-neuronal communication remained unchanged across the conditions. Furthermore, we observed that the dimensionality of L5 IT-ET neuron communication remained constant regardless of noise conditions, suggesting that disentangling signal from noise does not necessitate increased neural complexity. Finally, we trained a support vector machine to detect the presence of a tone based on neuronal population activity. Despite their differences at the single neuron level, both L2/3 and L5 populations exhibited improved discrimination in absence of noise, with higher d-prime values for similar tone intensities. Our findings suggest that tone responses at the single-neuron and population-level differ when in the presence of noise. Within the cortical column, L2/3 representations of tone in noise likely undergo local computations to disentangle pure tones from white noise. This dissociated information is then transmitted to L5, facilitating its broadcast to relevant cortical and subcortical structures.

Title: Alteration of behavior using optogenetic manipulation of auditory cortical circuits

Authors: *K. J. MAXIMOV, P. JENDRICHOVSKY, P. O. KANOLD;
Johns Hopkins Univ., Baltimore, MD

Abstract: Ensembles or small networks of coactive cells in the auditory cortex seem to be the key cortical representations of both stimuli and behavioral choice during auditory detection task performance (Francis et al., 2018). While modeling work suggests that activating one or few “pattern completion” neurons in these small ensembles may be enough to drive the activity of the full ensemble and hence recreate the stimulus representation or behavioral choice artificially (Carillo-Reid et al., 2021; Pancholi et al, 2023), experimental evidence is lacking. Thus, we investigated if small numbers of neurons in the auditory cortex could play a causal role in driving auditory behavior questions by holographic optogenetic stimulation, which allows one to precisely and causally probe the role of specific neurons during behavior. To first explore the parameter space of such stimulation and its effects on an auditory detection behavior task we trained mice on a simple go/no go detection task where the object was to respond to a tone in the presence of varying levels of white noise. We imaged neural activity in primary auditory cortex (A1) using GCaMP7. A1 cells also expressed a red-shifted opsin (e.g. ChroME), allowing for

both imaging and targeted stimulation. After mice reached the training criteria, stimulation was performed during behavioral trials interspersed with non-stimulation trials. Neurons were selected for stimulation either randomly or based on their tuning curves. We find that holographic stimulation can change the activity of targeted cells in A1. We also found that stimulation of small groups of A1 cells can alter tone-detection behavior. Our work suggests that holographic optogenetic stimulation of small groups of cells in A1 during behavior can alter auditory behavior. Thus, small groups of A1 neurons seem to be able to causally influence behavior.

Abstract: During sensorimotor learning, animals link a sensory cue with actions that are separated in time using circuits distributed throughout the brain. Learning thus requires neural mechanisms that can operate across a wide spatiotemporal scale and promote learning-related plasticity. Neuromodulatory systems, with their broad projections and diverse timescales of activity, meet these criteria and have the potential to link various sensory and motor components. Yet, it remains unknown the extent to which this proposed model of plasticity occurs in real-time during behavioral learning. The acquisition of sensorimotor learning in a go/no-go task has been found to be faster and more stereotyped than previously thought (*Kuchibhotla et al., 2019*). We trained mice to respond to one tone for a water reward (S+) and withhold from responding to another (S-). We interleaved reinforced trials with those where reinforcement was absent ("probe"). Early in learning, animals discriminated between S+ and S- in probe but not

reinforced trials. This unmasked a rapid *acquisition* phase of learning followed by a slower phase for reinforcement, termed '*expression*'. What role does cholinergic neuromodulation play in task acquisition? Here, we test the hypothesis that cholinergic neuromodulation provides a 'teaching signal' that drives primary auditory cortex (A1), and links stimuli with reinforcement. We exploit our behavioral approach and combine this with longitudinal two-photon calcium imaging of cholinergic axons in A1 during discrimination learning. We report both robust stimulus-evoked cholinergic activity to both S+ and S- and stable licking-related activity throughout learning at the level of the axon segment. While this activity mildly habituates in a passive control, in behaving animals the S+ and S- stimulus-evoked activity is enhanced (S+: duration, S-: amplitude and duration) on the timescale of acquisition. Additionally, we test the hypothesis that cholinergic neuromodulation impacts the rate of task acquisition. We expressed ChR2 bilaterally in cholinergic neurons within the basal forebrain of ChAT-cre mice and activated these neurons on both S+ and S- trials throughout learning. Test animals acquired the task faster than control groups. These results suggest that phasic bursts of acetylcholine, projecting widely to cortical regions, directly impact the rate of discrimination learning.

Title: Visual cues modulate auditory responses in the macaque inferior colliculus

Authors: *M. N. SCHMEHL[1], S. T. TOKDAR[2], J. M. GROH[3];
[1]Neurobio., [2]Statistical Sci., [3]Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: How the brain uses multisensory cues to process complex sensory environments remains a key question in neuroscience. Of particular interest is whether relatively early sensory areas, which are commonly considered to be unisensory in function, might take in information from other sensory modalities to inform the representation of the primary modality of interest (for review, see Schmehl & Groh, *Annual Review of Vision Science* 2021). We explored how visual cues might inform the representation of sounds in the macaque inferior colliculus, a subcortical auditory region that receives visual input and has visual and eye movement-related responses.
We conducted *in vivo* single- and multi-unit extracellular recordings in the inferior colliculus while two monkeys (*Macaca mulatta*, one female age 15 years, one male age 7 years) performed a localization task involving both auditory and visual stimuli. We found that pairing a visual cue

with a sound can change a neuron's response to that sound, even if the neuron is unresponsive to visual input alone. Visual cues also enhance localization behavior in both spatial precision and temporal latency. Finally, when two simultaneous sounds are present and one sound is accompanied by a visual cue, neurons are more likely to respond to the visually-paired sound on individual trials. Together, these results suggest that the inferior colliculus uses visual cues to alter its sound responsiveness and inform perceptual behavior, providing insight into how the brain combines multisensory information into a single perceptual object at a relatively early stage of the auditory pathway.

Title: Processing of valence-associated stimuli in the murine auditory cortex

Authors: ***J. JOHNSON**[1], Z. LI[2];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]NIMH, NIH, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The auditory cortex is recognized as the primary centre for sound processing in the brain; however, recent evidence suggests its involvement in the processing of an array of non-auditory information. The ability to associate stimuli with emotional or motivational valence is crucial for survival, and disruptions in these associations are observed in disorders like PTSD and schizophrenia. While the impact of rewarding or aversive associations on tone frequency processing has been investigated, the neuronal mechanisms underlying the intersection of these factors and the existence of innate or conditional valence responsiveness in the auditory cortex remain unclear. To address this, we employed longitudinal two-photon GCaMP imaging to examine auditory cortex neuronal responses during conditioning, recall, and combination switching of pure tones paired with rewarding or aversive stimuli. Following conditioning, a subset of auditory cortex neurons displayed responses to valence-coded stimuli when presented in both within pairings and in isolation, comprising cells with and without tone responses. These valence-responsive cells predominantly exhibited activity in the presence of solely rewarding or aversive stimuli, but some also demonstrated responses to both valences. Upon switching the initially conditioned pairings, a substantial subset of neurons exhibited a shift in their stimulus response to the emotionally opposing stimuli. This population additionally showed relationships to the stimuli induced behaviour, which was analysed with DeepLabCut. Using optogenetic activation of the valence sensitive population we observed ensembles with heterogenous

response types consisting of mixed valence and tone-responsive cells, suggesting a local mechanism that influences the effect of emotionally linked auditory information within the auditory cortex. These findings shed light on the complex interplay between auditory processing, emotional valence and behaviour in the murine auditory cortex.

Title: Neural Correlates of Residual Hearing in the Core and Belt Auditory Areas of Early-deaf Subjects

Authors: *Y. MERRIKHI[1], A. KHADIR[2], C. KRUGER[1], S. JAFARI[3], S. G. LOMBER[1]; [1]Physiol., McGill Univ., montreal, QC, Canada; [2]Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of; [3]Biomed. engineering, Amirkabir Univ., Tehran, Iran, Islamic Republic of

Abstract: The auditory brainstem response (ABR) is a neurophysiological test utilized to assess the electrical activity produced by the auditory nerve and brainstem in response to auditory stimuli. The absence of a measurable ABR response can indicate significant hearing loss but is not sufficient for confirming deafness. Some individuals classified as profoundly deaf may still possess residual hearing or sensation in response to auditory stimuli. The cortical manifestation of this residual hearing is not well understood. To explore the neural basis of residual hearing in the profoundly deaf, we conducted multiple single-unit recordings from four adult cats that were chemically deafened in the first postnatal month. We recorded in primary auditory cortex (A1) and a belt auditory area known as the Dorsal Zone (DZ), in lightly anesthetized cats. We examined the neural responses to acoustic (white noise bursts, 500 ms duration), visual (80 lux, 500 ms duration), and somatosensory (displacement distance of 1 mm, 500 ms duration) cues presented separately or in combination. We collected neural activity, including spiking activity and local field potentials (LFP), from 380 DZ and 330 A1 recording sites from which we isolated 329 DZ and 252 A1 single neurons. No activation was observed in terms of spiking activity or LFP in the early-deaf cats' auditory areas following acoustic stimulus presentation. However, we did find that an acoustic stimulus significantly decreased the visual or somatosensory responses of neuron populations in both A1 and DZ when it was co-presented with a cross-modal stimulus. Additionally, we observed a significant decrease in the amplitude of LFP responses to somatosensory stimuli in both A1 and DZ in frequency ranges higher than 8 Hz (>α band) following the co-presentation of an acoustic stimulus. In the >α frequency bands, when acoustic and visual stimuli were presented simultaneously, the amplitude of LFP responses in A1 showed

a significant reduction. Conversely, the co-presentation of acoustic and visual stimuli resulted in a significant enhancement of the amplitude of LFP responses in DZ sites. Collectively, these findings provide insights into the neural mechanisms associated with preserved auditory function in individuals with hearing loss and contribute to our understanding of the neural correlates of residual hearing.

Title: Encoding of two tone harmonic complexes and sample nonharmonic complexes in the mouse primary auditory cortex.

Authors: *A. DE, R. ARCHAK, S. BANDYOPADHYAY;
Advanced Technol. Develop. Ctr., Indian Inst. of Technol., Kharagpur, India

Abstract: Two tone harmonic complexes (TTHCs) are one of the common syllable types in mouse vocalization in different socio-behavioral contexts like courtship. TTHCs, containing simultaneously presented fundamental frequency (F_0) and its first harmonic ($F_1 = 2F_0$), showed differential encoding from its component tones at a single neuron resolution in the mouse primary auditory cortex (A1), in our previous study. However, whether the presence of a second component at $2F_0$ is necessary for the differential encoding was unexplored. We ask, how the presence of a second component at a frequency F_n, not an integer multiple of F_0, either below or above $2F_0$ (referred to as Low or High nonharmonic complexes, LTTNC and HTTNC respectively) is different from TTHCs in terms of single neuron response properties. We used only a sample of numerous nonharmonic combinations possible, keeping F_n at 0.25, 0.5, 1.25 and 1.75 octaves from F_0. With single unit responses, in general, two-tone nonharmonic complexes (TTNCs) showed similar percentages of units enhanced, suppressed or no-effect categories; i.e. TTNC responses are larger, lower or not different from the maximum of component tones, respectively. Single units response to TTHCs showed higher mean spike rates from that of TTNC when F_0 and F_n of TTNC is within a narrow range from the best fundamental frequency (BF_0) of the F_0. On the other hand, F_n, as a distant component from BF_0 showed relatively lower mean spike rate. But, normalized rate responses of TTHCs were significantly higher than TTNCs in case of units with best fundamental frequency (BF_0), such that BF_0=F_0, while differential effects were observed in a frequency specific manner when considering units with F_0s at different distances from BF_0. In the current study we also collected 2-photon Ca^{+2} imaging based responses of single neurons in A1 superficial layers of mice, chronically using the same set of stimuli. Similar results were obtained, however with different proportions of units in each class

of comparative responses detailed above. Our study thus shows that TTHCs and TTNCs are encoded differently, especially based on the BF_0 of neurons.

Title: Responses to unexpected sound omissions in human auditory cortex: electrocorticography and stereo-electroencephalography studies

Authors: *H. CHO[1,2], Y. M. FONKEN[3,4], M. ADAMEK[1,2], R. JIMENEZ[3], G. SCHALK[5,6], J. T. WILLIE[1,2], R. T. KNIGHT[3], P. BRUNNER[1,2,7];

Col., Albany, NY

Abstract: Context modulates sensory neural activations enhancing perceptual and behavioral performance and reducing prediction errors. However, the mechanism of when and where these high-level expectations act on sensory processing needs to be clarified. Here, we isolate the effect of expectation absent of any auditory evoked activity by assessing the response to omitted expected sounds. Electrocorticographic (ECoG, six subjects) and stereo-electroencephalographic (SEEG, another six subjects) signals were recorded. Twelve subjects listened to a predictable

sequence of syllables ('La-La-Ba La-La-Ga'), with some third syllables infrequently omitted ('Ba' or 'Ga'). We found high-frequency band activity (HFA, 70-170 Hz), a surrogate measure of neural excitations, in response to omissions, which overlapped with a posterior subset of auditory-active electrodes in the superior temporal gyrus (STG). However, we found no HFA responses to expected omitted sounds in a control experiment with a predictable omission in the syllable sequence ('La-La- '). Furthermore, the HFA omission response at posterior STG (PSTG) consisted of the six ECoG subjects, while we could not observe these HFA responses in SEEG due to the less coverage over the PSTG area. Interestingly, in ECoG data, the time series pattern of HFA in omission shows that the omission HFA response was increased from baseline and sustained until the next syllable stimulus. And then, the sustained HFA response returned to the baseline after the syllable stimulus. This pattern indicates that PSTG areas were anticipating for the expected stimulus. Furthermore, in both ECoG and SEEG, the HFA onsets in PSTG were earlier than other STG areas for both syllable and omission conditions, while in general, the earliest HFA responses are near the primary auditory cortex.The significance of the HFA responses to unexpected omission conditions is that the PSTG location is involved in omission processing and monitoring each expected syllable. Based on our results, we infer that PSTG monitors auditory inputs and anticipates for expected auditory information. We propose that the HFA responses at PSTG are involved in processing context information to enhance perceptual and behavioral performance and reduce prediction errors. HFA omission responses in this region appear to index mismatch-signaling or salience detection processes.

Internacional de Investigación sobre el Genoma Humano, Univ. Nacional Autónoma de México, Querétaro., Mexico; [4]QIMR Berghofer Med. Res. Inst., Brisbane, Australia

Abstract: Heritability of auditory cortex's morphology in the mexican populationThe auditory system consists of multiple brain regions, including the transverse temporal gyrus and the superior temporal gyrus, which contain the primary and secondary auditory cortices, respectively. These two regions are essential for high-order perceptual processes. The morphology of these regions varies across individuals, and these variations might be associated with auditory perceptual and cognitive skills (Turker et al, 2019). Cortical morphology has been shown to be heritable, variations on these phenotypes are partially explained by genetic factors. Heritability can be estimated by measuring the correlation of a quantitative trait in monozygotic twins (MZ) - who share around 100% of their DNA - against the correlation within dizygotic twins (DZ) - who share 50% of their DNA, on average. However, heritability could differ across populations. Most research on heritability has been conducted on people of European ancestry, while Latin Americans remain underrepresented. The objective of this study is to estimate the heritability of the auditory cortex's morphology. We acquired high-resolution T1w images in 214 twins (138 MZ and 76 DZ) from the Mexican Twin Registry (TwinsMX). These were preprocessed and parcellated using FreeSurfer's recon-all pipeline. Two brain regions within the temporal lobe were selected for analysis: transverse temporal gyrus, and superior temporal gyrus. We estimated the heritability of their cortical thickness and surface area for both hemispheres. For cortical thickness, we found a higher correlation among identical twins for the right (rMZ=.42, rDZ= .40), and left (rMZ=.57, rDZ=.41) transverse temporal gyrus, and for the right (rMZ=.67, rDZ=.56), and left (rMZ=.64, rDZ=.50) superior temporal gyrus. For surface area, we also found a higher correlation among identical twins for the right (rMZ=.57, rDZ=.40), and left (rMZ=.72, rDZ=.08) transverse temporal gyrus, and for the right (rMZ=.76, rDZ=.59), and left (rMZ=.77, rDZ=.70) superior temporal gyrus. These results suggest that variations in the morphology of the auditory cortex is partially explained by genetics.

