Abstract: We leverage cognitive strategies to enhance our motor performance. For instance, golfers can deliberately re-aim a shot to account for a crosswind, or they can try to recall and replicate a past swing. These kinds of strategies are also observed in the laboratory during visuomotor adaptation tasks (VMR). Participants readily re-aim to counteract a visuomotor rotation, investing processing time to flexibly discover the solution (algorithmic strategy). Participants can also cache solutions to previously-solved mental rotations in memory, allowing them to respond quickly without investing additional cognitive resources (retrieval strategy). While we know that both strategies are available, we do not know the extent to which each contributes to skill. Early on, algorithmic strategies dominate performance at the cost of increased preparation time. With training, preparation times gradually decrease without impacting performance - a classic marker of skill and automaticity. Building on prior work, we suggest two possible routes for skill refinement: improvements in spatial cognition may accelerate the execution of algorithmic strategies, or rapid retrieval strategies may replace algorithmic strategies. Here, we assessed the extent to which these two pathways to automaticity proceed with training during a VMR task. Participants conducted a center-out reaching task (visual feedback delayed to maximize cognitive strategy use). During training, they countered 20° and 60° rotations (clockwise and counterclockwise) at four target locations. With practice, the rotation size/preparation time slope decreased but remained above zero. Thus, participants improved their algorithmic strategies rather than using retrieval strategies, which would have resulted in equal preparation time regardless of rotation size. In a subsequent test phase, participants encountered new rotations (40° and 80°) in either trained or novel locations. Preparation times on trials with new rotations were consistent with the algorithmic strategy processing rate inferred from the trained rotations (2 ms/°), regardless of target location. This is in line with a general improvement in algorithmic strategies, as opposed to improvements exclusively for the practiced rotations. Altogether, we illustrate that a generalizable spatial cognitive process underlying algorithmic strategies executes more automatically with practice, although retrieval strategies may develop under different conditions. Nonetheless, these data suggest that training that improves the automaticity of algorithmic strategies may be a powerful tool for training broadly applicable motor skills.

Title: Motion-dependent motor learning based on explicit visual feedback demonstrates no anterograde interference to learning from physical perturbations

Authors: *W. ZHOU[1], K. D. FERNANDEZ[1], W. M. JOINER[2];
[1]Univ. of California Davis, Davis, CA; [2]Dept. of Neurobiology, Physiol. and Behavior, Univ. of California, Davis, Davis, CA

Abstract: The adaptation of arm reaching movements in response to physical perturbations, such as a velocity-dependent force-field (vFF), demonstrates anterograde interference - initial learning of Task A reduces the rate of subsequently learning Task B, usually the opposite perturbation. In our recent study, we investigated the ability of subjects to learn motion state-dependent modifications to motor output based on explicit visual feedback (eVF). Specifically, subjects were provided with visual information indicating the extent to which their applied temporal force pattern matched the required velocity-dependent force profile that would have been generated under the vFF perturbation. Here, we examined anterograde interference based on eVF, as compared to the interference caused by physical vFF perturbations. Two groups of subjects were recruited to participate in two separate experiments, both employing the same paradigms but involving different forms of information for motor recalibration. All participants performed 10 cm reaching arm movements between two targets using a robotic manipulandum. The experimental protocol consisted of a training block with perturbation A, and another training block with perturbation B. In the FF group, physical vFF perturbations were experienced during the perturbation A block, followed by the opposite physical vFF perturbations during the perturbation B block. In the EVF group, eVF of the required force-velocity relationship was provided during the perturbation A block, while the opposite physical vFF force-field was applied during the perturbation B block. In the latter group, during eVF perturbation trials, subjects performed movements within force channels, and visual feedback was given on the lateral force exerted during the movement, as well as the required force pattern based on the movement velocity. We compared the learning rates for perturbation A and B between the two groups. Our preliminary results (N = 9 for both groups) revealed that learning based on physical vFF demonstrated anterograde interference on the learning of the opposite vFF perturbation (exponential growth rate was reduced from r^{A}_{FF} =0.16±0.018 to r^{B}_{FF} =0.080±0.012), consistent with previous research findings. However, learning based on eVF did not exhibit anterograde interference on the learning (exponential growth rate r^{A}_{EVF} =0.16±0.043 was similar to initial learning, $r_{FF}{}^{A}$). These findings suggest that anterograde interference in the adaptation to physical perturbations may primarily result from motor recalibrations that utilize the same learning mechanisms.

Title: Reduced visual feedback shifts the representation of visuomotor memory from extrinsic to intrinsic

Authors: *S. GURGONE, T. IKEGAMI;
Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Osaka, Japan

Abstract: Motor learning behaviors such as stability, variability, and generalization are affected by how motor feedback is provided. The feedback-dependent learning mechanism is, however, poorly understood. Many studies have utilized three types of feedback, continuous, terminal, and binary, and examined its effect on motor learning using reaching tasks under a novel visuomotor transformation. The visual feedback of the cursor as a proxy for hand position is provided throughout the movement for continuous feedback and only at the end of the movement for terminal feedback. For binary feedback, the cursor is not visible and the success or failure of the task is provided. Previous studies have considered that different contribution of learning algorithms determines feedback-dependent learning. Continuous and binary feedback mainly involve error-based and reinforcement learning, respectively. Endpoint feedback involves both. However, differences in sensory information in feedback may also engage different learning processes. As visual information decreases from continuous to terminal to binary, the coordinate frame representing motor memory may change from the vision-based extrinsic (xy) coordinate to the proprioception-based intrinsic (joint) coordinate. To test this possibility, we examined a visuomotor adaptation of reaching with the three feedback. Three groups of participants, continuous (n=10), terminal (n=9), and binary (n=8), adapted to a gradually increased visuomotor rotation while reaching a training target. After the adaptation, we tested generalization with three untrained targets. The first was *extrinsically consistent* with the training target such that the identical hand motion led to the perfect generalization (E-C). The second was *intrinsically consistent* with the training target such that the identical joint rotation led to the perfect generalization (I-C). The third was *intrinsically inconsistent* with the training target such that the identical joint rotation leads to a zero-generalization (I-I). The generalization in the binary group was higher for the I-C target and lower for the E-C and I-I targets than the continuous group, and the terminal group was in between the two. A model analysis showed significantly different contributions of extrinsically and intrinsically represented motor memories between the groups. These suggest that reduced visual feedback shifts the motor representation from extrinsic to intrinsic. More visual feedback (continuous) may develop more extrinsic memory through error-based learning, while less visual feedback (binary) may develop more intrinsic memory through reinforcement learning.

Title: Spatial generalization and intermanual transfer of visuomotor adaptation in virtual reality

Authors: *S. WERNER, J. GERKEN;
German Sport Univ., Cologne, Germany

Abstract: Previous research showed greater spatial generalization of learning after adaptation to prism goggles than after adaptation to visuomotor rotations in computer-generated settings. One possible explanation for this is that looking at one's own hand during prism adaptation causes the error to be more strongly attributed to one's own movement than when seeing only a representative cursor. To confirm this hypothesis we compared, for the first time in a single experimental setup in virtual reality (VR), visuomotor adaptation when looking at one's own (virtual) hand and when looking at a representative cursor. Two groups of 15 participants each (H, C) wearing VR goggles performed centre-out reaching movements to virtual target spheres with their right arm. They received visual feedback about their movement by seeing either a virtual hand (H) or a cursor (C). This feedback was veridical at baseline. In a subsequent adaptation block, the feedback was rotated 40° counterclockwise around the central starting sphere. After adaptation, spatial generalization to untrained targets, intermanual transfer to the left arm and aftereffects were measured without visual feedback. In addition, a questionnaire was used to determine the sense of agency in both experimental groups. The analysis of the questionnaire data reveals a greater sense of agency in H than in C and the analysis of variance of participants reaching errors shows faster adaptation in H than in C. Thus, our results imply that the speed of adaptation indeed depends on attributing prediction errors to internal causes. Furthermore, Student's t-tests reveal no group differences in spatial generalization, intermanual transfer, or aftereffects. However, the reaching errors in these post-tests without visual feedback were highly variable. We therefore explain the lack of difference in generalization of learning by methodological aspects of adaptation measurement in VR. Our findings are discussed with reference to different mechanisms that encompass visuomotor plasticity.

Title: Role of Redundancy in Exploring to Learn New Coordinative Patterns in a Novel Task

Authors: *J. THOMAS, J. SMITH, R. M. BONGERS;
Human Movement Sci., Univ. Med. Ctr. Groningen, Groningen, Netherlands

Abstract: Learning the coordination of Degrees of freedom (DoF) requires the neuromotor system to explore different coordinative patterns. These patterns are temporary organization of DoFs into task specific units to achieve goal directed tasks. In the current exploratory study, we identify muscle activation patterns as DoFs. We characterize DoFs with respect to the unique size and location they occupy in the DoF space, which contains different DoF combinations during a task. The DoFs covary in a successful task to form solution within the DoF space. Learning can be strategised as exploring solutions by Central Nervous System (CNS) in the wider DoF space and within the solution space, by systematically employing DoFs over time. Moreover, the neuromotor system is redundant in that it has more DoF than necessary to perform a task, thus the CNS identifies the task relevant and task irrelevant DoFs through exploration. It is crucial to understand the exploratory behaviour of redundant DoFs to learn a novel task. Therefore, in this study we design a task to map muscle activity in isometric force production task to an object on a screen. We recruit right-handed participants to perform a continuous isometric task, whereby the muscle activation patterns in the left arm were recorded by Electromyographic (EMG) sensors. The muscle activity from groups of flexors and extensors was mapped onto a 1-dimensional spherical virtual avatar. The task was divided into 2 DoF (Low Redundancy) and 4 DoF (High Redundancy) conditions, whereby the participants had to control the position of this avatar through isometric contractions, to move it through virtual circular targets approaching towards it. Learning the mapping to navigate the avatar successfully into the targets would require the participants to explore new coordinative patterns. Results showed 40% and 10% success rate in 4 DoF and 2 DoF condition respectively, in the early phase of learning. In the late phase of learning, success rate of 10% and 5% in 2 DoF and 4 DoF respectively was observed. This may be attributed to the onset of fatigue in the late phase of learning. Results at the level of DoF indicated an increase muscle activity of all the muscles in the early phase of learning. Whereas an increase in only the agonists involved in mapping with a simultaneous decrease in activity of the other muscles that are not involved in the mapping, was observed in the late phase of learning. These findings suggest that exploration may have occurred, to converge onto a stable solution. This is in agreement with our hypothesis that learning exhibits co-activation of both agonist and antagonist pair earlier and reciprocal activation of muscles at later during the task.

Title: Adapting to errors in an unconstrained bimanual context

Authors: *R. VARGHESE[1], C. ROSSI[2], A. J. BASTIAN[3];
[1]Neurosci., Johns Hopkins Med. Institutions, Baltimore, MD; [2]Johns Hopkins Univ., BALTIMORE, MD; [3]KKI & Johns Hopkins, Baltimore, MD

Abstract: Many of the tasks we perform in our daily lives require the coordinated use of both hands. The purpose of this study is to better understand how people learn bimanual movements from errors that are distributed across the two arms. We forego traditional laboratory methods for a realistic 3D task that captures the complex interactions between the hands and environment, presented through a virtual reality headset (Meta Quest 2, Facebook Reality Labs). Participants were required to lift a (virtual) plate of grapes up to a perch to "feed the bird", using a virtual representation of their own hands tracked using the Leap motion controller camera (Leap Motion Inc.) mounted on the front of the headset. The motion of the arm and hand were fully unconstrained, and the visual interaction between the hands and the plate followed the natural laws of physics. We studied error-based adaptation to a visuomotor gain perturbation applied to the right hand, such that the virtual right hand appeared to move proportionally less than the true hand. Over a course of 260 trials, participants first learn to adapt to a gradually decreasing visuomotor gain by reaching higher with their true right hand and then deadapt in an abruptly introduced washout period. In addition to the online visual feedback of their arm and hand, participants also received a binary audiovisual reward feedback (trials were successful if the plate laid entirely in a rectangular target zone around the perch). In experiment 1, we compared adaptation of unimanual versus bimanual movements using our task: the unimanual group lifted the plate using the right hand alone (n = 21) and the bimanual group lifted the plate using both hands together (only the right hand was perturbed, matching the unimanual group; n = 22). We found that both groups adapted to a similar extent, but aftereffects were smaller and decayed more rapidly in the bimanual group. In experiment 2, we tested whether right hand aftereffects would be further reduced if the left hand can contribute to error correction. We doubled the size of the target zone from experiment 1. Consistent with our expectation, we found that when the target zone was wider, right-hand aftereffects were smaller and decayed at a similar rate as the bimanual group in experiment 1. There was faster deadaptation in the bimanual context suggesting that errors from both hands are integrated to estimate the position of the right hand. Understanding how the brain learns from errors in the bimanual movement context has ecological value and might be important for the design of error augmentation techniques and bimanual exercises.

Title: Repetition-based Motor Skill Learning is Preserved with Age

Authors: *Y. HAN[1,2,3], S. KORDE[1], A. OWUSU-OFORI[1,2], B. LIAN[1], J. SAMBANGI[1], M. DIASAMIDZE[1], L. M. WONG[1], E. J. HWANG[1];

Abstract: The biological aging process leads to impairments in both cognitive and motor function. While the impacts of aging on cognitive function have been well-documented, its effects on motor function decline remains unclear. Existing literature suggests that aging influences motor learning in a task-specific manner: older adults may perform on par with younger adults in certain tasks after learning, while performance disparities widen in others. To further elucidate this task-specific relationship, we investigated motor learning in mice across 4 different age groups (ranging from 3 to 22 months old; N=81; female and male) performing a novel stimulus-response association task. In this task, mice learn to maneuver a visual stimulus (a Gabor patch) to the center of the screen by turning a wheel leftward or rightward. When a Gabor patch appeared on the left of the screen, moving it to the center via a rightward wheel turn constituted a correct response, and vice versa. A correct response was reinforced with a water drop reward. We analyzed their motor function attributes including reaction time, peak velocity, and trial-to-trial movements correlations over 40 training sessions. Our data revealed that older mice exhibited the longest reaction and slowest peak velocities during early training sessions. However, despite this disadvantaged performance, older mice demonstrated unexpectedly rapid learning rates in these two attributes, thus offsetting the performance disparities. By the conclusion of the training period, no motor function attributes significantly differ between younger and older mice. The trial-to-trial movement correlation that measures the consistency of motor execution improved at a similar rate regardless of age. Our results suggest that although aging impairs the motor performance of older mice, it does not degrade their learning capacities. Thus, with training, older mice improved their motor performance to a comparable level to younger mice. This finding is in stark contrast to the finding that older mice were significantly impaired in cognitive functions (i.e., correct choice rate) in the same task. In summary, our results indicate no significant differences in motor performance between younger and older mice after extensive training in this specific task, underpinned by the preservation of motor learning ability in older mice. This highlights the potential for continued learning and adaptation for the elderly, thereby offering valuable insights for interventions aimed at mitigating age-related motor function decline.

Title: Changes in muscle activation patterns during learning a new motor task

Authors: *R. BONGERS[1], M. KRISTOFFERSEN[3], I. SLOOTER[1], V. SCHUURMANS[2]; [1]Dept. of Human Movement Sci., [2]Dept. of Rehabil. Sci., Univ. of Groningen, Univ. Med. Ctr. Groningen, Groningen, Netherlands; [3]Ctr. for Bionics & Pain Res., Gothenburg, Sweden

Abstract: Learning a new motor task implies learning a new coordination pattern among muscles. The current study examined how new coordination patterns emerge. The human neuromotor system is redundant and therefore there are multiple coordinative patterns that lead to successful task performance. Hence, this implies that when learning a new task the first step is to find coordination pattern fit to perform the task. The second step is to change this coordination pattern to a preferred coordination pattern. Stated otherwise, learning might be seen as search through coordination patterns of involved muscles. This exploratory study aimed to characterise this search process. In the experiment, EMG signals of muscles in the arm are mapped onto movements of a cursor on the screen to play a virtual game in which the cursor has to follow a path. We asked, 1) whether participants improved in the task performance, and 2) does the co-variation between muscles change during learning. Until now we collected the data of five right-handed participants (mean (std) age was 22.6y (1.7), 4 females and 1 male), who had no deficits in their neuromotor system. EMG of the Extensor Carpi Ulnaris (ECU), Extensor Carpi Radialis (ECR), Flexor Carpi Radialis (FCR) and Flexor Carpi Ulnaris (FCU) of the left arm was measured with a Delsys Trigno system at 1000Hz. Participants wore a wrist brace so that they could produce isometric contractions. For each EMG signal, the control signal of the game was computed using a RMS filter over the preceding 750ms for each data point. The game showed platforms oriented in different direction that became smaller during game progression. Using the control signals, a ball had to be steered over the platforms, while staying on them, to collect boxes by hitting those with the ball. The ball was controlled using a direct mapping between the control signal and ball position where ECR moved the ball UpLeft, ECU moved the ball UpRight, FCU moved the ball DownRight and FCR moved the ball DownLeft. Participants performed three sessions of 20 mins on consecutive days. Each session started with placing the EMG sensors and calibrating the system by making pre-defined movements. In each session participant started with the widest platform. When all boxes were collected the platform became smaller, indicating the next level. Preliminary results showed that all participants learned the task and completed more levels over the different sessions (Session 1: 1-6 levels and Session 3, 4-8 levels). Over training, muscles were more independently controlled for diagonal movement directions of the ball, whereas co-variation between muscles increased for horizontal and vertical ball directions.

Title: Reconfigurations of cortical manifold structure during reward-based motor learning

Authors: *Q. NICK, D. GALE, C. ARESHENKOFF, A. DE BROUWER, J. Y. NASHED, J. D. WAMMES, R. FLANAGAN, J. SMALLWOOD, J. P. GALLIVAN;
Queen's Univ., Kingston, ON, Canada

Abstract: Adaptive motor behavior depends on the coordinated activity of multiple neural systems distributed across cortex and subcortex. While the role of sensorimotor cortex in motor learning has been well-established, how higher-order brain systems interact with sensorimotor cortex to guide learning is less well understood. Using functional MRI, we examined human brain activity during a reward-based motor task where subjects learned to shape their hand trajectories through reinforcement feedback. We projected patterns of cortical and subcortical functional connectivity onto a low-dimensional manifold space and examined how regions expanded and contracted along the manifold during learning. During early learning, we found that several sensorimotor areas in the Dorsal Attention Network exhibited increased covariance with areas of the salience/ventral attention network and reduced covariance with areas of the default mode network (DMN). During late learning, these effects reversed, with sensorimotor areas now exhibiting increased covariance with DMN areas. However, areas in posteromedial cortex showed the opposite pattern across learning phases, with its connectivity suggesting a role in shifting from exploratory to exploitative modes of behavior. Our results identify the neural changes supporting reward-based learning, and indicate distinct transitions in the coupling of sensorimotor to transmodal cortex when refining behavior over time.
Our study sheds light on the coordination of multiple distributed neural systems during reward-based motor learning. Using functional MRI, we investigated the brain activity of human participants as they learned to shape their hand movements based on reward feedback, focusing on how different brain regions and networks interacted during the learning process. We found that when participants were uncertain about how to adjust their movements, regions of the dorsal attention and default mode networks segregated from one another; yet the same systems became integrated later, once the appropriate motor commands were acquired. Our findings suggest that changes in interactions between sensorimotor and transmodal networks enable the shift from exploratory to exploitative modes of behavior over time.

Title: Dorsal premotor cortical activity reflects deliberation about reaching choices even during the initial learning of a decision-making task

Authors: *T. PEEL, P. CISEK;
Univ. de Montréal, Montreal, QC, Canada

Abstract: Previous neurophysiological studies have suggested that decisions about actions involve a competition unfolding within the same sensorimotor regions involved in executing those actions. However, those observations were made in highly trained monkeys, raising the question of whether they only apply when behavior has become largely automatic or whether similar results would be found when an animal learns a novel task for the first time. Here, we investigated this question by recording neural activity in dorsal premotor cortex (PMd) while a monkey was being trained to perform a reach decision task (the "tokens task"). We used chronically implanted GrayMatter micro-drives to record individual task-related neurons and local field potentials (LFPs) over many weeks. In phase 1 of training, two target circles appeared and then, ~1s later, 15 small tokens jumped from the center into one of the targets, indicating it as the correct target to reach after a subsequent GO signal. It took the monkey about 78 trials to understand this rule. Coinciding with his moment of understanding, PMd activity responded less to target appearance, and began to instead respond to the token jump event, predicting the monkey's decision. In phase 2, tokens were randomly distributed to both targets, and the one that received the majority was rewarded. As the monkey learned this "more-is-better" rule, PMd activity reflected not just the choice, but also the level of evidence (difference in the number of tokens) on which the choice was based. In phase 3, the GO signal appeared before the token jumps, so the monkey could make his choice immediately. He was initially confused by this, and PMd activity no longer reflected the token evidence. However, after about 50 choices he became proficient again in applying the more-is-better rule, which was accompanied by the re-appearance of evidence scaling in PMd. Finally, in phase 4, the tokens began jumping one-by-one every 100ms. Already in the first days of training, PMd activity reflected the time-course of the changing evidence. For example, in "misleading" trials where the first 3 tokens jumped to the incorrect target, PMd activity was initially biased towards the incorrect target but later switched before movement onset in correct trials. Taken together, these results are consistent with a continuous flow of sensory evidence to bias action competition in PMd, suggesting that it is involved in action selection even when monkeys are learning a new task for the first time.

Title: Learning reaches to covert spatial targets in the corticostriatal forelimb circuitry

Authors: *A. C. MOSBERGER[1], L. J. SIBENER[1], T. X. CHEN[1], H. F. M. RODRIGUES[2], R. HORMIGO[1], J. N. INGRAM[1], V. R. ATHALYE[1], T. TABACHNIK[1], D. PETERKA[1], D. M. WOLPERT[1], J. M. MURRAY[3], R. M. COSTA[2];

Abstract: To learn novel actions, the brain assigns credit to the movement that led to reward and refines it through practice. Often different movement strategies can lead to reward, and the aspects of movements that are initially explored may determine what is learned. We developed a spatial target task for head-fixed mice to study the refinement of different aspects of a reaching movement, and probe the content of what is learned. Mice produce complex forelimb trajectories with a 2D joystick as they learn to move it from a set start position to a hidden target area. As animals learn, credit may be assigned to the correct initial reach direction, or the or the limb position at target entry. At first, target reaches (hits) are variable in their initial direction, tortuosity, and spatial directionality measured by vector field analysis. With learning, the hits are refined in all these movement aspects. To dissociate what has been learned, we relocate the start position in probe trials while maintaining the target position, testing if animals learned to move in a specific direction or to a specific endpoint. We find that some animals move in the learned initial direction from new starts (direction learners), while other animals guide the joystick into the target by adjusting their direction (endpoint learners). This suggests that different movement aspects were reinforced in individual animals, resulting in different reach strategies. The degree to which an animal showed direction vs endpoint learning correlated with their spatial directional variability early in training, indicating that exploration affects what was learned. Lesioning the

sensorimotor cortex impaired this spatial directional variability, pointing to a role for cortex in the generation of variable movements that are thought to be reinforced in striatum. But how are different aspects of the movement encoded in the corticostriatal circuitry, i.e., corticospinal neurons (CSpn) with striatal collaterals and intratelencephalic corticostriatal (IT-CStr) neurons? Using 2-photon calcium imaging and linear decoding, we found that an ongoing hand position command is conveyed particularly by CSpns. We are now using manipulations and ablations to investigate if selective disruption of this position command affects the degree of endpoint learning. Additionally, we found that an initial direction command is conveyed by thalamus to striatum and lesioning this area distinctly impairs the refinement of the initial movement direction but does not impair spatial directional variability, suggesting that different aspects of the spatial target reach is controlled by distinct sub-circuits of the forelimb motor system.

Title: Concurrent corticostriatal dynamics across multiple cell types underlying trial and error motor learning

Authors: *M. A. NICHOLAS[1,2], E. A. YTTRI[1,2];
[1]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: The performance of skilled motor actions is not instinctual; rather, it is learned through trial and error. While trial and error learning is crucial for survival, we still do not possess a mechanistic understanding of how the multiple motoric brain areas and cell types work together to facilitate this learning. We have proposed a functional model of motor performance in which pyramidal tract (PT) and intratelencephalic (IT) neurons of motor cortex (M1) dictate motor commands, while the direct and indirect spiny projection neurons (dSPN, iSPN respectively) of the dorsal striatum regulate the performance kinematics of those plans. To study how the brain can update motor commands, we trained mice to perform a goal-directed reach to target task and randomly changed the target bounds on a subset of blocks.
We found that mice (of both sexes) were able to learn multiple new target bounds based only on trial outcome and neural activity varied based on target location and error types. While phototagging multiple cell types and recording across M1 and striatum concurrently, we found that after changing the target bounds, neural activity on trials following errors increase more than

after rewards, specifically in the SPNs of the striatum. PT and IT neurons were less sensitive to errors but differentially modulated their activity after learning and the updating of performance after a change in target. This work suggests that following a target change, SPN activity may search out new performance policies to shape a relatively static motor command from M1 - pointing to a tiered learning approach that is delegated across different brain areas.

Title: The structural and functional neural architectures of implicit and explicit motor learning.

Authors: *C. N. ARESHENKOFF[1], A. J. DE BROUWER[3], D. GALE[2], J. Y. NASHED[1], J. FLANAGAN[1], J. P. GALLIVAN[1];

Abstract: The ability of the central nervous system to learn new mappings between motor commands and sensory feedback is critical for adaptive behaviour. Substantial evidence indicates that such learning is supported by two distinct, parallel processes: a non-conscious (implicit) process that adapts gradually through the updating of an internal forward model, and a strategic (explicit) process which is believed to be highly cognitive, and to be supported by prefrontal cortex. This latter, explicit process has been linked to executive functions, such as working memory processes, although relatively little research has attempted to systematically investigate its neural substrates.
Using functional MRI, we studied motor learning in two distinct tasks -- in the same human subjects (N = 36) -- providing different forms of feedback: A visuomotor rotation task (VMR) in which subjects learned through sensory errors, and a reinforcement-based motor learning task presenting only score feedback. By querying subjects' conscious knowledge of the rotation during VMR task performance, we identified gradients of cortical, cerebellar, and striatal functional connectivity with the motor cortex associated with subjects' explicit knowledge, as well as with their implicit adaptation. We then found that the expression of the explicit, but not implicit, gradient during the separate reinforcement-based task predicted learning in the same subjects.
While the implicit gradient agreed with a large literature characterizing the circuitry supporting the sensory-guided control of movement (including regions of the motor cerebellum, as well as

premotor and posterior parietal cortices), the explicit gradient was supported largely by regions of the default mode network. By comparing these gradients to existing cortical gradients in the published literature, we found that these two connectivity gradients could be singly explained as opposing ends of a principal axis of macroscale structural-functional cortical organization separating unimodal sensory and motor regions from higher-order, heteromodal association cortices. We argue that explicit learning is supported by task-general functional networks specialized for the encoding of high-level task structure, and for the assimilation of action-outcome association spanning multiple trials in episodic memory, and that the computations underlying these processes are facilitated by structural and neurophysiological differences between unimodal and heteromodal cortices.

Abstract: Learning a new task or skill involves synaptic plasticity that drives new patterns of activity in cortical circuits. Network models of learning have shown that learning can be driven by a variety of plasticity mechanisms including modification of long-range inputs, local synaptic plasticity and/or modifications of cell intrinsic properties. However, the degree to which these mechanisms contribute to learning is unknown. To explore the circuit mechanisms involved in learning we developed a robust optical brain computer interface (BCI) task, which we combined

with two-photon photostimulation to map learning-related changes in local connectivity. Mice learned to modulate the activity of a single 'conditioned neuron' (CN) in layer 2/3 of motor cortex to obtain reward. Mice improved the rate of rewarded trials from 55% to 75 % within the first 25 trials (5 minutes). Small groups (~ 10/500 per experiment) of 'enhanced neurons' increased their activity at a similar level to the CN. Photostimulation before and after learning revealed changes in cortical connectivity that were correlated with learning. The enhanced neurons increased their within-ensemble connectivity after learning. To better understand mechanisms underlying these learning-related changes in activity and connectivity, we developed recurrent neural network (RNN). With these models, we tested three potential mechanisms of learning: 1. 3-factor Hebbian plasticity of local synapses, 2. Changes in activity in long-range inputs, and 3. Changes in excitability of individual neurons. We found that all mechanisms could produce learning-related changes in CN activity. However, only local synaptic plasticity and changes in excitability were able to recapitulate the observed changes in connectivity within the learning ensemble. In contrast, activity changes in long-range inputs to the RNN produced non-specific changes in local connectivity. These results suggest that local plasticity in cortical circuits may be involved in fast learning.

Title: Dynamics of corticospinal ensembles activity throughout motor learning

Authors: *M. MACÍAS[1], M. ALTAMIRA-CAMACHO[1], R. OLIVARES-MORENO[1], M. LOPEZ-HIDALGO[2], G. ROJAS-PILONI[1];

Abstract: The ability to learn motor skills involves an improvement in accuracy, speed and consistency of movements. Motor control is related to movement execution and involves

corticospinal neurons (CSp), which are located in layer 5B of the primary motor (M1) and somatosensory (S1) cortices. M1 CSp neurons are functionally diverse, and is poorly explored if different classes of CSp change their activity throughout motor learning. It has shown that the population activity of M1 and S1 CSp neurons changes with learning and is different between both cortices. However, it is unknown whether these changes are due to subsets of CSp neurons within the population and how the activity of these subsets is related to different aspects of a learned movement. Given the importance and interaction between M1 and S1 related to movement, we investigated this issues in CSp neurons located in the sensorimotor cortex (SMC). We induced the expression of a jGCaMP7s calcium indicator to analyze motor-related Ca^{2+} transient dynamics of CSp neurons from SMC while C57Bl/6 wild-type adult mice learned and performed a cued lever-press task. In addition, we obtained the kinematic aspects of behavior to relate them to neuronal activity. CSp neurons exhibited correlations in their activity between them, forming ensembles throughout the training sessions. Furthermore, the activity of the different ensembles was more related to movement phases of the behavioral task, i.e., reaching movement, pressing and release of the lever with learning. These results suggest the association between corticospinal ensembles activity and movement changes as movement is learned and refined.

Title: Experience-dependent motor timing adaptation in ALM

Authors: *Z. YANG, S. MAJUMDER, M. INAGAKI, H. INAGAKI;
Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: Animals continually adapt behaviors to survive in the ever-changing environment. To do so, animals explore the environment through actions and update future movements based on the outcomes. Yet, how the brain encodes past experiences to influence future movements remains unclear. To fill this gap, we developed a motor timing task where adult mice (both

sexes) acquire a reward by licking after a delay following a cue signaling the trial onset. When we randomly switched the delay duration in a block of trials without signaling the delay duration (switching delay condition, 22 mice), mice rapidly adapted lick times (~ 10 trials). A linear regression model indicates that mice use trial history (lick times and reward outcomes in the last few trials) to guide future lick times properly. In contrast, when we fixed the delay duration in all trials (fixed delay condition, 20 mice), they stopped using trial history, likely because they learned the set timing. By leveraging optogenetics and *in vivo* large-scale electrophysiology, we systematically compared the neural dynamics underlying these two conditions (the same task structure but with or without trial history-dependent adaptation) to identify the neural mechanisms of adaptive motor timing. First, optogenetic loss-of-function screening of the dorsal cortical areas shows that the anterior lateral motor cortex (ALM) is required for motor timing and lick execution in both conditions, consistent with ALM's known role for planning and execution of lick. Second, we performed extracellular electrophysiology in ALM, and identified two activity modes that explain a large proportion of population activity before lick: 1) persistent mode, which shows persistent activity between trials and transient response upon cue presentation, and 2) ramping mode, which ramps up gradually before lick. In both task conditions, the slope of ramping mode predicts lick time, in line with literature showing that ramping preparatory activity determines action timing. Intriguingly, the amplitude of the activity along the persistent mode before the trial and during the cue encodes trial history and predicts future lick time only in the switching delay condition. In addition, manipulating activity along the persistent mode changed the ramping mode activity and lick times only in the switching delay condition, indicating the causality between these modes and behavior. Together, we identified the dynamics linking the past experiences and future actions: persistent spiking activity encodes past experiences across trials, and sets the initial state of the ALM dynamics to alter the ramping preparatory activity that determines the upcoming lick time.

Title: Cell-type-specific plasticity shapes neocortical spiking dynamics during motor learning

Authors: *S. MAJUMDER[1], K. HIROKAWA[1], Z. YANG[1], C. R. GERFEN[2], L. FONTOLAN[3], S. ROMANI[4], A. JAIN[1], R. YASUDA[1], H. K. INAGAKI[1];

Abstract: The neocortical spiking dynamics control aspects of behavior, yet how these dynamics emerge during motor learning remains elusive. The primary hypothesis is activity-dependent synaptic plasticity, as it can reconfigure network architectures that govern neural dynamics. Here, we examined how the mouse premotor cortex acquires its well-characterized neural dynamics that control the timing of movement. We developed a timing task where mice gradually learn to delay lick timing following a cue to obtain a reward, and acutely manipulated proteins involved in synaptic plasticity during learning. Specifically, we transiently inactivated Calcium/Calmodulin-dependent protein kinase II (CaMKII), a kinase essential for major forms of synaptic plasticity, using a genetically encoded light-inducible inhibitor of CaMKII, paAIP2 (photoactivatable autocamtide inhibitory peptide 2). PaAIP2 manipulation in the anterior lateral motor cortex (ALM; premotor cortex responsible for orofacial movement), but not the primary motor cortex (M1), blocked learning of new lick timing without affecting the execution of learned movements or ongoing spiking activity (n >= 4 mice per condition). The major excitatory cell types in the neocortex include pyramidal tract (PT) and intratelencephalic (IT) neurons, projecting outside and within the telencephalon, respectively, both of which highly express CaMKII. Notably, paAIP2 manipulation in PT neurons in ALM, but not IT neurons, impeded learning (n >= 6 mice per condition). We employed two additional acute cell-type-specific genetic manipulations that affect synaptic plasticity: CRISPR/Cas9 knockout of CaMKIIα (CaMKII isoform required for synaptic plasticity) and optogenetic inactivation of Cofilin (also required for major forms of synaptic plasticity). Both reproduced the necessity of ALM PT neurons but not IT neurons for learning new lick timing. Furthermore, by combining large-scale electrophysiology with cell-type-specific paAIP2 manipulation, we discovered that neural dynamics in the ALM progressively alter during learning, in a manner distinct from how activity changes when lick time fluctuates in expert animals, and such reconfiguration requires CaMKII activity in PT neurons (recorded 2704 neurons in ALM from 26 mice). Although nearly all cell types could induce synaptic plasticity, our findings support that they are not redundant. Instead, plasticity-related protein activity in a specific cell type, PT neurons, is required for sculpting neocortical dynamics to achieve new behavioral goals.

Title: Effect of DNA methylation inhibition in monkey primary motor cortex on performance of sequential movements after extensive practice

Authors: *M. OHBAYASHI[1,2];
[1]Neurobio., Univ. of Pittsburgh, Sch. of Med., Pittsburgh, PA; [2]Systems Neurosci. Ctr., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The acquisition of an expert level of performance of sequential movements requires extensive practice. Recent studies in monkeys indicate that extensive practice on sequential movements alters patterns of neural and functional activation in the primary motor cortex (M1) (Matsuzaka et al., 2007; Picard et al., 2013), and that manipulation of M1 disrupts the performance of acquired sequential movements (Ohbayashi, 2020). These findings and others led us to hypothesize that M1 becomes a site of long-term storage of the acquired sequential movements and remains critical for maintenance. To test this hypothesis, we injected an inhibitor for DNA methylation into M1 after extended practice of sequential movements. Change in DNA methylation has been shown to underlie the long-lasting maintenance of memory in the face of continued protein turnover (Miller et al., 2010; Jarome et al., 2014). We trained two monkeys (*Cebus apella*) on two tasks (Matsuzaka et al., 2007, Ohbayashi 2020). In the Random task, new visual targets were presented in a pseudorandom order, 100 ms after contact of the prior target. Therefore, the monkeys performed the reaching movements guided by the visual cues. In the Repeating task, visual targets were presented according to a repeating 3 element sequence (e.g., 234234 ...). New targets were presented 400 ms after contact of the prior target. The longer delay promoted the monkey to predict the next target in the sequence. With practice, monkeys reached the correct targets before the presentation of the visual cues. Therefore, the monkeys performed memory-guided sequential movements in this task. We injected an inhibitor for DNA methylation (2-3µl of 200 ng/µl 5-azadeoxycytidine) into M1 after more than 170 days of training and tested its effect on performance of the tasks. We analyzed the monkeys' behavior before and after the injection separately for each movement in each task. The injection had a significant effect on the performance of the movements during the Repeating task, but not during the Random task. In the Repeating task, the error rate for the most affected movements increased by 71 % after the injection. In 64% of trials, the monkey reached in the direction opposite to the correct target. In addition, response time in the Repeating task increased significantly. Notably, the monkey needed to be retrained for more than 20 days to recover the performance of the Repeating task to the pre-injection level. These effects were consistent over four injections in two monkeys (Monkey 1, n=3; Monkey 2, n=1). The results support the concept that M1 remains critical for maintenance of skilled sequential movements even after extensive practice.