Title: Identifying Features of Cochlear Implant Stimulation that Obstruct Tone Discrimination at the Network Processing Level

Authors: *C. STEINHARDT;
Columbia Univ., New York, NY

Abstract: Cochlear implants(CIs) are arguably the most successful neural implant in clinical use. They use sparse electrical encoding and simple pulsatile stimulation patterns but provide patients with enough information to perform speech recognition. Still, they have deficits such as poor restoration of tone information. Here, we investigate how tone discrimination capabilities are lost during auditory stream processing by analyzing how CI stimulation affects a recurrent neural network trained to perform tone discrimination to naturalistic cochlear fiber responses. "Natural" responses were simulated as a combination of low, medium and high spontaneous rate fiber response at 30 locations along the cochlear with different characteristic frequencies. A CI response to the same stimulus was created by simulating the location of Cochlea Nucleus-22 electrodes in the cochlea and using the Cochlear NMT Toolbox to simulate the transformation of sound into stimulation per electrode site. Gaussian current spread up to 1 mm from the electrode was assumed to determine the spiking per fiber. Thus, a natural or CI-induced cochlear response could be generated to any input. The tone task was determining whether the first or second tone in a sequence is higher. Tones were varied from 0.5 to 10 semitones above a base tone within frequencies less than 20,000 Hz. This produced a 1200 cases dataset that was split into a training and test set. Cross entropy loss was used to train the network. The network performed the task with 100% accuracy using natural inputs and at a chance level in using CI inputs on the test set. This performance indicates that tone information was lost when CI stimulation drove the network. Principal component analysis revealed that the network separates the two cases in representation space for naturalistic inputs. CI stimulation drives neural activity similarly for both cases into a network attractor. Using this model, we will investigate what aspects of CI stimulation cause this misrepresentation of tones and how the paradigm could be altered to restore tone encoding to a closer to natural level.

Title: Relational invariance through combinatorial population spiking

Authors: *T. S. MCPHERSON, B. H. THIELMAN, T. GENTNER;
Neurosciences, UCSD, La Jolla, CA

Abstract: Relational invariance—a network's ability to capture the geometric relationships between external inputs abstracted away from explicit variables—provides a potential

mechanism for robustness and generalizability in neural networks. Previous work from our group demonstrates relational invariance empirically, revealing a combinatorial spiking code that captures the relational geometry of acoustic stimuli in the songbird brain. To understand how relational invariance might emerge through combinatorial population spiking, we develop a spiking neural network (SNN) modeling framework that captures the relationships between different patterns of input signals. We train SNNs to autoencode continuous input streams via unsupervised, local, and biologically inspired learning rules. Using a probabilistic population model constructed from the receptive fields of individual SNN neurons, we show that the combinatorial population responses in the trained SNN intrinsically capture the relational geometry between input signals, demonstrating relational invariance in the SNN. This structure can be observed without the use of receptive-field models for inference, which assume a specific parameterization of the external inputs. We go on to explore how relational invariance emerges from this combinatorial code: (1) In the SNN, neural excitability and membrane voltage encode representational error, and we demonstrate the mechanism through which increased firing rates produce greater representational precision. (2) Excitation-inhibition balance is critical for the efficient representation of information, and we show that inhibition dominated networks produce a convex representational geometry through lateral inhibition between similarly tuned neurons. (3) We illustrate how relational invariance is a natural consequence of the network's convex representational geometry. The work demonstrates a novel combinatorial encoding framework through which relationships between any set of external variables can be captured in precise spike-timing dynamics. We suggest that similar coding schemes may be observed in both biological and artificial SNNs.

Title: Tools for neural network analysis of biological sound processing

Authors: J. R. PENNINGTON[1], ***S. V. DAVID**[2];
[1]Washington State Univ., Vancouver, WA; [2]Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Encoding models for the auditory system, such as the spectro-temporal receptive field (STRF) and related linear-nonlinear (LN) models, have proven valuable for understanding the auditory periphery. However, these tools are unable to account for high-order, invariant representations in more central brain areas, including auditory cortex. Numerous alternatives

have been proposed that improve on LN models, but the complexity of model fitting and evaluation has made it difficult to compare their performance directly. We have developed the Neural Encoding Model System (NEMS), an open-source Python library that implements a wide range of encoding models for analysis of auditory neural data. NEMS has a building-block design that permits a continuum of simple (LN) to complex (convolutional neural network, CNN) models. Models can use standard LN units or incorporate biological nonlinearities, such as short-term synaptic plasticity. They can also incorporate state variables that account for non-auditory context that modulates auditory processing. Different models can be fit and evaluated using cross validation and applied to fixed datasets, allowing unbiased comparison of alternative model architectures. One additional challenge to developing models of central auditory processing is understanding the functional properties captured in their complex non-linear transformations. To address this issue, we have incorporated the dynamic STRF tool into NEMS, which permits visualizing locally linear, LN approximations of a model under different stimulus conditions and contexts. Our current studies show that CNN-based models provide substantially greater predictive power than any other model tested.

Title: Single neuron and population codes for pitch in auditory cortex

Authors: *K. M. M. WALKER[1], V. TARKA[2], Q. GAUCHER[3];
[1]Physiology, Anat. & Genet., Univ. of Oxford, Oxford, United Kingdom; [2]Oxford Univ., Oxford, United Kingdom; [3]ENS, Paris, France

Abstract: Harmonic sounds in our natural environments almost always contain energy at a collection of frequencies. However, we experience these sounds as having a unitary tonal quality at a fundamental frequency, known as its pitch. Pitch perception plays a key role in our experience of speech and music, as well as our ability to segregate multiple sound sources. While some studies in marmosets and humans have suggested that pitch may be processed by a highly specialized subpopulation of neurons in auditory cortex, the evidence across animal models remains inconclusive and heavily debated. I will discuss our modelling, electrophysiological, and behavioural experiments in ferrets, which offer insights into how single neurons and populations of neurons in auditory cortex encode the pitch of sound. We show that different classes neurons can extract pitch from either the temporal periodicity of the soundwave in time, or the harmonicity of the sound in the frequency domain. I will discuss the extent to which well-known

tonotopic maps of sound frequency in the brain may contribute to pitch processing, and the open question of whether auditory cortex may contain a specialized pitch processing centre.

Abstract: Precise and efficient investigation of neuronal circuits underlying sensory perception remains to date one of the biggest technical challenges in neuroscience, despite the tremendous advancements integrated over the fields of molecular biology, engineering, optics, and computer science during the last two decades. Currently, two-photon (2P) microscopy is considered the state-of-the-art technique to record and simultaneously perturb the activity of large population of neurons, using an all-optical strategy. 2P functional imaging grants high (single cell) spatial resolution, with temporal resolution compatible with the most recent genetically encoded calcium sensors. When dissecting a neuronal circuit of interest, though, it would be ideal to directly access and manipulate the sub- and supra-threshold electrical activity of neurons. Recently, several genetically encoded voltage indicators have been developed, along with imaging strategies suitable for recording electrical signals (kilo-hertz range), without compromising spatial resolution. Among these, ULoVE (Villette et al. 2019) is an ultrafast high signal-to-noise ratio imaging technique, already validated for 2P voltage imaging *in vivo* (Villette et al. 2019; Liu et al. 2022). In this framework, similarly accurate 2P optogenetic perturbation is lacking. For this reason, we tested the possibility of using the same approach (ULoVE) to perform ultrafast excitation of multiple neurons. Employing low repetition rate femtosecond lasers, coupled with an AOD-based microscope, it was possible to perform exquisitely spatially and temporally precise photostimulation of ensembles of neurons *in vivo*. As a proof of principle, neurons co-expressing the calcium indicator GCaMP6m and the large conductance excitatory opsin ChRmine (Marshel et al. 2019) where simultaneously imaged and

briefly (< 150µs) photostimulated, resulting in successfully evoked fluorescent transients. These results demonstrate the feasibility of stimulating neuronal ensembles with unprecedented temporal resolution, matching kinetics and latency of physiological electricals signals. In this framework, we performed chronic voltage imaging using the most recent genetically encoded voltage indicator JEDI-2P (Liu et al. 2022) to monitor the electrical activity of L2/3 pyramidal neurons in mouse auditory cortex. In future experiments, we plan to perform all-optical electrophysiology experiments to investigate the role of specific ensembles of auditory cortex neurons in processing sounds information.

Title: Context-dependent priors in vestibular distance estimation

Authors: *S. C. M. J. WILLEMSEN[1], L. OOSTWOUD WIJDENES[1], R. J. VAN BEERS[1,2], M. KOPPEN[1], W. P. MEDENDORP[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [2]Dept. of Human Movement Sci., Vrije Univ., Amsterdam, Netherlands

Abstract: Perception and action depend on our sensory inputs as well as prior experience. How we combine these types of information is often studied with Bayesian models representing sensory and prior information as probability distributions. It has been suggested that the prior corresponds to the sensory statistics during natural activities. For example, we previously found that the distribution of vestibular input measured outside the lab was non-Gaussian. Yet, data from lab-based vestibular perception tasks are better explained using a Gaussian prior distribution. This raises the question whether people build up context-dependent priors for vestibular perception. To this end, we designed a vestibular distance reproduction task in the dark. Participants were first passively moved some distance using a linear motion platform, after which they actively reproduced this distance by moving the platform with a steering wheel. Distances were either sampled from a 'short' or 'long' distance distribution. We introduced two experimental conditions in which the same distances were presented but in different contexts:

short and long distances were either interleaved or presented in two separate blocks. Preliminary results indicate that participants made active movements that were generally shorter than the passive ones. Furthermore, the contexts in which the distances were presented influenced the reproduction behavior. In the blocked condition, the short distances led to shorter reproduced distances than in the interleaved condition and similarly, the long distances resulted in longer reproduced distances, possibly pointing to the presence of context-dependent priors built up during the experiment.

Title: Dance training alters eye-head coordination

Authors: *K. MOÏN-DARBARI[1,2,3], M. NOORISTANI[4], B.-A. BACON[5], F. CHAMPOUX[1,3], M. MAHEU[6,2];

Abstract: Long-term dance training is known to improve postural control, especially in challenging postural tasks. However, the effect of dance training on the vestibulo-ocular reflex (VOR) has yet to be properly assessed. This study directly investigated whether VOR parameters are influenced by long-term dance training by testing dancers and controls using the video head impulse test. VOR gains using two of the most common methods (area ratio and instantaneous gains), latency and amplitude of the first saccade, if applicable, were computed. Results revealed a larger VOR gain as measured by area gain and by instantaneous gain at 40ms specifically for left head impulses, but not for right head impulses. No significant differences in saccade frequency, amplitude or latency were observed between groups. These differences appear to stem from a modified eye to head relationship during high velocity head impulses in dancers. More specifically, the dancers' eyes lead head movement during passively applied head impulses, which result in higher VOR gain. This finding is discussed in line with the active inference theory based on the free-energy principle.

Title: Developmental switch in vestibulo-spinal neuronal phenotypes during the Xenopus metamorphosis

Authors: *F. M. LAMBERT[1], G. BARRIOS[1], T. FEVRIER[1], A. OLECHOWSKI-BESSAGUET[1], L. CARDOIT[1], M. THOBY BRISSON[2];
[1]INCIA CNRS UMR5287 Univ. of Bordeaux, Bordeaux, France; [2]Univ. De Bordeaux, CNRS UMR 5287, Univ. De Bordeaux, CNRS UMR 5287, Bordeaux Cedex, France

Abstract: Vestibular neurons involved in vestibular pathways exhibit distinct intrinsic membrane properties tuned to ensure various sensory-motor tasks. The frog metamorphosis represents a relevant neuronal plasticity model to investigate this neural computation. In adult frog, vestibular neurons present 2 phenotypes according to their discharge dynamic: 1) Phasic neurons exhibiting a high-frequency burst of 1-3 spikes, without subsequent continuous discharge, due to the ID conductance mainly supported by the Kv1.1 K+ channel and 2) tonic neurons firing continuously. However, such a characterization remains unrelated to a specific vestibular function and nothing is known about the maturation of these neuronal dynamics. This study aims to investigate the maturation of membrane properties specifically expressed in vestibulospinal (VS) neurons involved in postural control, during the re-modeling of the body induced by the metamorphosis in Xenopus. On brainstem slice preparations, patch-clamp recordings of retrogradely labeled VS neurons revealed a reverse proportion between tonic and phasic neurons from larva (20% of phasic) to juvenile (70% of phasic) whereas electrophysiological properties for both phenotypes did not change significantly during this period. Concomitantly Kv1.1 immuno-labeling also revealed a reverse proportion of Kv1.1+ VS neurons from larva (25% of Kv1.1+) to juvenile (65% of Kv1.1+). The highest proportion of Kv1.1+ VS neurons was even reached at the climax (stage 60: Kv1.1+ VS neurons = 77%), demonstrating that the switch occurred at the pro-metamorphosis (stage 54-58).BrDU PULSE-CHASE showed that none of VS neurons present in juvenile originated from mitotic cells older than larval stage 50 and only 15% from stage 50, suggesting that 85% of juvenile VS neurons originated from early larval period. Half of the 15% juvenile VS neurons originating from

mitotic cells at stage 50 were Kv1.1+ which represented only 11% of the total population of juvenile VS Kv1.1+ neurons, presumably exhibiting a phasic phenotype.Altogether these results revealed a developmental switch in the expression of neuronal phenotypes dedicated to vestibulospinal pathways and demonstrated that all VS neurons come from pre-mitotic progenitors established in early larval life. These progenitors could constitute a stock of post-mitotic neuroblasts until stage 50 when enter in their final neuronal differentiation phase (to become either phasic or tonic) when the metamorphosis starts, around stage 54.

Title: Complexity in discerning the effect of virtual reality immersion using simulator-sickness questionnaire (SSQ)

Authors: *E. SON, S. SHIN, Y. KO, S. LEE;
Dept. of Otorhinolaryngology, Yonsei Univ. Col. of Med., Yongin, Korea, Republic of

Abstract: Virtual reality (VR) technology can provide virtual environments tailored to match the specific needs of patients with dizziness for vestibular rehabilitation. The simulator-sickness questionnaire (SSQ) is widely used to assess the user's discomfort for newly developed VR programs. Since SSQ was originally developed for flight simulators, it remains to be determined whether the SSQ is adequate to measure the severity of subjective symptoms due to VR immersion. We have developed VR-based programs for customized vestibular rehabilitation to evoke subjective perception of motion. Twenty healthy volunteers and 10 patients with chronic dizziness performed VR programs, and SSQ and vertigo-VAS were measured after VR immersion. All subjects were exposed to VR environment, with >90 deg vertical and >180deg horizontal field of view using projected on virtual visual surround. Exploratory factor analysis for two was performed on 16 items of the SSQ, and the results supported the two factor structure ("nausea" and " oculomotor"). Items 1and 10 were loaded similarly to both factors. While the SSQ is widely applied for VR programs, some individual items might be related to increased stress during trials, rather than the direct effects of VR immersion. Further studies are needed to examine contribution of possible confounding factors including emotional stress and anxiety in SSQ surveys for VR immersion.

Title: Irregular fiber subpopulation distribution in central vestibular neurons

Authors: *D. NAQVI, S. KING, R. BRAUN, A. HOLT;
Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: The peripheral vestibular end-organs are innervated by regular and irregular afferent fibers which slowly and rapidly adapt to stimuli, respectively. Due to the physiological and sound-sensitive properties of the irregular fibers (calyx-only neurons), they are more susceptible to noise-induced trauma. Calyx-only terminal projections to the vestibular nuclear complex (VNC) have been shown to produce the calcium buffering protein, calretinin. Subsets of these irregular fibers may be present, which has not been previously shown. This gap in knowledge may be addressed by identifying colocalization of calretinin with vesicular glutamate transporters 1 and 2 (vGluT1 and vGluT2) in the VNC. vGluT has been previously used to define subsets of excitatory neurons. The present study focused on identifying subsets of calyx-only terminals in the VNC using calretinin and vGluTs without the induction of vestibular trauma. Following transcardial perfusion, Sprague-Dawley rat brains were collected, post-fixed, and serial sectioned. Immunohistochemistry was performed for calretinin, vGluT1, and vGluT2 on rostral and caudal VNC sections. Calretinin, vGluT1, vGluT2, colocalized calretinin/vGluT1, and colocalized calretinin/vGluT2 punctate were observed in VNC nuclei to evaluate irregular fiber subpopulations. Our findings demonstrate that calretinin positive terminals may colocalize with vGluT1 or vGluT2. These colocalized terminals were differentially observed throughout VNC subdivisions and in rostral and caudal VNC sections. Additionally, vGluT positive terminals that do not colocalize with calretinin were found throughout the VNC. All calretinin positive terminals did not label for vGluT. Our data indicate subpopulations of irregular afferent fiber projections to the VNC without vestibular injury. These subpopulations may have different functional properties, such as firing rate, which may be attributed to which vGluT is being utilized. Furthermore, differential patterns of colocalization among VNC subdivisions may stem from incoming peripheral end-organ projections. Future studies may evaluate changes in irregular fiber distribution in the VNC following vestibular injury, such as noise-induced trauma. Also, these irregular fiber subpopulations may have differential effects on descending vestibular pathways, therefore, affecting movement and posture.

Title: Influence of roll and pitch perturbation dynamics on postural responses in nonhuman primates

Authors: *O. M. E. LEAVITT[1], B. A. RAMADAN[2], K. E. CULLEN[3];
[1]Biomed. Engin., Johns Hopkins Med. Institutions, Baltimore, MD; [2]Biomed. Engin., [3]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Dynamic balance requires rapid and precise integration of vestibular, somatosensory, and visual inputs. While extensive research has been devoted to understanding human postural responses, questions still remain about the underlying neural control of these responses. To this end, it is essential to characterize normal postural responses in an animal model that allows for direct probing of the neural circuitry driving these responses—in this case, the rhesus monkey. Accordingly, here we investigated postural responses in rhesus monkeys, focusing on roll and pitch perturbations. Two monkeys were trained to perch in a natural position on a force plate in a chamber mounted to a dynamic hexapod motion platform. A head-mounted wireless IMU was used to measure head velocity and acceleration. Head orientation was tracked via a reflective optical tracker, while joint kinematics were estimated from video with DeepLabCut. All perturbations had a total displacement of 10 degrees. Two sets of perturbations were delivered in 2 directions for each rotational axis: one with ‘varying velocity’ (20, 40, 60 deg/s at 500 deg/s^2), and one with ‘varying acceleration’ (200, 500, 1000 deg/s^2 at 40 deg/s).
In response to roll perturbations, monkeys were able to maintain head stability in space throughout the platform motion, so that after the platform stopped the head remained earth-vertical. Responses were symmetrical for leftward and rightward perturbations. Notably, these responses strongly resembled responses to roll perturbations reported in prior studies of human and cat posture. We further found that as velocity increased, the peak roll velocity of the head increased slightly, and the peak torque generated by ground reaction forces showed a similar slight increase. In contrast, the changes in head motion and torque were much larger for platform acceleration.
In contrast, in response to pitch rotations, the monkey’s head motion followed platform motion more closely than for roll. Additionally, due to the asymmetry in the body plan of the animal, the responses to forward vs. backward pitch perturbations were asymmetrical. Interestingly, this led to much larger changes in peak head velocity and peak torque with increasing platform velocity. Finally, we observed increases in both head motion and torque responses with increasing platform acceleration as seen in roll.

These results suggest that rhesus macaque postural responses to support surface tilts depend on the angular acceleration of the platform and provide a platform for studies of the neural control of postural responses.

Title: Native and prosthetic vestibular contributions to postural responses in nonhuman primates

Authors: *B. A. RAMADAN[1], O. M. E. LEAVITT[1], K. E. CULLEN[2];
[1]Biomed. Engin., [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Clinical trials of vestibular prostheses have shown significant improvements in postural control and quality of life outcomes, but only mild restoration of vestibulo-ocular reflexes. To date, the stimulation mappings employed in these trials have not considered the natural dynamics of vestibular afferent firing patterns, leaving open questions around optimal prosthetic design. In this study, we initially characterized postural control following complete vestibular loss and then examined the ability to restore function using vestibular prosthesis in a rhesus macaque model.
First, we quantified postural responses following bilateral vestibular loss (BVL) in roll and tilt axes. Head movement and orientation were measured using an IMU and optical tracker, ground reaction forces via a force plate, and joint kinematics were estimated from video (DeepLabCut). Two sets of tilts were applied in pitch and roll axes, varying velocity (20, 40, 60 deg/s at 500 deg/s^2) and acceleration (200, 500, 1000 deg/s^2 at 40 deg/s). Overall, BVL resulted in impaired postural responses. Roll tilts resulted in reversed postural responses, while pitch responses were hypermetric to normal. Limb torque analysis during anterior-directed pitch tilts show compensatory behaviors, indicating the relevance of body plan to asymmetry in pitch tilt response. Roll responses align with the functional capacity demonstrated in humans with BVL.
Next, to assess our ability to restore postural control via prosthetic stimulation, we administered stimulation using both static and naturalistic mappings during repeated tilt perturbations with the same kinematics (40 deg/s at 500 deg/s^2). All tested prosthesis stimulation mappings led to improvements in postural responses within 20 tilts. Interestingly, the most significant enhancement in performance resulted from stimulation mappings that mimicked irregular vestibular afferents, closely associated with postural control. We confirmed the efficacy of the prosthesis by interspersing non-stimulation catch trials throughout the experiment. Catch trial responses more closely resembled pre-stimulation conditions, demonstrating that the vestibular

prosthesis stimulation was responsible for the improvement in postural responses.
In summary, our study demonstrates postural control deficits in monkeys with BVL, while suggesting deficit recovery through biomimetic stimulation using a vestibular prosthesis. These findings enhance our understanding of the vestibular system's role in postural control and provide key insights for developing targeted interventions to return independence to individuals with vestibular loss.

Title: The vestibular cerebellum performs computations to generate appropriate motor output to postural muscles for stability

Authors: *R. L. MILDREN, C. BAO, K. E. CULLEN;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: The brain integrates sensory information to generate motor output to maintain posture and balance while we are in motion. In particular, the vestibular cerebellum performs essential computations to estimate the motion of our head and body as well as our spatial orientation relative to gravity. This self-motion and orientation information is essential for controlling vestibulospinal reflexes to stabilize head and body posture during unexpected self-motion. However, it is unknown how the integration of vestibular and other self-motion cues by the vestibular cerebellum specifically shapes motor unit activity in postural muscles during everyday activities. Accordingly, the overall aim of this study is to link neuronal activity in the vestibular cerebellum with the behavioural output by simultaneously stimulating and recording from the cerebellar cortex and neck motor units.
First, to characterize cerebellar responses to self-motion, we applied whole body (vestibular stimulation), body-under-head (proprioceptive stimulation), and head-on-body (combined stimulation) linear translations while recording from cerebellar Purkinje cells and neck motor units in alert rhesus monkeys. We used 128-channel silicon read-write probes (Neuropixels) to record and stimulate in the cerebellum, and 40-channel thin-film electrodes to record motor units across the width of splenius capitis. Results showed both Purkinje cell and neck motor unit activity was modulated by vestibular, proprioceptive, and combined stimulation. Furthermore, we observed significant coherence between Purkinje cell spikes and motor units at low frequencies (~2 Hz), and spike-trigger average responses in motor units following Purkinje cell spikes. Next, to causally probe how activating Purkinje cells influences motor output, we applied

electrical microstimulation to Purkinje cells identified on channels of the read-write probe using current steering and observed stimulation-evoked excitatory responses in neck motor units. Taken together, our targeted experimental approach provides the ability to probe the involvement of specific cerebellar regions in the control of postural muscle activity. This approach will shed light on the mechanisms behind the coordination of movement and balance during self-motion in our everyday lives.

Title: Loss of alpha 9/alpha 10 nicotinic acetylcholine receptor subunit results in postural deficits in mice

Authors: *T. NIEBUR[1], K. E. CULLEN[2];
[1]Johns Hopkins Med. Institutions, Baltimore, MD; [2]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: The vestibular system is essential for ensuring the maintenance of posture and balance in daily life. The information transmitted via vestibular afferents in the VIII nerve to central pathways has been well characterized. However, the VIII nerve also contains efferent fibers projecting from the brain back out to the vestibular organs. To date, the functional role of the vestibular efferent system in mammals is not understood. One hypothesis is that the mammalian efferent vestibular system is responsible for the calibration of central vestibular pathways during development.Acetylcholine (Ach) is the primary transmitter of the mammalian efferent vestibular system. Ach binds to nicotinic Ach receptors on vestibular hair cells and afferent terminals, which are composed of functional alpha (α)9 and α10 (α9/α10) subunits. In vitro studies show that these subunits mediate efferent activation of the vestibular periphery. Here to understand the role of the efferent vestibular system in intact alert animals we characterized the vestibular function in mice lacking α9/α10 subunits. Three types of tests were performed: i) standard vestibular tests, ii) quantification of the vestibular ocular reflex (VOR), and iii) quantification of movement kinematics during challenging self-motion tasks. We first found no difference between α9-/α10- and control mice performance during standard testing, which included contact and air righting. Second, quantification of VOR was performed by measuring eye movements via video during whole-body sinusoidal rotations (0.2-3 Hz, 16 deg/s). Again, no significant difference was found between α9-/α10- and control mice; The gain and phase of the evoked VOR responses were comparable for both groups during whole-body sinusoidal

rotations. Likewise, no differences were observed in optokinetic response evoked by comparable rotation of the visual surround or quick phase eye movement dynamics. Finally, 6D head movement kinematics were quantified during challenging active self-motion tasks including balance beam and swim testing. Balance beam testing revealed that α9-/α10- mice demonstrated significantly lower power head dynamics than control mice, particularly at higher (> 5 Hz) frequencies. These differences were even more pronounced during the swim test, where significant differences are found across a wide range of frequencies and axes. Taken together, these results indicate that the loss of α9/α10 nicotinic acetylcholine receptors primarily impairs postural stability in mice, further implicating the role of the mammalian efferent vestibular system in maintaining posture and balance.

Title: Exploring self-motion perception in the macaque brain using functional ultrasound imaging

Authors: ***B. LIU**, Y. GU;
Inst. of Neurosci., Shanghai, China

Abstract: Path integration is a key strategy for organisms to perform spatial exploration activities, in which self-motion cues play an important role. Research on self-motion has made significant progress over the last two decades, particularly in studies of primates using functional magnetic resonance imaging (fMRI) and electrophysiological techniques. These studies show that certain brain regions such as 3a, 2v, PIVC, FEF, MSTd, VIP, 7a, VPS, and PCC strongly encode either vestibular or visual self-motion information in humans and macaques . However, due to the limitations of fMRI, experiments have only been able to use galvanic vestibular stimulation (GVS) or caloric vestibular stimulation (CVS) to simulate self-motion. In addition, studies in macaques using electrophysiological techniques do not allow for large-scale, rapid recordings, and only focus on few brain regions at a time. Functional ultrasound imaging (fUSI) has developed rapidly in recent years and has the advantage of high spatial and temporal resolution, a wide recording range, and good compatibility, which could help us to study multiple brain areas simultaneously during realistic self-motion. We have improved and refined this technique to enable long-term stable imaging of the macaque brain with motion. In combination with a virtual reality system, macaques were provided with real motion stimuli in different directions of translation and rotation in 3D space by a motion platform and simulated

visual motion stimuli by optic flow. We have systematically investigated the whole-brain network of self-motion information using the fUSI technique. Based on the correlation between ultrasound Doppler signals and motion stimuli, we screened out candidate brain regions that encode self-motion cues. Not only did we find that the classical brain regions reported previously show vestibular or visual responses, but we also clarified the encoding of different subregions of certain brain regions and found that Brodmann areas 1-2 and 5 encode both vestibular and visual signals, and that 3a and 2v, typical vestibular areas, also carry visual signals. Building on previous work in this area, our study not only improved the fUSI technique which has only been applied to stationary monkeys, but also helped fill a gap in the field by constructing a whole-brain network for vestibular and visual self-motion encoding, opening up new directions for future studies.

Title: A role of right middle occipital gyrus in egocentric spatial orientation when the body is tilted: Evidence from a pre-registered rTMS study

Authors: *K. TANI[1], E. NAITO[2], K. MIZOBE[1], S. HIROSE[1];
[1]Otemon Gakuin Univ., Ibaraki, Japan; [2]Cinet Nict, Osaka, Japan

Abstract: Awareness of the relative orientation of external objects in relation to the body, referred to as egocentric (body-centered) spatial orientation, is fundamental to goal-directed actions. The internal estimates of egocentric spatial orientation can be quantified using the subjective visual body axis (SVBA) task, in which participants align a visual line parallel to the perceived body (longitudinal) axis, and estimation errors are evaluated. It is known that when the whole body is tilted laterally, the SVBA is typically biased towards the body tilt. Previous research (Tani and Tanaka, 2021) showed that gray matter volume in the right middle occipital gyrus (rMOG) correlated with individual SVBA bias induced by whole-body tilt (tilt-dependent error: TE); however, the causal relationship between them remains unclear. To validate this, we employed low-frequency repetitive transcranial magnetic stimulation (rTMS) to the rMOG or right temporoparietal junction (TPJ; as a control site), which can induce a transient suppression of brain activity. Twenty right-handed healthy volunteers [5 women, Mean±standard deviation (SD): 20.3±0.28 years] underwent three TMS conditions (rMOG, rTPJ, or Sham). For each

condition, they performed the SVBA task in both an upright and a laterally tilted position with 10 degrees before and after stimulation. We calculated the rTMS-induced changes in the TE (ΔTE) for each condition by subtracting the TE before stimulation from that after stimulation. The number of participants, protocol, and statistical analysis were pre-registered in the Open Scientific Framework (OSF; https://doi.org/10.17605/OSF.IO/FEU8T). Statistical analysis (repeated-measures ANOVA and pairwise Dunnett test) showed that theΔTEs were significantly smaller in the rMOG condition (-2.65 ± 0.98°; $p = 0.04$) but not in the rTPJ condition (−1.99 ± 1.03° ; $p = 0.15$) than the sham condition (0.20 ± 0.84°), indicating the specific reduction of the tilt-dependent SVBA bias by the rTMS to the rMOG. Our results support the causality of the rMOG in egocentric spatial orientation during whole-body tilt.

Abstract: The optokinetic response (OKR) is a reflexive eye movement that follows large visual field motion to stabilize the retinal image. Previous research demonstrated the acquisition of a predictive (p)OKR in goldfish following prolonged exposure to temporally periodic visual stimulation (Marsh and Baker, 1997). A recent study further elucidated the crucial role of the cerebellum in the pOKR acquisition and maintenance (Miki et al., 2018). Interestingly, despite possessing similar basic vestibular and cerebellar neural circuitry to goldfish, other animal species such as zebrafish, medaka, and mice exhibited minimal or no pOKR (Miki et al., 2020; Yamanaka et al., 2022). Additionally, animals presenting the pOKR were found to exhibit long lasting optokinetic after nystagmus (OKAN), which is generated in the dark after prolonged constant velocity visual stimulation, while those that did not acquire pOKR showed little OKAN. OKAN is considered a manifestation of the velocity storage mechanism (VSM) which stores eye

velocity signal during visual and vestibular stimulations, and discharges it when the sensory signals are attenuated. These observations led to the conclusion that the VSM is a fundamental determinant in the pOKR acquisition (Miki et al., 2020). Notably, the VSM is shared between the OKR and the vestibulo-ocular reflex (VOR), which is another reflexive eye movement to stabilize visual images during head motion. Consequently, we hypothesized that the predictive ability acquired through visual training in the OKR may transfer to the VOR. In this study, we aimed to test this hypothesis using goldfish. Initially, we provided temporally periodic visual stimulation to the animals, rotating at a velocity of 20 deg/s for 8 s followed by an 8 s pause, continuously for a duration of over 3 hours. The goldfish subjected to this visual stimulation exhibited the acquisition of the pOKR and presented rhythmic eye velocity oscillation at the trained period in the dark. This oscillation decayed away after a certain number of cycles, as demonstrated previously. Subsequently, we provided a vestibular stimulus by rotating the animals at 20deg/s for 1min in the dark. As a result, the decayed rhythmic eye velocity oscillation, acquired through visual training, was reinstated during the vestibular stimulation. This finding suggests that the eye velocity oscillatory rhythm, obtained as the pOKR through visual training, is maintained within the shared neural substrate of the vestibular system, even after the decay of the predictive behavior. Furthermore, this memory can be recalled by vestibular stimulation, exhibiting as the predictive VOR.

Title: Exploring the benefits and limitations of a bilateral vestibular implant.