Title: Refinement of motor control: from coarse to fine movements in freely behaving zebrafish

Authors: Y. RUBINSTEIN[1], M. MOSHKOVITZ[2], S. TIOMKIN[4], ***L. AVITAN**[3];
[1]Hebrew Univ. of Jerusalem, [2]The Hebrew Univ. of Jerusalem, [3]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [4]San Jose State Univ., San Jose, CA

Abstract: The outcome of zebrafish movement in shallow, approximately 2d-environments, is theoretically defined by three variables. A common assumption is that two of these variables - swimming distance and the change in heading direction - are sufficient to fully describe the outcome of fish movement. This assumption neglects the third variable - azimuth angle, the direction along which the fish moves. We examined the relationship between the three variables and found that in the common case of coarse movements, these variables are correlated, and fish movements can be described by two variables, compatible with current literature. However, in cases where fine and more accurate movements are required, this dependency breaks, and a third variable is required to get an unambiguous description of the fish movement. We demonstrated this increase in movement dimensionality in larval zebrafish hunting behavior. Fine motor control is implemented throughout the hunting sequence, hence verifying that three parameters are required for a complete and accurate movement description. These findings provide a biological manifestation of the 'control refinement principle', where control is firstly applied in a coarse, low-resolution manner, followed by refinement with more precise control in a higher-resolution space. Moreover, we show that even in the common case, when two parameters are sufficient, using the full, three-parameter description sheds new light on the way zebrafish implement their hunting strategy. Together, it provides a complete and more accurate framework to analyze fish behavior.

Title: Cortico-cerebellar mechanisms of neuroprosthetic control

Authors: *A. ABBASI[1], R. RANGWANI[2,1], D. BOWEN[1], A. FEALY[1], N. DANIELSEN[1], T. GULATI[1,2];
[1]Cedars-Sinai, Los Angeles, CA; [2]Univ. of California Los Angeles (UCLA), Los Angeles, CA

Abstract: Introduction: Brain-machine interfaces (BMIs) or neuroprosthetics allow neural control over assistive devices. They also provide an important framework for studying neural plasticity in the sensorimotor networks . To understand the neural mechanisms of skill learning in cortico-cerebellar networks, we performed electrophysiologic recordings in the motor cortex (M1) and the cerebellum (Cb) of rodents while they engaged in M1-driven BMI control. We found that both regions' neurons developed task-related (*TR*) modulation, and this was coordinated with an emergent 3-6Hz oscillatory activity in the M1 and Cb local field potentials (LFPs). We also found that Cb optogenetic inactivation (at the level of Cb cortex or its deep nuclei) caused task impairments. **Methods:** We recorded single units and LFPs in adult Long-Evans rats (n=7) while they performed a neuroprosthetic task by implanting microwire arrays in M1 and tetrodes/polytrodes in Cb. During the task, activity of a subset of M1 neurons was transformed into the angular velocity of a feeding tube using a linear decoder. Rats modulated the activity of these 'direct' neurons (M1 TR_d) to obtain water reward. We analyzed how the activity in these neurons, as well as all other recorded 'indirect' neurons in M1 and Cb changed while learning the BMI task. We also analyzed band-limited oscillatory activity in both regions. Furthermore, we performed optogenetic silencing of Cb cortex and the deep nuclei in two groups of rats (n=3/ group), while they performed the BMI task and analyzed how silencing affected M1 activity and BMI control. **Results:** We found that learning BMI control was associated with the modulation of M1 TR_d, as well as robust task-related 'indirect' (TR_i) modulation in M1 and Cb. We also observed a 3-6 Hz synchronous oscillatory activity in M1-Cb LFPs which coordinated task-related neural spiking. We found that the canonical correlation between task-related M1 and Cb spiking activity increased with learning. Furthermore, we found that Cb TR_i activity well-predicted M1 TR_d and TR_i activity but not M1 task-unrelated activity (M1 *TU;* as analyzed through spike generalized linear models). We also found that optogenetic inhibition of Cb cortex and its deep nuclei weakened M1 *TR* activity and led to performance impairments in the BMI task. **Conclusion:** Our work has identified neural mechanisms in M1-Cb which are associated with learning of a M1-driven neuroprosthetic skill. This underscores the importance of optimal engagement of neural learning mechanisms in the larger motor network for learning proficient neuroprosthetic control.

Title: Robust neuroprosthetic control using cerebellar activity in the stroke brain

Authors: *R. RANGWANI[1,2], A. ABBASI[2], D. BOWEN[2], T. GULATI[2];
[1]Univ. of California, Los Angeles; CNSM, Cedars-Sinai, Los Angeles, CA; [2]Dept. of Biomed. Sci., Ctr. for Neural Sci. and Med. (CNSM), Cedars-Sinai Med. Ctr. (CSMC), Los Angeles, CA

Abstract: Over the years, impressive studies in rodent, non-primates and clinical applications in humans have demonstrated that activity of sensorimotor neocortical areas can be decoded as a control signal to replace lost motor function using brain-machine interfaces (BMI). Surprisingly, subcortical regions such as the cerebellum (Cb) have not received much attention for implementing direct neural control, despite studies revealing that Cb cortical neurons exhibit tuning to limb position, velocity, duration, and muscle activity during voluntary arm movements. It is important to study if Cb direct neural control is feasible, as cortical areas such as primary motor cortex (M1) are not viable for direct neural control after an injury like stroke. We validated the use of direct Cb cortical neural activity in a neuroprosthetic task in healthy/stroke rodent models as well as studied cortico-cerebellar interactions. We recorded single-units and local-field potentials (LFPs) from drivable polytrodes in the Cb cortex as well as microelectrodes in M1 while adult healthy long-Evans rats (n=11) performed a neuroprosthetic task using the M1 or Cb activity. Additionally, we conducted Cb BMI experiments in a cohort of M1-stroke injured animals (n=4; photothrombotic stroke), to test viability of Cb neural activity for BMI application with an injured M1. During the task, rats exerted control over the angular velocity of a water tube by modulating activity of a subset of experimenter defined Cb neurons, classified as ‘direct’ neurons and using a simple linear decoder (Gulati et al, 2017; Kim et al, 2019). Our results show that efficient Cb-driven BMI control is possible, and it is as robust as M1-driven control. We observed that direct Cb neurons develop robust task-related modulation as seen in M1-driven BMIs. Remarkably, robust learning was also seen in rats recovering from stroke that had their forelimb motor function compromised (assessed on a reach-to-grasp task). Furthermore, we observed extensive indirect task-related modulation in both Cb and M1. We found that synchronous 3-6 Hz oscillations emerged in M1-Cb LFPs as Cb-driven neuroprosthetic control was learned. Using regression, we found that Cb/M1 indirect activity predicted the Cb direct activity, but the timescale was different for local vs cross-region interactions. Cb BMI behavioral performance remained the same in M1-stroke injured vs healthy brain while cortico-cerebellar

interactions were affected post-stroke. Our work demonstrates feasibility of direct BMI control using Cb activity when M1 is stroke-injured, and elucidates the cortico-cerebellar neural mechanisms facilitating such control.

Abstract: Primary motor cortex (M1) and premotor cortex (PM) both participate in control of voluntary movements. M1 is commonly thought to execute movements while PM plans them, but these traditional roles do not fully explain the activity of M1 and PM neurons. For example, neurons in both areas were recently shown to be modulated by reward information – a factor seemingly independent of movement planning or kinematics. Might M1 and PM neurons be influenced by other non-kinematic factors? Here, we investigated whether the activity of M1 and PM neurons varied based on the modality with which the instruction was delivered, even when the instruction was for the same movement having the same reward. Two male rhesus monkeys were initially trained to reach to, grasp, and manipulate 4 different objects instructed by visual cues (LEDs), and then were implanted with microelectrode arrays in M1, PM, and the primary somatosensory cortex (S1). Subsequently, the monkeys were trained to perform the same task with ICMS instructions instead of the visual cues. ICMS instructions were delivered through a set of 3-7 electrodes on a different array in S1 for each object (1-64μA per electrode, 75 – 150Hz). Ultimately, visually- and ICMS-instructed trials were randomly interleaved while recording neural data from M1 and PM. From such sessions, we analyzed 39 M1 units and 42 PM units (both single- and multi-units) in one monkey; 36 M1 units and 33 PM units in the other. We rendered spike trains from visually- and ICMS-instructed trials comparable by convolving spike trains from the visually-instructed trials with trains of blanking windows that emulated collisions between spikes and ICMS pulse artifacts. We then compared the firing rates of each neuron between visually- and ICMS-instructed trials for each object separately (neuron-array pairs). We initially examined only neuron-array pairs in which ICMS pulses produced no direct modulation (DM-) of the neuron's activity in peri-stimulus time histograms triggered on

the ICMS pulses. For many DM- neuron-array pairs, neural activity was significantly different between visually- and ICMS-instructed trials, which we term “instruction-modality modulation” (IM). In M1, 14/34 (41%) of DM- pairs from monkey L and 14/36 (39%) from X displayed IM. For DM- PM pairs, 39/93 (42%) from L and 19/38 (50%) from X displayed IM. We also found IM in neural activity from neuron-array pairs that were directly modulated by S1-ICMS (DM+). Including both DM- and DM+ pairs, 102/144 (71%) of M1 pairs in L and 65/103 (63%) in X showed IM; 76/151 (50%) of PM pairs in L and 57/87 (66%) in X showed IM. The majority of neuron-array pairs in both M1 and PM were modulated by instruction modality.

Title: The effects of low-amplitude intracortical microstimulation in one cortical area don’t stay in that cortical area

Authors: *B. M. RUSZALA[1], M. H. SCHIEBER[2];
[1]Biomed. Engin., [2]Neurol., Univ. of Rochester, Rochester, NY

Abstract: Although the effects of electrical intracortical microstimulation (ICMS) are commonly assumed to activate only neurons near the tip of the stimulating electrode, ICMS effects are largely transsynaptic and can reach neurons far from the stimulation site. For example, ICMS delivered in the primary motor cortex (M1) can activate distant spinal motoneurons via corticospinal projections, evoking contractions in distal forelimb muscles. Similarly, the effects of ICMS delivered in one cortical area may not be confined to that area, potentially modulating the activity of neurons in distant cortical areas via cortico-cortical connections. Here, we examined the extent to which ICMS delivered in the primary somatosensory cortex (S1), ventral premotor cortex (PMv), or anterior intraparietal area (AIP) of rhesus macaques modulated neural activity in several distant cortical regions of the reach-to-grasp network: PMv, dorsal premotor cortex (PMd), M1, S1, AIP, and dorsal posterior parietal cortex (dPPC). Two male rhesus monkeys (Q, F) were initially trained to choose among 4 targets in a center-out target task instructed by visual cues, and then were implanted with microelectrode arrays in PMv, PMd, M1, S1, AIP, and dPPC. Subsequently, the visual instructions for the 4 targets were replaced by ICMS instructions delivered in one cortical area: S1, PMv, or AIP. Instructions were delivered as trains of simultaneous pulses through different sets of 4 electrodes for each target (20 - 35µA per electrode, 12.5-30ms jittered inter-pulse intervals). Neural data were recorded from the other 5

non-stimulated cortical areas as the monkey performed the task with S1-ICMS, PMv-ICMS, or AIP-ICMS instructions. In each monkey, we constructed peristimulus time histograms (PSTHs) using the spike times of each single- or multi-unit, triggered on the individual pulses of each ICMS instruction recorded in the first session ICMS was delivered in a given cortical region. We considered a unit to be directly modulated by ICMS if the corresponding PSTH was either significantly non-uniform (KS goodness of fit test, p < 0.01), or contained a significant peak or trough (±2 standard deviations of the baseline for 3+ bins). We found that S1-ICMS, PMv-ICMS, and AIP-ICMS each directly modulated neurons in all other implanted areas. ICMS with an amplitude of 35µA or less delivered in one cortical area directly modulated neurons across the cortical reach-to-grasp network.

Abstract: After several remarkable First in human clinical Trials, the Brain Computer Interface (BCI) Community is now striving for daily life use of motor handicap compensation or communication solutions. Our project benefits from WIMAGINE®, the 64 channels ECoG recorder and the software suite designed and manufactured by CEA Leti Clinatec to record and

decode in real-time the brain signals. Based on the results of two groundbreaking BCI clinical trials (NCT02550522, NCT04632290), we demonstrated the reliability and the promises of our BCI systems for tetraplegic or paraplegic patients using supervised algorithm and as an effector the exoskeleton [1] or the implantable spinal cord stimulator [2]. To work toward home use, we propose the auto-adaptive framework for unsupervised use of the decoder [3]. We adapted this strategy to gait trainings sessions, the self-adaptive unsupervised model recalibration was 24% better than random auto-adaptive training and 26% lower than to the supervised recalibration. We are working also on a neuromorphic decoding and self-adaptation real time algorithms that will be implemented in neuromorphic hardware in near future.In addition, we have started the optimization the decoding algorithms first by a full translation and acceleration in C++ to be able to run the decoding software on a portable platform such as a Raspberry pi hardware achieving decoding in less than 100 ms, which was our target to perform real-time decoding. In addition for sake of portability, a second objective is the miniaturization of the decoding hardware by designing an integrated circuit dedicated to ECoG based BCI decoding.[1] Benabid, Alim Louis, et al. Title: Cortical release of acetylcholine to deep brain stimulation of the sub pallidal forebrain in mice

Authors: *K. SHANAZZ[1], T. OLIVER[2], K. PENNINGTON[3], D. T. BLAKE[4];
[1]Dept. of Neurosci. and Regenerative Med., [2]Augusta Univ., Augusta, GA; [3]Augusta Univ. Dept

of Neurosci. & Regenerative Med., Augusta, GA; [4]Neurosci. and Regenerative Med., Med. Col. of Georgia at Augusta Univ., Augusta, GA

Abstract: Over 160k patients have received deep brain stimulation (DBS) implants and their use is growing. We have documented that chronic, one hour daily, intermittent stimulation of the sub-pallidal basal forebrain (BG) increases cortical levels of acetylcholine (ACh) and makes animals smarter. However, the dynamics of ACh release in response to DBS has not been sufficiently documented. Using fluorescent acetylcholine (GACh3.0) reporters in mice and 2-photon in vivo imaging we aimed to quantify ACh changes in response to DBS with the resolution of seconds. We stimulated the BG with 60Hz for 60s and recorded fluorescence change to a 10s test pulse every 5mins. Our data suggests that 1) depletion of the ACh response occurs within 60s; the physiologic half life of ACh release is likely 10-12s and 2) the recovery time from depletion is within 20mins; recovery time per second of stimulation is likely 10-12s. This study is ongoing and future studies will include manipulation of acetylcholinesterase and the choline transporter to examine mechanisms.

Title: Long-term sensorimotor cortex sensing using permanently implanted subgaleal leads in a patient receiving deep brain stimulation for Parkinson’s disease

Authors: *S. SANDOVAL-PISTORIUS[1], R. FERNANDEZ-GAJARDO[2], S. CERNERA[3], P. A. STARR[4];
[1]Neurolog. Surgery, Univ. of California San Francisco, San Fransciso, CA; [2]Univ. of California San Francisco, San Francisco, CA; [3]Neurolog. Surgery, Univ. of California, San Fransisco, San Francisco, CA; [4]Dept. of Neurol., Univ. of California, San Francisco, san francisco, CA

Abstract: Pathological oscillatory activity in cortico-basal ganglia (BG) circuits is linked to motor symptoms in Parkinson's disease (PD). Sensing-enabled deep brain stimulation (DBS) devices connected to subdural electrocorticography (ECoG) leads over sensorimotor cortex show that changes in synchronized oscillatory activity across the cortex-BG motor network correlate with motor signs and therapeutic response. Advances in adaptive DBS, which adjusts stimulation based on neural signals and changing brain states, requires identification of neurophysiological biomarkers that correlate with various motor symptoms. Cortical biomarkers have shown promise as feedback signals for adaptive DBS, but limited studies exist due to the invasiveness of subdural ECoG paddles. Using less invasive under-the-scalp (e.g., subgaleal; SG) permanent

leads to record cortical activity would reduce risks associated with placing permanent electrodes directly on the brain's surface and enable rapid scalability, inclusivity, and equitable access to adaptive DBS for PD using cortical signals. An individual with PD was implanted with bilateral sensing-enabled DBS devices, each connected to a directional lead targeting the subthalamic nucleus (STN) and a cortical lead placed in the SG space over sensorimotor cortex. For cortical sensing, an octopolar 10.5 mm segmented DBS lead was implanted over one side and an octopolar 57 mm paddle type lead, normally used for spinal cord stimulation, was implanted over the other side. At various time points post-implantation, we recorded local field potentials from both the STN and SG leads while the study participant was at rest either OFF stimulation or during STN stimulation amplitude titrations. We found that both SG leads were able to detect low frequency beta sensorimotor activity at rest and OFF STN stimulation. During stimulation amplitude titrations, the segmented SG lead, but not the paddle type lead, detected finely tuned cortical gamma entrainment at half the stimulation frequency (62.5 Hz) while on 4.0 mA STN stimulation. Cortical entrained gamma corresponded with a 62.5 Hz finely tuned gamma peak observed in the STN with 4.0 mA stimulation. These findings suggest that SG cortical recording from a permanent implant can detect sensorimotor activity in physiologically relevant frequency bands. Cortical finely tuned gamma (FTG) activity is a promising feedback signal for adaptive DBS. SG lead detection of cortical FTG suggests that SG sensing may be used in studies of adaptive DBS. Ongoing studies are investigating sensorimotor activity during various brain states, including on/off DBS, on/off medication, and during movement vs rest.

Title: Deep brain stimulation-induced entrainment of cortical finely tuned gamma oscillations: effects of voluntary movement in Parkinson's disease

Authors: *M. SHCHERBAKOVA[1], S. CERNERA[1], A. HAHN[1], S. LITTLE[2], P. A. STARR[1]; [1]Dept. of Neurolog. Surgery, [2]Dept. of Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: *Objective:* To study the role of voluntary movement in bilateral entrainment of finely tuned gamma oscillations (FTG) in the sensorimotor cortex via unilateral subthalamic deep brain stimulation (DBS).
Background: Prior studies show that FTG activity is associated with a prokinetic state and

increases with movement. We have previously described cortical gamma entrainment, or induction of FTG at a subharmonic of the stimulation frequency. DBS-induced FTG entrainment may be related to improved movement in Parkinson's disease (PD).
Methods: We recorded basal ganglia and sensorimotor cortex local field potentials in-clinic from six hemispheres of three PD patients receiving bilateral subthalamic nucleus (STN) DBS. Patients were implanted with an investigational bi-directional DBS device with subdural electrocorticography leads. We performed unilateral frequency-amplitude titrations, while off contralateral DBS therapy. The time subjects spent at each frequency-amplitude combination was divided between remaining at rest and completing a standardized finger-tapping task. We determined the amplitude of gamma entrainment present in both hemispheres using the FOOOF algorithm, and computed average FTG power over several time intervals during finger tapping to relate variability of gamma entrainment amplitude across time to the different stages of a voluntary movement.
Results: In all patients, we observed cortical FTG entrainment at half the stimulation frequency at a select set of frequency-amplitude combinations during movement and rest in both pre- and postcentral gyri. The amplitude of entrainment was larger during movement than during rest and in precentral gyrus than in postcentral, across parameter combinations and subjects. Entrainment was not linearly related to stimulation amplitude, decreasing with increasing stimulation amplitudes at select frequencies. In the precentral gyrus, and at 90 - 130 Hz stimulation only, we observed increased FTG activity during the first 3-6 seconds following movement onset that waned over time. Lastly, we report contralateral hemisphere FTG in two of three patients, at a narrower range of frequencies than ipsilateral entrainment.
Conclusions: We demonstrate specificity of ipsi- and contralateral FTG region and movement-related characteristics of DBS-induced entrainment unique to the precentral gyrus that may underlie the mechanism of motor regulation in PD. Contralateral cortical entrainment could be the physiological basis for the ipsilateral motor effects of therapeutic DBS described in prior reports. Next, we will relate these observations to their clinical manifestations.

Title: Independent use of an at-home intracortical BCI system

Authors: *W. HOCKEIMER[1,2], J. M. WEISS[1,2], B. M. DEKLEVA[1,2,4], D. WEIR[1,2], N. G. KUNIGK[1,3], S. M. CHASE[4,5,6], M. L. BONINGER[1,2,3], J. L. COLLINGER[1,2,3,4,5];

[1]Rehab Neural Engin. Labs, [2]Physical Med. and Rehabiliation, [3]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [4]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [5]Biomed. Engin. Dept., [6]Neurosci. Inst., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: A long-term goal of intracortical brain-computer interface (iBCI) research is to allow people with motor impairments to use iBCIs independently at home. A significant impediment to that goal is that iBCI use typically requires expert assistance to achieve good control and relies on cumbersome hardware systems. Here we present initial use of an upgraded version of our previously described at-home system, which had limited computational capabilities and battery life (Weiss et al., 2019). The participant is a 36-year-old man with tetraplegia due to cervical spinal cord injury with intracortical electrodes implanted in motor and sensory cortices. Updated neural recording hardware (Blackrock Neurotech, Salt Lake City, UT) was approved for independent use under an FDA Investigational Device Exemption. 256 channels of data are acquired and processed by a compact Neural Signal Processor that connects to AC power and these data are streamed via gigabit ethernet to a commercially-available tablet with 32 GB RAM and a 1 TB SSD. The participant and his caregivers were trained to operate the system prior to use. A custom mount is used to attach the recording hardware to the participant's wheelchair. The caregiver connects the implant pedestals to the iBCI system while the participant, who retains residual motor function of his proximal arm, initiates the software on the tablet touchscreen. During testing the participant first calibrates a decoder and completes a gamified click-and-drag center-out task (Dekleva et al., 2021). The participant can use a GUI to change cursor gains and biases. After an initial prototyping period, three sessions were collected to quantify performance. Performance at home was similar to 20 comparable lab sessions, with an average of 95% ± 5% trials correct compared to 88% ± 17% in lab. The mean path inefficiency (real path / ideal path) was 1.86 ± 0.12 compared to 1.88 ± 0.74 in lab; the mean target acquisition rate was 3.6 ± 0.84 targets / min compared to 4.4 ± 1.65 targets / min in lab; and the mean click time was 2.55 ± 1.5 s versus 1.66 ± 1.03 s in lab. The participant rated satisfaction with the iBCI system on scale from 0 to 10 (maximally satisfied) with an average of 7.6 ± 1.5 / 10. The NASA TLX (Hart and Staveland, 1988) was used to assess subjective task load on a 100 point scale (100 = highest load) with 5 point increments. The average weighted score of 5.74 ± 3.36 was lower than the average lab score of 19.13 ± 13.38, suggesting that iBCI use is no more difficult at home versus lab. These data demonstrate initial use of an improved at-home iBCI system. Further work will primarily focus on collecting long-term usage data and increasing online functionality to improve control.

Title: Spatial and Spectral Changes in Cortical Surface Potentials during Pinching versus Thumb and Index Finger Flexion

Authors: *P. KEREZOUDIS[1], M. JENSEN[2], H. HUANG[2], J. ROTTER[1], J. G. OJEMANN[4], D. HERMES[3], K. J. MILLER[2];
[2]Mayo Clin., [3]Physiol. and Biomed. Engin., [1]Mayo Clin., Rochester, MN; [4]Dept Neurosurg., Univ. of Washington, Seattle, WA

Abstract: Rationale: Electrocorticographic (ECoG) signals can resolve the activation of the sensorimotor cortex and the somatotopic representation of contralateral hand movements with high accuracy. The relationship between individual or synergistic finger movement and the corresponding ECoG neural signals has not been fully explored.**Objective:** To compare the spatial cortical representation of pinching versus thumb and index finger flexion. **Methods:** We analyzed the electrocorticographic signals of 3 patients (2 females, aged 18-21-19 years) implanted with subdural electrode arrays for identification of seizure foci. Patients were asked to perform screen cue-based flexion movement of the thumb or index finger, or a pinch movement of both. Hand movements were captured by a data glove simultaneously with ECoG recordings. Broadband power changes with each movement were estimated using a well-established principal component analysis of the power spectrum. Topological maps for each type of movement were created using CT-MRI co-registered brain renderings, and the overlap in spatial extent was quantified using a resampling metric.**Results:** Significant increase in broadband power was observed in all three patients when pinch (max signed r^2 0.67-0.84-0.82), thumb flexion (0.67-0.89-0.72) or index flexion (0.65-0.89-0.72) was performed compared to rest. Spatial overlap was significant between thumb and index flexion in all three subjects (60-70%), while spatial overlap between pinch and index flexion (67-90%, all $p<.001$) was considerably higher compared to pinch and thumb flexion (23-77%; significant in 2/3 patients). Finally, the geometric mean of thumb/index flexion resulted in similar results to the pinch-index comparison, with significant overlap in 2/3 subjects (82-89%) and 31% in one patient.**Conclusion:** For pinch, the ECoG signal seems to comprise a combination of the signals from the individual thumb and index movements, with considerably larger overlap with the latter. This analysis may provide insights into motor cortex tuning toward specific types of motor behaviors.

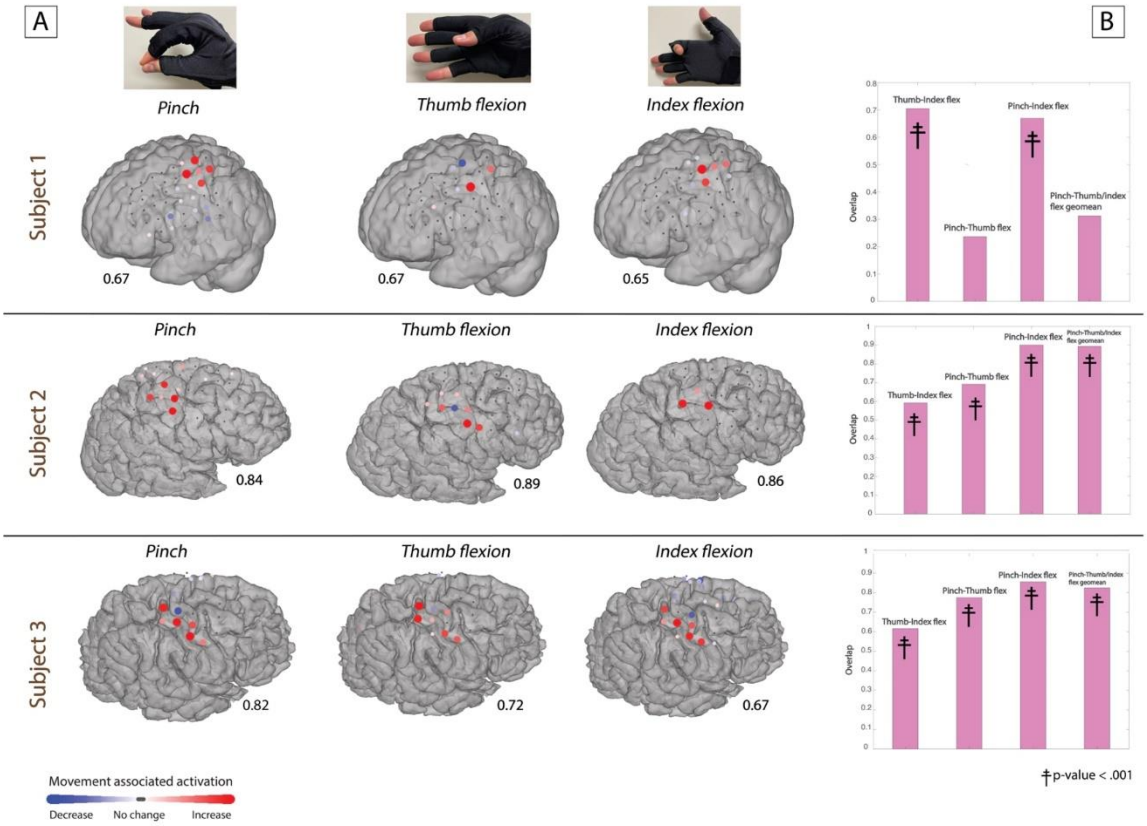

Figure legend. ECoG broadband power resolves somatotopic representation of finger movement. (A) Changes in broadband power at different cortical sites for pinching (left panel), thumb flexion (middle panel) and index finger flexion (right panel). Colors denote a signed R-squared measurement of increases and decreases in power with movement relative to rest (with maximum denoted in the lower left or right corner). (B) Quantification of spatial overlap between changes associated with the different types of finger-movements (1 is maximum possible overlap and 0 is no overlap). Resampling significance, double cross indicates p-value less than 0.001, that the overlap happened by chance. Within each diagram, from left to right, the bar plots represent overlap between a) thumb and index flexion, b) pinching and thumb flexion, c) pinching and index flexion, and d) pinching and the geometric mean of thumb/index flexion (calculated as the square root of the channel-wise product of significant broadband-related R-squared values between thumb and index).

Abstract: Epidural Electrical Stimulation (EES) of the spinal cord is a promising therapy that has alleviated gait deficits in animal models and patients with Parkinson's disease (PD). Here, we hypothesised that a closed-loop stimulation, targeted to specific phases of cortical oscillations, can refine the interaction EES with pathological network states. For this, we developed a real-time system that tracks peak-frequency within the beta-band to optimise signal to noise ratio during online phase-tracking. We used this system to deliver high-frequency bursts of stimulation in relation to ECOG signals from M2 cortex. Our results confirmed the presence of network alterations in the unilateral 6-OhDA rat model that were dependent on precise timepoints of stimulation. Experiments in sham animals verified that alterations were specific to neural modulation and not a result of stimulation artefacts. Together, our work provides a tangible solution for the future design of closed-loop stimulation strategies for clinical translation.

Title: Using an Orthogonal Neurofeedback Brain Machine Interface to Study the Relationship Between Intracortical High Gamma Activity and Spikes

Authors: *T. LEI[1], M. R. SCHEID[2], J. I. GLASER[2], M. W. SLUTZKY[2];
[1]NUIN, [2]Neurol., Northwestern Univ., Chicago, IL

Abstract: Local field potentials recorded from the cerebral cortex are derived from a mixture of brain activities, which are reflected in different frequency bands. Among them, the high gamma band is widely considered as a proxy of neuronal ensemble firing. Here, we investigated whether monkeys could dissociate the high gamma and spiking recorded with the same electrode. To do this, we designed an orthogonal neural feedback (ONF) brain machine interface paradigm that

required monkeys to control a cursor by modulating a control channel's spiking activity independently from high gamma activity (HGA) to reach targets in different directions Three macaques could reliably dissociate spiking activity from changes in HGA, with a correlation coefficient dropping from 0.5±0.22 to 0.1±0.13 before and after training. This indicated that high gamma activity is not simply a reflection of local neuronal spiking activity. Further, we sought to understand how HGA and the neuronal population's spiking activity were related. We used factor analysis to investigate how the variance of the individual control channel was shared with the neural population during ONF control, and we found that the shared variances of the spike rates were consistently and significantly lower when the monkeys were solely modulating spikes compared to solely modulating HGA. This result indicated that HGA recorded on a single electrode was correlated with the common co-firing patterns across the neuronal population. This again suggests that HGA is produced not simply by the sum of local neuronal activity, but by the synchrony (co-firing) of multiple neurons across a population. Further, it suggests that neurons can learn to fire independently without the interference of the common co-firing patterns using ONF. This robust relationship between HGA and neuronal population firing helps us further understand the origin of HGA.

Title: Temporal dynamics of sensations evoked through intracortical microstimulation in human brain-computer-interfaces

Authors: *R. LIENKAMPER[1,2], C. M. GREENSPON[5], T. HOBBS[3,2], S. BENSMAIA[6], R. GAUNT[4,2,1];
[1]Dept. of Physical Med. and Rehabil. at the Univ. of Pittsburgh, [2]Rehab Neural Engin. Labs, [3]Bioengineering, [4]Univ. of Pittsburgh, Pittsburgh, PA; [5]Dept. of Organismal Biol. & Anat., Chicago Univ., Chicago, IL; [6]Univ. of Chicago, Chicago, IL

Abstract: Brain-computer interfaces (BCIs) aim to improve the quality of life of severely paralyzed people by decoding movement intention from brain signals and translating them into control signals that can be used to control robotic devices. Invasive BCIs can be extended to also provide artificial somatosensory feedback using intracortical microstimulation (ICMS) through electrode arrays implanted into the somatosensory cortex.
Our prior work in humans has shown that ICMS evoked sensations can be reliably localized on the skin surface and that their perceived intensity varies depending on the stimulation

parameters. Further, the reaction times to ICMS are similar to the reaction times from mechanical stimuli. However, it is largely unknown how the temporal acuity of sensations evoked by ICMS compare to natural sensations. In this study, we investigate how the temporal dynamics of the evoked sensations are related to the dynamics of the ICMS trains themselves using a discrimination task. Three male participants with spinal cord injury participated in the study. All three had microelectrode arrays implanted into the hand representation of area 1 in the somatosensory cortex. We presented participants with two stimulation periods (with a fixed duration and stimulus amplitude) that were temporally separated by a pause of varying length. Participants were asked to report whether they felt a single sensation or two distinct sensations separated by a gap between them. The paradigm included both charged-matched and duration-matched control trials.
Surprisingly, we found that the participants often could not perceive even large gaps between stimulus trains – from 0.1 to 0.4 s. Indeed, while some electrodes conferred a high sensitivity to gaps, others did not. These differences could not be explained solely by differences in perceived intensity as changes in stimulation amplitude had only minor effects on discrimination performance. Even for the more acute electrodes, gap sensitivity was far lower than that observed in natural touch or even with electrical activation of peripheral nerves. These results highlight the differences between ICMS-evoked and naturally evoked sensations and suggest that the dynamics of the evoked sensations must be taken into consideration when designing encoding strategies for closed-loop BCI applications.

Title: A systematic review of implanted brain-computer interfaces for communication and motor control toward a roadmap for surgical brain-computer interfaces

Authors: *M. PATRICK KRUEGER[1], I. T. PAVLIDIS[2], J. L. CONTRERAS-VIDAL, Ph.D.[1]; [1]Electrical and Computer Engin., [2]Natural Sci. and Mathematics, Univ. of Houston, Houston, TX

Abstract: In 1996, PR Kennedy performed the first surgical implantation of electrodes into the brain of a Locked-in-Syndrome patient to demonstrate the feasibility of deploying a Brain-Computer Interface (BCI) system for communication via a neural-controlled cursor, with the first successful usage occurring in 1998. In the following decade, only seven new subjects received either Kennedy's electrodes or Cyberkinetic (now BrainGate) System to drive BCI systems

controlling neuroprosthetics for communication or motor control. Fifteen years after the first successful BCI deployment, the Obama Administration announced a US BRAIN Initiative, with funding initiated in 2014. Since then, the number of surgical BCI research groups has more than doubled, with subjects more than tripling to over 60 who have been implanted. With the BRAIN Initiative's 2025 conclusion concurrent with a profusion of novel devices moving toward marketability, this research provides a detailed assessment of the current implanted BCI landscape for communication and motor control that is needed to illuminate the gaps, missed opportunities, and challenges to enable the forward progression of the field. This in-depth systematic review combining findings from peer-reviewed and grey literature, which are enhanced with interviews of key stakeholders from research groups and device manufacturers, provides a complete summarization of the subjects who have had electrodes implanted, including demographics, etiology, and type of electrodes; the devices used in human subject testing including temporal signal quality and adverse events due to implantation; the communication and motor control experimental protocols carried out; and the composition of research teams. This detailed map spotlights the gaps in BCI research, such as the lack of pediatric applications and regulatory tools; missed opportunities such as data sharing, computational modeling, and reproducibility; and challenges such as interoperability, long-term reliability and prognosis, and ethical prospects for out-of-laboratory usage into clinical and home settings. With human trials starting in 2021 for Synchron and in 2023 for Precision Neuro and Nuralink, with other manufacturers (Paradromics, Blackrock Neurotech, Axoft) having secured FDA Breakthrough Device status, the number of new subjects receiving implants is poised to proliferate in the next decade. To ensure the safety, efficacy, reliability, and translatability of implanted BCI systems, these gaps, missed opportunities, and challenges must be addressed to smooth the transition from experimental to widespread clinical and home usage.

Title: Beta-band power modulation in the human corticolimbic circuit during arm-reaching movements

Authors: *R. MARTIN DEL CAMPO VERA, A. KAMMEN, J. CAVALERI, Z. GILBERT, R. CHUNG, S. ZHANG, S. SUNDARAM, A. LEONOR, C. LIU, S. KELLIS, B. LEE; Neurolog. Surgery, USC, Los Angeles, CA

Abstract: Recent developments in stereotactic electroencephalography (SEEG) have allowed researchers to study human deep brain areas, such as the corticolimbic system, which is thought to be involved in cognitive control and processing of uncertainty; however, little is known about its role in voluntary movements. This study aims to evaluate differences in spectral power over the beta-band across corticolimbic structures during two different arm-reaching tasks. Ten participants (five female, average age 35) had SEEG electrodes implanted as part of their epilepsy monitoring. These electrodes included the frontal, amygdala, hippocampus, and orbitofrontal cortex (OFC) areas. SEEG data were recorded during two variants of the classic Center-Out arm-reaching task. In the Go/No-Go task, participants were cued to reach a target (Go trials) or withhold movement (No-Go trials) based on a colored cue. In the Always Go task, participants reached a target in all the trials. The Wilcoxon signed-rank test was used to assess significant beta-band power changes with alpha level of 0.05. P-values were adjusted using the Benjamini-Yekutieli procedure to account for multiple comparisons. In the Always Go task, beta-band power significantly decreased during movement, with the frontal and hippocampal areas being the most common to exhibit a significant reduction in power (5 out of 6, and 8 out of 10 participants respectively), followed by the amygdala in 5 out of 10, and OFC in 4 out of 8. In the Go/No-Go task, beta-band power significantly decreased during Go trials and increased during No-Go trials. In Go trials, compared to the Always Go task, the proportion of patients with a significant beta-band power decrease remained unchanged in the hippocampus and OFC, whereas in the rest of the brain areas, the proportion of participants with a significant beta-band power decrease was higher (8 out of 10 in the amygdala, and 6 out of 8 in the OFC). In No-Go trials, the most common area with a significant beta-band power increase was the hippocampus in 8 out of 10 participants, followed by the OFC in 6 out of 8, the amygdala in 7 out of 10, and frontal in 4 out of 6. Measures of beta-band power between No-Go versus Go trials show that motor inhibition and execution modulate in opposite directions. When contrasting the two tasks, the presence of movement uncertainty in the Go/No-Go task can affect the magnitude of beta-band power modulation. The extent of such beta-band power modulation can vary across multiple brain areas in the corticolimbic system, suggesting that each of these areas may have different contributions to motor control.