Authors: ***J. PHILLIPS**[1], L. LING[1], Y. KOJIMA[1], J. T. RUBINSTEIN[2], S. D. NEWLANDS[3]; [2]Otolaryngology - HNS, [1]Univ. of Washington, Seattle, WA; [3]Otolaryngology, Med. Ctr., Rochester, NY

Abstract: Introduction: Vestibular neuroprostheses have limitations when implanted unilaterally. Stimulation current without spread to adjacent end organs is limited. Activation of afferents and secondary vestibular neurons is incomplete. Interleaved stimulation of multiple canal nerves produces nonlinear combinations of resulting eye movements. Amplitude or frequency modulated stimulation produces directionally polarized responses with distorted velocity profiles. It is unclear if this is due to the intrinsic nature of electrical stimulation, or to the limitations of unilateral stimulation per se. To explore this question, we compared unilateral

and bilateral prosthetic stimulation in monkeys implanted with a bilateral vestibular implant.
Methods: We implanted a bilateral vestibular neuroprosthesis in rhesus monkeys. The device consisted of 2 independent UW Cochlear 2x2x2x16 vestibular implants connected to a common controller via two external RF links. In these experiments, the device was computer controlled, providing different combinations of current or frequency modulated input to each ear. Behavior was recorded with the use of 3D scleral coil. Electrical stimulation could be provided in any combination to the 6 canals in both ears, and could occur in association with rotation using a computer controlled multi-axis rotator.
Results: Combined modulated vestibular stimulation of canal pairs produced summation of the vestibular responses elicited by individual semicircular canals or combinations of canals. This was seen with both stepped constant rate/constant current stimuli and with sinusoidal amplitude or frequency modulated stimulation. In addition, the elicited eye movements had dramatically improved symmetry and spectral purity. Although this was most pronounced during out of phase sinusoidal stimulation, the improvement was not contingent on modulation of inputs to both ears, suggesting that combinations of modulated and non-modulated prosthetic vestibular stimulation might prove beneficial in some patients. Furthermore, combination of natural and bilateral prosthetic stimulation in a lesioned monkey produced eye movements which resembled those of fully intact rhesus monkeys.
Conclusions: Bilateral vestibular prosthetic stimulation overcomes many of the limitations imposed by unilateral prosthetic stimulation. The increased risk to hearing of such implants would limit their initial application to patients with vestibular loss but requiring bilateral cochlear implantation, however these patients may significantly benefit from the increased performance of such a device.

Title: Effects of visual tilt illusion on vestibular sensitivity in the posterior cerebellum

Authors: *L. J. GÓMEZ[1], R. MILDREN[1], F. KARMALI[2], K. CULLEN, 21205[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Otolaryngology, Harvard Med. Sch., Boston, MA

Abstract: The ability to keep our head stable in space requires an understanding of our head's orientation relative to gravity. No sensory system directly encodes gravity; rather, the perception of gravity is an emergent property of the vestibular system, arising from the integration of linear acceleration signals (encoded by the otolith organs) and angular acceleration signals (encoded by the semicircular canals). In the cerebellum, the nodulus and ventral uvula (NU) of the posterior vermis are uniquely situated to perform this integration. Unlike other areas of cerebellar cortex that receive their vestibular input indirectly via the vestibular nuclei, NU also receives robust input directly from primary vestibular afferents. This direct input ensures that vestibular signals are conveyed faithfully to NU so that an internal model of the head relative to gravity can be continuously updated across behavioral contexts. In addition to vestibular inputs, NU also receives neck proprioceptive input (via mossy fibers) and visual motion information (via climbing fibers), both of which are thought to modulate the internal model computed by NU. The response profiles of many NU Purkinje cells clearly encode vestibular and proprioceptive input, which NU likely integrates to update postural reflexes. However, the mechanism by which visual motion information influences activity in NU—and, thus, how visual motion contributes to NU's internal model of gravity—is unknown. To investigate the effect of visual motion information on NU neural dynamics, we performed high-density (128-channel) recordings from NU Purkinje cells in behaving rhesus macaques during a visual tilt illusion paradigm. After priming the macaques with the visual tilt illusion, we examined whether baseline firing rates and responses to vestibular stimulation were altered in the simple spiking activity of NU Purkinje cells. We found that NU neurons did not consistently or appreciably alter their baseline firing rates in response to visual priming, but that visual motion did consistently alter sensitivity to vestibular stimulation. These results indicate that visual motion information does not have an overall modulatory effect on NU Purkinje cell activity; rather, it directly modulates Purkinje cell responses to vestibular input. Together, these results improve our understanding of how the posterior cerebellum uses multiple streams of information to generate an internal model of self-motion relative to gravity.

Abstract: INTRODUCTION. Mal de debarquement syndrome (MdDS) is a rare and poorly understood vestibular disorder that is recognized to significantly impact the quality of life. However, to date, the treatment options remain very limited. Vestibular rehabilitation (VR) is a well-documented, efficient, and widely available treatment option for peripheral vestibular impairment, but its efficacy is poorly known in MdDS. The objective of the study was to explore the influence of traditional vestibular rehabilitation on postural control in a patient diagnosed with MdDS. **METHOD.** Three different participants were assessed: 1- healthy control; 2- participant with identified peripheral vestibular impairment (VI); 3- participant diagnosed with MdDS. Postural control was assessed using a force plate (AMTI-AccuSway) under four conditions: A-Eyes open on firm surface/ B-Eyes closed on firm surface / C-Eyes open on foam/ D-Eyes closed on foam. The center of pressure was recorded and analyzed both in the temporal domain (sway velocity) and the frequency domain (wavelets). Additionally, the perceived handicap using the Dizziness Handicap Inventory (DHI) was assessed. Postural control and Dizziness Handicap Inventory (DHI) were assessed in each participant before (T0) and after (T1) the VR program. The VI participant and the MdDS patient performed a 4-week VR program when the healthy control was assessed twice separated by 1 week without any specific intervention. **RESULTS.** The VI participant showed clear improvement on DHI and sway velocity on condition eyes closed with foam (condition D). Accordingly, a reduction of energy content within frequency bands (0.39Hz-0.78Hz and 0.78Hz-1.56Hz) was observed post-rehabilitation for this participant in both conditions with foam (conditions C and D). Interestingly, the MdDS participant demonstrated a reduction in sway velocity in most of the conditions, but the frequency content was not modified by VR and was comparable to healthy control. Accordingly, the DHI of the MdDS participant failed to demonstrate any difference following VR. **Conclusion.** The results of the present study question the use of vestibular rehabilitation as an efficient treatment option for MdDS. Future studies will have to recruit a larger sample size and focus on the relation between the illusion of movement and postural characteristics such as sway velocity.

Title: Effects of gravity on the perception of rotation and time

Authors: O. KULDAVLETOVA[1], D.-C. NAVARRO-MORALES[1], G. QUARCK[1], ***P. DENISE**[2], G. CLÉMENT[3];

Abstract: While many results highlight the pivotal role of the vestibular system in space cognition only a few studies have shown that the vestibular system plays also a role in the perception of time. During vestibular stimulations, perceived time appears to contract (Utegaliyev et al., 2022) and the perceived timing of sensory input if affected (Binetti et al., 2013).
Weightlessness has also been shown to alter both spatial cognition and time perception. Distances are underestimated when subjects are in weightlessness during parabolic flight (Clément et al., 2008, 2016, 2020) and orbital flight (Clément et al., 2013). We also recently showed that spatial updating, i.e. the ability to estimate new spatial relationships with our surroundings as we move, is impaired during parabolic flights (Stahn et al., 2020).
While in space, astronauts under-produce duration (Navarro Morales et al., 2023; Kuldavletova et al., 2023). We have also found that, during parabolic flights, hypergravity and microgravity affect the reproduction of time intervals (Clément, 2018).
Recent studies have identified common neuronal circuits for judging time and space, suggesting that there may be a single and universal mechanisms in the central nervous system for analysing multiple dimensions, including time, space, numerals, volume, and frequencies (Chen et al., 2021; Cona, 2021; Walsh, 2003).
In weightlessness, as the vestibular system is less stimulated than in normal gravity (due to the absence of tonic otolith inputs) and due to the absence of the gravitational reference, we hypothesize that the cortical network representing spatial and temporal events is disrupted leading to i) alterations in spatial orientation and time perception and ii) that those alterations are correlated with each other.
To test this hypothesis, 18 subjects will be studied in 3 tasks at 1g, 0g and 1.8g during parabolic flights.
During the first task, the participant will be seated on a rotatory chair, and will have to evaluate the amplitude of rotation. During the second task, the participant, while free-floating during weightlessness, will be rotated around the yaw, roll or pitch axis and will have to evaluate the amplitude of rotation.
During the third task, a square will be displayed for 2 to 10 seconds (encoding) and after a few seconds, the square will reappear and subjects will have to judge when the previously displayed duration has been reached (reproduction). As we want to test if different levels of gravity will yield discrepancies between the evaluation and reproduction phases, the encoding will be applied during one gravity level and the reproduction will occur in another gravity level.

Title: Transient Changes in Sound-Evoked Vestibular Myogenic Potentials in a Preclinical Model of Noise Overexposure

Authors: *F. RACITI[1], K. MINESINGER[2], H. SNAPP[3], S. RAJGURU[4];
[2]Biomed. Engin., [3]Otolaryngology, [1]Univ. of Miami, Miami, FL; [4]Biomed. Engin. and Otolaryngology, Univ. of Miami, Coral Gables, FL

Abstract: The vestibular system, located in the inner ear, plays a crucial role in providing critical input for balance and posture by encoding changes in head rotation, translation, and gravity. Similar to the cochlea, the vestibular end organs also respond to loud acoustic stimuli, with the saccule and utricle being particularly susceptible to damage caused by hazardous noise or blast exposures. Over the years, extensive pre-clinical work has characterized the noise-induced changes in the morphological and functional features of the otolith organs using a combination of imaging techniques and the study of vestibular short-latency evoked potentials (VsEPs). However, due to challenges in recording VsEPs in humans, the clinical assessment of vestibular function in noise-exposed subjects rather relies on the analysis of vestibular evoked myogenic potentials (VEMPs). Although prior work has elucidated the neural basis of VEMPs, their use in preclinical studies to characterize the pathophysiology of vestibular dysfunctions has been limited, primarily due to the low level of reproducibility and high variability of the responses elicited in animal models so far. In this study, we employed a standardized preclinical cVEMP setup and test protocol developed by our group that closely mimics clinical methodologies. We provide a detailed characterization of cVEMPs evoked in noise-exposed rodents. Male Brown Norway rats (14-18 weeks) with normal hearing and vestibular function were screened using a Smart EP evoked potentials system (Intelligent Hearing Systems, USA). The animals were then exposed to broadband noise (4-16 kHz) at 110 dB SPL for 1 hour. Changes in thresholds, amplitude, and latency of auditory brainstem responses (ABRs) and cervical vestibular myogenic potentials (cVEMPs) evoked by pure tone bursts at 1 and 8 kHz were compared to baseline (pre-trauma) at multiple time-points up to 84 days post-noise. Within the cohort studied, measurements of auditory function showed a permanent threshold shift (PTS) following noise trauma. In contrast, cVEMP assessments at both frequencies tested revealed noise-induced temporary threshold shifts that recovered by Day 7. We also observed transient reductions in amplitude and increases in latency of vestibular responses to 90 dB SPL stimuli at 1 and 8 kHz, with full recovery by Day 28 and Day 14 respectively. The results of this study suggest that cVEMPs represent a reliable non-invasive diagnostic test in a preclinical setting, with significant implications for understanding early and long-term changes and potentially identifying the neural basis of vestibular disorders, including noise-induced vestibular deficits.

Title: Rapid gaze-shift adaptation during self-generated vestibular prosthetic stimulation

Authors: *K. WIBOONSAKSAKUL[1], C. C. DELLA SANTINA[2], K. E. CULLEN[1];
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Otolaryngology - Head & Neck Surgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The brain must differentiate between externally-generated and self-generated sensory inputs to build stable perception and generate appropriate behavior. Specifically for vestibular prosthesis users, the brain must learn to utilize prosthetic vestibular input to maintain visual and postural stability while also suppress/cancel these reflexes when they are counterproductive to behavioral goals. Here, we leveraged a gaze-shift task—a naturalistic behavior that requires the gating/canceling of vestibular input—to directly investigate how self-generated prosthetic stimulation affects reorientation behaviors. In a monkey with bilateral vestibular deficits, we implanted a vestibular prosthesis that senses head rotation and transforms this movement into vestibular nerve stimulation, substituting for the damaged periphery. The monkey was trained to make eye-head coordinated gaze shifts between horizontal targets while the head, eye, and gaze positions were recorded. Each session comprised a three-block learning paradigm: baseline gaze-shifts, gaze-shifts with prosthetic stimulation, and washout without stimulation. We hypothesized that 1) prosthetic stimulation would first engage vestibular reflex pathways, resulting in impeded head movements and truncated gaze-shifts but also that 2) the brain would then adapt to this new sensory input and no longer engage the reflex when it is counterproductive. Consistent with our predictions, gaze position error initially increased after stimulation onset and then exponentially decayed within ~90 trials. Prosthesis-evoked vestibulo-ocular reflex (VOR) gain and change in head position impeded by the prosthesis-evoked vestibulo-collic reflex (VCR) showed a similar decay though both at a slower rate (~200 trials), suggesting that the suppression/canceling of VOR and VCR both contributed to the observed improvement in gaze accuracy. In addition, early washout trials and catch trials during learning showed oppositely-directed gaze position error, indicating a central adaptation in addition to the observed reflex suppression/cancellation. This central adaptation could be due to the updating of the gaze controller or the updating of a forward internal model to predict and cancel self-generated prosthetic sensory input. Together, these results show that the brain can quickly adapt to self-generated prosthetic stimulation to improve behavioral performance. Importantly, these findings provide new insights on how prosthetic inputs interact with different vestibular pathways in a context-specific way.

Title: Early developmental contributions to directional tuning of the gaze stabilization circuit in the larval zebrafish

Authors: ***P. LEARY**[1], D. GOLDBLATT[2], K. HAMLING[1], D. SCHOPPIK[1];
[1]Neurosci. & Physiol., New York Univ. Grossman Sch. of Med., New York, NY; [2]New York Univ., New York, NY

Abstract: All vertebrates stabilize gaze with a simple circuit that transforms sensed head/body tilts into corrective counter-rotations of the eye. While it is known that the central vestibular nucleus of this circuit is indispensable for encoding directionally-specific stimuli, the factors influencing development of directional tuning are unknown. To investigate the maturation of directional sensitivity in the gaze stabilization circuit, we first measured longitudinal responses of birthdated central vestibular neurons to body tilts. We found that at 3 dpf, directional tuning is present in the earliest-born neurons but not the latest-born neurons. Following 3 dpf, the directional sensitivity of earliest-born neurons strengthens up to 5 dpf, while the directional sensitivity of the latest-born neurons strengthens up to 7 dpf. These results indicate that directional tuning is acquired and matures in a time-dependent manner. To investigate whether this tuning is present immediately upon neuronal birth or if it is acquired over time, we measured birthdated neural activity in response to body tilts directly after the entire vestibular nucleus became post-mitotic (53 hpf). At this time point, we found that all vestibular neurons are responsive to body tilt stimuli, but in an untuned fashion. By 72 hpf, the earliest-born cells show evidence of directional tuning. These findings demonstrate that a period of time exists in which responsive, untuned vestibular neurons acquire directional tuning. Over time, vestibular neurons strengthen their directional tuning as a function of birthdate. Ongoing sensory perturbation experiments during this window of tuning acquisition will reveal whether tuning properties are predetermined or dependent on proper sensory input during early development. Together, these findings will reveal how early development shapes the capacity of a sensorimotor circuit to stabilize gaze.

Title: A comparative molecular atlas of tree shrew and mouse superior colliculus neurons

Authors: *Y. LIU[1], J. A. MCDANIEL[1], E. L. SAVIER[2], J. CANG[1], J. N. CAMPBELL[1];
[1]Univ. of Virginia, Charlottesville, VA; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: The superior colliculus (SC) is a conserved midbrain structure, with its superficial layers (sSC) manifesting diverse visual responses and playing important roles in visual coding. Although the anatomy, connectivity, and function of the SC have been studied in many species, the degree to which molecular cell types and neural circuits are conserved remains unclear. To address this question, we performed single-nucleus RNA-sequencing (snRNA-seq) of both tree shrew and mouse sSC. While the mouse is more genetically tractable, the tree shrew is a better model for vision research given its advanced visual capacity and closer phylogenetic affinity to primate. We compared gene expression across tens of thousands of sSC neurons from the two species and unbiasedly classified 31 neuronal populations. Inhibitory neurons were enriched in the sSC of both species in terms of molecular subtypes and cell numbers, and they shared similar spatial distribution across depth. Furthermore, the majority of neuron subtypes were conserved between the two species, with some differing in abundance. Next, we compared gene expression between neuronal populations and anatomically mapped differentially expressed genes by fluorescence in situ hybridization (FISH). We found that some conserved cell types differed in expression of certain genes between the two species. Finally, we detected a distinct neuron subtype found in the tree shrew sSC but not in mouse, an inhibitory subtype restricted to the surface of the sSC. Together, our comparative molecular taxonomy of sSC neuron subtypes reveals molecular and cellular differences between tree shrews and mice which could underlie functional differences in visual processing. This information may provide insights into the evolution of SC function, connection, and development across species.