Title: Theoretical limits of a neural interface

Authors: *N. CALCINI, R. JOLIVET;
Systems Biol., Univ. of Maastricht, Maastricht, Netherlands

Abstract: Great efforts are being made to advance the technology of neural interfaces, with the development of better batteries, wireless sensors, the addition of more recording electrodes, or the application of AI algorithms for decoding neural signals. Regarding decoding, the field has yet to achieve a fundamental breakthrough. Here, we attempt to develop a formal and fundamental understanding of the interaction between *in silico* devices and neural tissue. We start to develop a framework, which allows us to estimate some theoretical limits of neural interfaces, by measuring the limits on information a neural interface can capture from neural signals about its network environment.
To do this, we activate a neural network using a binary stimulus representing an external sensory stimulus comparable to the ones used in go / no-go tasks. The stimulus activates the network, which represents the neural substrate acting as a filter between stimulus and a target population. The output spike trains of such a network are sent to a simulated target population. We then reconstruct the LFP, which is measured by a single point electrode. Finally, we reconstruct the mutual information between the signal captured by the electrode, and the original simulated sensory stimulus.
With this framework, and its modular approach, we pose the foundation for a thorough analysis of the current theoretical limitations of a number of neural interfaces, allowing us to examine a variety of interfaces, and the theoretical limits of their functional integration in a neural circuit.

Title: The Early Feasibility of Recording iEEG and Epileptic Spikes with the Brain Interchange System

Authors: *A. AYYOUBI[1], B. FAZLI BESHELI[1], M. QUACH[2], A. GOLDMAN[4], D. CURRY[3], S. A. SHETH[5], E. BARTOLI[5], J. GAVVALA[6], N. F. INCE[1];

Abstract: The use of implanted pulse generators for neuromodulation has proven to be a promising method for treating neurological disorders. For instance, responsive neural stimulation (RNS) for the control of seizures in epilepsy and deep brain stimulation (DBS) in movement disorders. However, implantable systems face various challenges, including recording only from a small number of brain sites, power management, and limited access to the assessed neural data in a continuous fashion. In this study, we investigated the feasibility of recording neural data from two human subjects with refractory focal epilepsy using a wireless, externally powered, portable bio-signal amplifier, the Brain Interchange (BIC) system (CorTec GMBH, Freiburg Germany). We established a MATLAB/Simulink environment to acquire the neural data at 1kHz from the 32 channels of the BIC system and visualize the captured neural activity in real-time. Afterward, the established environment was subjected to validation in a real-world setting, where the intracranial EEG (iEEG) data was split into two streams and simultaneously recorded using a clinical amplifier and BIC system within the epilepsy monitoring unit (EMU). Subsequently, the raw signal quality and background noise characteristics of each stream were quantified and compared. Although the clinical amplifiers utilizing a cable interface exhibited a significantly better noise floor (<25 dB), the BIC system demonstrated the capability to collect data of comparable quality wirelessly and continuously. The primary distinctions in noise floor between the two systems were predominantly observed above 100 Hz. Furthermore, the recorded data for each stream (BIC vs. Natus Quantum (Natus Medical Incorporated, Wisconsin, USA) and BIC vs. Nihon Kohden (Nihon Kohden Corporation, Tokyo, Japan)) underwent a spike detection analysis, ensuring similar/aligned time segments. The results showed a concordance of over 90% between the two systems. As a result of the BIC system's wireless data transfer capability, we may face losing the packets of data during the transfer process (Packet loss). We estimated the packet loss level of the recording interval for each subject. Moreover, to further investigate the effect of ambient noise on the packet loss, we conducted a series of tests in the lab and the electromagnetically shielded chamber, which revealed that there is a significant difference between the two environments (paired t-test, $p = 0.0090$) with an average of 1.47% packet loss in the lab and 0.74% in the shielded chamber.

Title: The Brain Interchange System for recording and stimulation on the sheep cortex: a case study towards functionality and safety of ECoG-based neural implants

Authors: *C. A. GKOGKIDIS[1], M. BUCHHEIT[1], H. CHO[2], S. C. CRAMER[4], J. OJEMANN[3], M. SCHUETTLER[5];
[1]CorTec GmbH, Freiburg, Germany; [3]Dept. of Neurolog. Surgery, [2]Univ. of Washington, Seattle, WA; [4]Dept. of Neurol., Univ. of California, Los Angeles, CA; [5]Cortec GmbH, Freiburg Im Breisgau, Germany

Abstract: Although not yet ubiquitous in modern medicine, fully implantable neural interfaces are at the cusp of becoming a widespread tool in transitional and medical research and ultimately for the development of novel therapeutic strategies to target a variety of neuropsychological disorders. Technical advancements allow to build bi-directional neural interfaces that have (concurrent) sensing and stimulation capabilities which allow for more elaborate approaches via electrical brain stimulation. To further advance the introduction of such implants into the daily clinic landscape, preclinical studies with devices currently under development for human application are mandatory to demonstrate basic requirements for medical use: long-term performance, reliability, and safety. With data and results from a preclinical 25-day functional implantation study in the ovine model (2 female adult sheep), we continue general efforts in the field of neural implants to address these crucial points. The Brain Interchange System (CorTec GmbH, Freiburg) used here is a fully implantable (i.e., no physical wire connection through the skin), bi-directional neural interfacing device equipped with two electrocorticographic (ECoG) electrode arrays implanted bilaterally and subdural to obtain electrophysiological signal from and apply electrical stimulation to the cortical surface. To address long-term performance, functionality, and reliability, we show behavior of signals recorded under different cognitive states and impedances across the implantation period and demonstrate stimulation functionality via single-pulse electrical stimulation potentially to be employed to elicit and record cortico-cortical evoked potentials. To underpin the safety aspects, we demonstrate stability of ECoG array implantation via x-ray imaging at the beginning and end of the implantation period and show outcomes of follow-up examinations and histology findings. In summary, the presented results expand the data available on functional implantation of fully immersible neural interfaces, especially on ECoG-based devices with both recording and stimulation functionality. The data and combination of system features presented here may be the basis to unfold the therapeutic potential especially in first human patients suffering from disorders largely affecting the cerebral cortex such as upper limb stroke and encourage the readiness of these systems for clinical use.

Abstract: A clinical Brain Computer Interface (BCI) system for chronic application in daily life is one of the major challenges in the field of neuroprosthetics. Motor controlled-BCIs system aim at providing users with control over upper or lower limb. The major challenge for BCI systems with home use for motor disabled subjects is the ability of recording long term stable neuronal signals, decoding this brain activity in real-time with robustness and precision as well as enabling the most transparent possible use for patients by addressing the issues of portability and ease of use without assistance. The CEA leti Clinatec team has developed a Brain-Computer Interface (BCI) system including the first 64-channel fully-implantable WIMAGINE® device enabling wireless electrocortigrams recording, along with a dedicated decoding software

environment. This WIMAGINE-BCI system has been evaluated in two clinical trials (NCT02550522, NCT04632290) to provide the proof of concept that this technology enables brain control of motor restoration devices in people with spinal cord injuries. In particular, we demonstrated that a tetraplegic patient is able to control a 4-limbs exoskeleton thanks to his brain activity monitoring and decoding [1]. The proof of concept of a brain Spine Interface combining the WIMAGINE system with a spinal cord stimulation therapy enabled a paraplegic patient to regain natural control over the movement of his paralyzed legs, allowing him to stand, walk and climb stairs [2]. The long-term stability of the chronic epidural wireless recorder WIMAGINE was also demonstrated over 5-year period after surgery. This WIMAGINE-BCI technology has therefore been developed to meet the main challenges of a Brain Machine Interface for daily life use, such as the ability to perform a chronic and stable measurement of brain activity as well as the accurate and robust decoding in real time with a reduced latency. We have also developed a new version of the system to make it portable (size divided by 6), with greater energy autonomy (multiplied by 3) and greater measurement precision, with the number of channels per implant transmitted simultaneously multiplied by 2. It has been optimized to enable patients to use it independently, without assistance and in complete safety, as part of their daily activities.

Abstract: Lateral spinal cord stimulation has shown promise in evoking somatosensory percepts in the missing limb in people with limb amputation. For prosthetic users, this enables them feel somatosensations with their artificial limbs. However, subjects also report sensation in their residual limb. To limit these unwanted sensations, we evaluated the ability of different stimulation configurations using paddle electrodes to selectively evoke sensations in focal regions of the limb.
In 3 acute feline experiments, we exposed the epidural surface of the spinal cord via a lumbosacral laminectomy. Flexible paddle electrodes with 32 contacts, arranged in a 16 × 2 array, were placed laterally on the lumbar spinal cord and secured under the border of the laminectomy. We placed the rostral end of the paddle at the caudal end of the *L6* vertebrae for animal 1, *L5* for animal 2 and *L4* for animal 3. We delivered monopolar and bipolar stimulations over a current range of 15 - 350 µA. Each stimulus train included 250 biphasic pulses with a 66 µs phase pulse width, and a 33 µs interphase interval. We recorded antidromic compound action potentials (CAPs) in the sciatic and femoral nerves and some of their branches in the ipsilateral hind limb. For each amplitude, we computed the number of nerves that produced CAPs using a stimulation-triggered average of the nerve responses. At threshold (i.e., the minimum amplitude that elicited a CAP) we noted nerves that were recruited as a metric of selectivity. In animal 1, 83% of bipolar electrode pairs selectively recruited nerve branches compared to 75% of monopolar electrodes. Both configurations were primarily selective for the tibial and distal tibial nerve branches. Only 1 caudal electrode recruited any femoral nerve branch activity at threshold using monopolar stimulation, albeit non-selectively. In animal 2, 66% of the bipolar trials and 69% of the monopolar trials were selective at threshold. Monopolar stimulation mostly recruited the distal tibial nerve whereas bipolar stimulation mostly recruited the sural nerve. No femoral branches were selectively recruited at threshold. In animal 3, 65% of all bipolar selective pairs and 70% of all monopolar selective electrodes recruited the saphenous branch of the femoral nerve. The common peroneal nerve was the second most selectively recruited nerve in both configurations. The average amplitude for selectivity with monopolar stimulation was 44 ± 28 µA which was higher than for bipolar stimulation 35 ±16 µA. These results demonstrate our ability to selectively recruit nerve branches, suggesting that we can specifically target regions of the limb innervated by those nerves in restoring sensation for amputees.

Abstract: A primary drawback of existing lower-limb prostheses is their inability to restore somatosensory feedback. Our lab has shown that epidural spinal cord stimulation (SCS) can generate focal sensations in the distal limbs of amputees. However, these sensations also cover more proximal regions of the residual limb, which may provide distracting information regarding the state of the prosthetic limb. In these studies, stimulation was delivered by commercially available electrodes with large contacts, which may limit their selectivity. Achieving selective stimulation and more focal sensations in the missing limb requires the design and development of new electrodes with better arrangements and smaller contacts. To better understand the target neural anatomy and optimize the design of SCS electrodes, we quantified the functional organization of the lumbar dorsal rootlets (DR) and measured selectivity of SCS using custom epidural electrodes. We performed experiments in three cats. We instrumented sciatic and femoral nerve branches with nerve cuffs, and we measured SCS selectivity by recording antidromic evoked compound action potentials (CAPs) in those nerves. We delivered SCS at L4-L7 spine levels through custom epidural electrodes with varying contact sizing (0.15 mm, 0.5 mm, 1 mm), placed laterally over the cord. We also resected the dura and used hook electrodes to repeat these experiments while stimulating individual DR to quantify their functional organization. We quantified SCS selectivity by the ability to evoke a CAP localized to one peripheral nerve branch while avoiding responses in other branches. The highest percentage of selective responses (80%) was achieved using electrodes with contact sizing of 0.5 mm, followed by contact sizing of 1 mm (69%), and contact sizing of 0.15 mm (62%). The threshold amplitude required to recruit the first nerve was the lowest (37.7 μA) using contact sizing of 0.15 mm, and the highest (50.8 μA) using contact sizing of 1mm. The dynamic range (difference between the threshold amplitude required to recruit the first nerve and the next higher amplitude that recruited other nerves) was similar between contact sizing of 1 mm and 0.15 mm, while it was larger using contact sizing of 0.5 mm. DR stimulation at L6-L7 primarily recruited sciatic branches, while DR stimulation at L4-L5 primarily recruited femoral branches. Rare instances of co-activation of both sciatic and femoral branches were observed during DR stimulation, indicating a somatotopic organization. These results provide important next steps to optimize electrode design for stimulating structures in the spinal cord, with the goal to restore somatosensory feedback.

Title: Characterizing stability of human motor cortical activity recorded with a stentrode

Authors: *N. CHETTY[1,2], J. BENNETT[4], P. E. YOO[4], A. SAWYER[5], K. KACKER[2], A. DALRYMPLE[2], D. SARMA[2], D. DESPRADEL[2], A. FRY[7], N. Y. HAREL[6], S. MAJIDI[6], R. G. NOGUEIRA[8], J. L. COLLINGER[9], N. L. OPIE[7], D. LACOMIS[8], T. J. OXLEY[4], D. F. PUTRINO[5], D. J. WEBER[2,3];
[2]Mechanical Engin., [3]Neurosci. Inst., [1]Carnegie Mellon Univ., Pittsburgh, PA; [4]Synchron Inc., New York, NY; [5]Icahn Sch. of Med., [6]Mount Sinai Hosp., New York, NY; [7]Synchron, Inc, New York, NY; [8]Univ. of Pittsburgh Med. Ctr., Pittsburgh, PA; [9]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The Stentrode is a novel endovascular brain-computer interface (BCI) that is implanted within the superior sagittal sinus to record bilaterally from the primary motor cortices. The first-in-human trial in Australia demonstrated computer control and digital communication in four people with severe paralysis due to amyotrophic lateral sclerosis (ALS). An Early Feasibility clinical trial began in the United States (US) in July 2022 at three sites. In order for the Stentrode to be viable long-term, these endovascular electrocorticography (eECoG) signals need to remain stable over time to enable decoding of user intent. Multiple factors could contribute to signal instability and/or loss of BCI functionality in people with ALS, including neuronal degeneration and cortical atrophy, cognitive decline, and device-related failures. Here, we explore the stability of eECoG signals recorded over 5 - 8 months. To date, four participants with severe paralysis have been consented and implanted in the US, three diagnosed with ALS and one with brainstem stroke. Data acquisition and system training with the Stentrode began approximately 7 weeks after implantation. Each testing session begins with recording two-minutes of resting state activity, followed by training or utilization tasks. The offline (non-feedback) training tasks consisted of 5-s (± 1 s) rest periods followed by a 5-s period of movement attempt, in which 5 repetitions of attempted movement occurred. The movements attempted included: both ankles, right ankle, left ankle, right hand, left hand, and both hands. Signal stability was assessed when participants were at rest or during motor attempts. The resting state signals were assessed through the root mean square (RMS) of the signal amplitude in the rest period, band power, and bandwidth. The attempted movements were evaluated using the movement (signal) and rest (noise) intervals for band power, percent change in RMS, and signal to noise ratio over the post-implant follow-up period to date. Band power was assessed in the standard frequency bands: alpha (8 to 13 Hz), beta (13 to 30 Hz), low gamma (30 - 60 Hz), and high gamma (60 - 200 Hz).Results obtained thus far demonstrate that the eECoG signals recorded with the Stentrode are visually stable during the current follow up period (max 8

months to-date). Temporal linear regression will be utilized to formally quantify any changes in slope during the follow-up period. The ongoing early feasibility study will continue to evaluate the signal stability beyond one year.

Abstract: The Stentrode™ is a novel endovascular brain-computer interface (BCI) technology implanted to measure field potentials, similar to electrocorticography (ECoG), from the primary motor cortex to enable communication after severe paralysis. However, the features of these neural signals have not been fully characterized in humans. Participants with severe paralysis due to amyotrophic lateral sclerosis (ALS) and brainstem stroke have been implanted in pilot clinical trials in Australia (n=4) and the United States (n=4). The first in-human study was conducted in Australia, followed by an ongoing early feasibility study at 3 sites in the United States to evaluate the Stentrode's safety. We aimed to identify robust spectral features for decoding the field potentials. Participants performed motor mapping experiments where they were instructed to attempt moving a specific body segment when prompted. The recorded field potentials were filtered into 3 frequency bands: beta (12-30 Hz), gamma (30-80 Hz), and high gamma (80-200 Hz). For each of the 3 band-limited signals, we calculated the change in root-mean-square voltage (Vrms) between rest and movement epochs, quantifying the percentage change of Vrms movement from rest (termed as modulation depth) for each trial. Principal component analysis (PCA) was used to merge signals that were correlated across channels. We also assessed the signal stability of the Stentrode over a 99-day period, by measuring power of every channel for each frequency band. We investigated the features of the Stentrode signals and identified the spectral characteristics that exhibit strong changes in amplitude between rest and attempted movement conditions. The high gamma frequency band exhibited the strongest modulation depth, showing ~100% increase in signal amplitude between rest and movement epochs. Analysis of somatotopic differences exhibited the strongest depth of modulation in the 'both ankles' and 'right hand' attempted movements. The signal power varied approximately 0.5 dB in the high gamma frequency band over the 99-day period, which signifies high stability of the signal over time. The results of our preliminary analysis of the Stentrode signals indicate that these endovascular neural signals exhibit properties similar to those reported for ECoG-based measures of motor intent.

Title: Selective activation of nerve fiber subpopulations with intrafascicular stimulation depends on size of electrode active site

Authors: *A. ORTEGA[1], M. ROUHANI[2], A. K. THOTA[1], J. ASBEE[1], L. REGNACQ[3], Y. BORNAT[4], F. KOLBL[3], L. MCPHERSON[5], J. ABBAS[1], R. JUNG[1];

Abstract: Bioelectronic medicine approaches use modulation of neural activity with peripheral nerve stimulation (PNS) to treat diseases. The selectivity of activating the necessary nerve fibers to get the desired outcome depends on the electrode and its configuration used for charge delivery. The effects of different sizes of the electrode active site on fiber recruitment was investigated using multiple longitudinal intrafascicular electrodes (LIFEs) implanted in the sciatic nerve of rats. Electrode impedance was used to estimate the size of the active site. Selectivity of fiber recruitment was assessed using a 32 channel High-Density surface EMG (HD-sEMG) that provided spatiotemporal information about motor fiber activation (M-waves) of the innervated gastrocnemius lateralis (GL) muscle. Experiments were conducted in adult male Sprague-Dawley rats *(n=4)* under isoflurane anesthesia. 2 to 4 LIFEs *(n=11)* were implanted in the sciatic nerve in the tibial fascicle. Pulse Amplitude was changed from threshold up to 2xthreshold at a pulse width at chronaxie based on the Strength Duration curves for each electrode configuration. Monopolar and bipolar configurations were utilized to deliver stimulus pulse trains at 10Hz for 5 seconds using a custom neurostimulator. Peak to peak amplitude of the

M-waves were used to assess spatiotemporal spread of muscle twitch. A similarity index that showed the magnitude of difference between the amplitude values for each channel for each electrode using monopolar vs bipolar configuration was calculated. A higher index value indicates that there is more difference between the configurations. Results showed that the regions of the muscle activated in bipolar configuration are similar to the regions activated by the electrode with lower impedance (bigger active site) in monopolar configuration, p &lt 0.01. There was a medium effect, $R^2 = 0.062$. This suggests that the fibers activated using the bipolar configuration are predominantly closer to the bigger electrode site because their threshold is smaller. In addition, studies using a computational model of a LIFE inside a fascicle demonstrated that LIFEs with longer electrode sites have lower thresholds for fiber activation. Cumulatively, these findings may provide insight for the design of targeted and selective stimulation strategies for using LIFEs for PNS.

Title: A real-time neuromorphic brain-to-brain interface for simulation and partial functional replacement of damaged brain regions

Authors: *E. B. DIJKEMA, C. M. A. PENNARTZ, U. OLCESE;
Cognitive and Systems Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The development of effective invasive brain-computer interfaces (BCIs) poses major technological challenges, one of which is the accurate, immediate and meaningful interpretation of recorded signals. In the case of (extracellular) spikes, these are commonly counted in quantized time bins and represented as a continuous variable. This approach inherently results in the loss of vital temporal information . To avoid this problem, spikes should be processed in an event-driven manner, using a spiking neural network (SNN).
We demonstrate the feasibility of a closed-loop brain-to-brain (B2B) interface designed to simulate - and not simply functionally replace - the activity of a cortical area to implement a form of functional restoration in the case of loss of function (e.g. induced by stroke or trauma). We combine real-time spike detection and spike injection into a SNN running on a SpiNNaker neuromorphic platform . By leveraging the massively parallel architecture of this neuromorphic platform, large SNNs can be run at biological timescales. This approach allows for the

immediate processing of spiking activity without the loss of temporal information.
For benchmarking experiments, we designed a multi-layer feedforward SNN with current-based leaky integrated-and-fire (LIF) neurons. An electrophysiology signal simulator (FB128, TDT) was used to generate 64 channels of raw data. By applying a high-pass filter (0.6 - 6 kHz) and thresholding, multi-unit activity (MUA) was detected. For each detection event on a channel, a spike was injected into a corresponding input neuron in the SNN. By varying the number of hidden layers and neurons in each layer, the relationship between roundtrip time and model complexity was assessed. Roundtrip latency was measured as the time between a detected spike and the consequent output spike of the SNN. We show a 7.4 ms roundtrip time for a model with no hidden layers, representing processing time for data filtering, thresholding, network serialization and communication from the workstation PC to SpiNNaker. Additional layers increase roundtrip time in a linear fashion, with 4.06 ms for each layer. Hidden layer population size does not significantly affect roundtrip latency.
We conclude that a SNN running on SpiNNaker hardware achieves low-latency, biologically plausible processing of real-time spiking data, and is suitable for functional simulation of brain activity. Future implementations will focus on partial functional replacement of a cortical area via closed-loop application of a SNN, in vivo electrophysiology and optogenetics.

Abstract: By considering neural oscillations and their dynamic nature, adaptive stimulation may be more effective in modulating brain connectivity. This greater control over connectivity may

indicate that adaptive stimulation approaches have the potential to better investigate the mechanisms underlying neurological conditions and inform stimulation design, resulting in improved therapeutic outcomes compared to open-loop techniques. With growing advances in sensing and stimulation technologies, there has also been a rising interest in the investigation of closed-loop methods. While such improvements have facilitated the progress of novel stimulation therapies, current clinical systems enable limited exploration of the adaptive stimulation design space. Here, we utilize the OMNI-BIC, an open-source software tool to enable customizable stimulation design with the CorTec Brain Interchange (CorTec GmbH, Freiburg, Germany), an upcoming investigational research device, to perform phase-locked stimulation. We implemented a processing pipeline within the OMNI-BIC to identify signals within a certain frequency band and send stimulation during a specific phase of the target signal. The pipeline incorporated elements, including real-time stimulation artifact mitigation to minimize contamination of neural signals, and a phase-locked loop design to dynamically trigger for more robust stimulation delivery. These signal processing components were included to minimize mistimed and over stimulation that could cause undesired effects. This phase-locked algorithm was then demonstrated within two sheep models to determine the feasibility of performing phase-locked stimulation with the OMNI-BIC. Implanted electrocorticography arrays were employed to record neural activity and deliver stimulation pulses. Collected resting state data was used to inform parameters, such as filter coefficients, target frequency, and trigger threshold. We characterized phase-locked stimulation performance across varying stimulation amplitudes for each animal model. Our findings show the OMNI-BIC and Brain Interchange ecosystem is capable of delivering phase-locked stimulation with limited instances of over stimulation, demonstrating the translatability of the OMNI-BIC from benchtop to clinical conditions. These results also illustrate that the customizability of the OMNI-BIC enables greater design control to develop and assess other phase-triggered stimulation or adaptive neuromodulation paradigms.

Title: Chronic electrocorticography in nonhuman primates by an implantable wireless device for brain-machine interfaces

Authors: *T. YAN[1], K. SUZUKI[2], S. KAMEDA[1], M. MAEDA[3], M. TAKUMA[3], M. HIRATA[1];
[1]Osaka Univ., Suita, Japan; [2]Nihon Kohden Corp., Tokyo, Japan; [3]Astellas Pharma Inc., Tokyo, Japan

Abstract: Introduction: electrocorticography (ECoG) signals have been proposed as a stable, good-quality source for brain-machine interfaces (BMIs), with a higher spatial and temporal resolution than electroencephalogram (EEG). However, long-term implantation may lead to chronic inflammatory reactions and connective tissue encapsulation, resulting in a decline in the signal recording quality. Few studies have reported the effects of the surrounding tissue on signal recording and device functionality thus far. Methods: in this study, we implanted a wireless recording device with a customized 32-electrode-ECoG array subdurally in two macaque monkeys for 15 months. We evaluated the neural activities after stimuli of auditory steady-state response (ASSR) and ketamine injection. We compared acute and chronic results of average root mean square (RMS) voltage and power spectral density (PSD). We also examined the chronic tissue reactions around the electrodes. Results: time-frequency analyses of the acute and chronic phases showed similar oscillation features. After 15 months, the RMS voltage for one monkey remained at approximately 80% from 39.8 μV (SD=5.7) to 32.8 μV (SD=3.5), while PSD showed relatively satisfied results. Histological examination revealed fibrous proliferation on both epidural and subdural sides of the dura mater. Dorsal encapsulation included the newly formed tissue and reactive dura mater, while there were only newly formed tissue in the ventral encapsulation. The average thickness of the dorsal encapsulation (1,760 ± 701 μm) was significantly greater than that on the ventral side (661 ± 339 μm, t-test, $p<0.01$). However, we found no evident of inflammation in the cortex. In addition, we measured the gain factor of the thickened reactive tissue and found that the newly formed ventral fibrous tissue attenuated amplitude of the ECoG signals. Conclusions: This study suggests that subdural ECoG may provide chronic signal recordings for future clinical applications and neuroscience research and highlights the role of reducing the thickness of ventral tissue proliferation in long-term recording performance.

Title: Beta-adrenergic receptor blockades enable enhanced cortical plasticity at high-intensity vagus nerve stimulation, and provide insight into the mechanism of vns-mediated plasticity

Authors: *C. L. NEIFERT[1,3], J. A. A. ADDO[1,3], T. T. DANAPHONGSE[3], S. PILLAI[3], J. MONTEFALCON[1,3], A. RAZACK[3], M. P. KILGARD[3,2], S. A. HAYS[1,3];
[1]Bioengineering, [2]Neurosci., Univ. of Texas at Dallas, Richardson, TX; [3]Texas Biomed. Device Ctr., Richardson, TX

Abstract: Stroke is a leading cause of long-term disability, with therapies targeting neural plasticity showing promise in supporting recovery. Vagus nerve stimulation (VNS) paired with rehabilitative training has been shown to facilitate recovery of motor function and is linked to structural reorganization of neurons. To inform and improve therapies, studies have developed a systemic understanding of the effect of VNS on structures throughout the brain. Norepinephrine (NE) is critical for VNS-dependent plasticity and recovery, but the dynamics of this relationship are not fully understood. Increasing VNS intensity raises the activity of noradrenergic neurons in the locus coeruleus and increases the activity of NE in the neocortex. However, the degree of VNS-driven cortical plasticity follows an inverted-U function corresponding to increased VNS intensity. This suggests a plasticity-stabilizing effect of high NE activity in the cortex. Identifying the contribution of NE to VNS-dependent plasticity holds promise to guide further improvements of VNS-driven therapies.
The goal of this study is to determine the role of adrenergic receptors in VNS-mediated plasticity. The primary hypothesis of this proposal is that β-adrenergic receptors (β-ARs) are critical for modulating VNS-dependent plasticity, and that β-ARs can be manipulated to enhance this plasticity. To test this hypothesis, rats performed a simple behavioral task in which VNS was paired with jaw muscle activation during chewing. For five days, each rat received 200 pairings of VNS delivered at a frequency of 30Hz, at varying intensities and with or without a β-blocker

drug injection. 8 groups were defined by combinations of the following drug and intensity parameters: injection of Propranolol or saline Vehicle injections; and VNS at 1.6 mA (High VNS), 0.8 mA (Moderate VNS), or Sham stimulation. Two additional groups received Atenolol injections with 1.6 mA VNS or Sham treatment. Following each animal's final behavioral session, intracortical microstimulation (ICMS) was used to assess movement representations in the motor cortex.
Preliminary results have shown that High VNS administered with Propranolol produce greater levels of VNS-driven plasticity than our group has ever reported. This suggests that β-ARs are a limiting factor of VNS efficacy, and that blocking β-ARs may further improve VNS therapeutic strategies. This study further elucidates the neuromodulatory mechanism of VNS-mediated plasticity and will form the basis for pharmacologically-augmented VNS therapy to improve post-stroke recovery.

Title: Cortical representation of inertial load during locomotion in the mouse

Authors: *E. KIRK, K. HOPE, B. SAUERBREI;
Case Western Reserve Univ., Cleveland, OH

Abstract: While the basic locomotor rhythm in rodents is produced by a spinal central pattern generator (CPG), walking in complex natural environments demands continual adjustment of muscle activity to compensate for changes in mechanical load, and is thought to require coordinated interactions across spinal, cortical, and cerebellar networks. Studies of voluntary arm movement in primates have shown the motor cortex generates commands to counteract inertial loads, and these commands are shaped, in part, by ascending cerebellar input. By contrast, cortical dynamics during load compensation in rhythmic, CPG-driven behaviors such as rodent locomotion remain largely unexplored. Here, we use three dimensional motion tracking, electromyography (EMG), neural ensemble recordings, and optogenetics to identify a neural

representation of inertial load in the motor cortex of unrestrained, locomoting mice, and demonstrate that this representation is robust to cerebellar perturbation. Mice were trained to trot on a linear treadmill as 0.5 g weights were attached to the wrist. The wrist weight induced an increase in biceps EMG during swing, consistent with an increase in elbow flexor torque to accelerate the loaded limb. This response was not abolished following suppression of cerebellar output by optogenetic stimulation of Purkinje cells. Next, cortical activity was recorded using silicon probes chronically implanted in the forelimb motor area (n = 558 neurons). A large number of cells were load-responsive (47%), exhibiting both firing rate increases (45% of responsive neurons) and decreases (55%). Responses to cerebellar perturbation were common (28%), and usually consisted of firing rate increases (71% of responsive neurons). At the population level, demixed principal component analysis revealed significant effects of load and cerebellar perturbation, which accounted for 24% and 11% of the explained firing rate variance, respectively. Strikingly, load-related activity was not strongly modulated by step phase, but consisted of a tonic shift. Furthermore, neural activity along load-related dimensions was not grouped by cerebellar perturbation, the interaction between load and cerebellar perturbation was small (1.1%), and the projection of firing rates aligned to stimulation onto load dimensions revealed a minimal response. This cerebellum-independent representation of load might enable cortical dynamics to evolve from an appropriate initial condition when a voluntary, cortically-dependent action must be coordinated with an ongoing, rhythmic, spinally-generated program.

Title: Balance perturbation training with a simultaneous cognitive task in older adults: a pilot study

Authors: *N. ALISSA[1], K. P. WESTLAKE[2];
[1]Physical Therapy and Rehabil. Sci., Univ. of Maryland Baltimore, Baltimore, MD; [2]Dept. of Physical Therapy & Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Background: Older adults display a greater tendency to use the reach-to-grasp strategy and a greater frequency of grasping errors. Age-related declines in attention shifting between working memory processes (cognitive task and balance response) may underlie this reduced grasp accuracy in older adults. Compared to older adult non-fallers, older adult fallers display increased movement time and markedly increased grasp error frequency under non-

spatial working memory conditions. This difference between older adult fallers and non-fallers suggests deficits in cognitive shifting ability beyond that which is observed in healthy aging. **Objective:** To investigate the feasibility of a dual task cognitive and balance perturbation reach-to-grasp training intervention in older adults. **Methods:** The 3-day intervention included 15 forward-backward stance perturbations and 15 right-left stance perturbations with a cognitive task. Assessments were conducted using the ActiveStep treadmill, which can deliver customized slip-like balance perturbations. Participants were assessed pre- and post-intervention under 2 testing conditions: a stance slip with a cognitive task in the presence of a handrail, and a walking slip with a cognitive task in the absence of a handrail. The post-intervention assessment also included a third condition: a walking slip with the handrail on the non-dominant side. We calculated in-task falls incidence during each of these conditions using a load cell attached to the safety harness on the treadmill. **Results:** We found reduced in-task falls incidence during slip-like balance perturbations with a secondary cognitive task in older adults after 3-days of perturbation training under the first two testing conditions. During the third condition with the rail on the non-dominant side, we found that participants relied on harness assist, but there were no in-task falls. **Conclusions:** Reduced in-task falls incidence during stance slips with a cognitive task indicates that this training intervention is feasible and effective in older adults. Reduced in-task falls incidence during walking slips without the handrail indicates that although we are training the grasp response, there is no negative effect on the balance response in the absence of a handrail. Our results also suggest that this training effect may generalize to the non-dominant arm.

Title: Flexible and rapid modulation of gait control assessed by long-range autocorrelations

Authors: *C. VANDAMME[1], V. OTLET[2], R. RONSSE[2], F. CREVECOEUR[1];
[1]ICTeam, [2]IMMC, UCLouvain, Louvain-La-Neuve, Belgium

Abstract: Gait, as many other physiological signals, possesses a complex temporal organization. Indeed, the fluctuations from one stride to another, originally considered as random noise, display long-range autocorrelations (LRA), meaning that the stride interval at any given time statistically depends on previous gait cycles. Previous works suggested that this feature may result from a selective regulation of stride length and duration while maintaining a target speed. In this framework, it has been suggested that constraining the stride time with a metronome impedes the flexible regulation of this gait parameter, leading to a deterioration of the autocorrelation function of series of stride durations. However, transitions between walking with

and without a metronome (and vice-versa) have not been measured, it is therefore unclear how people adapt to such a change of task. To investigate this, 18 healthy participants were asked to walk overground and synchronise one foot with an isochronous metronome set to their average spontaneous pace, measured prior to the testing involving the metronome. Each participant performed two conditions of 15 minutes in which the metronome was activated during either the first or second half of the session to test both transitions. The fractal exponent, reflecting the level of LRA, was computed with the adaptive fractal analysis (AFA). This method was applied on successive overlapping subsets of the stride series to outline the evolution of the fractal exponent. Results showed a clear transition in both conditions, with LRA of the series of stride duration gradually reduced when the metronome was turned on (difference in fractal exponent of -0.36 +/- 0.14, $P < 0.001$) and recovered when it was turned off (difference of 0.35 +/- 0.14, $P < 0.001$). The same transitions could be reproduced in a model within the framework of stochastic optimal control by an instantaneous change of the parameter linked to the regulation of stride time. Importantly, no significant difference in the standard deviation of stride series was observed between the parts of the series with and without the metronome. The LRA is therefore an essential metric to discern the behavioral properties of paced and spontaneous conditions. Together, our results validate the hypothesis that LRA emerge from a flexible control that rapidly regulates timing and amplitude parameters according to task requirements. In particular, the reemergence of LRA shortly after turning off the metronome establishes it as a robust marker of a meaningful and natural gait behavior.

Title: Motor Adaptation to Stance Slips among Healthy Young Adults: Associations Between Cortical Changes and Reactive Stability.

Authors: *R. PUROHIT[1], J. PITTS[1], S. WANG[1], J. FUNG[2], T. BHATT[1];
[1]Physical Therapy, Univ. of Illinois at Chicago, Chicago, IL; [2]Physical Therapy and Occup. Therapy, McGill Univ., Montreal, QC, Canada

Abstract: Background: Extensive neuroimaging evidence indicates the role of the cerebral cortex in human reactive balance control. Specifically, electroencephalography (EEG) studies have identified that cortical beta frequencies (13-30Hz) reflect sensorimotor processing of perturbations and possibly planning of balance responses (e.g., stepping). Sensorimotor beta power increases with perturbation intensity and is higher in individuals with lower balance ability. Additionally, frontal beta power is shown to increase in challenging postural conditions or in the presence of environmental constraints. However, it is still unclear how the cortical

control of balance is modulated as motor adaptation occurs. Thus, we examined changes in sensorimotor and frontal beta frequencies over repeated stance slips in healthy young adults. **Methods:** Twenty young adults (12 female; ages 18-35) were exposed to twelve stance slips (distance= 0.18 m, velocity=1.36 m/s, acceleration=11.35 m/s^2). Cortical activities were recorded using a 32-channel EEG device with an in-built low pass filter of 500Hz. Using single-trial analysis, beta power was extracted during two time-bins: pre-perturbation (400ms before slip onset) and post-perturbation (400ms after slip onset), focused over frontal (Fz) and sensorimotor (Cz) areas with baseline corrected (using first 200ms of trial). Kinematic variables including center of mass (COM) stability at recovery limb liftoff and touchdown were also assessed. A 2×2×3 ANOVA was used to test the effect of perturbation (pre vs post), cortical area (Cz vs Fz), and trial (S1 vs S6 vs S12) on beta power. A simple linear regression was used to test the correlation between beta power and COM stability. **Results:** There was a main effect of trial on beta power *($p<0.05$),* and post-hoc comparisons showed reduced power at Cz and Fz during both time-bins at S6 compared to S1 *($p<0.05$).* There were no significant changes in beta power between S6 and S12 *($p>0.05$).* There were no other main effects or interactions on beta power *($p>0.05$).* There was a negative correlation between post-perturbation frontal beta power and COM stability at liftoff *($R^2= 0.35$, $p<0.05$).***Conclusion:** Healthy young adults demonstrate reduced sensorimotor and frontal cortical beta power with motor adaptation, suggesting reduced engagement of or reliance on the cerebral cortex for balance recovery. Further, individuals with lower reactive stability demonstrated higher frontal beta power, suggesting higher demand of cognitive resources for subsequent balance recovery. Over repeated perturbations, individuals may rely less on the cortex for sensorimotor processing and response planning.

Univ. Sch. of Med., Cleveland, OH; [5]Akron Children's Hosp., Akron, OH; [6]Western Kentucky Univ., Bowling Green, KY

Abstract: Anterior cruciate ligament (ACL) injuries are most common in athletes in pivoting/cutting sports. One in four young athletes who return to sport (RTS) after ACL reconstruction will incur a second ACL injury. This suggests current criteria for RTS decision making may be missing underlying factors that contribute to secondary ACL injuries. The goal of this confirmatory study was to establish whether ACL-reconstructed athletes experience deficits in how they allocate limited-capacity neural resources between concurrent cognitive and neuromuscular tasks (*cognitive-motor interference*). Participants were ACL-reconstructed athletes who returned to sport (n = 8) and non-injured controls (n = 6) matched by sport, age (M = 21, SD = 1.1 years), sex, body mass index, and leg dominance. All research procedures were IRB-approved and aligned with the Declaration of Helsinki. The N200 event-related potential (ERP) component, a neural correlate of cognitive-motor interference, was recorded using 128-electrode EEG during the Flanker task while participants were seated (single task) and balancing on their reconstructed/matched limb (dual task). Participants completed eight randomized blocks of 16 Flanker trials (50% incongruent) in single-task and dual-task conditions. ERPs were stimulus-locked and averaged within four bins per participant: congruent and incongruent trials in single- and dual-tasks. The N200 was measured per bin as the mean amplitude of the difference wave (incongruent minus congruent) between 250-378 ms at FCz. Towards ensuring scientific rigor, data processing (EEGLAB/ERPLAB) occurred blind to group membership, appropriate matched controls were tested, a temporal principal components analysis derived an unbiased time window for the N200, and effect sizes and confidence intervals are reported. Results from a 2 (single, dual) x 2 (ACL, Control) mixed ANOVA indicated that the N200 was more negative for the ACL group than Controls, $F(1,12) = 5.50$, $p = .037$, $d = 1.27$ (95% CI = 0.11, 2.42), which was explained by this effect in the dual-task only, $F(1,12) = 6.64$, $p = .024$, $d = 1.39$ (95% CI = 0.21, 2.57). These results suggest that ACL-reconstructed athletes are more likely to allocate greater cognitive-control resources to their visual-cognitive environment than non-injured controls during dual-tasks. ACL-reconstructed athletes may experience neuroplastic changes in how they manage multi-task cognitive-motor environments, such as during sport. These preliminary findings support further evaluation as to how neuroplasticity may be involved in risk for second ACL injury.

Title: Cortical responses in modern dancers are more sensitive to balance perturbation but reflect more automatic balance control than nondancers

Authors: *K. G. KERR[1], S. E. BOEBINGER[1], J. L. MIRDAMADI[2], M. R. BORICH[2,1], L. H. TING[1,2];
[1]Biomed. Engin., Emory Univ. and Georgia Inst. of Technol., Atlanta, GA; [2]Rehabil. Med., Emory Univ., Atlanta, GA

Abstract: Cortical engagement during whole body movements such as walking and balance can augment ongoing subcortical processes as necessitated on an individual basis by task difficulty and ability. Individuals with worse balance exhibit increased cortical activity during balance recovery, but how this engagement varies with expertise is unclear. Typically, tasks require less cortical engagement with expertise. However, this has not been clearly demonstrated in individuals with highly trained balance skill such as dancers. We hypothesized that professional modern dancers require less cortical engagement during reactive balance than nondancers due to their fine-tuned sensorimotor integration and balance ability. After assessing balance ability via a difficult beam walking task, we recorded electroencephalography (EEG) in 11 healthy young adults, 6 nondancers (2F) and 5 dancers (5F) throughout recovery from support surface balance perturbations at two magnitudes that involved a single balance-correcting step. We assessed two metrics of cortical engagement from the Cz electrode: the cortical N1, an index of error assessment that peaks 100-150 ms post-perturbation, and sensorimotor beta power (β; 13-30Hz oscillations), an index of sensorimotor integration known to decrease after the N1 and prior to voluntary movement. The N1 is localized to the supplementary motor area and is larger in nondancers with worse balance ability. We predicted smaller N1 amplitudes and smaller decreases in perturbation-evoked β during balance recovery in dancers compared to nondancers. In line with previous studies, N1 amplitudes increased with perturbation difficulty in both cohorts. Contrary to our hypothesis, there was a trend for larger N1 amplitudes in dancers compared to nondancers, indicating dancers are more sensitive to balance error potentially due to training in detecting disturbances to body posture. Dancers also had higher balance ability scores, suggesting the N1 may not directly reflect balance ability but rather individual sensitivity to balance errors. Following the N1 response, β power decreased in all participants, presumably reflecting cortical engagement for a balance correcting step. β power tended to decrease less in dancers, suggesting dancer balance recovery is more automatic. These findings may improve our understanding of the mechanisms of balance control that can facilitate the development of individualized balance training interventions to reduce falls risk.

Title: Manual balancing of a visual inverted pendulum by quantized versus proportional joystick commands

Authors: *P. DIZIO[1], N. KRISHNASWAMY[2], S. MANNAN[2], P. HANSEN[2];
[1]Brandeis University, MS033, Waltham, MA; [2]Colorado State Univ., Fort Collins, CO

Abstract: OBJECTIVE: Manually balancing a visual inverted pendulum (VIP) with a joystick is a learned skill which exhibits drift and intermittent corrections, analogous to the sway and proportional ballistic corrections seen when the ankles are used for bipedal balancing. This study aimed to compare VIP balancing when commands are discretized versus proportional to joystick deflections. **METHODS**: A beam and bob display pivoted about its fixed base with inverted pendulum dynamics ($\ddot{\Theta}=K_P \sin\Theta$) driven by joystick commands. K_P was set to create an intrinsic frequency of .46 Hz, similar to postural sway. Two groups of 9 subjects were instructed to keep the VIP upright and as stable as possible and to avoid ±60° boundaries which defined a "fall". For the "P" group, VIP acceleration was proportional to joystick deflection times 0 .28 rad/s^2; For the "D" group, a discrete acceleration of .28 rad/s^2 was issued whenever joystick deflection exceeded ±1°. Every subject completed 30 trials in their assigned command mode plus a catch trial of the other type every 10 trials. **RESULTS:** The D group fell significantly more in their first 10 trials than the P group. Both groups showed significant fall reduction across trials, but the D group ended with significantly more falls than the P group. The RMS angular displacement and velocity of the VIP were also significantly higher for the D than the P group, across all trials. The first catch trial of each type was indistinguishable from the 10th main trial of its type, and the number of falls declined significantly across both types of catch trials. However, the final number of falls was greater for catch trials than for main trials of the corresponding type. The decline in falling among main and catch trials of both types was correlated with growth of the intervals between commands. In 18% of joystick deflections during the first 10 trials both groups made destabilizing commands which accelerated the VIP toward the fall boundary it was approaching, and both groups showed significantly fewer destabilizing deflections over trials. **CONCLUSION**: In this balancing task, proportional control improves performance by decreasing drift and improving the success of serial ballistic corrections when falls were imminent. However, VIP balancing can be learned without proportional control. The transfer of learning to catch trials indicates a common mode of learning for discrete and proportional control. In both control modes, the timing and duration of serial ballistic commands improved, and frankly destabilizing commands which are seen when falls are imminent declined. These results inform the modeling of human behavior in this task, e.g., with machine learning.

Title: The neural bases of sensory reweighting for postural control: a neuro-computational model

Authors: *M. MONTI[1], M. BISI[1], R. STAGNI[1], C. CUPPINI[2];
[2]Univ. of Bologna - Dept. of Electrical, Electronic and Information Engin., [1]Univ. of Bologna, Bologna, Italy

Abstract: Sensory reweighting (SR) involves integrating sensory inputs from various sensory sources, including vision, proprioception, and the vestibular system. The importance of SR lies in its ability to adaptively adjust the contributions of these sensory inputs based on their reliability and relevance in a given context, thus allowing the body to respond effectively to changing environmental conditions and sudden disturbances. Understanding SR can lead to advancements in rehabilitation for individuals with balance disorders. Although SR is considered crucial for postural control, the neural mechanisms underlying this process remain unclear. Existing computational models used to investigate SR are mainly "black-box" models. While these models can replicate the behavior of the brain, they do not explain why and how this is happening in the real brain. To fill this gap in the literature, in this work we use a classical biologically plausible neuro-computational model of multisensory integration, to elucidate the neural mechanisms at play in the sensory organization test (SOT), a widely utilized experimental protocol for investigating SR. Considering that the plastic remodeling in the nervous system occurs at a significantly slower temporal scale compared to SR, we put forth the hypothesis that there is no actual reweighting process taking place. Instead, we propose that the adaptive adjustments in the contribution of each sensory modality can be explained by the process of multisensory integration (MSI). In particular, we investigated two alternative hypotheses to explain the empirical findings in the literature: 1) the six conditions observed in the SOT can be attributed to a reweighting process, and the synaptic weights of each sensory modality adapt based on the amount of information contributed by that modality in a given situation; 2) the variations in the six SOT conditions are solely due to differences in the reliability of the stimuli and the MSI operation, without any reweighting process occurring. Our findings provide evidence that the SR theory cannot account for all six SOT conditions, while the MSI does, confirming the starting hypothesis. Additionally, the model is capable of explaining how these neural mechanisms are altered in different clinical populations (e.g., vestibular patients and autistic individuals). We will further validate the proposed model with newly collected experimental data, by analyzing the effect of incrementally varying visual and proprioceptive inputs on both model results and center of pressure-based postural sway measures.

Title: Aging alters dual-task resource allocation during concurrent speech comprehension and dexterous balancing tasks

Authors: J. A. HALEY[1], N. M. AMICHETTI[2], ***H. PARK**[3], A. WINGFIELD[4], P. DIZIO[4]; [1]Neurosci., Univ. of California San Diego, La Jolla, CA; [2]Volen Natl. Ctr. for Complex Systems, [4]Volen Natl. Ctr. for Complex Systems; Psychology, [3]Brandeis Univ., Waltham, MA

Abstract: Objective: Older adults tend to "stop walking when talking," a well-documented phenomenon associated with increased risk of falling. We sought to examine the allocation of cognitive resources during concurrent speech comprehension and manual balancing. We designed an animated visual inverted pendulum (VIP) balancing task similar to the experience of balancing a pencil on one's finger. With no feedback between a joystick interface and VIP displacement, we can isolate engagement of high-level oscillatory dynamics by circumventing biomechanical and reflexive levels of control which cannot be eliminated in real gait and posture tasks. **Methods**: Participants were 20 younger (YA; 18-31 years) and 20 older (OA; 62-81) adults, all healthy and with clinically normal hearing (PTA < 25dB). For the listening task, participants indicated whether the agent of an action was the same or different in sequential pairs of sentences with subject-relative and object-relative clause structures. For the balancing task, participants attempted to balance a VIP shown on a computer monitor via lateral deflections of a joystick; a "fall" was counted if VIP displacement exceeded ±90° from the center position. Easy and hard versions of the listening and VIP tasks corresponded, respectively, to different sound levels and pendulum acceleration constants. Participants completed 8 counterbalanced conditions: single- and dual-tasks in all combinations of task type and difficulty. **Results**: OA performed significantly ($p<.05$) worse on both tasks (i.e., increased VIP falls and comprehension errors) compared to YA across all difficulty levels. In both single- and dual-task conditions, all participants performed worse on the VIP task as difficulty increased. Dual-tasking impaired OA VIP performance but not speech comprehension as compared to single-task conditions. Dual-tasking impaired YA VIP performance and comprehension relative to single-tasking when both VIP and comprehension tasks were more difficult. **Conclusion**: YA showed dual-task degradation in both balancing and listening when both tasks were more difficult, indicating sharing of central processing resources which is not offset by prioritization of one task over the other. OA showed worse overall performance and steeper dual-task deficits in balancing than YA and no dual-task deficits in listening, suggesting prioritization of speech comprehension over potential resource interference. It remains to be seen 1) if VIP balancing and real bipedal balance share resources in a dual-task paradigm and 2) if OA still prioritize listening in a real postural task where falling has a high cost.

Title: Reinforcement feedback leads to greater motor exploration during gait

Authors: *J. JEKA[1], J. GRAY[1], A. ROTH[2], J. BUGGEIN[3], H. REIMANN[2], J. CASHABACK[2];
[1]Kinesiology and Applied Physiol., [3]Biomed. Engin., [2]Univ. of Delaware, Newark, DE

Abstract: Introduction: Error-based feedback is typically thought to play the dominant role in learning a new movement pattern. However, recent work has underscored how reinforcement (success/fail) feedback may play a critical role as well. During reaching we have recently shown that a lack of reinforcement (failure) causes greater variability and positive reinforcement (success) updates the intended motor action towards the last success, leading to greater spatial exploration of the solution space. Here we investigated the roles and interplay of reinforcement and error feedback on motor exploration while walking. **Methods:** Six healthy young subjects (age 22-26, 3m, 3f) walked on a instrumented treadmill with a 180º virtual reality screen showing an endless path of randomly generated flowing cubes. Subjects were instructed to match a target step length created from their baseline left step length plus 2 standard deviations in 3 conditions. Error feedback displayed their left foot step length as a horizontal line relative to a target left foot step length. Reinforcement feedback showed a gray target that would turn blue when their left foot step length was within the target boundary. Subjects did not have knowledge of the error magnitude during reinforcement, only hit/miss. Both types of feedback were simultaneously shown in the combined condition. Lag-1 autocorrelations of the step length were calculated for each condition. A greater lag-1 autocorrelation represents a greater level of exploratory behavior during the walking task.**Results:** Left step length was compared to the target step length on each step. A bootstrapped hypothesis test on the paired differences showed that the reinforcement feedback led to greater motor exploration during walking (i.e., a higher lag-1 autocorrelation).**Conclusions:** Preliminary results from our step length modulation paradigm provide promising evidence that exploration is a generalizable mechanism across reaching and gait, which can be used to adapt and potentially learn new movement patterns. Further study will help to understand the ways in which the upper and lower limb tasks may differ as well as investigating the neuroanatomical input to motor adaptation with basal ganglia impairments due to Parkinson's Disease.

Title: Posterior parietal cortex activity during visually perturbed gait

Authors: *P. MCDONNELL[1], A. B. GRIMMITT[1], A. KNIGHT[2], W. HOOGKAMER[1], D. N. MARTINI[1];
[1]Kinesiology, [2]Computer Sci., Univ. of Massachusetts, Amherst, Amherst, MA

Abstract: Real-world gait is complex, often requiring step adjustments to meet environmental demands. Poor gait performance, especially during perturbed gait conditions, is related to increased fall risk and mortality in older adults. Increased cortical activity has been identified during gait in older adults, however evidence is limited to frontal cortex regions during unperturbed gait. Quantifying activity in the posterior parietal cortex (PPC; critical for sensorimotor integration) during perturbed gait is an essential step toward understanding cortical mechanisms of gait impairment in older adults. The purpose of this preliminary study is to quantify PPC activity changes in healthy young adults during unperturbed and perturbed gait conditions. We present preliminary data from five young adults (mean age 23.0[2.1]yrs, 2 female). PPC activity was quantified using functional near-infrared spectroscopy, which uses near-infrared light to quantify changes in deoxygenated and oxygenated hemoglobin (HbO2) concentrations. Participants completed three, 3-minute treadmill gait conditions at their preferred speed: regular walking, visually cued walking, and visually cued walking with step adjustments (perturbed gait). For visually cued conditions, illuminated rectangular stepping targets, adjusted to the participant's foot size, were projected onto the treadmill belt's surface, and approached the participant at belt speed. The anterior–posterior (AP) and lateral distances between stepping targets were attuned to the participant's preferred step length and width, respectively. Step adjustments were imposed by random target perturbations in the AP or lateral direction, occurring once the approaching target came within 130% of step length from the participant. No significant differences in PPC HbO2 concentration changes were observed across gait conditions, however a moderate Cohen's *d* effect size was observed for change in HbO2 concentration between the two visually cued conditions ($t(4) = -1..53$, $p = 0.2$, $d = -0.69$), suggesting increased PPC activity where step adjustments were necessary. A small effect size was observed for increased PPC activity during visually cued as compared to regular walking ($t(4) = -0.54$, $p = 0.62$, $d = -0.24$). Considering our small sample in this preliminary study, these findings hold promise for larger effects in older adults. We will expand on these results by increasing the sample size and testing older adults with and without a fall history. Elucidating the role of the PPC in complex gait performance and fall prediction will better inform the development of neuromotor-based fall interventions.

Title: Cortical encoding of full-body posture and movement in freely-behaving mice

Authors: K. S. SEVERSON[1], J. LU[1], ***H. JIANG**[2], W. XIAO[1,3], S. CHOI[1], T. W. DUNN[4,5], F. WANG[1];

Abstract: The brain's internal representation of the spatial configuration of the body is called the "body schema." The body schema arises in higher-order cortical regions and is updated using proprioceptive and other sensory information originating in peripheral tissues. Neural activity correlated with body posture has been observed in higher-order cortical areas in primates and rodents, such as posterior parietal and secondary motor cortices, yet the circuit and network dynamical mechanisms underlying how proprioceptive information in the somatosensory cortex is integrated into the body schema remains is not well understood. Here, we investigated the sensory origins of body schema in the somatosensory cortex of freely-moving mice by recording simultaneous large-scale electrophysiological and 3D-calibrated multi-camera recordings. Full-body postures and movement were tracked by recording freely behaving mice with six synchronized cameras and utilizing DANNCE, a markerless 3D pose estimation tool. We then used geometric models to extract Euler angles for 16 major joints from the 44 3D-tracked keypoint positions. This set of joint angles thus parameterizes full-body posture, allowing for detailed analysis into how various postural, movement, and spatial features are encoded in single-unit electrophysiological activity recorded using 64-channel tetrode microdrives chronically implanted in either S1 dysgranular zone (S1dz), S1-M1 transition zone (S1tz), secondary somatosensory cortex (S2), or posterior parietal cortex (PPC). Tuning to joint angles was strongest in PPC and S1tz, weaker in S1dz, and weakest in S2. While neurons in S1tz, PPC, S1dz, and S2 showed relatively weak correlations with specific joint velocities at fast timescales, neuronal ensembles in these regions were modulated by brain states associated with non-specific movement on longer timescales. Finally, PPC neurons showed stronger tuning to features in spherical coordinates than somatosensory regions, suggesting a joint-centered reference frame present in early somatosensory regions may be transformed into a body-centered spatial reference frame in PPC, a known component of the body schema network. Thus, advances in full-body pose tracking enable deeper investigation into complex posture and movement

representations, which lay a foundation to study mechanisms underlying body schema and the neural control of posture and movement.

Title: Frequency-domain patterns in foot-force line-of-action: an emergent property of standing balance control

Authors: *R. SUGIMOTO DIMITROVA[1], K. SHIOZAWA[1], K. G. GRUBEN[2], N. HOGAN[1]; [1]MIT, Cambridge, MA; [2]Univ. Wisconsin, Univ. Wisconsin, Madison, WI

Abstract: Despite over half a century of studies on human standing balance, the underlying controller responsible for stably maintaining our center of mass high above our two feet remains elusive. Quiet standing studies are particularly appealing, as they allow for observations of natural, unperturbed stance. A metric that could capture aspects of quiet-standing-balance dynamics and control would be useful for understanding the underlying control mechanisms, and will also facilitate diagnosis of impairments and tracking recovery. A recent line of work suggests that the net behavior of the foot-ground interaction force provides insight into quiet-standing-balance dynamics and control. Through human subject experiments, Boehm et al. uncovered that the relative variations in the center of pressure and force direction emerge as a distinct pattern in the frequency domain, and through numerical analysis, Shiozawa et al. showed that different control strategies are reflected in the frequency-domain patterns. In this work, we develop a spectral-based approach to analytically predict the expected frequency-domain curve (reflecting the foot-force behavior) from any linear model of standing that gives as output the center of pressure and foot-force direction. The analytic method confirms that the metric depends on the controller and physiological noise, and not just mechanics. Furthermore, the method facilitates validation of mathematical models by providing fast and sure metric prediction to compare with experimental measurements. Finally, the analytic expression explains the sensitivity of the metric to different model parameters such as noise strength and noise dynamics, thereby allowing us to better interpret the metric, its strengths, and its limitations. As such, the

analytical description of the emergent foot-force behavior developed in this work further supports the utility of this metric in probing the quiet-standing-balance controller.

Title: Human Foot Force Informs Neural Control Strategies of Quiet Balance

Authors: *K. SHIOZAWA[1], M. RUSSO[2], J. LEE[1], N. HOGAN[1], D. STERNAD[3];

[3]Northeastern Univ., Boston, MA

Abstract: Despite the abundance of studies identifying the dynamics of perturbed human balance, understanding the control mechanisms of quiet standing has been difficult. Furthermore, although the ground reaction force is often measured to determine balance ability in subjects, only its vertical component and its point of application, i.e., the center of pressure, are usually considered. While the vertical component of the force dwarfs the shear component, the vertical force alone cannot achieve stable balance and the horizontal force is essential to provide translational stability. Previous work identified a point of intersection of ground reaction forces that combines the information from center of pressure with force direction. This intersection point exhibited consistent frequency-dependent behavior during quiet standing across multiple subjects. A recent study simulated balance and compared the results with human data to distinguish the roles of biomechanics and neural control. The current work aimed to further corroborate the analysis by applying it to experimental data of humans balancing in challenging

conditions: in tandem stance and on a narrow beam. A method based on linear-quadratic programming was used to control a double-inverted pendulum model with torque-actuated ankle and hip joints corrupted with white noise. The controller parameters were designed to facilitate exploration of two important features: the relative cost between state deviation and control effort and the relative magnitude of hip and ankle effort. Simulation results were compared to 15 healthy subjects' force data to identify the best-fit parameter sets for a controller. In all balance conditions, the best-fit controller minimized the overall control effort. For some balance conditions, the best-fit controller's penalty on the ankle and hip joints varied in a physiologically-plausible manner. For example, when subjects stood on a narrow beam, the model that best fit the frontal plane data reduced the penalty in the hip compared to other conditions. This result aligns with the observation that the center of pressure, and thus the ankle torque, was constrained in the frontal plane due to the presence of the beam. These results suggest that human balance can be best described by a controller that maintains minimal control through the adjustment of relative ankle and hip joint torques. This work supports the applicability of the proposed method to identify the control strategies of quiet posture. This work was supported in part by NIH-R37-HD087089 and NSF-M3X-1825942 awarded to DS and in part by the Newman Fund. KS was supported by the Hugh Hampton Young Memorial Fund Fellowship.

Title: Beta-gamma Phase Amplitude Coupling of Scalp Electroencephalography Can Predict Gait Disturbance in Parkinson's Disease.

Authors: *Y. KIMOTO, N. TANI, T. EMURA, T. MATSUHASHI, S. MIURA, T. FUJINAGA, K. HOSOMI, H. KHOO, R. FUKUMA, S. OSHINO, T. YANAGISAWA, H. KISHIMA;

Abstract: Background. There are many attempts to find biomarkers for the motor symptoms of Parkinson's disease. Adaptive deep brain stimulation system modulates stimulation using the beta-band power spectral density (PSD) from the subthalamic nucleus as an indicator to treat akinesia and rigidity in Parkinson's disease. However, it has difficulty improving postural reflex or gait disturbance by modulating stimulation. Recently, instead of PSD, beta-gamma phase amplitude coupling (PAC), which calculates the correlation of coupling between beta-band phase and gamma-band amplitude, has been increasingly reported to be an indicator of Parkinson's

disease symptoms. It is suggested that beta-band PSD in the basal ganglia reflects the signals relating motor symptoms whereas PAC is thought to represent the basal ganglia-cortical and cortico-cortical networks. Cortical PAC, not cortical PSD correlates with motor symptoms of Parkinson's disease. In this study, we evaluated whether PAC in scalp electroencephalography (EEG) can be a biomarker for gait disturbance. Methods. Cortical activities during 20m walking were measured using wireless scalp EEG in 11 patients with Parkinson's disease. Modulation index (MI) of beta-gamma PAC before and during walking was calculated from the signals on C3 and C4 in the 10-second sliding windows with 0.2 second step size. The MDS-UPDRS was evaluated before the trials, and the Postural instability and gait difficulty (PIGD) score was calculated as a subitem of UPDRS, which indicates freezing of gait (FOG) and gait instability. Results. Of the 28 trials, 20 trials had FOG score of 0 and 8 trials had FOG score of 1 or higher. Without FOG (0 point), MI was decreased significantly at the start of gait (p value=0.000714; MI at 10 seconds before walking=median: 0.71, 0.25-0.75 range: [0.31-1.74]; MI at the start of walking=0.46 [-0.09-0.99]), but with FOG (more than 1 point), MI did not decrease at the start of gait (p value=0.597; MI at 10 seconds before walking=0.86[0.66-1.23]; MI at the start of walking=0.81[0.36-1.33]). In addition, MI increased during walking in trials with higher PIGD scores, and MI and PIGD scores were positively correlated at 20 seconds after the start of walking (correlation coefficient=0.532, p value=0.000408). Conclusion. We found that the cortical PAC from scalp EEG reflects gait disturbance in subjects with PD. It is suggested that cortical network failure as well as basal ganglia deficits may be responsible for the gait disturbance or FOG in Parkinson's disease. This finding may provide important insights into the pathophysiology of gait disturbance in Parkinson's disease.

Title: Chronically implanted Neuropixels identify distinct prefrontal cortex neural states during fentanyl-induced respiratory depression

Authors: ***Z. T. GLOVAK**[1], N. E. BUSH[1], G. LEÓN[1], M. M. MCKINNEY[1,2], J.-M. RAMIREZ[1,2,3];

[1]Seattle Children's Res. Inst., Seattle, WA; [2]Neurolog. Surgery, [3]Pediatrics, Univ. of Washington, Seattle, WA

Abstract: Breathing during wakefulness is highly dynamic and varies as a function of an animal's behavioral state. Fentanyl causes significant respiratory depression and reduces electroencephalographic measures of arousal in rats (*Sci Rep* 9: 14122, 2019) and mice (*J Neurophysiol* 126: 1265, 2021). Reduced cortical arousal has been associated with decreased breathing (*Curr Biol* 28: 2145, 2018). The medial prefrontal cortex (mPFC) alters breathing (*Respir Physiol Neurobiol* 303: 103924, 2022) and behavioral arousal, however, the extent to which the mPFC modulates the relationship between arousal and breathing is not yet understood (*Trends Neurosci* 45: 722, 2022). This study is testing the hypothesis that systemic fentanyl administration induces a distinct neural state in the mPFC that correlates with changes in breathing. All methods adhered to the ARRIVE guidelines and were approved by the SCRI Institutional Animal Care and Use Committee. An adult male C57BL/6J mouse (n = 1, age = 20 wks) was anesthetized and implanted with a Neuropixel high-density probe aimed at the mPFC (1.94 mm anterior to bregma, 0.3 mm right of the midline). The probe was secured to the skull using a custom 3D printed headcap adapted from a previously validated model (*eLife* 8: e47188, 2019). After one week of recovery, the mouse was acclimated to a custom whole-body plethysmography chamber allowing for simultaneous measurement of mPFC local field potentials, single unit activity (n = 286), and breathing. Single unit Neuropixel recordings were viable for over 3 months. mPFC single neuron activity, as well as network activity quantified by principal components analysis, correlated with respiratory rate. Next, we subcutaneously administered fentanyl (0.1 mg/kg) which induced a depressed network state in the mPFC that also correlated with changes in breathing behavior. Compared to baseline, fentanyl significantly decreased population spiking activity in the mPFC ($p<0.01$, Wilcoxon rank-sum test) and caused a 50.1% decrease in respiratory frequency. These preliminary results are consistent with data from rats (*Sci Rep* 9: 14122, 2019) and indicate that decreased mPFC neuronal activity may contribute to fentanyl-induced respiratory depression. Ongoing studies are increasing sample size and exploring the feasibility of increasing cortex-driven arousal as a mitigation strategy for fentanyl-induced respiratory depression (*FASEB* 36: 00R71, 2022).

Title: Decrease in respiratory rate caused by prefrontal cortex administration of fentanyl can be described using a gain modulation model

Authors: R. S. HERZOG[1], D. P. WOODS[2], Q. W. SUN[1], Z. T. GLOVAK[1], H. A. BAGHDOYAN[1], *R. LYDIC[1];
[1]Psychology, [2]Biomed. Engin., Univ. of Tennessee, Knoxville, TN

Abstract: Breathing rate of C57BL/6J (B6) mice is significantly increased by prefrontal cortex (PFC) microinjection of neostigmine (10.1016/j.resp.2022.103924). Gain modulation was recently used to describe one mechanism by which PFC neostigmine enhances breathing (https://jpet.aspetjournals.org/content/385/S3/139). The **objective** of the present study was to determine whether the decrease in breathing rate caused by PFC fentanyl microinjection also was consistent with the gain modulation model. All **methods** using mice were reviewed and approved by The University of Tennessee IACUC. Breathing measures were obtained from awake, male B6 mice (n=7) via DSI whole body plethysmography after PFC microinjection (50 nL) of saline (control) or fentanyl (1 nmol). In the following gain modulation model, $F_o = (1 + F_{tonic}k)\ F_i$, the terms F_i represent pre- and F_o post-fentanyl respiratory frequency, F_{tonic} represents baseline respiratory frequency, and (k) is a unitless, multiplicative modulation coefficient (10.1016/s1569-9048(02)00042-3). **Results** Breathing rate was plotted as a function of time after PFC administration of saline or fentanyl. Breaths per min were measured during min 1 through 15 after PFC microinjection. Trendline slopes (dashed lines) quantified respiratory rate modulation after PFC saline (-9.80) or PFC fentanyl (-12.79) administration. When expressed as a relative percent change, the modulation values reveal a 30.5% decrease in respiratory rate caused by PFC fentanyl, relative to PFC saline. **Conclusion** The present finding that PFC fentanyl injection caused a 30.5% decrease in breathing frequency contrasts with the previous finding that PFC neostigmine injection caused a 32.6% increase in breathing frequency. The bidirectional, time-dependent changes in breathing rate caused by PFC neostigmine versus PFC fentanyl support the hypothesis that the PFC alters breathing via gain modulation of brainstem respiratory rhythm generation.

Title: A Comparative Examination of Morphine and Fentanyl: Unraveling the Differential Impacts on Breathing and Airway Stability

Authors: *N. BURGRAFF[1], N. BAERTSCH[1,2], J.-M. RAMIREZ[1,2];
[1]Ctr. for Integrative Brain Res., Seattle Children's Res. Inst., Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: The global opioid crisis continues to highlight the urgent need for a comprehensive understanding of the wide-ranging impacts of various opioid substances. Among the consequences of opioid use, opioid-induced respiratory depression (OIRD) remains the most significant and is the primary cause of fatality from opioid overdose. This study provides an in-depth analysis of the distinct consequences of the opioid drugs morphine and fentanyl during OIRD. We explored the physiological implications of both drugs on ventilation and airway patency. Our results revealed a similar reduction in respiratory frequency with equivalent scaled dosages of fentanyl and morphine, though the onset of suppression was more rapid with fentanyl. Additionally, fentanyl resulted in transient airflow obstructions during the inspiratory cycle, which were absent following morphine administration. Notably, these fentanyl-specific obstructions were eliminated with tracheostomy, implicating the upper airways as a major factor contributing to fentanyl-induced respiratory depression. Additionally, vagotomy prevented the occurrence of airway obstructions, demonstrating the potential for increased central parasympathetic drive in causing the obstruction. We further demonstrate that bronchodilators salbutamol and epinephrine effectively reversed these obstructions, highlighting the bronchi's contribution to fentanyl-induced airflow obstruction. Our study also uncovered a significant reduction in sighs during OIRD, which were eliminated by fentanyl and markedly reduced by morphine. Finally, we found that fentanyl-exposed mice had reduced survival under hypoxic conditions compared to mice given morphine, demonstrating that fentanyl becomes more lethal in the context of hypoxemia. Our findings shed light on the distinct and profound impacts of these opioids on respiration and airway stability and lay the foundation for improved opioid use guidelines and more effective OIRD prevention strategies.

Title: Identification of medullary neurons underlying congenital central hypoventilation syndrome

Authors: *K. CUI[1], Y. XIA[2], A. PATNAIK[3], L. HERNANDEZ-MIRANDA[4];
[1]Charité - Universitätsmedizin Berlin, Berlin, Germany; [2]Inst. für Zell- und Neurobiologie Charite Universitätsmedizin Berlin, berlin, Germany; [3]Charite Universtätsmedizin Berlin, berlin, Germany; [4]Charite Uviversitätsmedizin Berlin, Berlin, Germany

Abstract: Congenital Central Hypoventilation Syndrome (CCHS) is life-threatening respiratory disorder that is commonly dignosed in the childhood. The specific neural populations and circuits involved in CCHS pathogenesis are poorly understood. Here, we show that dysfunction of medullary neurons co-expressing Lbx1 and Phox2b (dB2 neurons) underlie CCHS. Using intersectional chemogenetics to transiently and reversely activate or silence dB2 neural activity, we show that these neurons play a crucial role in respiratory tidal volume dynamics, neonatal respiratory stability and the hypercarbic reflex, the natural acceleration of breathing in response to abnormally high levels of arterial pCO_2. dB2 neurons develop from rhombomere 2 to 6. To assess whether all or specific dB2 neuron subgroups (that is, dB2 neurons generated in distinct rhombomeres) regulate breathing homeostasis, we used distinct Cre-driver lines to diffentially ablate subgroups of dB2 neurons in a rhombomeric specific manner. We found that a specific subgroup of dB2 neurons (generated from rhombomere 5) is crucial for regulating the hypercarbic reflex. In addition, we also show that other dB2 neurons subgroups (generated from rhombomere 6) are essential for regulating respiratory tidal volumes and maintaining neonatal respiratory stability, and neonatal survival. Our study thus provides significant insights into the functional significance of dB2 neurons in respiration and in CCHS pathogenesis. Our data thereby add new neuroal components to the central respiratory circuit regulating breathing homeostasis, and provides with crucial knowledge that contributes to a deeper understanding of CCHS and its underlying pathophysiology.

Title: Glycinergic neurons contribute to features of Dravet syndrome

Authors: *B. M. MILLA[1], D. K. MULKEY[2];
[2]Physiol. & Neurobio., [1]Univ. of Connecticut, Storrs, CT

Abstract: Dravet syndrome (DS) is a severe form of epilepsy with a high incidence of sudden unexpected death in epilepsy (SUDEP.) Respiratory failure is a leading cause of SUDEP, despite

this it is unclear how DS-associated genetic variants or seizure activity disrupts respiratory control. Most DS cases are caused by mutations in the Scn1a gene encoding Nav1.1 channels preferentially regulating inhibitory neurons. Previously we showed that expression of a *Scn1a* loss of function variant (A1783V) in all inhibitory neurons resulted in seizures, breathing problems and premature death. However, it is unclear how loss of Scn1a function disrupts brainstem respiratory centers. To address this, we conditionally expressed $Scn1a^{A1783V}$ in subcortical brainstem respiratory centers by crossing floxed stop $Scn1a^{A1783V}$ mice with GlyT2-cre mice to generate GlyT2::$Scn1a^{A1783V/+}$ and control animals.
The novel open field assay was used to assess locomotor behavior and anxiety, EEGs characterized spontaneous and heat induced seizures, and whole-body plethysmography was used to assess baseline breathing and the ventilatory response to 3, 5 and 7% CO_2 (balance O_2). All experiments were performed in mice two months of age.
GlyT2::$Scn1a^{A1783V/+}$ mice were obtained at the expected frequency with grossly normal motor and anxiety behavior. These mice did not exhibit spontaneous seizures; however, 11 of 17 (~70%) GlyT2::$Scn1a^{A1783V/+}$ mice exhibited febrile seizures (at 42 ± .3 ºC.) Conversely, control mice do not show seizure activity over this same temperature range (n=12). GlyT2::$Scn1a^{A1783V/+}$ mice also showed reduced respiratory frequency (n=10) and increased post-sigh apnea (frequency and duration; n=7) under room air conditions and they showed a blunted ventilatory response to CO_2 compared to control mice.
Together, these results show that loss of Scn1a function in glycinergic neurons disrupts breathing and may increase febrile seizure propensity. Also, since febrile seizures are caused by respiratory alkalosis, these results suggest baseline breathing problems may serve as an early biomarker of febrile seizure propensity and risk of mortality in DS. These results show for the first time that disruption of glycinergic signaling contributes to clinically important aspects of DS.