Title: Spatiotemporal Receptive Fields of Superior Colliculus Neurons in Tree Shrew and Mouse

Authors: *C. LI[1], S. TANABE[1], E. L. SAVIER[2], H. CHEN[1], P. B. SEDERBERG[1], J. CANG[1]; [1]Univ. of Virginia, Charlottesville, VA; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Tree shrews (Tupaia belangeri) have shown great potential as an animal model for visual studies. They are diurnal animals with well-developed visual systems that are closer to primates than mice, and also offer more practicality than primates for laboratory-based studies. The success in applications of modern genetic, viral, and pharmacological techniques further opens up possibilities to study neural mechanisms of vision using tree shrews. However, our understanding of how the superior colliculus (SC) of tree shrews, a key visual processing center that receives direct retinal ganglion cell projections, responds to stimulus still largely rests upon studies from decades ago where traditional stimuli such as gratings and spots were used. These stimuli rely heavily on the prior knowledge we learned from other structures, and limit the investigation of broader feature space and spatiotemporal integration. Here we designed a more comprehensive set of visual stimuli including spatiotemporal white noise variants to compare the visual response properties of the SC in both awake tree shrews and mice. We recorded single-unit spikes using a 64-channel silicon microprobe. Measuring the spatiotemporal receptive fields with a sparse noise stimulus, our results show that the visual layers of the tree shrew SC have smaller receptive fields compared to mice on average, with a greater prevalence of center-surround substructures. In addition, the response latency of the tree shrew SC is very short (25-50 ms) compared to that of mice (60-80 ms). Furthermore, a noise stimulus that is denser than sparse noise resulted in smaller receptive fields in tree shrews, but not in mice, thus suggesting a higher level of nonlinear spatial interaction in tree shrews. To summarize, our study revealed differences in the SC visual response properties of tree shrews and mice, providing an evolutionary perspective on SC functionality for encoding visual information of their respective environment.

Abstract: The superior colliculus (SC) of both humans and monkeys contains topographic maps of different sensory and motor modalities which are used to guide (c)overt orienting behavior. Whereas an orderly representation of polar angle is well-documented, some controversies exist concerning (para-)foveal and far-peripheral eccentricity representations in primate SC. Previous monkey electrophysiology studies also reported distinct patterns of activity for behaviorally relevant stimulus categories. Here, we used sub-mm and conventional resolution fMRI to test for category-selectivity and to perform small- and wide-field retinotopic mapping of the SC in macaques. In seven monkeys we performed phase-encoded retinotopic mapping fMRI experiments at 3T, with 0.6mm (n = 3) and 1.25mm (n = 4) isotropic voxels. The stimuli consisted of slowly moving apertures (rotating wedges and expanding/contracting rings) superimposed on high-contrast, dynamic, colorful, and multi-object textures - covering either 80° (n = 2), or 25° (n = 5) of the visual field. In a separate passive-viewing fMRI experiment (n = 2), we presented spatially restricted stimuli (15° diameter on average) at different locations (center, and at 17° eccentricity in the lower left/right quadrants), consisting of luminance-matched monkey faces, bodies, objects, and their phase-scrambled versions. We obtained clear retinotopic maps of the SC in five animals. The polar angle and eccentricity maps revealed features consistent with previously reported fMRI maps in humans and electrophysiological findings in monkeys. Contralateral upper and lower quadrants are represented in medial and lateral parts of the SC, respectively. Moreover, the central and peripheral parts of the visual field are represented rostrally and caudally, respectively. Surprisingly, the representation of para-foveal fields differed between left and right SC in all five monkeys, being largely confined to the left colliculus. This

effect cannot be explained by interhemispheric differences in SNR of the fMRI signal. Furthermore, the responses to spatially-restricted stimuli confirmed this asymmetrical topographical representation but did not reveal category selective responses in the SC. In conclusion, our fMRI study demonstrates that the macaque superior colliculus harbors wide-field retinotopic maps, with no evidence for fMRI category specialization, but showing a surprising interhemispheric asymmetry in its retinotopic organization.

Title: Direction selectivity during self-generated visual motion in the mouse superior colliculus

Authors: H. CHEN[1], *V. DEPIERO[1], E. L. SAVIER[2], J. CANG[3];
[1]Biol., Univ. of Virgina, Charlottesville, VA; [2]Physiol., Univ. of Michigan, Ann Arbor, MI; [3]Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: Direction selective (DS) neurons play a crucial role in motion processing within the early visual system. However, their response to visual motion generated by the animal's own movement, known as optic flow, remains poorly understood. Similarly, how early DS neurons encode foreground object motion on a background of self-generated global motion is largely unknown. To address these fundamental questions, we investigated the responses of neurons in the mouse superior colliculus (SC) to visual stimuli in a virtual reality (VR) environment. Using *in vivo* two-photon Ca^{2+} imaging, we studied DS neurons in the superficial lamina of the mouse SC. We simulated a virtual corridor by projecting computer-generated images onto a dome surface. The walls and ceiling of the corridor were textured with random dots. We conducted both "closed-loop" and "open-loop" sessions to examine the neural response. In the closed-loop sessions, the rotation of a treadmill was coupled to the movement in the virtual corridor, allowing mice to self-generate visual flow feedback during locomotion. In the open-loop sessions the virtual corridor moved independently of the animal's locomotion. Additionally, moving dots (eight directions) were presented in a circular patch (30° or 40° diameter) either on a gray background or within the virtual corridor during both closed-loop and open-loop conditions. First, we compared the responses of neurons between presenting a patch on a gray background and a patch during a closed-loop session. Our results revealed that the preferred direction of DS neurons remained unchanged regardless of the background type. However, the global direction selectivity index (gDSI) of these neurons increased during closed-loop sessions. Subsequently, we compared the response properties of DS neurons between open-loop and closed-loop sessions. No significant differences were observed in terms of preferred direction or

gDSI between these two conditions. These preliminary findings suggest that DS neurons in the superficial SC are modulated by visual background but unaffected by locomotion or optic flow. These neurons appear responsive to local but not global motion cues, including those generated by self-movement. By harnessing a VR environment, we gained novel insights into how DS neurons in the mouse SC respond to visual stimuli during naturalistic behaviors.

Title: Characterization of visual response properties and connectivity of Wide-Field Vertical neurons in the mouse superior colliculus

Authors: *E. L. SAVIER[1,2], H. CHEN[2], J. CANG[3];
[1]Mol. & Integrative Physiol., Univ. of Michigan, Ann Arbor, MI; [2]Dept. of Biol., [3]Univ. of Virginia, Charlottesville, VA

Abstract: Vision is a sense that serves many different ethological functions across species. Visual information can be used to either detect preys or predators, and therefore generate orienting or escaping responses. The superior colliculus has been implicated in the orchestration of these behaviors. Within this structure, at the interface between the primary and the secondary visual pathway, lay the wide-field vertical neurons (WFV). WFV are a conserved morphologically defined cell-type found across many taxa from reptiles to highly visual mammals, independently of their visual ecology. These neurons display wide arborization and typical bottlebrush distal tips which form connections with retinal ganglion cells axonal terminals. In mammals, these neurons receive direct inputs from the retina and the primary visual cortex, and have the pulvinar as a known target, however, their brain-wide connectivity remains to be identified. These cells display peculiar response properties, but despite their ubiquity and unique morphology, their contribution to vision remains elusive.In this study, we have characterized WFV morphology, connection, and visual response properties in vivo in the laboratory mouse. Two-photon calcium imaging in awake mice using a transgenic Cre-line targeting specifically WFV (NTSR1-Cre) confirmed their unique response properties. WFV showed a strong preference for small moving stimuli and a slight bias for certain directions. Interestingly, visual responses showed strong modulation by locomotion, which is in contrast with what has been observed for superficial direction selective neurons in the SC. In addition, Cre-dependent rabies tracing unraveled a variety of sources of input which had not been

described previously.These results place WFV as a major integrator of visual information in the superior colliculus. Their modulation by locomotion and direction selectivity suggests a role in the integration of non-visual signals which might be linked to the processing of optic flow. Taken together, this initial characterization paves the way to elucidate the role of these neurons in guiding visual behavior.

Title: Neurons in the primate superior colliculus are selective for binocular disparity

Authors: I. KANG[1], G. YU[1], L. N. KATZ[1], R. J. KRAUZLIS[1], *H. NIENBORG[2];
[1]Lab. of Sensorimotor Res., Natl. Eye Institute, NIH, Bethesda, MD; [2]Lab. of Sensorimotor Res., Natl. Eye Institute, NIH, Washington, DC

Abstract: The superficial layers of the superior colliculus (SC) get prominent inputs from the visual cortex, where many neurons are selective for horizontal binocular disparity, a powerful cue for depth perception. Despite this strong binocular input to the SC, selectivity for binocular disparity has never been studied in the primate SC.
Here, we used multichannel linear arrays to record neurons in the superficial and intermediate layers of the SC of one rhesus macaque who had no prior training on disparity-based tasks. The monkey passively viewed random dot stereograms (RDSs) presented in the neurons' receptive fields (RF). The circular RDSs consisted of a disparity-varying central disc and a surrounding annulus at zero disparity. The eccentricity of the visual RFs ranged from foveal to peripheral (0.7 to 40.3°, mean±sd = 13.7±9.5°). Of the 193 isolated neurons, 121 units (63%) were significantly selective for binocular disparity (Disparity Discrimination Index, Prince et al., 2000, permutation test, mean±sd = 0.66±0.13). For most of these (93%) disparity tuning was well described by a Gabor function (explaining at least 60% of the variance, mean±sd = 82±60%). The tuning was typically even-symmetric: 88% were classified as tuned-excitatory (n=71) or tuned-inhibitory (TI, n=28), and the rest classified as Far (n=8) or Near (n=6) cells (Read and Cumming, 2003). The preferred disparity was broadly distributed around zero. Units recorded in the same session tended to prefer the same disparity sign suggesting clustering for disparity selectivity across SC layers. There was a positive correlation between the absolute preferred disparity and the RF eccentricity ($r = 0.38$, $p < 10^{-3}$, n=85, TI cells were excluded), and the tuning width ($r=0.44$, $p < 10^{-5}$, n =80), but no bias depending on whether the RF was in the lower or upper visual field ($p=0.98$, t-test). For all units, we also measured the response to anti-correlated RDSs (i.e., black

dots in the image of one eye were white in the image of the other eye, vice versa) and found the tuning tended to be inverse of that for the correlated RDSs albeit with a weaker amplitude and larger response variability. Lastly, SC neurons were functionally classified based on their responses during memory-guided saccades, but we found no difference in tuning strength across SC cell classes ($p = 0.37$ across 6 classes, ANOVA).
Overall, SC neurons possess selectivity for binocular disparity which shares many similarities with that of cortical neurons, especially of V1. This provides a plausible neural substrate for how the SC supports visual orienting in 3D natural environments.

Title: Reward modulates visual responses in mouse superior colliculus independently of arousal

Authors: *L. J. BARUCHIN[1], M. ALLEMAN[2], S. SCHRÖDER[1];
[1]Life Sci., Univ. of Sussex, Brighton, United Kingdom; [2]Ctr. for Theoretical Neurosci., Columbia Univ., New York, NY

Abstract: The processing of sensory input is constantly adapted to behavioural demands and internal states. Obtaining reward satisfies such behavioural demands and associating the reward with its source, a certain environment or action, is paramount for survival. Here, we show that water reward increases subsequent visual activity in the superficial layers of the superior colliculus (SC), which receive direct input from the retina and belong to the earliest stages of visual processing.
We trained mice in a visual detection task that required them to detect a stimulus of varying contrast in the left or right visual field. The mice had to interactively move the stimulus towards the centre of the visual field or refrain from movement in case of no stimulus. Correct choices were rewarded with water, incorrect choices were followed by auditory noise. We then used two-photon calcium imaging to record activity of neurons in the superficial SC (sSC) of 6 well-trained mice in a total of 22 sessions.
We quantified the effect of various task behaviours and pupil-linked arousal on the gain of the contrast tuning curve. Similar to previous studies, we found that arousal modulated the visual responses of sSC neurons, leading to increased and decreased activity in different neurons.

Additionally, we discovered that visual responses of about 20% of sSC neurons increased after reward delivery in the previous trial. Modulation by reward, but not arousal, significantly improved the performance of a population decoder to detect visual stimuli. The effect of previous reward on visual responses was independent from modulations by pupil-linked arousal and could not be explained by eye movements/position, licking, whisking, wheel turns, slow fluctuations in neural responses across trials, or reward history.
Lastly, we validated our results using electrophysiology with Neuropixels probes in 6 separate well-trained mice. By recording from the entire depth of the SC, we discovered that 26% of visually responsive sSC neurons were reward-modulated compared to 18% in the dSC. In contrast, 10% of visually responsive sSC neurons were modulated by arousal compared to 13% in dSC.
Our findings show that visual responses of sSC neurons are strongly influenced by two independent state variables: pupil-linked arousal and previous reward. Future studies may reveal how these non-visual modulations help downstream processes in guiding behaviour.

Title: Relative salience-dependent stimulus competition in the mouse superior colliculus

Authors: *S. MYSORE[1], N. B. KOTHARI[2], E. SCHURINK[3];
[2]Psychological and Brain Sci., [3]Undergraduate Program in Neurosci., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Selecting the most salient (or more generally, the highest priority) stimulus for subsequent neural processing is a critical component of spatial selective attention and adaptive behavior. For such target selection for spatial attention, it is well-established that competitive interactions among stimulus representations in the intermediate and deep layers of the superior colliculus (SCid), a midbrain sensorimotor hub, are critical. However, little is known about the rules governing the relative-salience dependence of competitive interactions in the mammalian SCid. Here, drawing inspiration from work in owls, we recorded extracellular responses of SCid neurons in passive head-fixed mice viewing single and competing stimuli. Mice were presented with one visual stimulus inside the receptive field (S_{in}) and another competing stimulus far outside (S_{out}). The salience of S_{out} was systematically varied, while that of S_{in} was held constant, and the resulting competitor salience-dependent response profiles of SCid neurons were

analyzed. We found several notable results. First, we found that firing rates of SCid neurons were negatively correlated with increasing salience of the competitor and these profiles were well fit by sigmoidal functions. Second, we found that a sizeable number of neurons encoded relative salience with an abrupt switch-like transition from high to low firing rates, while the remaining had a more gradual transition. Third, and importantly, we found that, on average, the value of competitor salience at which the responses transitioned from high to low values, the transition value, was equal to the salience of S_{in} (i.e., when relative salience was zero). Indeed, when the strength of S_{in} was increased, the transition value also increased by the same amount, revealing that SCid neurons signal accurately whether or not the stimulus inside their receptive is the most salient. Separately, we examined whether these properties of signaling of the most salient stimulus depended on rostro-caudal and medio-lateral location of the neuron's receptive field. Combined, our results demonstrate that the mammalian SCid accurately, precisely and flexibly signals the most salient stimulus across space.

Title: Population signaling of the most salient stimulus in cluttered scenes by neurons across the optic tectum space map

Authors: *S. MARTIN, G. T. ANANDAN, J. H. HUNTLEY, S. P. MYSORE;
Johns Hopkins Univ., Baltimore, MD

Abstract: The superior colliculus (SC, called optic tectum, OT, in birds) is a midbrain sensorimotor hub known to play a critical role in selective visuospatial attention. Specifically, competitive interactions among the representations of stimuli in the intermediate and deep layers of the SC (SCid/OTid) are critical for the selection of a target among distracters. Thus far, studies of the neural correlates of selection in the SCid/OTid have focused predominantly on competitive interactions among two competing stimuli, with a few exceptions. In one study, it was shown in monkeys that SCid responses decrease systematically as the number of competing distractors increases. Separately, ongoing work in our lab in the barn owl OTid shows that in addition to the overall reduction in the evoked responses, there is also an impairment in the accuracy with which individual SCid neurons signal the most salient among competing stimuli, as the number of competing stimuli increases. Inspired by work in other brain areas (including the OTid of owls), here, we wondered whether population signaling by the OTid network is also

similarly impaired, or whether it might allow improved signaling accuracy as the number of competitors increases. We tested this hypothesis with electrophysiological experiments in the barn owl OTid in conjunction with multi-stimulus competition protocols. Our results suggest that signaling of the most salient stimulus by the OTid network is more accurate than that by individual OTid neurons, particularly as the number of competing stimuli increases. The measured responses also suggest a potential computational mechanism for this improvement in the network signaling accuracy. Together, our results shed new light on the neural basis of stimulus competition in complex, cluttered scenes with greater than 2 stimuli.

Title: Cholinergic modulation of Imc neural response properties

Authors: *L. ZHANG[1,2], S. P. MYSORE[3];
[1]Neurosci., [3]Johns Hopkins Univ., [2]Johns Hopkins Univ., Baltimore, MD

Abstract: The Imc, a conserved group of inhibitory neurons in the vertebrate midbrain tegmentum, is interconnected bidirectionally with the midbrain sensorimotor hub, the optic tectum (OT; or superior colliculus, SC, in mammals). It is known to control long-range competitive interactions among the representations of stimuli in the OT/SC, which, in turn are critical for the control of selective spatial attention. Indeed, the Imc exhibits a special pattern of donut-like connectivity with the OT - it receives glutamatergic drive from focal portions of the OT space map but sends broad GABAergic projections back across all locations of the OT space map except the ones from which it receives input. This unique pattern of connectivity is responsible for OT's ability to signal the strongest of competing stimuli categorically and reliably. Despite these detailed insights about Imc from the literature, several aspects of Imc function still remain mysterious. Specifically, on the one hand, it is widely believed that Imc receives excitatory input (as glutamatergic drive) solely from the OT. On the other hand, some histological findings in the literature indicate an intriguing localization of acetylcholinesterase to the Imc, suggesting the presence of cholinergic synapses as well on Imc neurons. Whether this staining indeed represents functional cholinergic input onto Imc neurons, and if so, what the functional role of this cholinergic input may be, are unknown. Here, we measured evoked responses of owl Imc neurons extracellularly without and with selective and reversible iontophoretic inactivation of cholinergic inputs. We found that cholinergic input powerfully and

multiplicatively amplified both evoked and spontaneous Imc responses. Our results are consistent with a presynaptic modulation of excitatory drive onto Imc neurons by acetylcholine. Additionally, we find that perturbation of cholinergic input onto Imc produces a modulation of the strength of response suppression in the OTid. This cholinergic modulation of Imc neurons may represent a novel mechanism for modulating signaling by OTid neurons.

Title: Corticotectal encoding of visual information

Authors: *D. CASSATARO[1], E. M. CALLAWAY[2];
[1]Neurosciences Grad. Program, UCSD/Salk Inst., La Jolla, CA; [2]Salk Inst., La Jolla, CA

Abstract: An organism makes decisions based on a combination of cognitive and sensory information. How the brain combines, prioritizes, and uses information for organismal goals are major questions in systems neuroscience. The superior colliculus (SC) receives cortex-wide inputs and encodes features and spatial coordinates of points of interest within the space immediately surrounding the organism, with superficial SC responding to sensory features and deep SC signaling its motor outputs. More mysterious is the influence of the prefrontal cortex (PFC) on SC responses; PFC information tends to be abstract, cognitive, and non-spatially-mapped. We hypothesize that SC neurons play a role in spatially mapping potential cognitive information from PFC alongside sensory and motor information. To investigate this, we record neuronal activity from the SC and PFC using multi-shank silicon microprobes while mice perform a visuo-spatial two-alternative forced choice task. Here, we show visual responses of SC neurons and how they are influenced by behavioral variables, visual features, and spatial location of relevant and irrelevant stimuli. We also show how the encoding of these variables changes across the superficial, intermediate, and deep anatomical regions of the SC.

Title: The impact of natural movement on visual processing in the mouse superior colliculus

Authors: *S. L. SHARP, D. M. MARTINS, C. M. NIELL;
Univ. of Oregon, Eugene, OR

Abstract: Vision is a dynamic process that involves sampling of the visual scene and exploring the environment through eye, head, and body movements. Traditionally, vision in animal models has been studied through non-natural laboratory paradigms, such as under anesthesia or during awake head-fixation. These approaches have experimental benefits such as precise control of behavior and of the visual input. However, it cannot be ignored that studying vision while constraining movement, as in head-fixation, severely limits our understanding of neural computations that occur during natural vision. Previous research in head-fixed mice has shown that two major brain regions involved in visual processing, primary visual cortex (V1) and superior colliculus (SC), both show neural modulation in response to locomotion, with greater gain modulation in V1 as compared to SC. Recently we implemented methods to study the impact of natural movement on visual processing in V1 of freely moving animals, using chronically implanted high density electrodes combined with head-mounted cameras to measure eye movements and the visual scene from the animal's perspective. We found modulation by head/eye position and an impact of eye movements on temporal dynamics. Here we extend this to superior colliculus in order to investigate natural movement modulation in both visual and multimodal layers of SC. We have demonstrated the ability to successfully record large populations of SC neurons in freely moving animals, measure visual responses, and assess the impact of head, eye, and body movements. This data will allow us to determine how natural movement modulates activity across the layers of SC, from sensory input to motor output.

Title: Choosing their battles: developmental improvement in zebrafish hunting behavior

Authors: *M. MOSHKOVITZ, S. SHAPIRA, S. TISHBY, Y. RUBINSTEIN, I. LIFSHITZ, L. AVITAN;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Goal directed behavior consists of a sequence of actions performed by the organism in order to achieve a desired target. These sequences often become more efficient as the organism gains experience interacting with the world. It remains unknown what features of the interaction with the external world change with experience. To address this question, we recorded freely swimming developing larval zebrafish (5-15 dpf) while hunting Paramecia using a high-speed camera (500 fps). By tracking the features of the fish and all paramecia in the dish, we found that placing the target in the strike zone does not guarantee a successful event (hit). The complexity of the visual field plays a role in determining the outcome of the event (hit/miss/abort). Over development fish select sparser scenes to initiate their hunt events, and more efficiently handle complex visual scenes. These results form the basis to uncover the neural mechanism mediating the improvement in hunting behavior.

Title: Learning when to look: saccade target selection and timing in dynamic environments

Authors: *S. RENGARAJAN, H. SUNDARAM, L. CHUKOSKIE;
Northeastern Univ., Boston, MA

Abstract: Humans use gaze to actively explore the surrounding environment. Timing gaze behavior to environmental events is essential to respond promptly and accurately to fleeting stimuli. Furthermore, the ability to capture and assimilate temporal information about the environment permits predicted responses to future time-limited events. This type of behavior is especially important in tasks embedded in dynamic environments such as ball sports, video games, and even many types of social interaction. When exposed to visual rhythms, such as oscillating patterns, humans are able to synchronize their saccadic eye movements with the temporal structure of the stimuli. This synchronization allows our gaze to align with moments of peak relevance or saliency in the visual scene. By coordinating with the rhythm, saccades optimize the allocation of attention and facilitate efficient information processing. Although we know quite a bit about the spatial deployment of gaze and how we learn where to look in a novel environment (see for example Chukoskie, et al., PNAS 2014), we know considerably less about

how humans learn when to deploy their gaze in dynamic environments. To fill this gap in our knowledge, we designed a paradigm in which saccade targets are defined on the basis of when they occur, not where they occur. Participants engaged in a gaze timing task that required them to identify target bubbles among distractors by shifting their gaze to bubbles that appear at a particular frequency, ignoring bubbles oscillating at distractor frequencies. We use eye tracking to make the paradigm gaze-contingent, such that a correct target selection will be recognized immediately after fixation. We characterize learning through target accuracy, and latency to acquire targets over time. We will also investigate the extent to which saccades entrain to different types of visual rhythms. By analyzing eye movement data in conjunction with psychophysical measurements, we will quantify the temporal dynamics of saccadic synchronization and examine how it influences perception and attentional processes. Future work will relate the behavior of neurotypical participants to participants on the autism spectrum who have in other work exhibited differences in generating well-timed responses to dynamic stimuli and accurately generating predictive behaviors for upcoming events.

Title: Temporal sources of endpoint error in interceptive saccade to moving target

Authors: *Z. XIAO[1], F. YANG[2], C. BOURRELLY[3], S. WILLETT[3], J. MAYO[4], N. GANDHI[2]; [1]Ctr. of Neurosci., Univ. of Pittsburgh, PITTSBURGH, PA; [2]Bioengineering, [4]Dept of Ophthalmology, [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: To achieve spatiotemporal accuracy in generating saccades towards moving targets, the brain needs to compensate for sensorimotor delays and accurately predict the target's location at the movement end. Previous studies have demonstrated that interceptive saccades account for target velocity and displacement. Notably, the movements exhibit reduced peak velocity and increased ending error compared to matched saccades toward stationary targets. The underlying factors contributing to this degradation need further investigation, as it will facilitate our understanding of how eye movement system responds differently between dynamic and stationary environments. In the current study, we are interested in how delays in sensory-motor integration affect the endpoints of interceptive saccades. A preliminary analysis was conducted on two macaque monkeys during horizontal, leftward saccades. We found that while saccadic latencies towards inward-moving, outward-moving, and stationary targets were in a similar

range, the magnitude of saccadic ending error increased as a function of reaction time in most moving target conditions. This relationship between reaction time and endpoint error was not observed when the target was stationary. The relation between ending error and reaction time was also a function of target velocity. These results suggest that sensorimotor processing time may contribute to the accuracy of interceptive saccades. We hypothesize that longer processing time is associated with degraded target motion processing, thereby increasing movement output error. To more rigorously examine the initial findings and test this hypothesis, we have designed an experimental paradigm that minimizes the influence of target displacement and saccadic amplitude on the ending error and instead isolates the temporal factor. In the second experiment, human participants will be required to make interceptive saccades toward a target moving along a circular path. Since the target eccentricity remains constant during motion, participants' ideal saccadic amplitudes will remain unchanged and independent of the targets' displacement. We expect that as processing time increases, the initial saccade direction will exhibit a larger deviation (until the neural processing resets). Saccade ending error will also be positively related to processing time.

Title: Moving target prediction: deciphering gaze and low beta EEG patterns in pursuit and saccade visual strategies

Authors: *R. KOSHIZAWA[1], K. OKI[2], M. TAKAYOSE[3];
[1]Nihon Univ. Col. of Econ., Tokyo, Japan; [2]Nihon Univ. Col. of Sci. and Technol., Chiba, Japan; [3]Nihon Univ. Col. of Industrial Technol., Chiba, Japan

Abstract: Accurate prediction of the trajectory, position, and time of arrival of a ball is of importance in ball sports, such as bat or racket sports. Although some studies have attempted to predict the trajectory, position, and time of arrival of a parabolic moving target, there is a lack of research regarding the brain processing involved. Hence, we examined gaze and low beta electroencephalography (EEG) activity patterns when predicting the trajectory, arrival position, and arrival time of a parabolic moving target. Participants' EEG signals were recorded while they engaged in two tasks: the pursuit strategy task (PST) and the saccade strategy task (SST). In the PST, participants were instructed to visually track the target throughout its trajectory and

indicate when it reached its endpoint. Conversely, in the SST, participants were instructed to shift their gaze to the anticipated endpoint of the ball's arrival. No significant differences were observed in the position error (PE) associated with the target's arrival position between the SST and the PST, which suggests that successful prediction of the arrival position can be achieved even without employing a "strategic" pursuit approach. Notably, the SST elicited significantly higher levels of low beta EEG activity in the secondary visual cortex ($p<.05$), primary motor cortex ($p<.05$), and right posterior parietal lobe ($p<.05$) compared to the PST. This low beta EEG activity during the SST likely corresponds to visuospatial attention directed towards the moving target, tracking of the moving target, and focusing on the arrival position. Furthermore, the small PE group at response exhibited significantly higher levels of low beta EEG activity in the middle temporal (MT) visual area ($p<.05$) compared to the large PE group, suggesting that the low beta EEG activity in the MT visual area may more accurately detect the speed and direction of the moving target for individuals with a smaller PE at response. The results of this study indicate that it is unnecessary to keep an eye on the moving target and keep pursuing it. In addition, our study suggests that it is necessary to quickly detect the speed and direction of the moving target in the MT visual area and perform a saccade strategy.

Title: Varying reward expectancies do not affect trial-by-trial amplitude learning in a random error saccadic adaptation context

Authors: *M. SHAFIEI[1], P. THIER[2];
[1]Thier Lab, Hertie Inst. for Clin. Brain Res., Tübingen, Germany; [2]Cognitive Neurol. Lab, Hertie Inst. for Clin. Brain Research, Univ. of Tübingen, Tübingen, Germany

Abstract: Previous studies have indicated that motivation reflecting reward expectancies has an impact on dynamic aspects of saccadic eye movements with higher motivation entailing shorter reaction times and larger peak velocities (Hikosaka et al., J Neurophysiol., 2006). Moreover, higher reward expectancies accelerate saccadic directional adaptation driven by retinal errors that occur in a consistent manner, although the overall magnitude of learning remains unaffected (Kojima and Soetedjo, Neurosci., 2017). Previous research has established that saccadic learning does not require error consistency as even single errors have an impact on a subsequent saccade (Junker et al., PloS Biol., 2018). More specifically, a single inward error results in a larger subsequent saccade, while an outward error entails a smaller one. We hypothesized that varying

reward expectancies might also modulate the impact of such individual errors rather than requiring the consistency prevailing in the aforementioned study of Kojima and Soetedjo. To critically test this expectation, we studied two monkeys in a paradigm in which saccadic over- and under-shoots resulted from randomly shifting the target inward or outward during a target directed saccade. We implemented directional rewards that were independent of the type of error induced. In a given block, only saccades made to either the left or right side of the display were rewarded. The direction-reward contingency was reversed from one block to the next with 8-10 blocks constituting an experimental session. Our findings from the first monkey (analysis of data from the second monkey in progress) showed that rewarded saccades exhibited significantly shorter reaction times by 50.2 ms, on average, and higher peak velocities by an average of 36.3 deg/s compared to the non-rewarded saccades. We could also replicate the findings Junker et al. (PlosBiol., 2018), showing that trial-by-trial changes in the amplitude of future saccades are a function of the past retinal errors (beta coefficient = 0.08, $p << 0.0001$). Surprisingly and in contrast to our initial hypothesis, we found that that reward did not modulate the impact of a given retinal error on the amplitude of the subsequent saccade. In a nutshell, in this first monkey reward expectancies clearly influenced the dynamic characteristics of saccades, however, without exerting a discernible influence on the extent of learning from individual past errors. Hence, an impact of reward expectancies on learning from past errors may need a certain amount of consistency over time, dispensable for the reward-dependent control of saccade dynamics.

Title: A dynamical system model of monkey superior colliculus activity for stationary and moving targets

Authors: *F. YANG, N. GANDHI;
Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is a laminar subcortical structure essential for converting visual inputs into motor commands for eye movement generation. The neural response to a stationary visual stimulus and the corresponding motor signal for saccade execution have been well-studied. Computational studies have advanced dynamical systems models that accurately simulate visuomotor firing rates of individual and population of neurons, while incorporating known intracollicular connectivity. In contrast, SC response to a moving target and the

interceptive saccade directed to it are understudied. We previously published that the tuning curve shifts during the motor epoch based on the direction and the speed of the target, which indicates the possibility of shifting the entire neural population on the SC or morphing the population representation. Our preliminary work indicates that, during the visual epoch, single-neuron activity may be similar for moving and stationary targets, although information about the moving target may be encoded in the latent factors. It is not known whether current models of SC can simulate neural activity associated with moving targets and interceptive saccades. Thus, we propose to start with a one-dimensional dynamical system model based on the Arai et al. (1994) architecture for visual and motor responses to a stationary target. The framework will be updated to include superficial, intermediate, and deep layers, each with its own parameters for local excitation and inhibition. Communication across layers, global inhibition from basal ganglia, and feedback from the downstream brain generator will also be considered. We will train the model with data recorded from monkeys producing saccades to stationary and moving targets as well as no-go trials associated with a moving target. Our objective is to have the same model simulate accurate sensory and saccade-related activity in individual neurons and across the SC population for both stationary and moving targets. We will also validate our model by analyzing the weights in each layer to assess whether it is consistent with local excitation and distal inhibition results reported in the previous studies.