Abstract: We found that photo stimulation of the dorsal skull of transgenic neonatal rats in which Phox2b positive neurons expressed one of the channelrhodopsin variants, ChRFR (C167A), caused rhythmic opening/closing movements of the mouth under conscious free-moving conditions. To examine detailed motor pattern, we recorded electromyograms from digastric, masseter and diaphragm muscles while video was recorded. During this rhythmic mouth movement, digastric muscle actives during the opening phase, and masseter muscle actives during the closing phase, suggesting the sucking activity. However, the extent of activation was dependent on the rats or trials, and there was digastric activity dominant pattern and masseter activity dominant pattern. The respiratory activities in the diaphragm were not correlate with the rhythmic activity in the digastric and masseter muscles. We also found other two types of rhythmic motor activity without apparent mouth movement. One was repetitive swallowing-like activity and another was hiccup-like activity. The swallowing-like activity was composed of the burst activity of the digastric muscle and the preceding the burst activity of diaphragm. Since the mouth did not open during the digastric muscle activity, it was thought that the hyoid bone was elevated and swallowing occurred at this time. To characterize hiccup-like activity, movement analysis was applied to not only mouth but also thorax and abdomen. The thorax and abdomen showed expanding movement during normal breathing. During hiccup-like movement, however, the thorax was dented in phase with the burst activity in diaphragm. This indicates the upper air way closed during the diaphragmatic activity. These results suggest that the activation of the Phox2b positive neurons in the dorsal brainstem is involved in triggering the sucking, swallowing and hiccup movement.

Title: The role of intracellular calcium dynamics in sigh rhythmogenesis

Authors: *J. GU, M. STETTLER, D. BORRUS, C. GROVER, G. CONRADI SMITH, C. DEL NEGRO;
Col. of William and Mary, Williamsburg, VA

Abstract: The preBötzinger Complex (preBötC) of the lower brainstem generates inspiratory breathing rhythm giving rise to two distinct types of breaths: eupnea and sigh. Eupnea refers to normal breaths that ventilate the lungs whereas sigh breaths are characteristically greater in

volume and lower in frequency and are responsible for optimizing pulmonary function. However, the sigh-generating mechanism in the preBötC remains elusive. Here, we test a mathematical model of preBötC eupnea-sigh rhythmogenesis, wherein eupnea results from an excitatory network oscillator and sigh rhythm results from intracellular calcium dynamics in preBötC neurons. SERCA pumps and IP3 receptors modulate calcium uptake and release, respectively, in the endoplasmic reticulum. Nerve (CN XII) and field recordings were made from rhythmically active brainstem preparations that contain the preBötC in neonatal wildtype mice. We applied drugs that selectively block IP3 receptors and SERCA pumps. In line with model predictions, selective antagonism of IP3 receptors slows down or stops the sigh rhythm, and antagonism of SERCA pumps speeds up or stops sigh rhythm depending on drug concentration. By validating model predictions, we provide evidence that sighs are attributable to periodic calcium release from the endoplasmic reticulum and this rhythm operates independently with eupnea rhythm in the same cell population. This work advances our understanding of the neural basis of breathing and particularly the origin of sigh breaths, which are critical for the healthy functioning of compliant lungs in mammals.

Title: On the mechanisms of respiratory sensitivity to CO2: systematic review and meta-analysis of experimental and clinical evidence

Authors: N. PANZO[1], C. BRAGG[1], A. V. GOURINE[2], ***S. SHEIKHBAHAEI**[1];
[1]Neuron-Glia Signaling and Circuits, Natl. Inst. of neurological Disorders and Stroke, Bethesda, MD; [2]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Respiratory carbon dioxide (CO2) chemosensitivity is a crucial mechanism that regulates breathing in accordance with blood and brain PCO2/pH. Current models of central respiratory CO2 chemosensitivity focus on specialized neurons in the retrotrapezoid nucleus (RTN) and medullary raphé and suggest that these pools of neurons are primarily responsible for mediating the effects of CO2 on breathing. However, evidence also indicates the presence of CO2/pH-sensitive neurons in other brainstem areas. Further evidence suggests that astrocytes, non-neuronal cells, may also contribute to central CO2 chemosensitivity. All these data present key challenges in understanding regional specificity and the underlying mechanisms of respiratory CO2 chemosensitivity. We conducted a systematic review and meta-analysis of the

published primary literature to examine the relative contributions of different CNS sites and peripheral arterial chemoreceptors in mediating respiratory sensitivity to CO2 and the signaling mechanisms involved. The results of our analysis support the distributed central chemosensitivity hypothesis and indicate that central respiratory sensitivity to CO2 is mediated by multiple central chemoreceptor sites and the carotid body, with each region providing tonic drive to breathe in eucapnia and a fraction of the total response to systemic hypercapnia.

Title: The impact of chronic intermittent hypoxia (CIH) on cellular/molecular functions of distinct cell types in the pons and medulla of adult mice as revealed by single-nucleus RNA sequencing.

Authors: *H. BHAGAVAN[1], A. D. WEI[1], J. M. RAMIREZ[1,2];
[1]Ctr. for Integrative Brain Res., Seattle childrens research institute, Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Chronic intermittent hypoxia (CIH) is a prevalent condition that arises from recurring episodes of oxygen deprivation in respiratory disorders such as obstructive sleep apnea (OSA) and apneas of prematurity. Prolonged CIH impacts neuronal function, and leads to chronic inflammation, oxidative stress, and endothelial dysfunction, which are key factors in comorbidities including hypertension, metabolic disorders, and cardiovascular disease. Our objective is to understand the CIH-induced changes in gene expression (transcriptome) within different cell types of the brainstem. We performed a comparative analysis of the CIH response, leveraging highly multiplexed single-nucleus RNA sequencing (snRNA-seq). This enabled us to examine the expression profiles of 12,990 nuclei from six samples (C57BL6/J) of pontine-medullary adult tissues. Our analysis revealed the presence of major clusters, including neurons (9061), oligodendrocytes (3371), microglia (201), and astrocytes (357). Within the neuronal nuclei, we further identified 21 distinct subclusters broadly categorized as inhibitory (Gad1, Gad2, Slc32a1, and Slc6a5) and excitatory (vGlut1 and vGlut2) cell types. We uncovered dysregulated genes with a notable impact observed in inhibitory neurons and oligodendrocytes, while the dysregulation in excitatory cells was minimal (DESeq2; FDR corrected using

Benjamini-Hochberg, p-0.05). Pathway enrichment analysis revealed dysregulation associated with intrinsic membrane excitability (ion channels), synaptic transmission (neurotransmitter receptors), immune response, and structural remodeling (extracellular matrix and cell adhesion molecules) within the neuronal clusters. Oligodendrocytes exhibited dysregulation to oxidative stress. These observations contribute to our understanding of the molecular mechanisms underlying the impact of CIH in specific cell types and provide valuable insights for further investigation and potential therapeutic strategies.

Title: Comparison of intrinsic chemosensitivity of acutely dissociated medullary serotonergic neurons and retrotrapezoid neurons

Authors: Y. WU, E. BRAVO, ***G. RICHERSON**;
Univ. of Iowa, Iowa City, IA

Abstract: Rationale: Serotonergic neurons of the medullary raphe and Phox2b/Neuromedin B (Nmb) expressing neurons of the retrotrapezoid nucleus (RTN) are both putative respiratory chemoreceptors proposed to detect changes in CO_2/pH. However, their relative contribution to respiratory chemoreception is unknown. We directly compared their responses to hypercapnic and isocapnic acidosis after acute dissociation to study their intrinsic chemosensitivity.
Methods: The midline medulla was dissected from P10-P18 mice expressing YFP under control of the enhancer region of Pet1, which is selective for serotonergic neurons. Tissue was enzymatically digested and triturated, and plated onto glass coverslips etched with a grid for later identification of recorded neurons. Cells were fed with culture medium and allowed to attach to the substrate for 2-3 hours. Patch clamp recordings were then made in current clamp mode either immediately or after 1-8 days. In some cases, glial growth was inhibited by cytosine arabinoside. After recordings, coverslips were fixed with 4% formalin and immunostained with antibodies for MAP2 or GFAP, and it was determined whether any synaptic or glial contacts were present on recorded neurons. The same methods were used for RTN neurons except that dissections were made from P6-P11 Phox2b-Cre::Floxed tdTomato::ChAT-GFP mice, and recordings were made from Phox2b+/ChAT- neurons 1-2 days later. In some cases, neurons were stained for Nmb using RNAScope.
Results: In response to an increase in CO_2 from 5% to 9% (pH 7.4 to 7.2), 47 of 69 5-HT neurons (68%) increased their firing rate by more than 20% from baseline, with an average

response of 121%. In contrast, 11 of 32 RTN neurons (34%) increased their firing rate by more than 20% from baseline, with an average response of 37%. In response to isocapnic acidosis (pH 8 to 7), 43 of 61 5-HT neurons (70%) increased their firing rate by more than 50% from baseline, with an average response of 417%. In contrast, 9 of 64 RTN neurons (14%) increased their firing rate by more than 50% from baseline, with an average response of 122%. Preliminary data indicate that RTN neurons that were Nmb+ were not more likely to be chemosensitive, and 5-HT neuron responses were not larger if there were nearby processes or glia. There was no effect in either type of neuron of the number of days after dissociation.
Conclusions: Serotonergic neurons have a high degree of intrinsic (cell-autonomous) chemosensitivity. A smaller number of RTN neurons are chemosensitive and they have smaller responses, consistent with a more important role of the RTN as a relay from other chemoreceptor sites than as pH sensors.

Title: Enhanced peripheral chemoreception contributes to disordered breathing in Rett syndrome.

Authors: *M. STRAIN;
Univ. of Connecticut, Storrs, CT

Abstract: Enhanced peripheral chemoreception contributes to disordered breathing in Rett syndrome. Monica L. Strain[1], Michelle L. Olsen[2], Daniel K. Mulkey[1]. [1]Dept. of Physiology and Neurobiology, Univ. Connecticut, Storrs, CT, [2] School of Neuroscience, Virginia Polytechnic Institute and State Univ., Blacksburg, VA.
Rett syndrome (RTT) is a severe neurodevelopmental disorder caused by mutations in the methyl-CpG-binding protein 2 gene (MECP2). Symptoms of RTT include autistic-like behavior, seizures, and respiratory problems that typically manifest during wakefulness as episodes of hyperventilation followed by hypoventilation and apnea. The basis of respiratory dysfunction in RTT is not known; however, periodic breathing in general is predicted to result from over-activation of central or peripheral chemoreceptors that regulate breathing in response to hypercapnia or hypoxia, respectively. Therefore, the goals of this study are to characterize baseline breathing in MeCP2-deficient mice during the dark/active and light/inactive states, and to determine the extent to which central or peripheral chemoreception contributes to periodic breathing in this mouse model. All experiments were performed in adult (P40) male MeCP2-

deficient mice (MeCP2-/y; JAX #003890) and litter mate controls (n=6-7/genotype). Whole-body plethysmography was used to measure baseline breathing and ventilatory responses to graded increases in CO_2 (0-7% CO_2, balance O_2) and hypoxia (10% O_2, balance N_2). Reminiscent of RTT patients, we found that MeCP2-/y mice display severe periodic breathing in air with the phenotype being more pronounced in the wake state. We also found that MeCP2-/y mice have a normal ventilatory response to CO_2 ($p= 0.7661$) but exhibited an augmented ventilatory response to hypoxia ($p<0.0001$), particularly during the dark/active state. Interestingly, periodic breathing in MeCP2-/y mice was eliminated when peripheral chemoreceptor drive was diminished in 100% O_2. These results are consistent with previous work showing that loss of MeCP2 from peripheral sensory neurons recapitulated features of RTT including unstable breathing. Together, the findings from this study suggest that enhanced peripheral chemoreceptor drive contributes to diurnal periodic breathing in a mouse model of RTT.

Title: Endogenous hydrogen sulfide in the medullary respiratory center stabilizes the frequency and power of respiration in a regionally distinct way.

Authors: *M. OKAZAKI[1,2], T. KOGANEZAWA[1,3];
[1]Dept. of Neurophysiology, Inst. of Medicine, Univ. of Tsukuba, Tsukuba, Japan; [2]Grad. Sch. of Comprehensive Human Sciences, Univ. of Tsukuba, Tsukuba, Japan; [3]Transborder Med. Res. Center, Univ. of Tsukuba, Tsukuba, Japan

Abstract: Hydrogen sulfide (H_2S) is synthesized in the central nervous system and regulates the neural network. We have found that inhibiting the H_2S synthase in the brain disrupts respiration. However, it is still unclear where in the medullary respiratory center and how the endogenous H_2S works. In this study, we aimed to investigate the contribution of the H_2S synthesized at each compartment of the medullary respiratory center to respiratory pattern generation and its underlying mechanism. We observed the central respiratory outputs by recording the phrenic and vagus nerve activity in the *in situ* arterially perfused preparation of decerebrated male rats. To identify the functional role of H_2S synthesized at each compartment of the medullary respiratory center, the pre-Bötzinger complex (pre-BötC), the Bötzinger complex (BötC), or the rostral VRG (rVRG), an H_2S synthase inhibitor was locally injected into each compartment of the medullary

respiratory center and the effects on the respiratory pattern were evaluated. Moreover, to investigate whether H_2S regulates respiratory output via modulating the synaptic transmission, an antagonist of a glutamatergic receptor or the cocktail of GABAergic and glycinergic receptors was locally injected. We compared the changes in the respiratory outputs by inhibiting H_2S synthesis in the absence and presence of those antagonists. When the H_2S synthase inhibitor was injected into the pre-BötC or the BötC, the amplitude of the inspiratory burst decreased, and the respiratory frequency increased according to the shorter inspiration or expiration, respectively. These respiratory changes were abolished or attenuated in the presence of the antagonist of a glutamatergic receptor. On the other hand, when the H_2S synthase inhibitor was injected into the rVRG, while the amplitude of the inspiratory burst was attenuated as similar to that at the pre-BötC or the BötC, the respiratory frequency decreased, which was the opposite alteration by injecting the cocktail of GABAergic and glycinergic receptors at the rVRG. These results indicate that the H_2S synthesized in each compartment of the medullary respiratory center functions to sustain the respiratory frequency and the power of inspiration in a region-dependent manner. The underlying mechanism might be the modulation of the excitatory and inhibitory synaptic transmissions.

Title: The role of phenytoin in generating multi-rhythmic inspiratory patterns in the preBötzinger Complex

Authors: *B. THADARI[1], K. KAM[2];
[1]Neurosci., Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Breathing is a fundamental behavior that sustains life in mammals. While its primary function is gas exchange, intermixed with regular breathing are other rhythmic inspiratory patterns, such as sighing and sniffing, each with a distinct function. Inspiratory rhythm is generated by the preBötzinger Complex (preBötC). While a slower sighing rhythm interspersed with eupnea can be elicited with a neuropeptide injection into preBötC, a mechanism to produce shifts to faster inspiratory rhythms, as observed in sniffing, has not been determined. Changing regulators of preBötC excitability such as extracellular $[K^+]$ ($[K^+]_{ext}$) or extracellular $[Ca^{2+}]$ ($[Ca^{2+}]_{ext}$) can modulate inspiratory frequency, but appear insufficient to generate intermixed rhythmic inspiratory patterns *in vitro.* Persistent sodium current (I_{NaP}) also regulates preBötC

excitability, but the effects of partial blockade have not been rigorously explored. We hypothesized that alterations in I_{NaP} might produce unique dynamic states in preBötC that include intermixed inspiratory rhythms. We used rhythmically active transverse medullary slices (550-650 μm) from neonatal mice containing preBötC. We recorded inspiratory-related XII activity in response to bath application of phenytoin, a blocker of I_{NaP}. We found that applying phenytoin in increasing concentrations (125→225→325 μM) in ACSF containing 9mM $[K^+]_{ext}$ and 1.5 mM $[Ca^{2+}]_{ext}$ slowed down rhythm in a dose-dependent manner and, at 325 μM, ultimately stopped rhythm. During wash-off of phenytoin, we observed fast "runs" of 2-5 bursts, which we called "inspiratory multiplets," interspersed with the slower burst rhythm. Multiplets were absent once the burst rhythm fully recovered. We suggest that the brief appearance of slow and fast rhythmic bursting in preBötC represents a transitory multi-rhythmic state. To stabilize this multi-rhythmic state, we bath applied phenytoin in decreasing concentrations (185→50→10 μM) to mimic the phenytoin wash-off and increased excitability by lowering $[Ca^{2+}]_{ext}$ to 0.8 mM. While a few multiplets were interspersed with the slower inspiratory rhythm in 185 μM, multiplet generation was more robust after phenytoin was decreased to 50 or 10 μM. Multiplets occurred in phase with the burst rhythm, and the interval following a multiplet was longer than the average interburst interval, suggesting that preBötC burst- and multiplet-generating mechanisms interact. We conclude that combining changes in I_{NaP} and Ca^{2+} are one mechanism to achieve multi-rhythmicity in breathing. These findings contribute to our understanding of mechanisms underlying generation and modulation of breathing rhythm.

Title: The role of enkephalinergic neurons in respiratory rhythm modulation

Authors: *G. LOGINOV[1], J. W. ARTHURS[1], N. A. BAERTSCH[1,2];
[1]Seattle Children's Res. Inst., Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Opioid-induced respiratory depression (OIRD) is the primary cause of death during opioid overdose, characterized by diminished respiratory frequency and regularity. Activation of mu-opioid receptors (MORs) within the ventral respiratory column (VRC) of the medulla is partly responsible for the decrease in breathing following exogenous opioid administration. However, the role of MORs and endogenous opioid signaling in normal respiratory rhythm generation remains largely unknown. We hypothesized that endogenous opioids are released in the VRC to stabilize the respiratory rhythm under certain conditions of high network excitability.

To test our hypothesis, we used a combination of optogenetic and pharmacological approaches targeting endogenous MORs ligands -- enkephalins. Contrary to our expectations, optogenetic activation of enkephalinergic neurons in the preBötzinger Complex, the inspiratory rhythm-generating region of the VRC, increased the frequency of inspiratory bursts in brainstem slices of neonatal mice. These excitatory effects persisted after the application of MOR antagonist Naloxone, suggesting a non-MOR mediated mechanism. Further, high fidelity and temporal coordination of evoked bursts with optical stimulation implicated glutamatergic transmission as the primary source of excitation. In urethane-anesthetized spontaneously breathing mice, optogenetic activation of enkephalin-expressing neurons revealed anatomically dependent effects on breathing along the VRC. Continuous optical stimulation of the rostral VRC resulted in a significant decrease in respiratory frequency compared to spontaneous activity. However, activation of enkephalinergic neurons in the mid-VRC transiently increased the respiratory frequency and significantly increased breath amplitude. These findings suggest that the coexpression of enkephalin with other excitatory or inhibitory neurotransmitters may vary along the rostrocaudal axis of the VRC, resulting in differential effects of enkephalinergic neurons on respiratory rhythm. Alternatively, the functionally opposing effects of rostral and caudal enkephalinergic neurons may result from differences in their projection targets within the network. Future work will test these possibilities by dissecting enkephalinergic VRC inputs and local circuitry. Intersectional AAV approaches will allow for anatomical and functional characterization of enkephalin coexpression with glutamate or GABA within the network. These studies will help elucidate the role of endogenous enkephalinergic signaling and establish potential therapeutic targets for preventing OIRD.

Title: Inhibitory prebötzinger complex neurons regulate rhythmic breathing in vivo

Authors: *K. BAKER[1,2], C. SCARPELLINI[2], G. MONTANDON[1,2];
[1]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [2]St. Michael's Hosp. Keenan Res. Ctr., Toronto, ON, Canada

Abstract: Breathing is an essential process that is controlled by the rhythmic activity of brainstem breathing centers to generate respiratory rhythms. The preBötzinger Complex (preBötC) is a brainstem nucleus critical to generating breathing and contains excitatory and inhibitory cells that coordinate inhalation and exhalation. Approximately half the neurons in the preBötC are inhibitory and express γ-aminobutyric acid (GABA) or glycine but how these cells control respiratory rhythms is unknown. Additionally, brainstem breathing centers are vulnerable to drugs like sedatives such as benzodiazepines, which target these inhibitory circuits and can cause respiratory depression. To understand how these drugs cause respiratory depression, it is critical to first determine how the inhibitory cells in the brainstem control breathing. We aim to identify the role of inhibitory preBötC cells in the control of breathing in vivo.
To study the function of inhibitory preBötC cells, we used optogenetics to selectively activate and inhibit inhibitory preBötC cells with temporal precision. We stereotaxically injected a cre-dependent adeno-associated virus expressing either the excitatory channelrhodopsin or the inhibitory archaerhodopsin in the preBötC of vesicular GABA transporter (*vGAT*)-cre mice. Following the virus injection, we measured diaphragm activity in anesthetized mice and respiratory activity using whole-body plethysmography in freely behaving mice, while stimulating *vGAT* cells with blue (470 nm) light and inhibiting *vGAT* cells with green (554 nm) light to determine the functional output of these cells.
We found that *vGAT* excitation depresses breathing depending on the phase of the respiratory cycle when the laser stimulation occurred. Photostimulation of *vGAT* cells increased the delay between inspirations, therefore extending expiration. However, photostimulation of vGAT cells had no effect on inspiratory duration or the diaphragm amplitude in both freely behaving and anesthetized mice. Additionally, photoinhibition of *vGAT* cells increased respiratory rate by triggering inspiration before its natural occurrence, therefore decreasing expiratory duration. These data suggest that the preBötC inhibitory neurons are important for the initiation of inspiration as activating and inhibiting these cells alters when inspiration occurred. Our study is the first study to show the role of these inhibitory preBötC neurons in freely-behaving rodents. Our study contributes to a better understanding of the basic neural inhibitory circuits in the medulla regulating inspiration in freely-behaving rodents.

Title: Inhibitory subpopulations in preBötzinger Complex play distinct roles in modulating inspiratory rhythm and pattern

Authors: *K. KAM, Z. CHANG, J. SKACH;
Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL

Abstract: Inhibition shapes breathing, walking, chewing, and other rhythmic motor behaviors, but, in many cases, the role of inhibitory neurons embedded within the mammalian neural circuits controlling these behaviors has not been rigorously determined. At the core of the neural circuit controlling breathing is the preBötzinger Complex (preBötC), a nucleus in the ventrolateral medulla necessary for generation of inspiratory rhythm. In the preBötC, a recurrently connected network of glutamatergic Dbx1-derived ($Dbx1^+$) neurons generates rhythmic inspiratory drive. Functionally and anatomically intercalated among $Dbx1^+$ preBötC neurons are inhibitory neurons defined by the GABAergic markers GAD1/GAD2 ($GAD1^+$/$GAD2^+$) and/or the glycinergic marker GlyT2 ($GlyT2^+$). Proposed roles for these neurons include modulation of burst pattern, tonic regulation of excitability, maintenance or coordination of phasic firing, and rhythm generation, but their function continues to be debated. We hypothesized that unrecognized heterogeneity among inhibitory preBötC neurons might explain the myriad roles proposed for these neurons. We first characterized the spatial distribution of molecularly-defined inhibitory preBötC subpopulations in double reporter mice expressing either the red fluorescent protein tdTomato or EGFP in $GlyT2^+$, $GAD1^+$, or $GAD2^+$ neurons. We found that, in postnatal mice, the majority of inhibitory preBötC neurons expressed a combination of GlyT2 and GAD2 while a much smaller subpopulation also expressed GAD1. To determine the functional role of these subpopulations, we used holographic photostimulation, a patterned illumination technique with high spatiotemporal resolution, to specifically excite small groups of $GlyT2^+$ or $GAD1^+$ preBötC subpopulations in rhythmically active medullary slices from $Dbx1^{tdTomato}$;$GlyT2^{EGFP}$ and $Dbx1^{tdTomato}$;$GAD1^{EGFP}$ double reporter mice. Stimulation of 4 or 8 $GlyT2^+$ preBötC neurons during endogenous rhythmic activity prolonged the interburst interval in a phase-dependent manner and increased the latency to burst initiation when bursts were evoked by stimulation of $Dbx1^+$ neurons. In contrast, stimulation of 4 or 8 $GAD1^+$ preBötC neurons did not affect interburst interval or latency to burst initiation, but did prolong both endogenous and evoked burst duration when stimulation occurred during the burst. We conclude that the majority of inhibitory preBötC neurons express both GlyT2 and GAD2 and affect breathing rhythm by delaying burst initiation while a smaller $GAD1^+$ subpopulation affects inspiratory patterning by prolonging burst duration.

Title: A novel respiratory interneuron population sustains breathing under hypercapnia

Authors: *M. LIN, P. PHILIPPIDOU;
Dept. of Neurosciences, Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: The ability to rapidly and reversibly modulate breathing in response to environmental challenges is essential for daily life. Under conditions of increased air CO_2 (hypercapnia), mammals breathe deeper to eliminate carbon dioxide intake. Phrenic motor neurons (PMNs) control breathing by integrating signals from diverse inputs to initiate the contraction of the major inspiratory muscle, the diaphragm. While central chemoreceptors that can sense changes in carbon dioxide levels have been identified, it is unknown whether PMN activity can be regulated directly by first-order inputs to adapt to hypercapnic challenges. Here, we mapped first-order inputs to PMNs, and discovered a local spinal cholinergic interneuron population that contributes around 10% of total PMN inputs. These interneurons are located within cervical levels of the spinal cord and are highly activated under a hypercapnic challenge. In addition, specifically silencing cholinergic neurotransmission in these interneurons impairs the breathing response under moderate, but not mild, hypercapnia (10% CO_2) specifically in adult mice, indicating the function of spinal cholinergic modulation in breathing is age- and intensity-dependent. Our findings identify a novel respiratory population with the ability to respond to hypercapnia and implicate spinal first-order PMN inputs in regulating breathing.

Abstract: Breathing must be readily adjusted to meet changing metabolic demands. It is well established that the rhythm is generated in the brainstem; however, mounting evidence points toward roles for cervical spinal interneurons (INs) in adjusting respiratory output.
Here we used a combination of mouse genetics, immunohistochemistry, calcium imaging and electrophysiology to study spinal cholinergic modulation of breathing and interrogate underlying

neural mechanisms. We focused on C-boutons - large cholinergic modulatory synapses derived from Pitx2$^+$ INs previously shown to facilitate motoneuron (MN) output in a task-dependent manner, via M2 muscarinic receptor signaling.
Anatomical studies utilized mice that express a red fluorescent protein in Pitx2$^+$ INs. Phrenic MNs were retrogradely labelled via either intrapleural injection of cholera toxin B subunit or by applying pseudorabies virus to the diaphragm. For functional analysis, respiratory activity was recorded *in-vitro* from the C3/4 ventral roots of isolated brainstem-spinal cord preparations from neonatal mice, or *in-situ* from the phrenic nerve in working heart-brainstem preparations from adult rats. Calcium dynamics were visualized *in-vitro* using tissue from mice expressing GCAMP6s in Pitx2$^+$ INs.
We found that Pitx2$^+$ INs form synapses onto phrenic MNs. We also found that cervical Pitx2$^+$ INs are active during respiration, albeit not in phase with individual bursts of respiratory motor output. Pharmacological blockade of M2 receptors reduced the amplitude and increased the frequency of respiratory-related activity *in-vitro*. The reduction in amplitude was reproduced when M2 receptors were selectively blocked in the cervical spinal cord, suggesting endogenous spinal cholinergic modulation through M2 receptors. *In-situ* experiments confirmed that M2 modulation of phrenic MN output is also present in the adult. However, modulating Pitx2$^+$ IN activity in animals expressing excitatory or inhibitory DREADDs did not alter respiratory-related output *in-vitro*, suggesting that these INs might not be involved in maintaining respiratory output at the early postnatal period. Interestingly, preliminary data suggests that hypercapnic facilitation of diaphragm activity may be diminished in animals where cholinergic Pitx2$^+$ INs are genetically ablated, implying a role in facilitating breathing during states of increased metabolic demand. Together, these data demonstrate a role for cholinergic modulation in the maintenance of respiratory output that is intrinsic to the cervical spinal cord and lasts throughout development, although the contribution of C-boutons to this modulation remains unclear.

Title: Unravelling the role of the putative proton-coupled organic cation antiporter in triptan transport across the blood-brain barrier

Authors: *N. SVANE[1], A. PEDERSEN[1], A. RODENBERG[1], B. OZGÜR[1,2], L. SAABYE[1,3], M. KRISTENSEN[1], C. BUNDGAARD[2], P. TFELT-HANSEN[4], B. BRODIN[1];

[1]Dept. of Pharm., Univ. of Copenhagen, Copenhagen, Denmark; [2]H. Lundbeck A/S, Valby, Denmark; [3]Bioneer: FARMA, Bioneer A/S, Hørsholm, Denmark; [4]Rigshospitalet-Glostrup, Copenhagen, Denmark

Abstract: Triptans are 5-hydroxytrytamine$_{1B/1D}$ receptor agonists used to treat migraines. The anti-migraine effect of triptans involves peripheral mechanisms that counteracts migraine-associated intracranial vasodilation. Besides peripheral mechanisms, there are indications suggesting that triptans may also act on $5HT_{1B/1D}$ receptors within the central nervous system, although the exact mechanism by which this occurs is not well understood (1). Triptans are believed to have limited ability to passively cross the blood-brain barrier (BBB) due to their relatively hydrophilic nature (1). This study aimed to assess the role of the putative proton-coupled organic cation (H^+/OC) antiporter in the uptake of triptans into brain capillary endothelial cells and to examine whether triptans interacted with the efflux transporter, P-glycoprotein (P-gp). We applied human brain capillary endothelial cells (hCMEC/D3) to investigate uptake characteristics of prototypical H^+/OC antiporter substrates and triptans (almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan and zolmitriptan). Time-, concentration-, and pH-dependent uptake was evaluated, as well as inhibitory properties. In addition, we applied porcine epithelial cells (IPEC-J2) transfected with human MDR1 to study P-gp-mediated efflux of triptans across IPEC-J2 MDR1 monolayers. We demonstrated functional expression of the H^+/OC antiporter in hCMEC/D3 cells. Prototypical substrates of the H^+/OC antiporter, [^{3}H]-pyrilamine and oxycodone, exhibited time-, concentration-, and pH-dependent uptake into hCMEC/D3 cells. The triptans revealed varying degrees of inhibition on the uptake of [^{3}H]-pyrilamine with IC50 values ranging from 15 ± 4 to 1729 ± 1209 µM. Among the triptans, eletriptan exhibited the strongest inhibitory effect, as well as time-, concentration-, and proton-dependent uptake into hCMEC/D3 cells. Furthermore, only eletriptan interacted with the P-gp efflux transporter demonstrating an efflux ratio of 28.9 ± 1.8, which was eliminated in the presence of the P-gp inhibitor, zosuquidar. In conclusion, we found that some triptans, particularly eletriptan, can be transported into the brain endothelium via the putative H^+/OC antiporter. This study provides valuable insights into the molecular mechanisms of triptan transport into and across the BBB, which may contribute to a deeper understanding of potential central mechanisms of triptans in migraine treatment.(1) Tfelt-Hansen PC. Title: Modeling the mouse blood-brain barrier: A simple method for generating mouse brain endothelial cell monolayers

Authors: *A. B. V. PEDERSEN[1], H. C. C. HELMS[2], B. OZGÜR[1], M. KRISTENSEN[1], B. BRODIN[1];

Abstract: The brain capillary endothelium forms the blood-brain barrier (BBB), tightly regulating drug transport into the brain. This poses a challenge for developing new central nervous system (CNS) drugs. *In vitro* BBB models using brain capillary endothelial cells (BECs) are valuable for drug screening, studying cell interactions, and predicting transport rates. However, translating results from non-rodent BBB models to preclinical rodent models is hindered by species-specific differences. Therefore, a validated mouse BBB model is needed to overcome these limitations. In this study, we aim to establish a validated monoculture *in vitro* BBB using primary BECs for transendothelial transport studies. To establish the model, the cortex from 4-week-old C57BL/6 male mice was harvested and homogenized. Brain capillary fragments were isolated through several steps, including centrifugation with dextran and enzyme treatment. After 9 days of cultivation, the isolated mouse BECs were prepared for experiments. Primary mouse BECs were used to develop monoculture models on Transwell supports. The successful formation of tight junctions was confirmed through immunocytochemical staining, which illustrated the location of junctional claudin-5 and ZO-1. The functional tightness was demonstrated by transendothelial electrical resistance (TEER) measurements and permeability studies using the small hydrophilic molecule, mannitol (180 Da). The identity of the isolated mouse BECs was validated through immunocytochemical staining and gene expression analysis of cell-specific proteins, including von Willebrand Factor (vWF), platelet derived growth factor receptor beta (Pdgfrβ) and platelet and endothelial cell adhesion molecule 1 (Pecam1). Notably, the presence of P-glycoprotein has been demonstrated in previously studies (Hinca et al., 2021). These results demonstrate that the established mouse BBB model using monocultured BECs successfully formed monolayers with functional tight junctions. The purity of the isolated cells as endothelial cells was confirmed. This validated mouse BBB model serves as a valuable tool for studying transendothelial transport experiments and holds promise for the development of accurate and translatable preclinical models in CNS drug discovery. Abstract: Temporary compromise of blood-brain barrier (BBB) integrity is commonly observed in acute neurological disease states. Endothelial cells are a key component of the BBB, and thus barrier dysfunction is associated with structural and molecular changes to these cells. Previously, we used low-intensity pulsed ultrasound with microbubbles (LIPU/MB) to enhance drug delivery to the brains of humans. This temporary and targeted model of BBB dysfunction offers an opportunity to study how these endothelial cells respond to loss of barrier integrity and potentially initiate repair. To do this, we used single-cell RNA sequencing (scRNAseq) and transmission electron microscopy (TEM) to examine transcriptional and structural changes in the cerebral endothelium after inducing targeted BBB dysfunction by LIPU/MB in patients (n = 6) undergoing surgical resection of recurrent glioblastoma. We used intraoperative fluorescent microscopy and fluorescein administered after LIPU/MB to identify and to biopsy “sonicated” brain tissues with evident BBB dysfunction, alongside “non-sonicated” control tissues. On a Uniform Manifold Approximation and Projection (UMAP) plot, sonicated and non-sonicated endothelial cells formed distinct clusters. The sonicated cells exhibited unique gene expression profiles, with alterations in various genes previously linked to BBB function such as *MFSD2A, Cav1, VE-Cadherin, COL4A1*,and specific SLC-family transporters. These changes aligned with gene ontology themes such as *Regulation of Endocytosis, Cell-Cell Adhesion, Cell-Matrix Adhesion, Cell Migration,* and *Abnormality of the Cerebral Vasculature.* Further, TEM analysis revealed a time-dependent shift in endothelial structure, with a decrease in the number of endothelial caveolae and an increase in cytoplasmic vacuoles. Sonicated capillaries demonstrated granular deposits within the basement membrane, and rarefaction of the cytosol.Our transcriptional data are likely reflective of the mechanical nature of LIPU/MB-mediated BBB dysfunction, where the endothelium is attempting to reestablish inter-cellular connections and to reattach to the basement membrane, while simultaneously addressing the ionic imbalances induced by transient BBB dysfunction. We also observed transcriptional and TEM evidence of diminished caveolar transcytosis shortly after LIPU/MB, which could reflect the secondary ability of caveolae to serve as membrane buffers that accommodate to mechanical stretching of

the cell membrane. Future studies should investigate these pathways as mechanisms of barrier repair for neuro-protective benefit in other models of BBB dysfunction.

Abstract: Brain vascular dysfunction contributes to the development of neurodegenerative disorders, including Alzheimer's disease (AD). We and others have shown that pericytes, which are vascular mural cells embedded in the wall of brain microvessels, play an essential role in regulating blood-brain barrier (BBB) integrity, controlling cerebral blood flow, clearing neurotoxins, providing neurotrophic support, and angiogenesis. Previous studies by our group have shown that pericyte degeneration and loss occurs in AD and that pericyte loss in the AD mouse model results in a significant increase in BBB leakage and neuronal loss. The goal of the present investigation is to generate and characterize induced pluripotent stem cell (iPSC)-derived forebrain pericytes (iPSC-PCs), then to assess their potential as a cell therapy treatment. First, we show by quantitative proteomic analysis that iPSC-PCs share 96% of total proteins and 98% of protein phosphorylation sites with primary adult human brain pericytes. Then, we show that

iPSC-PCs home to microvessels in live brain tissue slices from pericyte-deficient mice. Finally, we show that transplantation of iPSC-PCs into hippocampi of pericyte-deficient mice leads to restoration of BBB integrity and improved neuronal retention. These fully-characterized iPSC-PCs that share molecular and phenotypic similarities with endogenous human adult brain microvascular pericytes hold potential as a future non-neuronal, pericyte-based cell therapy for AD and related neurodegenerative disorders.