Title: Local field potential features in the primate superior colliculus during visually-guided saccades inside and outside the response field

Authors: *C. BOURRELLY, N. GANDHI, *C. BOURRELLY;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The superior colliculus (SC) is a central node in the neural circuit that mediates visually-guided saccades. The topographic organization of space along its rostrocaudal and mediolateral dimensions and the systematic transformation of sensation to action along its dorsoventral axis have been well characterized for spiking activity but to a lesser extent for the local field potential (LFP). Spiking activity represents the output of neurons, and the LFP signal reflects integrated activity including input signals within a volume of tissue around the recording site. We recently described visuomotor features of the LFP signal along the dorsoventral axis of SC during saccades directed in the response field (RF) of neurons encountered in the track. We

now evaluate this signal for targets and saccades away from the optimal location. Specifically, we applied current-source density (CSD) analysis to LFP signals and identified sources and sinks across the SC layers to assess functional connectivity during sensation and action epochs. Given the hypothesis that intracollicular circuitry is dominated by local excitation and distal inhibition connectivity of SC neurons, particularly in the intermediate layers, we expected to observe inhibitory signatures in the CSD signal during the movement epoch, especially between the two SC. Using multi-contact laminar electrode inserted orthogonal to the SC, we recorded spiking and LFP activities in rhesus monkeys performing a visually guided delayed saccade task. In our current datasets, the target was placed at one of 8 locations radially equidistant in direction. Using CSD analysis, we compared LFP activities during both the sensory and the motor epochs and across depth for each target location. During the sensory period, a strong sink (putatively excitation) in the CSD signal was found after the appearance of the target in the RF but not when the target was presented outside the RF. During the motor epoch, when the target was presented in the RF, strong source and sink activities were observed in the CSD signal around the time of the saccade. Interestingly, when the target was located outside the RF, we observed solely a source in the CSD signal around the time of the saccade. This source in the CSD signal for outside RF targets likely reflects an inhibitory input present in the LFP activity. This result suggests a global inhibition in the SC during the production of the saccade and supports the hypothesis that the LFP can represent the input signal. All together, these results are informative about spatial and temporal processing in the SC during saccade generation.

Title: Signaling of trans-saccadic prediction error by foveal neurons in the monkey superior colliculus

Authors: *T. ZHANG[1,2,3], A. BOGADHI[4], Z. HAFED[1,2,3];
[1]Univ. of Tübingen, Tübingen, Germany; [2]Werner Reichardt Ctr. for Integrative Neurosci., Tübingen, Germany; [3]Hertie Inst. for Clin. Brain Res., Tübingen, Germany; [4]Central Nervous Syst. Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach Riß, Germany

Abstract: The superior colliculus (SC) possesses visual machinery supporting both foveal analysis and peripheral object detection. This structure also emits movement-related discharge that is relayed to both the downstream oculomotor control network and upstream cortical areas. This places the SC in an ideal position to both control orienting responses as well as bridge periods of sensory uncertainty associated with rapid eyeball rotations. Yet, the mechanisms with which peripheral visual information may be trans-saccadically relayed to foveal SC visual

representations are not fully understood. Here we asked 2 macaque monkeys to generate 8-10 deg delayed, visually-guided saccades to peripheral grating targets, while we recorded foveal SC neurons. Intra-saccadically, we flipped the target appearance such that the foveal neurons experienced a post-saccadic image that was different from the peripheral pre-saccadic one. We tested pre- and post-saccadic images having different spatial frequencies (circular grating of 1 or 4 cycles/deg; cpd), different shapes (circle or square encompassing a grating texture that did not change intra-saccadically), or a combination of the two (both shape and texture within it changed intra-saccadically). Importantly, the foveal neurons did not respond to the peripheral stimulus onsets on their own, suggesting that the pre-saccadic images did not directly stimulate these neurons' response fields (RF's). We analyzed the post-saccadic visual reafferent responses of the foveal SC neurons with or without intra-saccadic image changes. Foveal SC visual reafferent responses were enhanced when the spatial frequency content of the saccade target image changed intra-saccadically. Shape changes only increased reafferent responses when the texture within the shape had a high spatial frequency; and, shape and frequency changes reflected the results of the previous two manipulations. These effects did not occur when we simulated saccades during fixation by rapidly translating a peripheral grating to the fovea and changing its appearance mid-flight. Our results suggest that foveal SC visual representations might receive a predictive signal about the visual appearance of the peripheral pre-saccadic target. One potential source of such a predictive signal could be the SC motor bursts themselves, which we recently found to reflect the visual appearance of the eccentric saccade target (Baumann et al., 2022).

Title: The different role of the dorsolateral prefrontal cortex (dlpfc) and the lateral intraparietal cortex (lip) in the hierarchical control of learned saccade sequence

Authors: *Q. WANG, B. SHI, J. JIA, J. HU, H. LI, X. JIN, A. CHEN;
East China Normal Univ., Shanghai, China

Abstract: Action sequences are suggested to be organized in a hierarchical manner in which individual actions are organized into elements, subsequences, then sequences. However, how these different levels of sequence are processed in the brain remains unknown. Here, we investigated and compared the role of the dorsolateral prefrontal cortex (DLPFC) and the lateral

intraparietal cortex (LIP) in sequence execution by training monkeys (Macaca mulatta, male, 8 ~ 12 kg) to perform a set of hierarchically organized saccade sequences (e. g. left-left-right-right and right-right-left-left). We found that inactivating DLPFC significantly increased the response latency of the first saccade at the sequence level, and the “start” signal of sequence was also observed in neuronal activities. Differently, LIP exhibited a unique feature at the subsequence level: it represented the end of the ipsilateral subsequence (e.g. left-left subsequence if the cell was recorded in left LIP), and the start of the contralateral subsequence, indicating that LIP might play a role during the subsequence transition. Further electrical microstimulation experiments on LIP significantly changed the structure of saccade sequences. Our results suggest that DLPFC might be actively involved in the sequence initiation, whereas LIP may serve as an important intermediate layer in the hierarchical motor control network for subsequence switch.

Inst. of Mental Hlth., Bethesda, MD; [5]Dept. of Neurosci., [6]Human Brain Res. Ctr., Grad. Sch. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: Several areas in the dorsal frontal cortex (DFC) and their downstream, superior colliculus (SC), are involved in both saccade generation and cognitive functions, such as attention, in primates. In the SC, a topographic organization of saccadic control (small to large saccades controlled by rostral to caudal SC; upper to lower visual field saccades controlled by medial to lateral SC) has been well studied. However, because the upstream DFC are in the sulci in macaques and are difficult to map accurately, whether the same principle applied in those areas remains elusive. Here, we aim to use the common marmoset, with its lissencephalic cortex and human-like saccadic behavior, to investigate the saccade related areas in the DFC and their projections to the SC. We applied electrical microstimulations (biphasic current at 250 Hz for 30 trains) with tungsten electrodes in the DFC while two marmosets performing gap saccade task to identify the saccade evoking areas. We systematically varied the initial gaze locations to assess the evoked saccade types. In separate animals, we injected viral tracers with TET amplification (AAV1-Thy1S-tTA mixed with either AAV1-TRE-clover or AAV1-TRE3-Vamp2-mTFP1) into the same brain areas and analyzed their projection to the SC. All microstimulation and viral injection sites were transformed to the BMA 2019 marmoset atlas template for comparison across animals. We successfully evoked saccades in areas 45, 8aV, 8aD, 6DR, and 6Va. The evoked saccades were mainly goal-directed. Vector-based saccades could only be evoked in a small region around areas 45, 8aV and 6Va. Areas 45, 8aV, and 6Va exhibited lower evoking threshold (< 50 μA), lower evoking latency (< 60 ms), and projection to the intermediate layer of the SC, whereas 8aD and 6DR showed higher evoking threshold, higher evoking latency, and

projection to the deeper layer of the SC. Topographic projection to the SC was also observed, with area 45 to 8aV projected rostral caudally and rostral to caudal 8aV projected medial laterally to the SC. The systematic change in evoking saccade amplitude and direction in these areas was in line with the established topographic control of saccades in the SC, considering the corresponding topographic projection. Taken together, we identified the topographic organization of saccade related areas in the marmoset frontal cortex functionally using microstimulation and anatomically using viral tracing and both methods showed consistent results with the SC topography. Our results will not only help us to fill the gap in previous primate oculomotor research, but also provide guidance in identifying these areas for studying other cognitive functions.

Title: The Effect of Muscimol Induced Inactivation of the Frontal Eye Field in Common Marmosets

Authors: *W. AMLY[1], C.-Y. CHEN[2], H. ONOE[4], T. ISA[3];
[1]Kyoto Univ., kyoto, Japan; [2]Dept. of Neurosci., Kyoto Univ., Kyoto-Shi, Japan; [3]Dept. of Neuroscience, Grad. Sch. of Med. & Fac. of Med., Kyoto Univ., Kyoto, Japan; [4]Human Brain Res. Ctr., Kyoto Univ. Grad. Sch. of Med., Kyoto-Shi, Japan

Abstract: For over a century, researchers have discovered the involvement of the frontal eye field (FEF) in eye movements in macaque monkeys. Neurons within the FEF exhibit activity prior to and during saccades, and electrically stimulate the FEF have demonstrated the ability to elicit saccades. However, the fact that removing the FEF surgically has caused only minor saccade deficits made its contribution to saccade generation elusive. Only until the late nineties, a series of studies were conducted to reversibly inactivate the FEF, revealing significant impairments in saccade and smooth pursuit eye movements. These findings have once again highlighted the critical role of the FEF in the cortical control of eye movements.Our lab has been exploring the putative FEF areas in the marmosets, a new world monkey, using electrical stimulation and tracer injections. However, to conclusively determine whether these areas in marmosets truly correspond to the FEF and exhibit similar functions in the cortical control of eye movements as observed in macaque monkeys, we recognize the need for an ultimate test: the

acute reversible inactivation. Therefore, we decided to use muscimol, the $GABA_A$ agonist, to perform the experiment. To target the putative FEF, we performed MRI scan of the marmoset and designed a chamber that covered areas 45, 8aV, 8C, 8aD, 6Va, 6DR, 6DC following our stimulation results. We injected 0.5µl of 5mM muscimol (at a rate of 0.2µl/min) per injection site. One-hour post-injection, the marmoset performed the visually guided saccade tasks, and we collected its eye movement data. To ensure recovery and obtain control data, we administered muscimol every other day.Due to the lissencephalic nature of the marmoset brain, we were able to shift our inactivation location systematically within the chamber area and we observed focal saccade deficits as predicted from our stimulation results. Similar to what have been described in macaques, the marmoset exhibited a slowdown in saccade latencies, partial neglect of the contralateral hemifield, decrease in success rate, more scattered saccade starting and landing point and saccade duration prolongation after muscimol injection. Furthermore, we observed saccade overshooting on the ipsilateral side of the inactivation, likely due to disturbance in the balance of population coding in the FEF. In conclusion, our study confirms the previous micro-electrical stimulation study findings and provides evidence that marmosets possess a fully functional FEF, similar to what has been observed in macaques. Additionally, we have demonstrated the effectiveness of muscimol inactivation as a valid method for mapping the FEF in marmosets.

Abstract: Exogenous visual stimuli exert a dramatic, and inevitable, inhibitory effect on saccade generation, even before overt orienting to the stimuli is possible. This effect manifests itself as an almost complete cessation of saccade generation within <100 ms from stimulus onset, in a phenomenon known as saccadic inhibition. Although the dynamics and functional implications of saccadic inhibition have been extensively studied over two decades, the underlying neural circuits mediating such rapid sensory-driven oculomotor effect are still debated. Indeed, while current models of saccadic inhibition invoke lateral inhibitory interactions in structures like the

superior colliculus (SC) and frontal eye field (FEF), reversible inactivation of both areas did not eliminate, or even modulate the properties of, saccadic inhibition (Hafed et al., 2013; Peel et al., 2016). Here, motivated by the fact that saccadic inhibition is necessarily initiated by first sensing the presence of an exogenous stimulus, we investigated whether the primary visual cortex (V1) is necessary for this phenomenon to occur. In two macaque monkeys, we first electrically stimulated V1 with a brief microstimulation pulse train simulating a visual burst (300 Hz biphasic stimulation; 50 ms duration; ~90-100 μA). The monkeys fixated a small spot, and we either presented a visual stimulus or an electrical pulse train. We measured fixational saccades and found that they were robustly inhibited in both cases, with the inhibition starting earlier with electrical microstimulation than visual stimulation, due to the bypassing of retinal afferent signaling. Thus, V1 is sufficient for saccadic inhibition. In contrast, the same experiments in the SC (~10-30 μA) did not lead to inhibition at all, but rather to increased microsaccade likelihood. We then reversibly inactivated V1 in one monkey via muscimol. We presented stimuli in the visual field location affected by the muscimol injection or in a similar location in the other (intact) hemifield. Saccadic inhibition was completely abolished in the affected side, suggesting that V1 is necessary for inhibition. Finally, to investigate whether visual pathways other than the geniculo-striate one can still be relevant for saccadic inhibition under some circumstances, we analyzed eye movements in two blindsight monkeys having had long-lasting chronic V1 lesions. Saccadic inhibition occurred in these animals, likely due to plasticity and reinforcement of alternate pathways. Our results show that, in the intact brain, visual signals in the oculomotor system that ultimately dictate the visual feature tuning properties of saccadic inhibition must pass through V1.

Title: Modulation of Saccadic Inhibition by Distractor Repetition during Letter Scanning

Authors: *J. A. EDELMAN, C. KYAN;
Biol., City Col. of New York, New York, NY

Abstract: Real-world visuomotor behavior often occurs in the face of potentially distracting visual events. While suddenly appearing visual distractors have been shown to temporarily but dramatically hinder saccade initiation ~90 ms after their appearance, a phenomenon referred to as saccadic inhibition (SI), we hypothesized that during naturalistic tasks the saccadic system would habituate to repeated distractors, allowing the desired behavior to proceed unhindered. This study addressed this hypothesis by measuring saccadic inhibition in a letter-scanning task

with distractors presented in various spatiotemporal contexts. Eye movements were recorded using an Eyelink II eye-tracking system (SR Research) at a sampling rate of 500 Hz. Visual stimulus presentation, using a CRT monitor (85 Hz), and data collection were performed using Experiment Builder (SR Research). Participants were instructed to scan a horizontal 64-alphanumeric character array, silently count the small number (0-9) of embedded digits among the letters in the array, then indicate the number of digits seen by a key press. There were four distractor conditions: 1) no distractors, 2) square (2°) distractors appearing every 300-400 ms at different locations or, 3) at one location in a trial, and (4) two large horizontal bars spanning the visual display above and below the linear letter array. Large distractors induced a substantial amount of SI. The smaller, square distractors appearing at different locations elicited less SI, while distractors presented repeatedly at a single location resulted in minimal SI. These findings indicate that the size and positional constancy of distractors influence saccadic inhibition during a letter scanning task. Performance on the task, measured by counting accuracy, total time of scanning, and number of saccades per trial, was at most only modestly affected by distractor condition and exhibited variability across participants. These results suggest that the saccadic system can partially habituate to repeated distractor presentation, except when distractors are large in size. Moreover, even large, repeated distractors have a limited effect on the performance of naturalistic tasks that require a rapid sequence of saccadic eye movements.

Abstract: Curiously, knowledge of how smooth and saccadic fixational eye movements are controlled is lacking despite that much of visual perception occurs during fixation. This may be partially because we assume Hering's Law of oculmotor control in which the eyes are yoked and moved with identical signals. However, there is evidence that smooth movements, often referred to as "drift", undergo periods of vergence during fixation, possibly to enable fusion. To test this, we investigated ocular fixation using stimuli that varied in fusional demands, a .2 deg dot or a 6 deg diameter ring. Observers fixated the center of each stimulus in 20 sec trials. Consistent with previous literature, a fixation spot evoked significant horizontal "microvergence" where eye drift was oppositely directed. Curiously, the 6 deg ring also produced microvergence, and both stimuli produced similar proportions of vertical and horizontal microvergence. This suggests that

microvergence is the result of stochastic neural noise. In contrast, microsaccades were always conjugate, suggesting a different mechanism for their generation. We previously introduced a binocular eye movement model which incorporates independent eye control signals that interact with a unitary conjugate one (Heinen et al., SfN 2022). Here, using our ISMYS model (Independent Smooth Movements/Yoked Saccades) we test whether neural noise explains observed microvergence by adding independent white noise to each eye controller. As a result, the model generated slow microvergence in the same proportion as observed in the human data. Providing a monocular position step to the model produced conjugate microsaccades. The results suggest that microsaccades are generated by a unitary conjugate mechanism, and slow drift is generated by independent ocular control, which during simple fixation is driven by neural noise.