Abstract: Strokes and bleeding in brain parenchyma are cerebrovascular events that can cause long-term dysfunction. Stroke alone affects >795,000 people in the U.S. annually. The occurrences of strokes and microbleeds are not random; they occur in the early day and early night. Intracerebral bleeding will cause further havoc to brain homeostasis by increasing permeability of the blood-brain interface (BBI). Recent evidence suggests that components of the BBI are under circadian regulation, but the circadian dynamics of the BBI endothelial cells' circadian clocks and tight junction proteins are yet to be determined. In this report, we studied the daily variations of BBI endothelial cells isolated from mice bearing a clock fluorescent reporter, Per1-Venus. We found that after synchronization of BBI endothelial cells by dexamethasone, Per1-Venus expression over 24-h peaked at 8-h and 16-h post-synchronization ($p < 0.0001$, one-way ANOVA of mean fluorescent intensity (MFI)). The clock reporter expression in isolated brain microvessels showed a similar pattern of variation. The permeability of the BBI is determined by tight junctions between brain endothelial cells and, thus, may be

influenced by circadian rhythms. Hence, we also investigated a key tight-junction protein of rodent brain microvessels, Claudin-5. We examined temporal expression and localization of Claudin-5 over the day-night cycle. Based on western blot and immunofluorescent results, we found two significant peaks of Claudin-5 expression and localization over 24-h ($p < 0.001$, one-way ANOVA of MFI). We performed transepithelial/transendothelial electrical resistance (TEER) assays to measure barrier tightness between primary brain endothelial cells. The TEER assay is non-invasive and offers the advantage of continuously monitoring living cells throughout the circadian cycle. When we monitored the integrity and permeability of the *in vitro* barrier between endothelial cells for 4 days, we found that permeability fluctuated significantly according to time-of-day ($p < 0.001$, one-way ANOVA of TEER measurements). We found two daily peaks in permeability about 12-h apart. Our findings indicate that endothelial cells of the BBI possess self-sustained autonomous clocks, circadian-dependent expression of the tight junction protein, Claudin-5, and time-of-day-dependent variation in a functional measure of permeability. These results may address the periods of vulnerability to stroke and cerebral microbleeds in early morning and evening. Further research will contribute to the prevention, treatment, and long-term care for stroke patients based on circadian rhythms.

Title: Role of extracellular vesicles in iron transport to the mice brain

Authors: *K. PALSA[1], E. NEELY[1], I. A. SIMPSON[2], J. R. CONNOR[1];
[1]Neurosurg., [2]Neural and Behavioral Sci., Penn State Col. of Med., Hershey, PA

Abstract: Iron is essential for normal brain development and function. Hence, understanding the mechanisms of iron efflux at the blood-brain barrier and their regulation is critical for establishing brain iron homeostasis. Herein we investigated the role of extracellular vesicles (EVs) in mediating the transfer of Transferrin (Tf) bound iron to the mice's brains. EVs secretion is prevented by inhibition of neutral sphingomyelinase 2 (nSMase2), a key regulatory enzyme generating ceramide from sphingomyelin, with GW4869. Using the C57BL/6 mice, we show that intraperitoneal injection of GW4869 reduces the levels of brain and serum EVs compared to the control. When mice were injected intraperitoneally with ^{57}Fe-Tf, the ^{57}Fe concentration in the brain parenchyma was decreased compared to the control group. Furthermore, the EVs inhibition increased the retention of ^{57}F in the brain microvasculature compared to the control group

suggesting ^{57}Fe-Tf uptake into the microvasculature is not interrupted but release into the brain is negatively impacted. In addition, EVs synthesis inhibition decreased the serum iron levels, whereas the liver iron levels increased compared to the control group. These results indicate that blood-brain barrier endothelial cells release EVs and those EVs are mediating a major iron delivery pathway to the brain.

Title: A mouse model of the CCM1/KRIT1 mutation causing human cerebral cavernous malformations

Authors: *K. SHARIFI[1], Z. SAIZ[2], D. ANTROBIUS[2], W. XU[2], P. TVRDIK[3];
[1]Neurosurg., Univ. of Virginia Neurosci. Program, Charlottesville, VA; [3]Neurosurg., [2]Univ. of Virginia, Charlottesville, VA

Abstract: Cerebral cavernous malformations (CCM) are typically modeled in the mouse using conditional Cre/lox recombination systems, resulting in the deletion of a large portion of the causative gene after induction with tamoxifen. However, these genetic changes are not consistent with human neuropathology, which is usually due to single nucleotide polymorphisms (SNP), or small DNA rearrangements such as microdeletions. This discrepancy complicates experimental approaches to gene therapy in the mouse model. To provide a more translational genetic system, we injected fertilized mouse eggs with Cas9, sgRNA, and ss donor DNA to mutate codon # 455 in *Krit1*, which is one of the most common pathogenic mutations in the human *KRIT1* gene. To this end, we created a 13-bp microdeletion in exon 11 of *Krit1*. This mutation causes a premature polypeptide termination, which is very similar to the nonsense Gln455Ter *CCM1(KRIT1)* mutation originally discovered in the Mexican-American Hispanic population. Next, the identified founders harboring the mutation were bred to *Krit1* "floxed" animals and the *Cdh5-CreERT2* strain. The animals harboring *Cdh5-CreERT2; Krit1-flox/13del* animals were induced with tamoxifen on postnatal day P5 and the mice were characterized with MRI and histology. We found that the 13del allele is pathogenic and causes brain lesions. We have also found splenomegaly in these mice that appears to be related to enlarged blood vessels in splenic red pulp. This phenotype leads to early mortality at 1-2 months of age. Our new model of *Krit1* can facilitate future approaches to gene therapy for this vascular disease.

Title: Physiological roles of the choroid plexus: lessons learnt from the zebrafish

Authors: *N. JURISCH-YAKSI[1], I. JEONG[1], S. N. ANDREASSEN[2], M. POULAIN[4], M. FÜRTHAUER[4], H.-C. PARK[5], N. MACAULAY[3];
[1]NTNU, Trondheim, Norway; [3]Univ. of Copenhagen, [2]Univ. of Copenhagen, Copenhagen, Denmark; [4]Univ. Côte d'Azur, Nice, France; [5]Korea Univ., Ansan, Korea, Republic of

Abstract: The choroid plexus produces cerebrospinal fluid (CSF) in the brain, by uptaking nutrients and water from blood vessels via various transporters. Disturbed fluid homeostasis by the choroid plexus is one of common causes of hydrocephalus. Accumulating evidence suggests that the choroid plexus plays additional roles in brain development and homeostasis by secreting neurotrophic molecules, serving as a CSF-blood barrier and an immune interface. Yet, how the choroid plexus impacts brain physiology remains understudied. To provide novel insights into the physiological roles of the choroid plexus, we use zebrafish juvenile and adult as model systems. We first identified upon histological and transcriptomic analyses that the zebrafish choroid plexus is highly conserved with the mammalian choroid plexus and that it expresses all transporters necessary for CSF secretion. Using a novel transgenic line, we also identified that the choroid plexus actively secretes proteins into the CSF. Next, we developed a genetic tool to ablate epithelial cells specifically in the choroid plexus. Using the ablation system, we identified a reduction of the ventricular volume but no leakage of tracers at the CSF-blood barrier. Altogether, we observed that the zebrafish choroid plexus is evolutionarily conserved and critical in maintaining CSF homeostasis, which sets the basis for our long-term goal to unravel how the choroid plexus modulates brain physiology in health and diseases.

Abstract: The blood-brain barrier (BBB) plays a vital role in the exchange of molecular substances between the blood and brain to maintain central nervous system (CNS) homeostasis and its proper function. The barrier property of the BBB is given by endothelial cells in the blood vessels in the brain. The tight control of the molecular transport via endothelial cells is necessary to supply nutrients and protect the brain from toxic substances, and the BBB dysfunctions underlie the pathophysiology of several neurological disorders and psychiatric disorders. Thus, it is important to identify key molecular factors and pathways mediating transport mechanisms in endothelial cells and investigate their alterations in brain disorders. We have found that Ahnak expressed in vascular endothelial cells (EVs) in the brain is a novel regulator of behavioral adaptations in response to chronic stress. In a mouse chronic social defeat stress (CSDS) paradigm, the protein levels of hippocampal Ahnak are lower in stress-resilient mice but higher in stress-susceptible mice compared to the levels in non-defeated mice, being inversely correlated with social interaction scores. Ahnak is highly expressed in ECs in the hippocampus. However, the function of Ahnak in vascular ECs is unknown. To investigate Ahnak function in ECs, we have generated EC-specific Ahnak KO mice. Interestingly, EC-specific Ahnak KO mice display baseline antidepressant-like behavior and stress-resilient phenotype in the CSDS paradigm. We have also observed that EC-specific Ahnak deletion does not cause BBB disruption, and Ahnak does not colocalize with tight junction proteins. Instead, Ahnak protein is mainly expressed in vesicles in ECs. Our EC-specific translational profiling data indicates alterations of several molecule transporters in Ahnak-deleted ECs. Our study suggests that antidepressant-like behavior or stress resilience can be induced by targeting Ahnak pathway in vascular endothelial cells in the brain.

Title: Multiple exposures to the anesthetic sevoflurane cause blood vessel regression in the neonatal mouse hippocampus

Authors: *Y. MATSUMOTO, M. TORII;
Children's Natl. Hosp., Washington, DC

Abstract: Children who receive multiple exposures to anesthesia for surgery may have an increased risk of developing cognitive impairment. Sevoflurane, a commonly used anesthetic in clinical practice, has been reported to induce permeability of the adult blood-brain barrier (BBB), which is pivotal to maintain the homeostasis of brain microenvironment, leading to perioperative neurocognitive dysfunction. However, the effect of sevoflurane on blood vessels in the neonatal brain remains unclear. This study aims to reveal the impact of multiple exposures to sevoflurane on the vasculature of the hippocampus in neonatal mice. C57BL6/J mice in the anesthesia group received inhalation of sevoflurane (3%) plus 40% oxygen (balanced with nitrogen) for 2 hours daily for 3 consecutive days (P6 to P8). Mice in the control group received only 40% oxygen. Brain slices were collected on post-anesthesia day (PAD) 1, 7, 14, 21, and 28, and stained for the basement membrane and endothelial cells with anti-CollagenIV and anti-CD31 antibodies, respectively, to investigate structural changes in brain blood vessels after anesthesia. Some parts of CollagenIV+ blood vessels in the CA1 regions of the hippocampus lacked CD31 expression, as an indication of the blood vessel regression. The number of such CollagenIV+/CD31- blood vessels per field of view in the anesthesia group (mean ± SD: 5.33 ± 3.3, n=6) was higher than that in the control group (1.00 ± 0.63, n=6) on PAD7. This number on PAD7 was also higher than those on PAD1 (2.50 ± 1.4, n=6) and PAD28 (1.83 ± 1.7, n=6) in the anesthesia group. The CollagenIV+/CD31- blood vessels on PAD28 lacked cell nuclei assessed by 4’,6-diamidino-2-phenylindole (DAPI) staining, suggesting the loss of endothelial cells on those blood vessels. We also detected extravascular IgG around the CollagenIV+/CD31- blood vessels, indicating BBB breakdown. These results collectively suggest that multiple exposures to sevoflurane induce pathological regression of blood vessels in the neonatal hippocampus through its impacts on endothelial cells, causing the breakdown of BBB and disrupting the homeostasis of brain microenvironment. These findings would facilitate mechanistic studies on anesthesia-induced neurotoxicity in young patients.

Title: Applications of a human iPSC-derived blood-brain barrier (BBB) model

Authors: M. E. DONEGAN, C. A. SAVIC, M. K. LIVINGSTON, K. TOMOTOSHI, R. K. FIENE, *J. LIU, R. VAIDYANATHAN, C. B. CARLSON;
FUJIFILM Cell. Dynamics, Madison, WI

Abstract: The blood-brain barrier (BBB) is a specialized network of cells that function to maintain a tightly controlled microenvironment around the brain. A robust BBB model is needed to evaluate barrier function, test drug permeability, and study how different diseases can affect it. Harnessing the power of iPSC technology, we were able to generate specific cell types of the human brain required to assemble such a model, including astrocytes, pericytes, & brain microvascular endothelial cells (BMEC). Importantly, the same donor iPSC line (01279) was used to make each of these cell types, yielding a fully isogenic tri-culture system. Marker expression and other cellular characterization data has been presented previously; therefore, we focused on the functional performance of the BBB model in various assay platforms. The traditional trans-endothelial electrical resistance (TEER) assay using cell culture inserts resulted in robust & reproducible signal (>1500 ohms▪cm^2) after 3 days. TEER measurements were further investigated using impedance-based instrumentation and barrier disruption with VEGF and mannitol was quantified. BBB permeability of fluorescent dextran molecules was assessed, and the apparent permeability of drug compounds (e.g., atenolol, caffeine, chlorpromazine, & propranolol) was quantified via LC-MS/MS. Generation of 3D spheres was accomplished using ULA plates and imaging revealed insightful structural features. Development of a receptor-mediated transcytosis assay was also initiated, beginning with characterization of transferrin receptor expression and evaluation of detection techniques. Finally, integration with emerging organ-on-a-chip technologies, such as MIMETAS OrganoPlate and Emulate Brain Chip, offers a unique way to further enhance biological complexity. Importantly, the keys to success here were consistency of supply made possible by differentiation at-scale resulting in large batches of cells, cryopreservation of all three cell types for subsequent on-demand use, and an optimized formulation of media/supplements to enable long-term survival. Taken together, this study highlights the modular and flexible nature of an isogenic human iPSC-derived BBB model as a new capability to advance the understanding of BBB function with respect to human health and disease.

Title: Role of Sigma-1R in modulating the blood-brain barrier permeability

Authors: J. L. BARR[1], E. BRAILOIU[1], S. INAN[1], E. M. UNTERWALD[1], ***G. C. BRAILOIU**[2];
[1]Ctr. for Substance Abuse Res., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA;
[2]Jefferson Col. of Pharm., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Sigma-1R is an intracellular chaperone protein residing on the endoplasmic reticulum at the mitochondrial-associated membrane (MAM) region. Upon agonist stimulation, Sigma-1R dissociates from the complex with other proteins and translocates to the cell membrane where it regulates the function of receptors and channels, or to the nucleus where it regulates gene transcription. Sigma-1Rs are significant regulators of signaling, gene expression, and cell function in physiological conditions and disease states. We previously reported that Sigma-1R is expressed in rat brain microvascular endothelial cells (RBMVEC). We now investigated the role of Sigma-1R on blood-brain barrier permeability *in vitro* using Electric Cell-substrate Impedance Sensing (ECIS) and *in vivo*, using Evans Blue extravasation method and live imaging, in rats. RBMVEC were cultured on gold electrodes of ECIS arrays. Sigma-1R agonist PRE084 produced a dose-dependent reduction in RBMVEC monolayer resistance; the response was reduced by pretreatment with Sigma-1R antagonist BD-1047. *In vivo* assessment of BBB permeability indicates that PRE-084 increased dose-dependently the Evans Blue brain extravasation; the effect was reduced by the Sigma-1R antagonist, BD-1047. We also directly visualized brain microcirculation in the prefrontal cortex of awake rats with a miniature integrated fluorescence microscope (aka, miniscope; Doric Lenses Inc) and sodium fluorescein. Miniscope studies indicate that PRE-084 increased sodium fluorescein extravasation *in vivo.* Taken together, our results indicate that Sigma-1R activation increased the BBB permeability *in vitro* and *in vivo.*

Title: Characterization and comparison of the blood-ganglion barrier in sympathetic versus sensory ganglia

Authors: *J. LI[1], R. KURUVILLA[2];
[1]Biol., [2]Johns Hopkins Univ., Johns Hopkins Univ., Baltimore, MD

Abstract: Proper neuronal function relies on selective barriers that maintain a homeostatic microenvironment of the nervous system. While barrier breakdown can lead to inflammation, neuronal damage, and potentially neurological diseases, an intact barrier can also be a challenge for therapeutic delivery. The blood-brain barrier (BBB) in the central nervous system (CNS) is well studied. However, the blood barrier in the peripheral nervous system (PNS) is poorly understood. In the PNS, the sympathetic nervous system controls the body's "fight or flight" response to stress and maintains body homeostasis, while the sensory nervous system is responsible for transmitting sensory information from the body to the brain. The cell bodies of sympathetic and sensory neurons are found in clusters called ganglia, where in addition to neuronal cell bodies, the ganglia contain non-neuronal cells including satellite glial and vascular cells. The goal of this study is to understand the structure and function of the blood-ganglion barrier (BGB) in sympathetic and sensory ganglia. Using tracer injections, we found that the permeability of blood vessels is different between sympathetic and sensory ganglia, with that in sensory ganglia being leakier than in sympathetic ganglia. The BBB function in the CNS is mainly conferred by endothelial cells with their specialized tight junctions and low level of transcytosis, as well as by other cell types, including pericytes and astrocytes, which contribute to barrier formation and maintenance. To identify the cellular and molecular bases for the differential vascular permeability between sympathetic and sensory ganglia, we are currently identifying the cellular unit of the BGB using whole mount immunostaining to label endothelial cells, pericytes, and satellite glial cells, the latter proposed to be analogous to astrocytes. We are assessing the expression and distribution of candidate tight junction proteins, including Claudin-5, ZO-1, and Occludin, which are known to be critical for BBB structure and function. We are also visualizing transcytosis in endothelial cells in peripheral ganglia using tracer injections and electron microscopy. Together, these studies will provide rare insight into the cell types and molecular mechanisms that define a blood barrier in peripheral ganglia, which will facilitate new treatments for pathologies that affect the peripheral nervous system.

Title: The state-gate hypothesis: Key behavioral events and VTA activity predict rapid increases in local blood-brain barrier permeability

Authors: *S. FEKIR[1], K. TURNER[2], S. SCOTT[2], A. SHANKAR[2], E. KLEIN[2], B. R. GALLAGHER[3], C. DEISTER[2], Y. ZHAO[4], C. I. MOORE[2];

Abstract: Adaptive behavior depends on body state: The correct response to sensory inputs, and learning from decisions, requires a detailed understanding of current needs. Signals within vessels are a well-established source of such internal context, including hormonal, metabolic, and immunological indicators. However, the blood-brain barrier (BBB) is believed to sharply restrict such transmission, as sustained increases in permeability are a major health risk. Here, we test a resolution to these competing needs for information versus protection: **We predict the BBB is dynamic, providing increased access to body state at the time, and in Forebrain regions, where behaviorally relevant information is worth the risk.** This 'State-Gate' Hypothesis predicts that many brain systems that index relevance may exert such control. The Ventral Tegmental Area (VTA) is an ideal candidate, as its activity signals behavioral relevance and its axons closely encircle Forebrain vessels. We use 2-photon imaging, optogenetics and behavioral training to test this State-Gate/VTA-BBB Hypothesis. To track rapid changes in BBB permeability, we inject fluorescent molecules IV (e.g., 70kD Rhodamine B) and test if they are transmitted to parenchyma of mouse Primary Somatosensory Neocortex. **Our Preliminary Data supports this prediction**. During consolidation of a novel sensory association, **BBB permeability increases at cue onset and reward** (N = 3 mice). Axons from rostral VTA neurons ramify in SI (N=21 mice: Aransay et al., 2015). **Selective optogenetic activation (Chrimson) in these axons drives BBB permeability, and their endogenous calcium 'spikes' (GCaMP) predicts it** (N= 6 mice, 63 axons, 21,666 spikes). **Behavioral, optogenetic and spike-aligned data show similar rapid (> 250 ms) and discrete increases in permeability**, suggesting a common mechanism**.** In sum, in contrast to the common conception, we find the BBB responds rapidly, and is well-positioned to relay behaviorally relevant state information for integrated computations that produce adaptive behavior. These findings may have clinical import: In Alzheimer's Disease, mesocortical DA projections and the BBB are substantially altered: Failed communication between them may contribute to behavioral and health deficits. More generally, BBB compromise is central to many conditions, including addiction and sleep disorders, that are also associated with altered DA signaling.

Title: Neural population dynamics in the midbrain and pons during sleep

Authors: *D. LOZANO, J. STUCYNSKI, S. CHUNG, F. WEBER;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Rapid eye movement (REM) sleep is characterized by a desynchronized electroencephalogram (EEG), muscle atonia, and vivid dreaming. The core circuits generating REM sleep are distributed throughout the brainstem and are composed of REM sleep-promoting (REM-on) and REM sleep-suppressing (REM-off) neurons. While much progress has been made in identifying specific neuronal populations that promote or suppress REM sleep, the neural dynamics that arise from the interactions between these REM regulatory populations and the dynamical mechanisms which gate transitions into REM sleep are largely unknown. We have previously demonstrated using optogenetic manipulations in mice that GABAergic neurons in the dorsomedial medulla (dmM) promote the induction of REM sleep via their projections to the dorsal and median raphe nuclei. To identify the neural dynamics within these downstream areas underlying NREM-to-REM sleep transitions, we employed Neuropixels probes to record the population activity in the dorsal and medial raphe, as well as neighboring midbrain and pontine brain areas, during spontaneous sleep in mice. We applied principal component analysis (PCA) to describe the population dynamics across the recorded brain regions. We found that the population activity during NREM and REM sleep is captured within low-dimensional subspaces. Furthermore we found that wakefulness, NREM, and REM sleep correspond to distinct areas along the trajectories traversed by the population activity within the PCA space. The REM sleep promoting effect of dmM stimulation largely resulted from an activation of REM-on and inactivation of REM-off neurons, effectively forcing the population activity towards REM sleep. Overall, these results demonstrate that the population activity during sleep in midbrain and pons areas are low-dimensional and provide a geometric description of how inputs from the REM promoting dmM neurons affect the population dynamics within these areas to induce NREM to REM sleep transitions.

Title: Cortical regulation of two-stage REM sleep

Authors: *D. YUFAN[1], J. LI[1], M. ZHOU[1], Y. DU[2], D. LIU[1];
[1]Inst. of Neuroscience, CAS, Shanghai, China; [2]Arizona State Univ., Arizona State Univ., Tempe, AZ

Abstract: The sleep-wake cycle, including rapid eye movement (REM) sleep and non-REM sleep, are generally considered to be primarily regulated by distributed subcortical circuits, and cortical regions are involved in generating sleep-related EEG oscillations. However, recent studies showed that cortical neurons could be actively involved in non-REM sleep generation and homeostatic sleep regulation. Although cortical activation during REM sleep is considered to be associated with vivid dreaming, the global cortical dynamics and its role in regulating REM sleep remain unclear. Cortex-wide calcium imaging showed that REM sleep was accompanied by highly-patterned cortical activity waves, with the retrosplenial cortex (RSC) as a major initiation site. Two-photon imaging of layer 2/3 pyramidal neurons of RSC revealed two distinct patterns of population activities during REM sleep. These activities encoded two sequential REM sleep substages, characterized by contrasting facial movement and autonomic activity, and distinguishable EEG theta oscillation. Closed-loop optogenetic inactivation of RSC during REM sleep altered cortical activity dynamics and shortened REM sleep duration via inhibiting the REM substage transition. These results highlight a critical role of RSC in dictating cortical dynamics and regulating REM sleep progression.

Title: Diverse, state-dependent modulation of local and long-range circuit elements in the retrosplenial cortex across the wake-sleep cycle

Authors: C. N. BERGE[1], E. HENNESTAD[1], K. VERVAEKE[1], A. R. CHAMBERS[2];
[1]Dept. of Mol. Med., Univ. of Oslo, Oslo, Norway; [2]Dept. of Otolaryngology, Head and Neck Surgery, Harvard Med. Sch., Boston, MA

Abstract: Across the wake-sleep cycle, cortical networks engage in large-scale oscillations associated with distinct cognitive functions. During active wakefulness (AW), theta rhythms organize hippocampal-cortical activity to support navigation. Quiet wakefulness (QW) and sleep support learning and memory via hippocampal sharp-wave ripples (SWRs), sleep spindles, and slow waves. Cortical circuits flexibly shift information processing regimes in a state-dependent manner, but the implementation of this at the cellular level is unclear. The retrosplenial cortex (RSC) is involved in state-dependent functions, e.g. sensory-motor processing, memory and sleep regulation, and receives a dense projection in layer 1 from the thalamus, which is implicated in state control. Due to the difficulty of measuring precise circuit activity across the wake-sleep cycle, it is not known whether state-dependent changes in RSC activity reflect thalamic inputs or are generated locally, and to what degree they differ by cell type. To explore this, we used two-photon calcium imaging and electrophysiology to monitor excitatory and inhibitory neurons and thalamic axons in RSC across the wake-sleep cycle in mice. We virally targeted GCaMP exclusively to the somata of local neurons and to thalamic axons in the superficial layers of RSC. A nuclear marker identified inhibitory neurons. We detected states/ oscillations via LFP, ECoG and EMG recordings from hippocampus, neocortex, and neck muscles, respectively. State dependence was most prominent in thalamic axons, with mean activity highest in AW and REM sleep, followed by QW and NREM sleep. L2/3 excitatory cells were not strongly state modulated on average, apart from decreased activity during REM. Inhibitory neurons displayed diverse average activity profiles across states. We also observed slow, within-state activity ramps, which could signal past or future state shifts. These ramps occurred in RSC neurons and thalamic axons to differing degrees. Finally, as large-scale oscillations can take place in different states—e.g. SWR in QW and NREM—we asked whether RSC is modulated primarily by state, oscillation, or both. Thalamic SWR responses were similar whether they were in QW or NREM. By contrast, SWR responses in RSC neurons exhibited state dependence. Ongoing analyses ask whether state- or oscillation- dependence changes over days in the same cells. In summary, thalamic axons convey a dense state-dependent activation to superficial RSC, but local neuron subtypes exhibit diverse modulation to states and oscillations across the sleep-wake cycle. This may underlie RSC's participation in diverse brain functions across states.

Title: Somato-dendritic decoupling in the Retrosplenial cortex neurons during REM sleep

Authors: M. BORSA, M. AIME, *A. ADAMANTIDIS;
Univ. of Bern, Bern, Switzerland

Abstract: Rapid eye movement (REM, also called paradoxical) sleep correlates with enhanced cellular activity in region-specific thalamo-cortical circuits and subcortical structures including the hippocampus, midbrain or hypothalamus. This REM sleep specific neuronal activity is hypothesized to promote structural plasticity and provide a window for the consolidation of contextual and emotional memories previously acquired during wakefulness, yet the underlying mechanism remains unclear. Amongst the cortical structures, the activity of neurons located in the retrosplenial cortex (RSC) is increased during REM sleep. Here we characterized the activity of RSC microcircuit across the sleep-wake cycle using simultaneous 2-photon calcium imaging and electrophysiological recordings in spontaneously head-restrained sleeping mice. We observed a REM sleep-specific reduction of pyramidal cell somatic activity concomitant to the activation of the interneurons expressing either parvalbumin (PV), somatostatin (SST) or vasoactive intestinal peptide (VIP). Furthermore, preliminary results showed a partial pyramidal somato-dendritic decoupling in REM sleep with an increase in local dendritic activities as compared to sporadic global events. Collectively, these observations suggested a region-specific fine-tuning of excitatory/inhibitory balance in RSC during REM sleep that may be involved in synaptic plasticity and contribute to information integration, memory consolidation and ultimately behavioural optimization.

Title: Circadian control of dorsolateral bed nucleus of the stria terminalis ($BNST_{DL}$) via hypothalamic vasopressin (AVP) projections

Authors: *L. M. MONROY[1], S. H. OLSON[1], V. GRINEVICH[2], J. DABROWSKA[1];
[1]Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Lab. of Neuropeptides, German Cancer Res. Ctr. and Central Inst. of Mental Hlth., Heidelberg, Germany

Abstract: The bed nucleus of the stria terminalis (BNST) is a limbic forebrain structure that regulates many physiological and behavioral processes, notably, fear and anxiety-like behaviors. The BNST receives inputs from many hypothalamic nuclei that regulate crucial physiological processes (water/electrolyte balance, temperature regulation, feeding, wake/sleep cycle). Our current studies demonstrate that hypothalamic hormone and neuromodulator arginine-vasopressin (AVP) has a direct excitatory effect on neurons in dorsolateral BNST ($BNST_{DL}$), particularly neurons expressing striatal-enriched protein tyrosine phosphatase (STEP). However, the source of specific peptidergic inputs containing AVP in the $BNST_{DL}$ are elusive. Hence, we used AVP-Cre transgenic rats (Cre-recombinase under the AVP promoter) injected with Cre-dependent pAAV hSyn Flex mGFP-2A-Synaptophysin-mRuby into the suprachiasmatic nucleus (SCN) or the supraoptic nucleus (SON) of the hypothalamus and we show that both these nuclei send AVP-containing inputs to the $BNST_{DL}$. To determine whether the SCN and $BNST_{DL}$ have synchronous activity, we quantified immunoreactivity patterns for AVP and STEP in the SCN and $BNST_{DL}$ across four zeitgeber times in rats housed in 12:12 light-dark cycles. We used STEP as an indirect marker of $BNST_{DL}$ neuronal inactivity. We found the highest AVP expression in the SCN occurred at ZT 11, which corresponded to the lowest STEP expression in $BNST_{DL}$ neurons, whereas the lower AVP expression in the SCN and higher STEP expression in $BNST_{DL}$ occurred at ZT 1. These results suggest that SCN-AVP and $BNST_{DL}$-STEP neurons show direct relationship, such as the higher AVP-SCN signals, the more active (expressing less STEP) $BNST_{DL}$ neurons are. We next used the Period2 Clock protein (PER2), a key gene of the circadian clock, to determine whether the SCN imposes circadian control over the $BNST_{DL}$. We found higher PER2 expression at ZT 1 in the $BNST_{DL}$ and SCN compared to PER2 expression at ZT 11. These results demonstrate an anatomical and functional connection between the SCN and $BNST_{DL}$ and have implications on how changing physiological conditions, in particular the wake/sleep cycle, through AVP prompt, can directly impact BNST activity and BNST-dependent fear- and anxiety-related behaviors.

Title: Regulation of sleep and wake by corticotropin-releasing hormone neurons in the paraventricular nucleus of the hypothalamus

Authors: *A. WIEST, S. CHUNG;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Sleep is characterized by transitions between different vigilance states: wake, rapid eye movement (REM) sleep, and non-REM (NREM) sleep. As sleep has many beneficial and restorative effects, good quality sleep is important for mental and physical health. It has been well established that stress and sleep have a bidirectional relationship. Stress is known to be a major cause of disrupted sleep. Chronic sleep disruption can lead to an increased risk of developing psychiatric disorders. Studies have shown that there is a strong relationship between stress and impaired memory consolidation. Likewise, sleep disturbances can lead to memory impairments. The paraventricular nucleus of the hypothalamus contains corticotropin-releasing hormone (CRH^{PVN}) neurons that become activated by stress. Central or systemic administration of CRH induces wakefulness. While CRH has been implicated as a regulator of wakefulness, the role that CRH^{PVN} neurons play in the sleep-wake cycle after stress has not been fully investigated.We hypothesized that inhibition of CRH^{PVN} neurons during acute stress improves sleep and, subsequently, enhances performance on a hippocampus-dependent memory task. When mice were subjected to acute restraint stress, NREM and REM sleep were significantly decreased while wake was increased within the first few hours following the stress. When CRH^{PVN} neurons were inhibited during restraint stress, NREM and REM sleep percentages were increased and wake percentage was decreased compared to restraint stress only control mice. Because sleep is crucial for memory, we also tested memory consolidation with a hippocampus-dependent task, spatial object recognition. Mice that underwent restraint stress after training had impaired memory performance. However, mice with CRH^{PVN} inhibition during restraint stress after training performed better on the memory task. Thus, inhibition of a population of wake-promoting, stress-active neurons during restraint stress improved sleep and reversed memory consolidation deficits seen after restraint stress.

Title: Estrous cycle dependent changes in transient oscillation dynamics during sleep in the hippocampus and cortex of adult female rats

Authors: *R. JANG[1], G. R. POE[2];
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]Dept. of Integrative Biol. and Physiol., UCLA Chapter, Los Angeles, CA

Abstract: In mature female rats, the estrous cycle is characterized by fluctuating progesterone and estrogen hormones which are known to influence cognitive function, processing of emotionally salient memories, and sleep. Work from our lab has shown that sleep architecture and features of sleep critical for memory consolidation, such as slow oscillations and spindles, are modulated by the phase of the estrus cycle in a brain region-dependent manner. We sought to build on prior work by using the Dynamic Oscillations (Dynam-O) toolbox to characterize time-frequency coupling dynamics of local field potentials across the estrus cycle in females. We used slow oscillation power as the objective measure of sleep depth, enabling characterization of sleep as a continuous time-varying process as opposed to restricting analyses to discretized states. *We hypothesized that females would show changes in the density of transient oscillatory events coupled to slow oscillation (SO) power in an estrous cycle dependent manner.*
Four adult female rats were implanted with electrodes in the CA1 region of the hippocampus and medial prefrontal cortex and recorded across sleep and wake. Estrous cycle tracking was performed by histological determination. Distinct time-frequency (TF) peaks from the spectrogram were detected using the MATLAB implementation of the watershed method in the Dynam-O toolbox. Individual TF-peaks in the 4-25 Hz range were identified for all animals across each phase of the estrus cycle using recordings from the first 6-hours of the lights-on period. Within this range, clear theta and spindle events were observed. The density (# events/min) and proportion of TF-peak occurrences remaining after noise removal (~2% of peaks) were analyzed relative to power and phase of SO events (0.3-1.5 Hz) to generate TF-power and TF-phase histograms. We then compared high hormone (HH) vs low hormone (LH) days. We found distinct regions of the SO power histograms correspond to sleep/wake states when compared to sleep staging by an expert scorer. Additionally, density of events that are coupled to the SO varied by frequency in an estrous phase and brain region dependent manner. For example, when compared to LH, in the HH condition the hippocampus showed decreased while the cortex showed increased spindle (10-16 Hz) density during NREM sleep. Furthermore, they were differentially coupled to SO phase such that the hippocampus showed greater spindle coupling at the SO-trough, while the cortex showed enhanced coupling at the SO-peak. Further research is needed to explore how these time-frequency dynamics influence learning and memory across the estrus cycle.

Title: Cholinergic modulation of network dynamics during NREM and REM sleep and their differential roles during sleep consolidation

Authors: M. SATCHELL[1], D. MCKINSTRY[2], S. ATON[4], *M. ZOCHOWSKI[3];
[1]Neurosci., Brandeis Univ., Waltham, MA; [2]Molecular, Cellular, and Developmental Biol., [3]Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Mchigan, Ann Arbor, MI

Abstract: Across vertebrate species, sleep states are known to cycle consistently from non-rapid eye movement (NREM) to REM sleep. However, the functional significance of these transitions is unknown. We use a simplified biophysical network model to show that state-specific changes in cholinergic signaling during NREM and REM sleep can mediate dramatic changes in network activity patterns and subsequently can play differential and critical role in sleep dependent memory consolidation. Specifically, we show that the sequential, bidirectional changes in cholinergic neuromodulation during these sleep states plays a vital role in consolidation, particularly when multiple memory traces are being stored simultaneously. In the low-ACh (NREM-like) state, the inhibitory interneurons regulating the activity of the principal cells are less active leading to network disinhibition and allowing for rapid recruitment of new cells into the memory engram, and their consequent enlargement. In the subsequent high-ACh (REM-like) state, ACh mediates activation of these interneurons that competitively suppress activity among newly recruited excitatory pyramidal neurons during prior NREM, leading to the orthogonalization of newly enhanced representations of different memory traces. We observe analogous suppression experimentally when Medial Septum cholinergic cells are activated optogenetically during NREM. We further find that, in the in silico model, this iterative sequence of state-specific activations during NREM/REM cycling is essential for memory storage in the network, serving a critical role during simultaneous consolidation of multiple memories. These results are contrasted to NREM-like only and, separately, REM-like only sleep.

Title: Different simultaneous sleep states in the hippocampus and cortex are associated with learning and memory in rodents

Authors: *W. PETTIBONE[1], C. ALDACO[2], K. SWIFT[5], B. T. RILEY[6], J. J. EMRICK[7], A. M. WIKENHEISER[3], G. R. POE[4];

Abstract: Sleep has long been assumed to be both unitary and global, that is, sleep states inferred from one region of the brain are thought to be representative of all other regions. Recent work has demonstrated that the brain may, in fact, be in multiple sleep states at once. Given the prominent role of sleep in many types of learning and memory consolidation, this novel asynchronous sleep phenomenon may play a role in how sleep helps to shape behavior and accommodate learning. We trained Long-Evans rats on four tasks: a motor learning task (the complex ladder), two spatial hippocampal tasks (the hidden goal task and the eight-box maze), and a cue-based striatal task (the light-cued circular maze), each over the span of seven days. Rats completed all seven days of one task before proceeding on to the next. On all four tasks, rats demonstrated continuous behavioral learning over the course of each week: markedly increased performance initially, followed by a gradual plateau. We recorded the rats' sleep simultaneously in motor cortex, hippocampus, and prefrontal cortex. Each recording channel was subsequently analyzed to determine sleep state. Asynchronous sleep was defined as any epoch in which at least one region was in a different sleep state than any other region. We found that, at baseline, asynchronous sleep comprised approximately 50% of total sleep time on average. There was no significant difference in the time each region spent in each stage. Asynchronous sleep initially increased as the rats learned each task, before settling back to a level close to baseline. Number of bouts of asynchronous sleep similarly increased and then declined. Rats that had a greater change in asynchronous sleep demonstrated improved performance on the task the next day. In the eight-box maze, hippocampal REM increased ($p < 0.05$, $n = 10$); in the rest of the tasks, the region-specific results remain to be assessed. These findings suggest that learning may be enhanced or modulated by different sleep states in an asynchronous manner.

Title: The population of GABAergic neurons in the ventrolateral periaqueductal gray is implicated in the occurrence of cataplexy in narcoleptic mice.