Title: Target-distractor competition varies between allocentric and egocentric reference frames depending on the state of the decision-making process

Authors: *M. FALLAH, C. OLENICK, H. JORDAN;
Col. of Biol. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Recent studies have shown that during the active perceptual decision-making process, saccade trajectories are shifted towards the distractor, but once the process is completed and the distractor is inhibited, trajectories shift away from the distractor (Kehoe, et al, 2018, 2021; Giuricich, et al, 2023). Furthermore, the magnitudes of the shifts were dependent on the distance between the target and distractor (Giuricich, et al, 2023). While saccade motor plans are encoded in egocentric reference frames, prior studies used iso-eccentric stimuli and thus could not determine if the target-distractor competition shifts in trajectories were based on egocentric or allocentric reference frames. We used a saccadic response delayed match-to-sample task where the target and distractor varied in both allocentric and egocentric distances. This allowed us to determine the reference frames underlying the target-distractor competition driving the shift in saccade trajectories. The results (38 participants: 30 female, 8 male) show that during the active decision-making process, the distance between the target and distractor in both allocentric and egocentric reference frames contributed to shifts in saccade trajectories towards the distractor. There was also a response bias for the nearer item in egocentric coordinates (shorter saccades).

In contrast, when the perceptual decision-making process was complete and the distractor was inhibited, only the distance in the allocentric reference frame contributed to trajectory shifts away from the distractor. There was no clear pattern for sex differences, although the low number of male participants limited this analysis. Therefore, saccade planning and execution depend on both perceptual processing (target-distractor discrimination) in allocentric reference frames and the competition between oculomotor plans in egocentric reference frames during active decision-making. However, when the target is identified and the distractor is inhibited, the effect of distractor inhibition on saccade trajectories is based on an allocentric reference frame, suggesting it is maintained in visual rather than oculomotor areas.

Title: Effects of saccades on visual perception in mice

Authors: *A. BUTEAU, J. HUNT, A. POLEG-POLSKY, G. FELSEN;
Physiol. and Biophysics, Univ. of Colorado, Anschutz Med. Neurosci. Grad. Training Program, Aurora, CO

Abstract: Rapid orienting eye movements - saccades - are thought to cause modulation of neural activity throughout the visual hierarchy in order to stabilize representations of the visual world. Little is known about the circuit and mechanisms underlying this phenomenon. Our overall goal is to relate the circuits that govern saccadic modulation to the perceptual effects of saccades on visual behavior. We have therefore developed a mouse model to examine saccadic modulation at the levels of circuitry and perception. In this study, we focus on the effect of saccades on visual perception in wild-type mice. We hypothesized that perceptual acuity will be altered by saccades due to saccadic modulation of neuronal visual representations. To test this idea, water-restricted head-fixed mice were presented with a static grating that incremented in contrast 0% to 30% from baseline for 50 ms at pseudorandom intervals, and were trained to report the contrast change by licking a spout for a water reward. On a subset of trials, we reliably elicited saccades with an air puff to the ear. Trials occurred every 8-10 seconds, and consisted of either the contrast change, the air puff, or both, to control for potential effects of the air puff and isolate the perisaccadic effects on perception. We are currently examining whether and how perceptual thresholds for reporting the contrast change are altered by the presence of saccades. Our preliminary data suggest that saccades affect perception in mice, which will inform future investigation into the circuits mediating active vision.

Title: Peri-saccadic modulation of visual neurons in the mouse superior colliculus

Authors: *J. HUNT[1], G. FELSEN[2], A. POLEG-POLSKY[3];
[1]Univ. of Colorado, Anschutz Med. Campus, Aurora, CO; [2]U. of Colorado Sch. of Med., U. of Colorado Sch. of Med., Aurora, CO; [3]Univ. of Colorado Sch. of Med., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Animals use ballistic reorienting movements called saccades to actively explore their environment for salient visual targets. Saccades result in a transient modification of visual perception such that it becomes difficult to perceive luminance- and contrast-modulated stimuli which appear around the time of saccades, a phenomenon referred to as saccadic suppression. Saccadic suppression is associated with a decrease in responsiveness across the visual system including the midbrain superior colliculus (SC), a highly conserved visuomotor structure required for generating saccades. In primates, many studies have shown that visual responses in SC neurons are significantly attenuated around the time of saccades, but the neural circuitry which produces this neural suppression has yet to be elucidated. Ex vivo slicework in mice has identified a putative circuit for saccadic suppression in the SC which remains to be examined in vivo. To understand how saccadic suppression arises in the SC, we collected high-density in vivo extracellular recordings of single-unit activity within the superficial layers of the SC while mice made SC-dependent saccades. Headfixed mice were placed within an immersive visual arena and shown a low-contrast drifting grating stimulus to elicit the optokinetic reflex (OKR). Periodically, the contrast of the grating was briefly elevated to evoke discrete visual responses from visually-responsive SC neurons. Visual responses within the peri-saccadic epoch (-50 ms to 50 ms before and after saccades) were compared to visual responses outside of the peri-saccadic epoch. We found that visual SC neurons exhibited peri-saccadic modulation of visual responses around the time of saccades. These data are the first to demonstrate that visual neurons in the mouse SC are modulated around the time of saccades. Future work will focus on manipulating individual elements of the putative circuit for saccadic suppression in the SC using combined chemogenetics and high-density extracellular recordings.

Abstract: Developing behavioural biomarkers for neurodegenerative disease will prove a significant advancement in their diagnosis. Due to extensive overlap between oculomotor and neurodegeneration-affected circuitry, quantifying saccade behaviour during eye movement tasks produces many objective potential biomarkers for neurodegenerative diseases. Both structured and unstructured tasks yield parameters that comprehensively characterize saccade behaviour, but understanding links between task parameters and their relationships to disease processes is crucial to use of eye movements as the foundation of future disease screening and diagnostic tools. We evaluated saccade behaviour in a large cohort of neurodegenerative disease patients from the Ontario Neurodegenerative Disease Research Initiative: 33 Alzheimer's disease (mean age 72, 19 male), 73 mild cognitive impairment (mean age 71, 41 male), 20 amyotrophic lateral sclerosis (mean age 61, 13 male), 19 behavioural variant frontotemporal dementia (mean age 68, 14 male), 9 progressive supranuclear palsy (PSP, mean age 71, 5 male), and 117 Parkinson's disease (mean age 68, 91 male), and 101 healthy age-matched controls (mean age 67, 34 male). All completed a structured task (interleaved pro- and anti-saccade task (IPAST): looking at or away from a peripheral visual stimulus according to the colour of a central fixation point) and an unstructured task (free viewing task (FV): instruction-free viewing of rapidly switching video clips). Examination of differences between disease groups in each task revealed that both can differentiate diagnoses and disease features. IPAST revealed increases in anti-saccade error rates (indicating voluntary control deficits) with cognitive impairment, and motor impairment (e.g. saccade hypometria) in movement disorders, but few limitations in fast visuomotor processing. FV revealed key disease features such as vertical gaze impairment in PSP and between-group

saccade rate differences immediately following clip change-induced visual perturbation. Inter-task correlations may illuminate shared underlying neural circuitry; preliminary results suggest parameters from early epochs following FV clip change correlate to fast visuomotor parameters from IPAST, while saccade rate in later epochs correlates to IPAST parameters measuring voluntary control. Full behavioural characterization of structured and unstructured oculomotor tasks in neurodegeneration, and links between tasks, will enable development of an objective behaviour-based clinical screening tool leveraging the breadth of oculomotor data to diagnose neurodegenerative disease.

Title: Saccurate: saccade curation gui for ground truth dataset construction, post curation and evaluation

Authors: J. ZANG[1], **M. FAKHARIAN**[1], P. HAGE[3], J. PI[2], A. SHOUP[1], *R. SHADMEHR[4]; [1]Johns Hopkins Univ., Baltimore, MD; [2]Johns Hopkins Univ., Ellicott City, MD; [3]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [4]Johns Hopkins Univ. Dept. of Biomed. Engin., Baltimore, MD

Abstract: Saccades are essential for neuroscience tasks involving reward, motor function, and learning. Deep learning networks have emerged as a superior saccade detection tool, outperforming traditional thresholding methods across a wide range of saccade amplitudes. However, the field lacks reliable ground truth datasets and effective curation tools to reduce false positive errors in neural data analysis. To address this, we developed a user-friendly GUI that enables human experts to build ground truth datasets and curate results obtained from deep networks. Our approach utilizes saccade kinematics features such as acceleration to deceleration time ratio (Van et al. 1987), Q factor (Baloh et al. 1975), main sequence plot (Bahill et al. 1975), and confidence scores from the deep network itself. In our study, we recorded eye movements from three common marmosets using two video-based acquisition devices at 1000 and 2000 Hz.

We compared performance of deep networks developed by Bellet et al. (2019) with their recommended pretrained weights, networks retrained on our own datasets from different periods of the animals' lifetimes, along with the traditional thresholding methods. Results showed that the pretrained network does not generalize well to our dataset, but after retraining on curated datasets, the networks achieved around 96% accuracy and outperformed traditional thresholding methods, particularly in detecting micro saccades. Furthermore, the network demonstrated the ability to capture the variability of saccades across the animals' lifespan by incorporating training data from multiple time points. Interestingly, a network trained on data from one marmoset yielded promising results when applied to another marmoset's data, with only minor timing adjustments. In summary, we built a new tool that begins with a deep neural network to detect saccades and then allows the user to curate the results to improve accuracy. The technique is much more accurate in detecting saccades than simple threshold methods.

Title: Reaching beyond the lab: virtual reality platform to study adaptation in real-world conditions

Authors: *C. ROSSI[1,2], R. VARGHESE[1,2], A. J. BASTIAN[1,2];
[1]Johns Hopkins Univ., BALTIMORE, MD; [2]Kennedy Krieger Inst., Baltimore, MD

Abstract: Real-world movements are characterized by many degrees of freedom and complex interactions between our body and the surrounding environment. However, traditional motor learning research has focused on simplified and highly constrained motor tasks. For example, studies of reaching movements often involve moving a single-point cursor to a target on a two-dimensional screen. While these studies provide a rigorous understanding of specific laboratory tasks, their applicability to natural movements is limited. To address this gap, we developed a platform to study reaching movements and adaptation in realistic conditions.
Participants wore a virtual reality headset (Meta Quest 2) and were immersed in a three-dimensional virtual environment that mimicked the visual landscape and sounds of a real-world garden. The task involved lifting a plate of grapes up to a bird while keeping the plate flat to prevent spillage. Crucially, participants saw their own hands in virtual reality and used both

hands to balance and lift the plate, mirroring real-life movements. Each virtual hand was represented using a 3D model with 16 bones (palm and 3 bones per finger), which tracked the position and orientation of the participant's real hand bones using cameras on the headset. The interaction between the virtual hands and plate adhered to the laws of physics (physics engine, Unity development platform), and participants had full freedom of upper limb motion.
As a proof of concept, we investigated adaptation to a gain perturbation applied to the right hand. Specifically, the position of the virtual right hand was manipulated to move slower / proportionally less than the real right hand. As expected, participants adapted by lifting the real right hand higher than the left, aligning the vertical positions of the virtual hands and keeping the plate flat. Also as expected, participants exhibited aftereffects by continuing to lift the real right hand higher after the perturbation was removed post-adaptation. These results demonstrate that adaptation of reaching movement can be induced using a task that mimics real-life conditions in important ways: unconstrained degrees of freedom, and realistic representation of hands, environment, and their interaction. This approach has the potential to enhance our understanding of real-world motor control and learning, facilitating the translation of research findings to rehabilitation interventions.

Title: Childhood development of reinforcement motor learning under probabilistic and deterministic rewards

Authors: *N. M. HILL[1,2], L. A. MALONE[1,2], H. M. TRIPP[1,2], D. M. WOLPERT[3], A. J. BASTIAN[1,2];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD; [3]Columbia Univ., New York, NY

Abstract: Motor abilities develop over the course of childhood. In the cognitive domain, learning by reinforcement develops with age; however, less is known about how children acquire the ability to use reinforcement to guide motor learning. We designed computer-based motor learning tasks to collect data remotely from participants at home to investigate how age affects children’s ability to incorporate a binary reward signal (success or failure) to modify motor behavior. Participants used a mouse, trackpad, or touchscreen to move an onscreen cartoon penguin. We created four paradigms by varying two task factors: 1) target type (continuous vs.

discrete) and 2) reward feedback (probabilistic vs. deterministic). In the continuous conditions, participants could choose to move the penguin to any location on a continuous horizontal target. In the discrete conditions participants could move to one of seven targets spread horizontally. For probabilistic feedback, the reward was determined by an unseen position-based probability gradient with a small 100% reward zone away from which reward probabilities decreased linearly to a baseline. For deterministic feedback, reward was always given within a reward zone but not elsewhere. In the key learning block, participants repeatedly reached and received binary reward. This was followed by two "clamped" feedback blocks where reward did not depend on the movement. In the first of these blocks all reaches were rewarded and in the second no reaches were rewarded. We first sampled a cohort of 93 children (age three to 17 years old) and 33 adults (age 18 to 35 years old) using the continuous target and probabilistic reward task. Over 60% of participants age nine and older learned the reward landscape and consistently moved within the 100% reward zone by the end of the learning block. In contrast, only 14% of three to eight year olds learned in this task structure. These results point to an age-related component in the ability to learn from probabilistic binary reward. Increased exploration after failure relative to after success (in the clamp blocks) predicted better overall learning performance. We sampled three additional 40 participant cohorts of three to eight year olds on the other three tasks. With discrete targets and a probabilistic reward structure, 43% of participants learned. Removing the probability gradient increased the portion of the cohort that learned to 66% (continuous target) and 88% (discrete targets). While type of target and reward structure have a combined effect on learning, a probabilistic reward structure is the biggest inhibitor to learning in young children.

Title: Temporal credit assignment in reward-based motor learning

Authors: *T. ZHU[1], J. P. GALLIVAN[1,2,3], D. M. WOLPERT[4,5], J. R. FLANAGAN[1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Dept. of Psychology, Queen's Univ., Kingston, ON, Canada; [3]Dept. of Biomed. and Mol. Sciences, Queen's Univ., Kingston, ON, Canada; [4]Zuckerman Mind Brain Behavior Institute, Columbia Univ., New York, NY; [5]Dept. of Neuroscience, Columbia Univ., New York, NY

Abstract: In reward-based motor learning, the movement to be learned often consists of a series of sequential steps with feedback related to the performance only arriving after all steps have

been completed. Learning under such conditions involves determining the contribution of each step to the final reward received. How humans solve this temporal credit assignment problem in the context of motor learning remains largely unknown. Here we tested human participants' capacity to solve this problem during a hand path learning task. In each trial, participants drew a top-down path crossing 4 horizontal bars, which visually divided the task into 4 steps. A single score was given at the end of the trial based on the distance between the location where the cursor crossed each bar and a preset "target" location on each bar (unknown to the participants), and the participants' goal was to maximize the score. The cursor could only cross each bar through a specific region which was colored green. The whole first bar was green, while for the next 3 bars, the green region (40% of the bar) would appear centered on the direction of the cursor's displacement vector from the previous step. This constraint on possible paths created a dependency chain between successive steps. Participants were randomly assigned to one of two groups in which the final score depended on all 4 steps equally weighted (Group 1: N = 13) or based on the last step alone (Group 2: N = 14). Participants were not informed about the weighting of the steps. Participants completed 200 trials divided into 4 blocks (50 trials each). We found that, in both groups, most participants improved their scores. In the final block, both the average score and the average absolute error in the last step were similar between Groups 1 and 2. During earlier trials, participants explored paths with little curvature. However, as trials progressed, path curvature increased in Group 1, in which the optimal path was curved, but not in Group 2, in which a maximum score could be obtained with a straight path. In Group 1, 8 out of the 13 participants obtained an average score, in the final block, that was greater than the highest possible score with a straight path. We also calculated the correlation between crossing locations in step 1 and step 4 across trials in the final block. The correlation was lower in Group 1 than in Group 2, indicating that the control of crossing locations for different steps was more independent in Group 1. Together, our results show that participants were able to shape their movement steps separately based on the overall performance score. We show that this learning process can be modeled by the Monte Carlo method with forgetting.