Authors: *S. JEONG[1,2], S. UCHIDA[2], S. SOYA[1,2], T. SAKURAI[1,2];
[1]Univ. of Tsukuba, Tsukuba / Ibaraki, Japan; [2]Intl. Inst. for Integrative Sleep Med. (WPI-IIIS), Tsukuba, Japan

Abstract: Cataplexy is characterized by sudden episodes of muscle atonia during wakefulness, often triggered by intense positive emotions, and is associated with the loss of orexin-producing neurons. It has been regarded as an abnormal intrusion of rapid eye movement (REM) sleep into wakefulness. Recent research has revealed the involvement of that glutamatergic neurons in the sublaterodorsal tegmental nucleus (SLD), especially those projecting to the ventromedial medulla (VMM) (referred to as $Glu^{SLD\rightarrow VMM}$ neurons), in muscle atonia during both cataplexy and REM sleep.By utilizing the cell-type-specific TRIO (cTRIO) method in *vGlut2-IRES-Cre* mice, we identified the upstream input neurons of $Glu^{SLD\rightarrow VMM}$ neurons, including those in the ventrolateral periaqueductal gray (vlPAG), deep mesencephalic nucleus (DpMe), and various other brain regions. These findings suggest that these neurons may play a role in the neural circuit underlying cataplexy and REM atonia.The vlPAG is known to be crucial in the regulation of REM sleep. However, its precise involvement in cataplexy remains incompletely understood. To address this, we conducted optogenetic activation of GABAergic neurons in vlPAG of narcoleptic mice. We injected Cre-dependent AAV carrying SSFO-eYFP into the vlPAG in *vGAT-IRES-Cre;orexin-ataxin3* male mice and stimulated these neurons with blue light during wakefulness. The activation increased the propensity of transitioning into cataplexy-like episodes (CLEs). To confirm whether the SLD acted as the downstream target of vlPAG GABAergic neurons, we optogenetically activated axons of vlPAG GABAergic neurons by implanting optic fibers into the SLD. This manipulation also increased the probability of inducing CLEs. Notably, these cataplexy-related effects were not observed when performing the same optogenetc manipulation of the vlPAG or its axons in non-narcoleptic mice. Taken, together, these observations suggest that there is a population of vlPAG GABAergic neurons that positively regulate the occurrence of cataplexy in midbrain region, acting as upstream regulators of SLD neurons. Although these findings appear to contradict previous research indicating an inhibitory role of the midbrain region in the regulation of REM sleep or cataplexy, these observations suggest that there may be specific regulation mediated by diverse populations within the ventrolateral periaqueductal gray (vlPAG).

Title: A role for interoceptive vGluT2-expressing neurons in the jugular-nodose ganglion of the left vagus nerve in the regulation of sleep architecture and spectral composition

Authors: *N. CHERRAD[1], A. OSORIO-FORERO[2], R. CARDIS[1], Y. EMMENEGGER[1], L. M. FERNANDEZ[1], P. FRANKEN[1], A. LUTHI[1];
[1]Univ. of Lausanne, Lausanne, Switzerland; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: When awake, external sensory stimuli and bodily sensations determine how we perceive our surroundings. Once asleep, we disconnect from the sensory environment and react poorly to external stimuli. However, little is known about how interoceptive stimuli are processed by the sleeping brain. The vagus nerve is a mixed sensory-motor nerve that interfaces between the autonomic periphery and the central nervous system. We asked whether stimulating specifically vagal sensory afferents modulates sleep. To address this question, we decided to use viral transfection techniques to enable a sustained chemogenetic activation of vGluT2-expressing neurons in the jugular-nodose ganglion of the left vagus nerve, in combination with polysomnographic, local field potential (LFP), thermistor, fiber photometry, in freely moving conditions after low (1.5mg/kg i.p.) or high (2.5mg/kg i.p.) CNO injections or NaCl at ZT0. Whole-cell patch-clamp recordings confirmed that our viral transfection approach targetted functional vagal glutamatergic synaptic contacts in the brainstem nucleus tractus solitarius. We found that chemogenetic activation of the vagal sensory afferents suppressed rapid-eye-movement sleep (REMS) in its major spectral and autonomic correlates in a dose-dependent manner. The REMS onset latency was increased from 13±2min after NaCl injection to 82±16min after low-dose (Wilcoxon-sign-rank-test, $p=4.8e^{-4}$, n=11) to 185±27min after high-dose CNO injection (Wilcoxon-sign-rank-test, $p=2.4e^{-4}$, n=11). Moreover, heart rate remained decelerated throughout the period during which REMS was not detectable. In contrast to the suppression of REMS, the spectral properties of non-REMS were moderately affected, with evidence for a minor increase in low-frequency power (delta (1.5-4Hz) (n=11, $p=1.8e^{-4}$, Student's-t-test) and slow oscillations (0.5-1.5Hz) (n=11, $p=6.6e^{-4}$, Student's-t-test) and a decrease in sigma (10-15Hz) power (n=11, $p=1.5e^{-4}$, Student's-t-test) after a low dose of CNO. To characterize more comprehensively the physiological correlates of sleep during elevated vagal activity, we measured the cortical brain temperature and found a drop in temperature (-4.3±3°C, n=7) after vagal sensory stimulation. The mechanisms underlying these alterations are currently being addressed using fiber photometry techniques in combination with LFP recordings. Our findings point to a major role for sustained vagal afferent activity in body-brain physiology in the balanced between non-REMS and REMS. Moreover, they indicate that vagus nerve stimulation could offer non-invasive strategies to improve sleep architecture in pathological conditions.

Title: Locus coeruleus activity fluctuations set a non-reducible time frame for mammalian NREM-REM sleep cycles.

Authors: *G. FOUSTOUKOS[1], A. OSORIO-FORERO[2], R. CARDIS[1], N. CHERRAD[1], C. DEVENOGES[1], L. FERNANDEZ[1], A. LUTHI[1];

Abstract: The noradrenergic locus coeruleus (LC) is both wake- and sleep-active. While the LC supports vital brain functions during wakefulness, it can both promote and disrupt sleep, leaving its roles for sleep unclear. Here, we show that the LC is essential for the progression of undisturbed sleep because it creates a non-reducible time frame for the non-rapid-eye-movement (NREM) sleep-REM sleep cycle. Fiber-photometric jGCaMP8s-based LC activity measures, closed-loop optogenetics and mouse sleep-wake monitoring revealed that LC showed ~50-s-activity fluctuations, of which high levels promoted NREMS and occasional spontaneous arousals, while low levels permitted NREMS-to-REMS-transitions. LC high activity prevented precocious REMS entries in the undisturbed NREMS-REMS cycle, and LC fluctuations spaced repeated REMS entries to no shorter than ~50-s-intervals during REMS restriction. A stimulus-enriched wake experience strengthened LC fluctuations, which contributed to subsequent NREMS fragmentation and delayed REMS. The LC fluctuations hence constitute a fundamental time interval for the NREMS-REMS cycle, but they can become sleep-disruptive as a result of prior wake experience.

Title: Altered locus coeruleus activity during sleep leads to age-related cognitive decline

Authors: V. N. COMPERE[1], M. ANDERSEN[1], A. TSOPANIDOU[2], T. RADOVANOVIC[2], M. NEDERGAARD[2], ***C. KJAERBY**[1];

Abstract: As we age, cognitive abilities as well as the quality of sleep decline. Sleep disturbances frequently precede the onset of dementia in neurodegenerative diseases and include an excessive number of micro-arousals. We and others recently demonstrated a link between micro-arousals and the norepinephrine (NE)-producing neurons of the locus coeruleus (LC), whereby periodic LC activity maintains and shapes memory consolidating NREM sleep domains. Interestingly, loss of LC neurons is reported both in aging and neurodegeneration and remaining LC neurons display altered functionality. In this project, we wanted to test the hypothesis that age-related LC dysfunction leads to cognitive decline through compromised regulation of memory consolidating NREM sleep domains. To answer this question, electroencephalograms (EEG) and electromyograms (EMG) recordings were combined with fiber photometric measures of NE and optogenetic manipulations of the LC in aged mice. We demonstrated that older mice display hippocampus-dependent cognitive decline and altered sleep composition in comparison to healthy young adult control mice. Furthermore, aged mice were less responsive to manipulations of the LC-NE system indicating reduced dynamics of the system. The less responsive LC-NE system was implicated in cognitive deficits, since LC manipulations during sleep could boost memory in young, but not old animals. These findings pave the way for future therapeutic investigations focusing on restoring sleep heterogeneity in the elderly generation to improve healthy aging.

Title: Evidence for a central pattern generator (CPG) controlling the ultradian sleep cycle

Authors: *L. FENK, J. L. RIQUELME, G. LAURENT;
Max Planck Inst. for Brain Res., Frankfurt am Main, Germany

Abstract: Sleep is ubiquitous in the animal kingdom, yet our understanding of its possible functions, its control and evolution, remains rudimentary. Two main sleep states have traditionally been distinguished in mammals – rapid-eye-movement (REM, also *paradoxical* or

"*dream sleep"*) and slow-wave (SW, also non-REM) sleep – but biphasic sleep is widespread, also exists in birds (Ookawa and Gotoh, 1964) and non-avian reptiles (Shein-Idelson, Ondracek et al., 2016; Libourel et al., 2018), and was recently reported in fish (Leung et al., 2019), suggesting a possibly common origin. Studying sleep in the Australian dragon *Pogona vitticeps*, we have previously described a reptilian homologue of the mammalian claustrum and its role in generating activity patterns characteristic of SW sleep (Norimoto, Fenk et al., 2020). By recording from the two claustra bilaterally, we then showed that claustrum activity is precisely coordinated across the midline during REM, but not during SW sleep, revealing a fundamental difference in inter-hemispheric coordination during the two main phases of sleep (Fenk et al., 2023). Exploring the possible identity and functional properties of circuits that could underlie the generation of the ultradian sleep cycle, we now provide evidence supporting the existence of a central pattern generator (CPG)-type circuit driving the regular alternation between SW and REM. Specifically, exploiting the accessibility of key brain structures together with the extreme regularity and short duration of the *Pogona* sleep cycle (~120 sec at room temperature, compared to 90-100 min in humans), we reveal two hallmarks of CPG circuits described in other systems: (1) phase-resetting in response to a phasic input, in conjunction with a clear phase dependence of the effectiveness of this perturbation in causing a phase delay or advance, respectively, and (2) entrainment of an identical rhythm in the awake state, in response to a regular sensory drive whose statistics match those of the natural sleep rhythm. These results are consistent with the existence of a CPG-type circuit driving the ultradian sleep rhythm, and lend support to early studies in mammals suggesting the existence of oscillator circuits in the brainstem (Kleitman, 1963; McCarley and Hobson, 1975).

Title: Crf neurons in the latera lpart of the interstitial nucleus of the anterior commissure promote wakefulness

Authors: *C. HUNG[1], S. UEDA[1], S. M. RAHAMAN1[1], M. YAMAMOTO[1], N. FUKATSU[1], S. TAKEMOTO-KIMURA[1], A. YAMANAKA[2], D. ONO[1];
[1]Univ. of Nagoya, Nagoya city, Japan; [2]Chinese Inst. for Brain Res., Chinese Inst. for Brain Research, Beijing(CIBR), Beijing, China

Abstract: Sleep and wakefulness are regulated by numerous factors, such as stress and physiological illness. Among various stressors, novel environmental induces an acute pattern of sleep disturbances similar to stress-induced insomnia in humans. However, it remains unclear how the novel environment affects sleep and wakefulness. To clarify, we performed c-Fos staining after exposure to the novel environment. We found that the number of c-Fos positive neurons was increased in several brain regions, such as corticotropin-releasing factor (CRF)-producing neurons in the paraventricular nucleus (PVN), the lateral part of the interstitial nucleus of the anterior commissure (IPACL). CRF, a key stress-responsive molecule, has been previously shown to promote wakefulness through PVN-CRF neurons. Thus, we focused on investigating the role of IPACL-CRF neurons in sleep and wakefulness. To investigate the function of IPACL CRF neurons in sleep and wakefulness, we employed the designer receptors exclusively activated by designer drugs (DREADD) system via viral injection, and vigilance states were assessed using electroencephalography (EEG) and electromyography (EMG). Our results revealed that the activation of IPACL-CRF neurons increased wakefulness. Inhibiting these neurons did not affect sleep/wakefulness, but reduced novel-environment-induced wakefulness. These results suggest that IPACL-CRF neurons promote wakefulness under novel environments. Further experiments are necessary to clarify how the IPACL-CRF neurons promote wakefulness.

Title: Characterization of Sleep/Wake and EEG Spectral Patterns in Chrna4 and Chrna5 Null Mutant Mice

Authors: *H. L. MATHEWS[1], J. A. STITZEL[2], S. AKI[3], M. BROWN[3];
[1]Inst. for Behavioral Genet., [2]Inst. Behav Genet., [3]Univ. of Colorado Boulder, Boulder, CO

Abstract: The sleep/wake cycle is a complex process involving numerous brain regions and neurotransmitter systems. The cholinergic system is involved in the promotion of cortical arousal and the initiation and modulation of REM sleep. Little is known about the contribution of nicotinic cholinergic receptors (nAChRs) in sleep and wakefulness. The present study examined the sleep/wake cycle and EEG spectral patterns in male C57BL/6J (C57), and genetically null mutant mice for either Chrna4 [α4(-/-)] or Chrna5 [α5(-/-)]. Relative to C57 mice, both α4(-/-) and α5(-/-) had decreased NREM sleep during the active phase (AP). Conversely, α4(-/-) showed increased REM during the inactive phase (IP) compared to C57 mice. The most robust finding with regard to the sleep/wake cycle was the observation of increased sleep fragmentation in α4(-

/-) mice compared to both C57 and α5(-/-) mice. This effect was observed during both phases. When examining individual sleep states, NREM sleep in α4(-/-) was severely fragmented during both phases, while REM sleep was only affected during the IP. These results suggest a role of α4(-/-) in NREM sleep consolidation during both phases, and a role of α4(-/-) in REM sleep consolidation during the IP only. Several between genotype differences were also observed in EEG spectral patterns. Significant findings include decreased relative theta rhythms (4.10-8.00hz) during REM in α4(-/-) compared to C57 and α5(-/-) mice, compensated by non-significant increases in relative Beta (15.01-30.00Hz) and Gamma (30.01-50.00Hz). Findings for Gamma rhythms are perhaps the most interesting. During wake, gamma rhythms were consistently but non-significantly reduced in α5(-/-) compared to both C57 and α4(-/-); during NREM, gamma rhythms were increased in α4(-/-) compared to both C57 and α5(-/-) mice, this effect was significant at ZT20-23; and during REM, gamma rhythms were significantly decreased in both α4(-/-) and α5(-/-) at all time points relative to C57 mice. These observations suggest a role of α4 and α5 in the generation of gamma rhythms that is state dependent. Cumulatively, these findings inform on the individual role and function of the α4 and α5 nAChRs in the generation and maintenance of sleep, wakefulness, and brain wave spectral frequencies.

Title: A non-oscillatory, millisecond-scale embedding of brain state provides insight into behavior

Authors: *A. M. SCHNEIDER[1], D. F. PARKS[2], K. B. HENGEN[3];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Univ. Of California Santa Cruz, Santa Cruz, CA; [3]Biol., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Sleep and wake are understood to be slow, long-lasting processes that span the entire brain. Brain states correlate with many neurophysiological changes, yet the most robust and reliable signature of state is enriched in rhythms between 0.1 and 20 Hz. The possibility that the fundamental unit of brain state could be a reliable structure at the scale of milliseconds and microns has not been addressable due to the physical limits associated with oscillation-based definitions. Here, by analyzing high resolution neural activity recorded in 10 anatomically and functionally diverse regions of the murine brain over 24 h, we reveal a mechanistically distinct

embedding of state in the brain. Sleep and wake states can be accurately classified based in 10^0 to 10^1 ms of neuronal activity sampled from 100 μm of brain tissue. In contrast to canonical rhythms, this embedding persists above 1,000 Hz. This latent fast embedding is robust to substates and nested neurophysiological events. To ascertain whether such fast and local structure is meaningful, we leveraged our observation that individual circuits intermittently switch states independently of the rest of the brain. Brief state discontinuities in subsets of circuits correspond with brief behavioral discontinuities during both sleep and wake. Our results suggest that the fundamental unit of state in the brain is consistent with the spatial and temporal scale of neuronal computation, and that this resolution can contribute to an understanding of cognition and behavior.

The habenulo-interpeduncular pathway is a highly conserved conduction system in the vertebrate brain, that is present from primitive fish to humans. Neurons in the bilaterally paired dorsal habenulae (dHb) predominantly innervate an unpaired midbrain target, the interpeduncular nucleus (IPN) through the fasciculus retroflexus fiber bundles. The habenular nuclei influence a wide range of behaviors, from sleep and reward to fear and anxiety and have been a recent focus in research on addiction. Despite increasing functional studies, our knowledge of the neuronal properties, organization, and connections of the dHb and IPN is limited. We identified transcripts enriched in the dHb by performing RNA-seq on dHb dissected from adult zebrafish brains relative to the remaining tissue. Comparison with a single-cell transcriptomics dataset, together

with customized cluster analysis, enabled generation of a hierarchical transcription profile for dHb neurons. We then performed RNA in-situ hybridization to confirm spatial patterns of expression in larval and adult fish. Through the adoption of the QF/QUAS binary transcriptional regulatory system and CRSIPR/Cas9 targeted genomic integration, we successfully recovered transgenic QF driver lines for newly identified dHb-expressing genes. Axonal endings of labeled dHb neuronal subpopulations were mapped to specific target regions along the dorsoventral extent of the IPN using genes for membrane-tagged fluorescent reporters under QUAS control. On the basis of overlap between dHb clusters, we can predict the patterns of IPN innervation for additional neuronal subtypes. Together, the transgenic and computational approaches provide a more complete map of dHb-IPN connectivity in the zebrafish brain.

Title: The temporal dynamics of aperiodic activity track changes in sleep structure

Authors: M. AMEEN[1], ***J. JACOBS**[2], K. HOEDLMOSER[1], T. DONOGHUE[2];
[1]Univ. of Salzburg, Salzburg, Austria; [2]Columbia Univ., New York, NY

Abstract: Electrophysiological data has an aperiodic (1/f-like) property whereby power decreases as a function of increasing frequency. The degree of this decay, which can be measured as the aperiodic exponent (or the 'spectral slope'), has been shown to relate to states of consciousness. Here, we further investigate aperiodic activity across sleep stages, extending the methodological approaches to address limitations of previous work, including a) the use of simplified estimation-models (examining a narrow frequency range with a simple model form) and b) low temporal resolution. To address these limitations - which can miss features and dynamics that occur over a broader frequency range and/or a short time frame - we explored changing the frequency range and complexity of the model used to estimate aperiodic activity, as well as applying these models in a time-resolved manner to track features with and between sleep stages. We analysed both an intracranial electroencephalography (iEEG) dataset (n=91) from human patients sleep scored into non-rapid eye movement (NREM; stages N2 and N3) and rapid eye movement (REM) sleep, as well as a high-density EEG dataset collected from 17 healthy humans across a full night of sleep. Spectral features were estimated using the specparam toolbox (formerly 'fooof'), comparing model-forms and computing time-resolved estimates. We show that switching from the narrowband frequency range (30-45Hz) that has been used in sleep

literature to a broader frequency range improves the model performance. Further, using a more complex model from that incorporates the knee frequency, i.e., the frequency at which the slope of the power spectrum changes, revealed that stage-dependant changes in the spectral exponent of the iEEG data is driven by a change in the knee frequency. Finally, in the EEG signal, we were able to demonstrate temporally resolved estimates of aperiodic activity whose time courses differentiated transitions to between sleep stages (comparing, for example, transitions from N2 to N3 from transition from N2 to N1). Overall, our results show that aperiodic activity during sleep tracks changes in sleep (micro-) structure, and that this can be characterized by expanding the model complexity and temporal resolution of the applied methods. Through this project, we also propose updated guidelines for the estimation of aperiodic activity in neural data that, based on the findings here, can lead to better characterization of electrophysiological signals leading to improved quantifications that can be used to examine relationships between neurophysiological signals and behavioural states of interest.

Title: Identifying hidden states of consciousness during sleep using multivariate autoregressive models

Authors: X. LIU[1], B. M. KRAUSE[1], K. V. NOURSKI[3], ***M. I. BANKS**[1], B. D. VAN VEEN[2]; [1]Anesthesiol., [2]Electrical and Computer Engin., Univ. of Wisconsin, Madison, WI; [3]Neurosurg., The Univ. of Iowa, Iowa City, IA

Abstract: Stages of sleep identified by standard polysomnography are superpositions of actual consciousness states. For example, during deep sleep, humans transition between unconsciousness (UC) and disconnected consciousness (DC, dreaming). Previous studies also showed that the brain exhibits different electrophysiological activity during different sleep stages and consciousness states. However, how to identify those consciousness states is still an open question. Here, we developed a novel sequential multistate multivariate autoregressive (SM-MVAR) model clustering algorithm. SM-MVAR uses a Gaussian mixture model to assign data segments to one of several MVAR models representing different conscious states. The MVAR models are learned from the data as part of an iterative assignment process in which segments are assigned to the most likely model, the models are re-estimated from the assigned segments, and the iterative reassignment process continued until the assignments do not change. We divided

multichannel human intracranial electrophysiological data recorded during sleep into short 4-second segments. Each segment was labeled by sleep stage (W, i.e., wake, N1, N2, N3, and REM) obtained using standard polysomnography. We then applied the SM-MVAR algorithm to those segments with the assumption that four consciousness states exist during sleep: two states of connected consciousness (CC+, i.e., awake and alert, and CC-, i.e., awake but drowsy and inattentive), disconnected consciousness (DC, i.e., dreaming), and unconsciousness (UC). We initialized the MVAR models by assigning N3 segments to UC, REM segments to DC, W segments to CC+, and N1 segments to CC-. We then ran the algorithm to iteratively update the assignments and MVAR models. We compared the classification of data segments into consciousness states with standard polysomnography, and the results suggest our method could capture transitions among consciousness states during sleep at high temporal resolution. We also performed 4-fold cross validation on our SM-MVAR algorithm and found that our algorithm could stably reveal the underlying clusters of data segments. Directed connectivity derived MVAR model coefficients revealed changes in network structure that may underlie transitions between consciousness states. Overall, we believe our method has broad utility for identifying hidden states in any multichannel system that can be reasonably approximated by MVAR models and specifically to gain mechanistic insights into the neural correlates of consciousness.

Title: Is paradoxical sleep a paradoxical state of sleep?

Authors: *F. BOSCHER[1], N. URBAIN[2];
[1]Lyon neuroscience research center (CRNL), 95 bd Pinel, Bron, France; [2]Lyon neuroscience research center (CRNL), Bron, France

Abstract: Paradoxical sleep (PS), coined as such by Jouvet in 1959 for the striking resemblance of its electroencephalogram (EEG) to the one observed during the fundamentally different cognitive state of wakefulness, is characterized by muscular atonia and the occurrence of rapid eye movements. Recently, this has led to a distinction between two substates: phasic (during eye movements) and tonic PS. In mice, we also observed whisker movements during PS. The

whisker system therefore offers the unique opportunity to study cortical and thalamic modifications associated with whisker movements in both wakefulness and PS.
We performed extra- and intracellular recordings of thalamic cells in head-fixed mice, combined with local field potential (LFP) recordings in the primary somatosensory (S1) and motor (M1) cortices, while simultaneously monitoring the EEG, the electromyogram and the whisker movements with a high-speed camera.
Whisker movements (whisking) in PS occurred significantly more toward the end of the episodes and differed from whisking in wakefulness by a higher frequency of protraction/retraction cycles and a lower amplitude. On the EEG, they were associated with an increase in the mean Theta (5 - 12 Hz) wave frequency as well as an increase in Gamma (60 - 90 Hz) power. On S1-LFP, whisking was associated with a significant decrease of Delta (2-6Hz) power in both wakefulness and PS. While this Delta activity seemed widely distributed across the cortex (EEG, S1-LFP, M1-LFP) in quiet wakefulness, it appeared restricted to S1 during PS. Remarkably, we also observed spindles oscillations in the S1-LFP during PS, but only outside whisking periods. In the sensory thalamus, whisking was associated with an increase in the firing rate, in both wakefulness and PS. In addition, 49% (18/37) of the recorded cells modified their firing pattern during whisking in PS: while they fired bursts of action potentials outside whisking, typical firing pattern of thalamic cells during SWS, they switched to a tonic activity during whisking. Interestingly, we also observed during PS membrane potential oscillations in the spindle frequency range in a subset of thalamic cells (n=3 out of 6), like in SWS.
Taken together, our results show that a substate of PS, outside phasic events, bears clear SWS characteristics, opening a new insight on the function of PS.

Title: Changes in the core architecture of brain network during propofol-induced unconsciousness in human ECoG

Authors: *M. CHOE[1], S.-H. JIN[1], J. KIM[1], C. CHUNG[2];
[1]Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Since consciousness is upheld through communication in the brain network, its characteristics should change as consciousness emerges and disappears. The k-core percolation is

a way to describe the core structure of the brain network by eliminating peripheral structures of the network. In the present study, we investigated the core structure changes of the brain network during the propofol-induced unconscious state using human electrocorticography (ECoG).We recruited 4 medically intractable epilepsy patients (4 females; age: mean = 27.3, SD = 6.4 years) with ECoG monitoring. Conscious ECoG was acquired in the ward or operating room with subjects' eyes closed without any stimuli. Unconscious ECoG was acquired after the subject lost the ability to respond to verbal commands with general anesthesia using the target-controlled infusion of propofol and remifentanil. The average recording time during conscious and unconscious states was 113.4 seconds (standard deviation, 63.1 seconds). The ECoG data during conscious and unconscious states were segmented into 10-s epochs having 50% overlap. The complex Morlet wavelet transform with a wave number of 2.48 was applied for time-frequency analysis. We estimated the power correlation for functional connectivity using the Pearson correlation coefficient. We calculated the correlation matrix of each frequency band of interest (delta: 1-3 Hz, theta: 4-7 Hz, alpha: 8-12 Hz, beta: 13-30 Hz, low gamma: 30-90 Hz, high gamma: 90-140 Hz). We constructed the adjacency matrix using the threshold of 40%. We estimated k-maximum core structures and the number of nodes in cortical regions of k-maximum core structures using k-core percolation. We computed the regional difference of k-maximum core structures between conscious and unconscious states using Wilcoxon signed rank test ($p < 0.05/8$).Compared to the conscious state, the number of k-maximum core nodes decreased in the frontal region, whereas the number of k-maximum core nodes increased in the posterior regions during the propofol-induced unconscious state. The reconstruction of core structure in the brain network with increased coreness in posterior regions and decreased coreness in the frontal region would be associated with states of consciousness.

Title: Broadband coupling to slow wave phase during propofol-induced unconsciousness reflects both spiking and non-spiking dynamics at the cortical surface

Authors: *P. F. BLONIASZ[1], J. TAUBER[3], S. BRINCAT[4], E. K. MILLER[4], E. P. STEPHEN[2]; [1]Grad. Program For Neurosci., [2]Mathematics and Statistics, Boston Univ., Boston, MA; [3]Brain and Cognitive Sci., [4]The Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Propofol, a gamma-aminobutyric acid (GABA) potentiating anesthetic, is a widely used agent to induce unconsciousness in clinical settings. Several electroencephalographic (EEG) indicators of propofol-induced unconsciousness (PIU) have been reported, including widespread slow oscillations, a frontal alpha rhythm, and phase amplitude coupling (PAC) between the phase of the slow wave (0.1 Hz - 4 Hz) and broadband amplitude (5-50 Hz; Purdon et al., 2013; Stephen et al., 2020). The slow wave-broadband PAC indicator has been shown to occur on more posterior electrodes when participants initially become unconscious, but later becomes ubiquitous across both frontal and posterior electrodes as the dose of propofol increases. Thus, PIU is thought to comprise at least two discrete unconscious brain states that are distinguishable at the level of scalp EEG signals. Furthermore, the broadband PAC indicator was hypothesized to reflect up- and down-states in spiking activity at the cortical surface, predicting that propofol may influence cortical spiking activity differently in frontal vs posterior brain areas. Hence, there is a pressing need to characterize the cortical counterparts of the broadband-slow wave phase PAC observed in EEG. Here, we establish a broadband-slow wave paradigm in non-human primates using chronic Utah arrays to record local field potential (LFP) and multiunit spiking data from two macaques (Bastos et al. 2021). PAC was calculated via two different analyses that were based on 1) the mean vector PAC between the instantaneous slow wave phase and broadband amplitude of LFP data and 2) the generalized linear model-based prediction of broadband power as a function of slow wave basis functions. It was found that, like human scalp indicators of PIU, there are discrete brain states defined by dose-dependent broadband-slow wave coupling across brain regions. Additionally, it was found that cortical spike times coincide with elevated broadband power, but changes in broadband power can occur in the absence of detected spikes - suggesting that broadband can contain more complete local network information than multiunit spiking. We observe systematic changes in spectral shape and slope as a function of the slow wave phase, which we interpret in terms of local excitatory and inhibitory tone.

Title: Monitoring and predicting brain states in unresponsive patients with EEG-and machine learning-based approaches in the intensive care unit

Authors: *L.-M. KRUMM[1], C. MEISEL[2];
[1]Computat. Neurol., Charite Universtätsmedizin Berlin, Berlin, Germany; [2]Computat. Neurol., Charié Universitätsmedizin Berlin, Berlin, Germany

Abstract: Prognosticating for patients with Disorders of Consciousness (DOCs) is a complex process due to their diverse etiologies and pathophysiologies. However, advancements in the field of Machine Learning (ML) and the increased availability of long-term EEG and multimodal data, supported by comprehensive data warehouses, may provide improved methods for monitoring and prognosticating DOCs. We here propose to address the complexity of DOCs by assessing the divergence of a patient's EEG from what may be considered 'normal', and to detect long-term trends for prognostication over time. Specifically, we employ deep autoencoders (AE) to map normal healthy EEG signals and deviations from it into latent space. For healthy normal EEG signals we use publicly available datasets (Temple University Hospital (TUH) dataset) and datasets covering different vigilance states (Cleveland Family Study sleep dataset). To estimate differences from normal in latent space we use three datasets: the TUH slowing and seizure dataset (dataset 1), a dataset from patients with a diverse set of DOCs obtained from the intensive care unit (DOC defined as Glasgow Coma Scale Score < 9, dataset 2), and a long-term EEG dataset from patients during recovery from cardiac arrest (dataset 3). Using these data, we employ three different methodological approaches: a unimodal data approach (using only EEG powerbands), a bimodal data approach (using correlation measures between pairs of EEG channels), and a raw EEG time-series data approach (without predetermined data features). All AE approaches are benchmarked to simpler machine learning approaches, including logistic regression classifiers. We use the Rand index as a metric to quantify how well the data is clustered in latent space. Initial results indicate that power spectral densities features provide the best clustering in latent space for normal, seizure, and slowing EEG data.Our results indicate that AE can capture EEG dynamics in latent space relevant for prognostication of DOCs across diverse etiologies and pathophysiologies. Our ultimate goal is to develop a data processing pipeline with the best-performing algorithm for prospective bedside application. By continuously monitoring the brain states of ICU patients with respect to distance from normal, healthy dynamics, we aim to identify long-term trends that can enhance prognostication.

Title: Age-related changes in EEG during isoflurane-induced surgical anesthesia

Authors: *P. SOJA[1], ***P. SOJA**[2], T. MARIAM[1], R. TADAVARTY[1];
[2]Fac. of Pharmaceut. Sci., [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: We recently reported that during protracted periods of isoflurane anesthesia (IA), the cortical EEG signature of male but not female adult rats revealed oscillatory behavior characterized by high-power up state and low-power down states (Soja *et al., Soc. Neurosci. Abstracts*, 2018, 125.04/H4). The present study investigated whether similar EEG dynamics occurred in old (~18 months, n=11) *vs.* adult (4 - 6 months, n= 13) male rats. Cortical EEG activity was recorded bilaterally (S1) using stainless steel electrodes under IA (1.0-1.25%). The concentration of isoflurane was adjusted to keep the animals' EEG activity at a stable surgical anesthetic plane characterized by delta wave activity. A tagging procedure was used to identify the onset and offset of up states. The tagged EEG states were then re-constructed as continuous up and down state EEG records. Age-related differences occurred in the number and spectral features of the up *vs.* down states. Adult rats averaged 11 up-state oscillations/hr that lasted ~6.3 min while aged rats revealed ~4.5 up-state oscillations/hr lasting ~6.6 min. Relative power differences between up and down states were assessed in δ (1-4 Hz), θ (5-8 Hz), α (9-12 Hz) and β (13-25 Hz) bandwidths. Adult rats revealed ~30% decrease and ~48 % increase in relative power values for δ and θ bands, respectively when comparing up *vs*. down states. In old rats, a ~ 33% decrease and 20% increase in power values occurred in δ and θ bands, respectively when up *vs*. down states were compared. Power in the α band increased by ~69 %, and ~53% in adult *vs.* old rats, respectively when up *vs.* down states were compared. These findings demonstrate distinct differences in EEG activities between adult and old male rats during prolonged periods of surgical IA. The functional consequence of these age-related differences in EEG oscillations requires further investigations.

Title: Determining a sedative dose of dexmedetomidine in the African green monkey

Authors: J. MORGAN[1], T. WHITTY[1], G. CAPACIO[1], D. CRAIG[1], B. TRAVIS[1], *H. MCCARREN[2];
[1]US Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD; [2]Res. Div., USAMRICD, Aberdeen Proving Ground, MD

Abstract: Dexmedetomidine (DEX), an α2-adrenergic receptor agonist, is frequently used in combination with other drugs to induce sedation in non-human primates (NHPs). DEX has proven especially useful for imaging studies, where it acts as an anesthetic-sparing agent to improve functional MRI signal. All published protocols in which DEX is used as a sole sedative agent have been performed in rhesus macaque monkeys. This project sought to determine an intravenous (IV) sedation protocol for DEX in African Green monkeys (AGMs). Ten AGMs were fitted with steel collars, removed from their home cage using pole capture, and placed in a restraint chair, where an intravenous catheter was placed in their saphenous vein. DEX was infused at a fixed rate via syringe pump, and the AGM was monitored for signs of sedation and changes in heart rate and blood pressure. The rate and cumulative dose of DEX infusion was adjusted between AGMs until an infusion rate and duration was identified that consistently led to ~15 minutes of hand grip loss accompanied by a mean arterial pressure (MAP) that remained >45mmHg throughout the infusion. An infusion of 10 μg/kg of DEX at 40 μg/kg/hr met this criteria. Signs of sedation observed included markedly reduced muscle tone, loss of grip, yawning and brief periods of eye closure. At this infusion rate (n = 6), loss of hand grip response occurred 9.3 ± 2.1 minutes (mean ± SD) after initiation of infusion. Animals that received a total of 10 μg/kg (n = 3) lost hand grip for 14.3 ± 0.6 minutes. All 10 animals were able to return to their home cages without incident after a brief period of recovery in the chair. DEX has a strong safety profile and a broad therapeutic index, but bradycardia and hypotension are important potential complications. The AGMs that received the optimized DEX dosing protocol in this study maintained MAP in a safe range, with minimum MAP measurements ranging from 73-77 mmHg. This illustrates that AGMs can be successfully sedated with DEX short-term, with minimal detrimental cardiac effects.

Abstract: Slow waves are prominent features of pharmacologically-induced general anesthesia, characterized by oscillatory local field potentials and neuronal activities that are separated into UP and DOWN states. These slow waves bear a resemblance to those observed during deep non-rapid eye movement sleep. Yet, the debate regarding the similarity of underlying neuronal firing patterns that constitute the slow waves in both brain states persists. This study presents a novel approach to address this longstanding controversy. Our approach combines 'transparent electrodes,' embedded in a PDMS film, with a specialized transgenic mouse strain that expresses GCaMP6f sparsely at superficial cortical layers. This combination allows us to capture individual neuronal activity over a large cortical area while recording the spatiotemporal structures of slow waves. Importantly, our technique enables ultrafast high-speed calcium imaging, faithfully capturing neuronal spikes throughout the entire dorsal neocortex along with local field potentials. This facilitates the differentiation of large-scale spatiotemporal features of slow waves with fine resolution. By employing our unique approach, we achieve a comprehensive characterization of the neuronal firing patterns associated with cortical slow waves under various conditions. This enables us to compare natural sleep with general anesthesia induced by isoflurane and dexmedetomidine, which induce slow waves via drastically different mechanisms. Additionally, our approach allows versatile cortical stimulation paradigms that reveal distinct signatures of neuronal and local field activity closely linked to consciousness states, as evaluated from a behavioral perspective. In summary, our study introduces an innovative methodology that combines electrophysiological and optical techniques, allowing for high spatiotemporal resolution recordings of neuronal activity across a large cortical area during slow waves. By shedding light on the similarities and differences between anesthetic-induced and natural sleep-related slow waves, our findings contribute to a deeper understanding of the mechanisms underlying general anesthesia and sleep states.

Abstract: Sleep and many general anesthetics, including propofol, ketamine, and dexmedetomidine, cause profound slow waves (0.5-4 Hz) in the cortical field potential. These slow waves reflect widespread, synchronous oscillations between depolarized and hyperpolarized membrane voltages of nearby neurons and may be important for preventing consciousness. Although the molecular targets of propofol, ketamine, and dexmedetomidine are known, it is unknown whether their respective slow waves are generated in the same way at the neural circuit level. Moreover, whether the slow waves of these anesthetics share a common mechanism with the slow waves of sleep remains unknown. Previous research from our lab showed that the efficacy of brainstem stimulation to reduce anesthesia-induced slow waves depends on the anesthetic's molecular target, suggesting distinct slow wave mechanisms. We tested this hypothesis in 6-8 month old female Sprague Dawley rats by using a miniscope to record calcium transients from individual neurons in the prelimbic cortex of the prefrontal cortex (PFC) during sleep and administration of general anesthetics. Simultaneously, we recorded electrophysiological signals (EEG/LFP) near the imaged area of the PFC. Finally, for each condition (sleep or anesthetic), we observed the relationship between the activity of individual neurons and the electrophysiological signal by plotting vectors of unity length at each calcium event's respective slow wave phase. Then, we calculated the mean vector for each neuron and found the mean of all neurons' mean vectors for a given rat/condition (the mean vector of the rat).We found variability in both the strength of slow wave phase-locking (the radius of the mean vector of the rat) and the preferred (mean) slow wave phase between rats and between conditions. For two rats with three conditions each, we found the following mean vectors [phase (rads), radius]: Rat 1, sleep, [-1.98, 0.15]; Rat 1, dexmedetomidine, [-2.18, 0.07]; Rat 1, propofol, [-0.71, 0.08]; Rat 2, sleep, [1.24, 0.13]; Rat 2, dexmedetomidine, [0.85, 0.05]; Rat 2, propofol, [-0.19, 0.19]. While different phase preferences were seen among the rats for a given condition, the preferred phase of dexmedetomidine was closer to that of sleep than propofol within both rats. These early results may indicate a greater degree of similarity in cortical activity during sleep- and dexmedetomidine-induced slow waves than sleep- and propofol-induced slow waves.

Title: Whole Brain Network Changes During Propofol-induced Unconsciousness

Authors: *X. CHEN[1,2], S. R. CRAMER[3], N. ZHANG[2];

Abstract: The altered level of consciousness induced by general anesthetics is associated with various dynamic changes in whole brain communication. Previous studies have identified the altered neural electrical activity using electrophysiology (ephys) recording during loss of consciousness. However, ephys signal can only provide information about regional changes, leaving the brain-wide communication during this process largely unknown. To investigate the whole-brain functional alteration during loss of consciousness, we simultaneously recorded electrophysiology-fMRI (ephys-fMRI) signal from six rats during propofol-induced loss of consciousness, verified by the test of loss of righting reflex (LORR). We found the power of low frequency-band ephys data exhibit a sudden increase within a narrow time window when animals lost consciousness. Brain network-level changes were assessed using the whole-brain fMRI signals during the same time window. This study provides data revealing global brain network level changes during the process of loss of consciousness.

Title: Brain state modulation of cortical network topography: the role of the retrosplenial cortex

Authors: *F. RESTA[1], A. SCAGLIONE[2], F. S. PAVONE[3];
[1]Univ. of Florence, Sesto Fiorentino, Italy; [2]Univ. di Firenze, Sesto Fiorentino, Italy; [3]LENS, LENS, Sesto Fiorentino, Italy

Abstract: Large-scale cortical dynamics play a role in many cognitive functions such as goal-directed behaviors, motor learning, and sensory processing. The spatiotemporal patterns of neuronal activity across multiple brain regions undergo substantial alterations during different brain states, including wakefulness and anesthesia. Although there is considerable knowledge regarding the overall changes in neuronal firing and synchronization in different brain states, the specific network topography engaged remains less understood. The aim of this work was to identify the cortical networks modulated by the anesthesia level. To achieve this goal, we employed the GroupICA analysis method on widefield mesoscale imaging recordings. This approach enabled us to identify spatially independent components (ICs) that represent elements of cortical networks shared among subjects as the anesthesia level decreased from deep anesthetized towards the awake state. Our findings revealed a marked dependence of ICs associated with the retrosplenial cortices on brain state. These ICs were most prominent during deeper levels of anesthesia, while they were less prevalent during the awake state. Analysis of IC occurrence unveiled a strong correlation between the retrosplenial cortices during deeper anesthesia states, which diminished as anesthesia lightened. In summary, our results indicate that coactivation of the posterior-medial cortices predominates over other connectivity patterns during deeper anesthesia levels, whereas a more rich repertoire of dynamics is expressed in lighter anesthesia and in the awake state.

Abstract: Disordered sleep is a widespread health problem, yet how the brain homeostatically regulates sleep, driving a pressure to sleep after prolonged wakefulness, is poorly understood. To identify neurons that encode sleep pressure, I used single nucleus RNA sequencing to observe transcriptional changes in sleep deprived (SD) vs rested larval zebrafish forebrain. The small size of the larval zebrafish brain, conserved sleep wake machinery, large clutch sizes for high throughput behavioral assays, and transparent larval state make the zebrafish an excellent system in which we can address these questions. To control for any effects driven by the method of sleep deprivation (e.g. arousal or stress from gentle handling), I conducted the same analysis in *sik3* Sleepy mutants, a genetic model of high sleep pressure. I have identified a cluster of neurons, marked by *tac1*, that exhibits *th* upregulation in both in the *sik3* mutant compared to wild type controls, as well as in sleep deprived compared to rested controls. Secondly, I observe a widespread reduction in *RAMP1* in forebrains of SD vs rested control and in *sik3* mutant compared to wt controls. To experimentally induce sleep pressure in zebrafish, we employ sleep deprivation techniques such as gentle handling with a paintbrush. This method is not ideal, as it 1) limits the number of experimental animals; 2) does not allow simultaneous behavioral tracking; 3) introduces red light for visibility during the dark cycle; and 4) is taxing on the experimenter, limiting SD duration to 4-6 hours. Therefore, I have developed a high throughput and automated method of sleep deprivation by applying randomized water pulses to individual larvae while simultaneously tracking their behavior. I have successfully induced sleep pressure with this approach, observing a rebound sleep in the hours following the pulses. Sleep pressure is dissipated by rebound sleep, but whether an anesthesia-induced sleep-like state can dissipate sleep pressure is unclear, varying with organism and type of anesthesia. Understanding the neuronal basis of how anesthesia controls consciousness could help us distinguish circuits for sleep pressure vs loss of consciousness. By coupling single nucleus transcriptomics with HCR fluorescent *in situ* hybridization, I identified a cluster of telencephalic neurons, marked by *tac3b*, that respond with immediate early gene upregulation to diverse anesthetics, including tricaine, isoflurane, and benzocaine. Together these preliminary datasets lay the groundwork to understand the neuronal encoding of sleep pressure and anesthesia.

Title: Neuron-class specificity of volatile anesthetic action in C. elegans

Authors: *A. S. CHANG[1], C. W. CONNOR[2], C. V. GABEL[1];
[1]Dept. of Pharmacology, Physiology, & Biophysics, Boston Univ. Sch. of Med., Boston, MA;
[2]Anesthesiol., Brigham and Women's Hosp., Boston, MA

Abstract: The mechanism of action of the volatile anesthetics at the molecular and local neuronal network level have yet to be thoroughly explicated. Through the implementation of high-speed volumetric whole nervous-system imaging in *C. elegans*, our previous work has characterized how exposure to isoflurane, a commonly used volatile anesthetic, results in breakdown of neuron-to-neuron communication. However, the question remains whether particular neuronal sub-populations are more sensitive to volatile anesthetic-induced breakdown, and if patterns of suppression of neuronal communication in distinct sub-populations can characterize observed differences in shallow and deep anesthesia. In this study, we address this question through the implementation of a fluorescent marker system (NeuroPAL) to identify neurons within the simple and completely mapped C. elegans nervous system. Single neuron-resolution calcium imaging was performed on *C. elegans* (n=10) under awake conditions, and during exposure to levels of atmospheric isoflurane analogous to light and moderate anesthesia in mammals. Identified neurons were assigned to presynaptic-postsynaptic pairs based on previously characterized synaptic maps of the *C. elegans* connectome. Synaptic pairs were then sorted by presynaptic neurotransmitter identity: acetylcholinergic, glutamatergic, GABAergic, and aminergic. We found that under light anesthesia acetylcholinergic neurons displayed decreased synaptic pair correlation ($n = 405$, $p = 0.002$, paired sample t-test) and reduced mean signal power ($n = 160$, $p < 0.001$), while other neuron sub-populations were largely unaffected. Under moderate anesthesia, acetylcholinergic synaptic pairs exhibit significant correlation suppression ($n = 270$, $p < 0.001$) as do glutamatergic synaptic pairs ($n = 184$, $p = 0.01$) and aminergic synaptic pairs ($n = 102$, $p = 0.002$). Interestingly, we additionally observed suppression of correlation between pairs of neurons known to be linked by gap junctions under both light ($n = 183$, $p=0.002$) and moderate ($n = 100$, $p < 0.001$) Anesthesia. These findings show that some distinct populations of neurons are indeed more sensitive to volatile anesthetics than others. Our results specifically implicate acetylcholinergic synapses, and potentially gap junctions, as being the most sensitive to volatile anesthetics and thus the potential initiating points of anesthetic action. Greater depths of anesthesia may then be characterized by an increasing cohort of affected neuron types.

Title: Detecting Sleep and Wake with Frequency-Based Algorithms Using Ambulatory EEG Devices

Authors: *M. HACOHEN[1], G. EYLON[2], I. DINSTEIN[3];
[1]Ben-Gurion Univ., Beer-Sheva, Israel; [2]Ben-Gurion university, Beer-Sheva, Israel; [3]Ben Gurion Univ., Beer Sheva, Israel

Abstract: Objectives: To develop an automated pipeline that can filter out various EEG noise sources and classify sleep and wake segments throughout an overnight EEG recording using an ambulatory wireless EEG device. **Background**: Sleep and wake differ in their neural activity patterns as evident in EEG recordings. During wakefulness the cortex is dominated by fast oscillations of low amplitude, and conversely, when sleep begins, cortex becomes dominated by slow oscillations of high amplitude. Despite these dramatic changes in cortical activity, there are few trusted algorithms for detecting sleep onset and final awakening. Here we demonstrate the accuracy of an algorithm that utilizes the ratio between alpha and theta bands to identify sleep onset and final awakening. **Design/Methods**: Data was collected from three adult men over a period of three consecutive weeks (total of 80 nights) using commercially available wireless EEG headbands (Dreem Inc.). We developed an algorithm for automated detection of noise originating from movements, muscle contractions, and poor electrode impedance. Specifically, the algorithm detected noisy EEG epochs according to their variance, skewness, kurtosis, mobility, and complexity. After extracting noisy segments, the algorithm detected the top 20 consecutive 30-second epochs that had the highest delta power (i.e., slow wave sleep), which are expected to indicate the first sleep cycle. The algorithm then identified sleep onset by moving backwards in time and detecting the last epoch with an individually defined alpha/theta ratio. Final awakening was identified as the last epoch of the recording with the same alpha/theta ratio. **Results**: The accuracy and robustness of the algorithm was evaluated by comparing its results to manual scoring. The algorithm labeled sleep onset times did not differ significantly from those labeled manually ($t(79)=1.34$, $p = 0.18$), with the algorithm exhibiting a mean bias of 2 minutes. Similarly, algorithm labeled final awakening times did not differ significantly from those labeled manually ($t(79)=1.4$, $p = 0.9$), with the algorithm exhibiting a mean bias of 0.3 minutes. Comparison of the algorithm with the Dreem staging showed a significant difference in sleep onset detection (($t(79)=5.16$, $p = 0.01$), with the algorithm exhibiting a mean bias of 10 minutes. In contrast, final awakening times did not differ significantly from those scored by Dreem ($t(79)=-1.3$, $p = 0.2$), with the algorithm exhibiting a mean bias of 2 minutes. **Conclusions**: The developed pipeline offers a useful approach for analyzing large datasets of sleep EEG recordings even when collected with wireless ambulatory EEG devices.

Title: Apolipoprotein E genotype impacts murine skeletal muscle mitochondrial coupling efficiency in a late-onset Alzheimer's disease model

Authors: *C. JOHNSON[1], C. LYSAKER[1], C. S. MCCOIN[1], V. DRUMMOND[1], R. KEMNA[1], E. FRANCZAK[1], A. BLANKENSHIP[1], C. S. JOHN[1], X. CAO[1], M. E. MORRIS[1], J. P. THYFAULT[1], H. M. WILKINS[1], P. C. GEIGER[1], J. K. MORRIS[2];
[1]Univ. of Kansas Med. Ctr., Kansas City, KS; [2]Alzheimer's Dis. Ctr., Univ. of Kansas Med. Ctr., Fairway, KS

Abstract: Apolipoprotein ε4 (*APOE4*) is the greatest genetic risk factor for Alzheimer's disease (AD). *APOE4* carriers who are obese are at even greater risk of developing AD. This human condition is replicated in *APOE4* targeted-replacement (TR) mice, with high-fat diet (HFD) reducing spatial memory compared to *APOE3* TR mice. Further, *APOE4* genotype increases risk for developing diabetes and cardiovascular disease, conditions that alter bioenergetic function in skeletal muscle. Interestingly, lipid-driven mitochondrial respiration is reduced in muscles of individuals in the early stages of cognitive decline. Despite this, the impact *APOE4* has on muscle metabolism and the role this would play in modifying AD susceptibility is unclear. Here, we sought to determine if *APOE4* modulates lipid metabolism in muscle in response to a HFD. We used 8-month old male and female *APOE4* (n=13) and *APOE3* (n=15) TR mice on a C57BL/6 background fed a low-fat diet (LFD) or HFD for 4 months prior to sacrifice. Lipid-driven mitochondrial oxygen consumption was measured in isolated mitochondria from quadriceps muscle using high-resolution respirometry (Oroboros Oxygraph-2k). Coupling efficiency was calculated from basal and state 3 (ADP-stimulated) respiratory states. Western blot was used to quantify the expression of gastrocnemius muscle proteins involved in lipid metabolism, including apolipoprotein E (APOE), fatty acid binding protein 4 (FABP4) and carnitine palmitoyl transferase 1B (CPT1B). Basal and state 3 mitochondrial oxygen consumption in muscle are not affected by genotype or diet. However, *APOE4* reduced coupling efficiency compared to *APOE3* ($p=0.012$), regardless of diet. There was no effect of genotype on the expression of lipid metabolizing proteins measured. However, HFD increased muscle APOE ($p<0.001$) and FABP4 ($p<0.001$) expression, and resulted in a trending elevation in CPT1 ($p=0.077$) expression compared to LFD-fed mice. Reduced mitochondrial coupling efficiency in *APOE4* mouse muscle suggests reduced pairing of lipid-driven oxygen consumption to ATP synthesis. Reduced coupling and oxidative stress is a hallmark of aging muscle. Current ongoing studies are being conducted to determine the relationship between coupling efficiency and the production of reactive oxygen species. The lack of genotype-driven effects on protein expression suggests that differences in lipid handling by *APOE* genotype occurs independently of changes in the expression of key metabolic proteins measured in this study. Further studies are needed to determine the mechanism underlying differences in lipid-driven coupling efficiency and the impact this has on muscle and brain health.

Abstract: Mechanosensory feedback from the digestive tract to the brain ensures that animals consume appropriate amounts of food and water. Our group previously found that neurons in the parabrachial nucleus expressing the prodynorphin gene (hereafter PB^{Pdyn} neurons) are activated during ingestive behavior, as well as mechanical probing of the oropharyngeal cavity, esophagus, and stomach (Kim *et al*., Nature 580:376-380), suggesting that these neurons can monitor ingestion using mechanosensory signals from the upper digestive tract. However, the precise origin of the signal during natural ingestion (i.e. in which digestive tract region, by which sensory neurons or mechanoreceptor molecules) still remains unclear. As a first step to answer these questions, we mechanically probed several subregions of each upper digestive tract organ in anesthetized mice and recorded the response of PB^{Pdyn} neurons using fiber photometry. Furthermore, to test the necessity of signals arising from each digestive tract organ, we transected the nerve branches innervating each digestive tract region. Collectively, our preliminary data suggest that PB^{Pdyn} neurons may monitor ingestion using signals generated from the esophagus and/or the adjacent digestive tract areas. While performing further experiments to pinpoint the region and the nerve responsible for the generation of signals related to PB^{Pdyn} neurons, we are also exploring the identity of mechanoreceptor cells and molecules underlying detection of ingestion.

Abstract: Norepinephrine (NE) is a well-known appetite regulator and several anti-obesity drugs target adrenergic system. To better understand the circuitry underlying adrenergic control of appetite, we investigated the paraventricular hypothalamus (PVN), a key brain region that integrates energy related signals and receives dense adrenergic input. We found that PVN NE level increases with signals of energy deficit and decreases with food access. This pattern is recapitulated by the activity of PVN innervating catecholaminergic axon terminals originating from NTS^{TH} (tyrosine hydroxylase) neurons. Optogenetic activation of rostral-NTS^{TH} to PVN projection elicited strong motivation to eat, comparable to 24 hours fasting, whereas its inhibition attenuated both fasting-induced & hypoglycemic feeding. We found that NTS^{TH}-axons functionally target PVN^{MC4R} neurons by predominantly inhibiting them, in part, through α1-adrenergic receptor mediated potentiation of GABA release from ARC^{AgRP} presynaptic terminals. Furthermore, glucoprivation suppressed PVN^{MC4R} activity, which was required for hypoglycemic feeding response. These results define an ascending NTS^{TH} to PVN^{MC4R} adrenergic circuit that conveys peripheral signals of energy deficit to the melanocortin pathway.

Title: Analysis of gaping reactions induced by emetine and cisplatin.

Authors: *M. FUNAHASHI, Z. WEI, H. HUANG, T. YOSHIZAWA, T. INUI;
Oral Physiol., Hokkaido Univ, Grad Sch. Dent. Med., Sapporo, Japan

Abstract: Emetine is an ingredient of the root of Carapichea Ipecacuanha, and its oral administration cause acute severe vomiting. Cisplatin is an antineoplastic drug that induces acute, late-onset and predictive nausea and vomiting. We previously reported emetine- and cisplatin-induced conditioned taste avoidance (CTA) to saccharin in rats. In the present study, we investigated gaping reactions induced by emetine and cisplatin to confirm if the emetine and cisplatin induce conditioned taste aversion. Gaping reactions were measured by using taste reactivity test (TR test) in male Sprague-Dawley rats (6-7 weeks old at the beginning of the experiment). Surgery was performed on rats to install an oral catheter under anesthesia with a combination anesthetic containing (mg/kg, i.p.): 0.15 medetomidine, 2 midazolam and 2.5 butorphanol. To analyze gaping reactions, the mouth movements of rats were recorded on video. We measured the number of gaping using offline video images. We performed TR test with administration of 0.1% saccharin (0.5ml/min, 8 min, p.o.) in rats that acquired CTA to saccharine by the conditioning with emetine (5.54 mg/kg, 1% BW, i.p.) and cisplatin (3 mg/kg, 1% BW, i.p.). The number of gaping reactions in rats conditioned with emetine and cisplatin was 58.0 ± 10.7 / 8 minutes (n = 5) and 123.67 ± 25.97 / 8 minutes (n = 6) ($p < 0.01$ in both groups). These results indicate the conditioned nausea produced by emetine- and cisplatin-induced CTA to saccharin, suggesting the aversive memory to sweetness produced by conditioning with emetine and cisplatin. These findings demonstrated that emetine and cisplatin induce conditioned nausea and that rats develop conditioned aversion to saccharin. The emetic effect of cisplatin is implicated to be greater than emetine.

Title: The role of diabetes insipidus in the fluid intake suppression hypersensitivity to central glucagon-like peptide-1 in the Brattleboro rat

Authors: *S. A. DAVID[1], D. J. BRAKEY[1], G. VARAVENKATARAMAN[1], M. J. PAUL[2], D. DANIELS[1,2,3];

[1]Biol. Sci., [2]Psychology, [3]Ctr. for Ingestive Behavior Res., State Univ. of New York, Univ. at Buffalo, Buffalo, NY

Abstract: Physiologically and behaviorally, fluid and food intakes are entangled. There is overlap in the brain regions that control the two types of ingestive behavior, and signaling peptides that affect one often affect the other. For example, glucagon-like peptide-1 (GLP-1) suppresses both food intake and fluid intake. The vasopressin-deficient Brattleboro rat has emerged as a potential model organism to separate fluid intake from food intake and could help isolate brain regions particularly involved in fluid intake control. Brattleboro rats drink copious amounts of water, but eat a similar amount of food when compared to wildtype rats. Moreover, Brattleboro rats are hypersensitive to the fluid intake suppression caused by central administration of a GLP-1 receptor (GLP-1R) agonist, Exendin-4 (Ex4), with no differences in sensitivity to the food intake effects. To evaluate if the hypersensitivity is directly related to the untreated diabetes insipidus (DI) in these rats, we implanted osmotic mini pumps containing desmopressin (ddAVP, a vasopressin type 2 receptor agonist). We found that alleviation of DI reduced the hypersensitivity, suggesting something transient and correctable is responsible for the hypersensitive response to Ex4. In an attempt to identify a brain region responsible for the exaggerated response to Ex4, we made direct injections of Ex4 into the tissue adjacent to the anteroventral third ventricle (AV3V) in wildtype and Brattleboro rats. There was a drug*genotype interaction on water intake after Ex4 when it was given in the AV3V at a dose that was ineffective at suppressing water when delivered to the 3V. This finding suggests that the anterior portions of the 3V are at least partly responsible for the hypersensitive response to Ex4 observed in Brattleboro rats. Together with previous work, these data provide useful context that will help identify specific brain areas that underlie different responses to GLP-1.

Title: Effects of conditioned taste aversion to saccharin on sweet food intake.

Authors: *Z. WEI, H. HUANG, T. YOSHIZAWA, T. INUI, M. FUNAHASHI; Hokkaido Univ., Sapporo, Hokkaido, Japan

Abstract: We examined whether rats avoid ingestion of saccharin-containing sweetened diet when they acquire conditioned taste aversion (CTA) to saccharin. The amount of saccharin

solution decreases in rats acquired CTA to saccahrin when they are reexposed to saccharin solution despite they feel thirst by 21 hours and 40 minutes water deprivation. In other words, the thirst-induced drinking behavior was suppressed by the taste aversive memory. Therefore, the present study was conducted based on the hypothesis that rats avoid intake of sweetened diet in defiance of hunger due to taste aversive memory. The male Sprague-Dawley rats (7 weeks old) were used as experimental animals, and we measured food and water intake, and body weight before and after the acquisition of CTA. The conditioned stimulus was 0.1% saccharin solution, and the unconditioned stimulus was nausea induction by injection of emetine hydrochloride (5.54 mg/kg, 1% BW, i.p.). Rats injected with saline (1% BW, i.p.) served as the control group. The sweetened diet was prepared by mixing powdered normal solid feed with an equal amount of 0.2% saccharin solution, forming it into the same shape as the solid feed, and drying it completely in a drying machine. Normal diet was made in the same way to ensure consistency in texture. After a one-day recovery day after CTA acquisition, the sweet diet test was conducted for five days, and the intake of sweet feed was significantly reduced on days 1-4 of the test compared to the intake of the normal diet on the conditioning day ($F(5,30) = 4.644$, $P < 0.01$, Dunnett's test). The control group did not show a significant decrease in sweet diet intake on any of the test days, but rather showed an increasing trend in intake on test days 3-5 compared to the conditioning days. These results indicate that the rats' feeding is suppressed by the taste aversion memory despite hunger. This suggests that the central mechanism of CTA may be implicated in the pathogenesis of eating disorders.

Title: Trap2-dreadd mice for analyzing conditioned taste aversion: expression after lithium chloride and taste aversion after clozapine-n-oxide

Authors: J. M. COTE, *T. A. HOUPT;
Biol. Sci., Florida State Univ., Tallahassee, FL

Abstract: Static high magnetic fields (MFs) interact with the vestibular system of rodents. MFs cause perturbations such as head movements, circling, suppressed rearing, nystagmus, conditioned taste aversion and c-Fos in vestibular nuclei. While a useful correlate of neuronal activity, c-Fos expression alone is not informative of the functional contribution, if any, these active populations have in the behavioral effects of MF exposure. To prepare a model for elucidating the role of these active cells, we bred and validated TRAP2 mice expressing DREADDs in c-Fos-positive cells, which allows permanent genetic access to the cells activated

by the magnet. Because we plan to manipulate magnet-induced CTA by stimulating the DREADDs with the synthetic Clozapine-N-Oxide (CNO), we also determined whether CNO induced a CTA by itself. Targeted Recombination in Active Populations (TRAP2) mice (*Fos*$^{2A\text{-}iCreER}$ which express a tamoxifen-inducible Cre recombinase without disrupting endogenous c-Fos (Denardo et al. 2019) were bred with two floxxed effector lines expressing either excitatory (R26-hM3Dq/mCitrine) or inhibitory (R26-hM4Di/mCitrine) designer receptors exclusively activated by designer drugs (DREADD) generating *Fos*$^{2A\text{-}iCreER}$*-hM4Di and Fos*$^{2A\text{-}iCreER}$*-hM3Dq* mice. DREADD expression was induced by intraperitoneal injections of LiCl or NaCl (40ml/kg, 0.15M) paired with 4-hydroxytamoxifen (4-OHT; 50mg/kg) or sesame oil (5ml/kg) vehicle controls separated by one hour. DREADD expression was histologically verified by visualizing mCitrine with an anti-GFP antibody (Rockland Immunochemicals #600-101-215, 1:500) which was validated in transgenic hTh-GFP rats. Compared to uninduced vehicle controls, mice given LiCl paired with 4-OHT showed higher expression. However, there was noticeable baseline expression in uninduced controls, suggesting that a subtractive analysis will be required to control for transgene leakage. To assess the unconditioned effects of CNO in CTA wild-type male and female mice were placed on a water restriction schedule. On conditioning day, mice were given access to saccharin paired with CNO at 3 different doses: 0, 1, 3 and 10mg/kg (n=4/dose). CTA was assessed in 24-h, 2-bottle preference tests of saccharin vs water. Mice did not form a CTA at any dose of CNO, with all mice showing a high saccharin preference. This model can be used to selectively reactivate or inhibit cells activated by MF exposure, clarifying the role of these active cellular populations in MF behavioral effects.

Title: Food preference in different reproductive states in the experimental model of gestational diabetes

Authors: K. M. GODEGUEZI, M. S. AGOSTINI, M. G. MARTINS, ***A. C. I. KISS**; UNESP Botucatu, Botucatu, Brazil

Abstract: Gestational diabetes mellitus (GDM) is one of the most common complications of pregnancy. It is known that inadequate nutrition can worsen GDM and that food preference is an important aspect to guide food intake. The nutrition of pregnant women has an impact on the glycemic homeostasis and is an important tool in the treatment of pregnant women with GDM.

The study of different aspects of maternal food preference can contribute to a better understanding of food choices and can also serve as a basis for clinical studies that can improve nutritional counseling for women with GDM. Therefore, the aim of the present study was to evaluate the food preference of rats in different reproductive states in the experimental model of gestational diabetes. To achieve this goal, an experimental model of mild hyperglycemia induced by the administration of streptozocin (STZ) during pregnancy was used. Part of the rats received i.p. injection of STZ diluted in citrate buffer on day 7 of pregnancy (STZ, n=11), while the other females received only buffer (Control, n=9). The food preference test was conducted at 4 different times: before mating, during pregnancy, during lactation, and post-lactation. The test consisted of offering 3 types of special diets (high sugar, high fat, and high protein) for a period of 12 hours and later calculating the food preference index for each diet. As expected, food preference was modified according to the reproductive state. Overall, there was a reduction in the preference for the high fat and high protein diet and an increase in the preference for the high sugar diet over time. Maternal hyperglycemia reduced the preference for high protein diet during lactation, but there was no significant interaction between maternal metabolism and reproductive state for none of the diets. In conclusion, food preference changed according to the reproductive state and maternal diabetes contributed to a reduced high protein diet preference during lactation.

Title: The role of AgRP neurons in the regulation of feeding following vertical sleeve gastrectomy

Authors: *C. R. TEDESCO, C. S. MITCHELL, I. SUCQUART, D. P. BEGG;
Sch. of Psychology, Univ. of New South Wales, Randwick, Sydney, Australia

Abstract: The prevalence of obesity has risen dramatically in recent decades, representing a serious public health concern. Currently, bariatric surgeries such as the vertical sleeve gastrectomy (VSG) are the most effective long-term treatment for obesity. The efficacy of VSG is primarily mediated through a reduction in food intake. Although the VSG procedure involves removing the greater curvature of the stomach, evidence suggests that reduced feeding after surgery is *not* due to any kind of physical restriction on the amount of food that can be consumed. Instead, VSG potentially causes alterations in neuronal pathways involved in the

regulation of feeding. We investigated whether VSG was associated with changes in the regulation of food intake by Agouti-Related Peptide (AgRP) neurons in the arcuate nucleus of the hypothalamus (ARC). To address this question, we used male transgenic AgRP-Cre C57BL/6 mice that were maintained on a high-fat diet for 8-12 weeks prior to VSG (n = 7) or sham (n = 7) surgery. First, we selectively expressed excitatory designer hM3D(Gq) receptors in ARC AgRP neurons of VSG and sham mice via bilateral injection of a DIO-hM3D(Gq) virus into the ARC. Activation of these neurons via administration of clozapine-N-oxide (1 mg/kg; i.p.) increased consumption of various diets (including standard rodent chow, high-fat chow, sucrose solution, and a lipid emulsion) relative to a vehicle injection across counterbalanced test days. Further, stimulating ARC AgRP neurons increased feeding to the same degree in both VSG and sham animals. This lack of difference in food consumption between VSG and sham groups demonstrates that VSG does not physically restrict feeding, and suggests that VSG does not alter how ARC AgRP neurons respond to chemogenetic stimulation. To examine whether VSG alters the basal activity of these neurons in response to feeding, we next conducted in vivo fibre photometry experiments to monitor bulk calcium signalling as a proxy for neuronal activity. In a separate cohort of VSG (n = 7) and sham (n = 6) mice, we selectively expressed the calcium indicator GCaMP6s in ARC AgRP neurons and implanted a fibre optic cannula above the ARC. Animals were food-deprived overnight and presented with a pellet of high-fat chow after a baseline recording window. Analysis of calcium signals pre- and post-consumption indicated greater suppression of bulk ARC AgRP neuronal activity upon feeding in VSG compared with sham mice. Together, our findings demonstrate that VSG does not disrupt AgRP-mediated feeding, and indicate that VSG may restore the functioning of ARC AgRP neuronal activity in response to feeding.

Title: Mnemonic and metabolic interactions across the hippocampal-hypothalamic circuit

Authors: *E. KAYA[1], E. WEGIENKA[3], A. AKHTARZANDI-DAS[3], A. EBAN-ROTHSCHILD[2], G. ROTHSCHILD[4];

Abstract: For all organisms from bacteria to humans, life is a journey in search of resources to keep the internal environment in a desirable state. To find these resources, organisms perform stimulus-seeking behaviors during which actions resulting in improved bodily states are repeated while others are not. While even bacteria exhibit such coordination of behaviors informed via consequences of earlier actions, the evolution of the nervous system has allowed more complex organisms to use more sophisticated strategies to learn from the past, anticipate the future, and respond quickly for effective metabolic regulation. In mammals specifically, the hippocampus matches internal signals to actions to form memories and guide future behavior. To date, numerous studies have shown that hippocampal-cortical communication during a hippocampal oscillatory event called sharp wave ripples (SWR) is critical for memory processes. However, SWRs can also propagate to subcortical structures that are involved in metabolic regulation, which implies a potential dual role of SWRs in memory and metabolism. Indeed, a recent study showed that SWRs can modulate peripheral glucose metabolism. Yet, we still lack a comprehensive understanding of the metabolic functions of SWRs and downstream pathways that communicate SWRs to the body. To address these gaps, we tested the effects of feeding and metabolic hormones on SWRs in freely behaving and naturally sleeping mice. Our results show that SWRs during sleep are modulated by recent food intake and by metabolic hormones in a dose-dependent manner. To determine whether feeding-modulated hippocampal SWRs influence downstream subcortical structures involved in feeding regulation, We combined electrophysiological recordings in the hippocampus and optical recordings in the lateral hypothalamus via fiber photometry. We found that lateral hypothalamic GABAergic and Glutamatergic populations exhibit a robust and consistent increase in activity that peaks ∼300 ms after SWRs. Together, we identify the modulation of SWRs by metabolic signals, and offer hippocampal-lateral hypothalamic communication around SWRs as a potential mechanism by which SWRs can modulate peripheral physiology and behaviors.

Title: Dietary GABA enhances the postprandial activation of vagal afferents to promote satiation

Authors: *Y. IWASAKI[1], U. NAKAMURA[2], T. NOHMI[1], R. SAGANE[2], M. KIM[2], K. OHBAYASHI[1];

Abstract: [Background] Gamma-aminobutyric acid (GABA) is known as the main inhibitory neurotransmitter, and it is also present in foods. Recently, GABA has become widely available as a dietary supplement with beneficial effects on brain functions, such as reducing stress and enhancing sleep. However, it has long been believed that GABA is unable to cross the blood-brain barrier. Therefore, it remains unclear how dietary GABA affects the brain. [Aim] In this study, we aimed to investigate the effects of single peroral (po) administration of GABA on feeding behavior, a brain function, and determine the involvement of vagal afferents. [Methods] We measured the food intake after a single GABA administration via oral gavage in C57BL/6J mice. We investigated whether a single po GABA administration could increase the expression of phosphorylated ERK1/2 (pERK1/2), serving as cellular/neuronal activity markers, in vagal afferent nodose ganglion neurons. [Results] Po GABA immediately before refeeding transiently reduced food intake in overnight fasted mice without causing aversion. This effect was blunted by surgical and chemical denervation of vagal afferents. However, po GABA alone did not alter the expression of pERK1/2 in vagal afferent nodose ganglion neurons, and po GABA 30 min before refeeding did not alter feeding. These findings suggested that GABA interacts with factors triggered by meals and regulates feeding. Simultaneously po administration of GABA and liquid diet (Ensure H) potentiated the postprandial activation of vagal afferents and robustly enhanced meal-evoked satiation. [Conclusions] The findings of this study indicate that dietary GABA enhances the activation of postprandial vagal afferents, potentially through interaction with meal-evoked factors, leading to the regulation of brain functions such as feeding behavior.

Title: Ghrelin-responsive mediobasal hypothalamic neurons mediate exercise-associated food intake and exercise endurance

Authors: *O. SINGH[1], S. B. OGDEN[1], S. VARSHNEY[1], K. SHANKAR[1], D. GUPTA[1], S. PAUL[1], S. OSBORNE-LAWRENCE[1], C. P. RICHARD[1], N. P. METZGER[1], C. LAWRENCE[1], L. LEON MERCADO[1], J. M. ZIGMAN[1,2];
[1]Dept. of Intrnl. Medicine, Ctr. for Hypothalamic Research,, [2]Dept. of Psychiatry, UT Southwestern Med. Ctr., Dallas, TX

Abstract: The orexigenic hormone ghrelin doubles during high-intensity interval exercise (HIIE). Without the action of this increased ghrelin (as in mice lacking the ghrelin receptor, GHSR), exercise reduces food intake. Further, GHSR-null mice exhibit diminished exercise endurance. These data suggest that ghrelin limits the capacity of exercise to restrict food intake but enhances endurance. In this study, we aimed to determine whether GHSR-expressing neurons in the mediobasal hypothalamus (MBH) mediate the effects of exercise on food intake and regulate exercise endurance. We stereotaxically delivered the inhibitory DREADD virus AAV2-hSyn-DIO-hM4D(Gi)-mCherry to the MBH of GHSR-IRES-Cre mice. CNO was administered to chemogenetically inhibit the activity of GHSR-expressing neurons infected with the inhibitory DREADD virus. Mice were subjected to HIIE and exercise endurance protocols, and we assessed food intake and MBH c-fos induction in response to administered ghrelin. We used histochemistry to classify mice as correctly targeted ("hits," n=16) or incorrectly targeted ("misses," n=11). Also, we evaluated the impact of the DREADD virus on the activity of GHSR-expressing MBH neurons by performing immunohistochemistry for c-fos following exercise endurance. DREADD-assisted inhibition of GHSR-expressing MBH neuronal activity suppressed food intake by 33.8% following HIIE, as well as maximal running distance (by 20.7%), total running duration (by 14.5%), and maximum running speed (by 14.5%) during the exercise endurance protocol (compared to "hits" treated with saline). Moreover, DREADD-assisted inhibition of GHSR-expressing MBH neuronal activity increased blood glucose levels by 18.4% and blood lactate levels by 24.6% following the exercise endurance protocol (compared to "hits" treated with saline). "Hits" treated with CNO also exhibited a 57.2% reduction in food intake and a 71.4% reduction in c-fos induction within the arcuate nucleus (ARC) in response to ghrelin administration, compared to "misses" treated with CNO. We also observed reductions in numbers of c-fos-positive cells in the ARC (by 20.3%) and ventromedial hypothalamus (by 22.4%) in the hM4Di-injected "hits" compared to control mCherry virus-injected "hits" after CNO + endurance exercise. All listed %'s are significant (P-values<0.05). Thus, activation of ghrelin-responsive MBH neurons is necessary for the normal feeding response to HIIE, the typical endurance exhibited by mice during a forced exercise endurance protocol, food intake and MBH neuronal activation in response to administered ghrelin, and the usual blood glucose and lactate responses to prolonged exercise.

Title: Pde4 inhibitor acts in the brain to ameliorate obesity-induced neuroinflammation

Authors: *H. DA SILVA[1], L. DUARTE[1], M. SEIXAS[2], J. ANTUNES-RODRIGUES[2], F. DE PAULA[3], L. ELIAS[2];
[1]Physiol., Univ. of Sao Paulo, Ribeirão Preto, Brazil; [2]Physiol., [3]Intrnl. Med., Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: Obesity is associated with peripheral and central low-grade inflammation characterized by increased pro-inflammatory cytokines, such as tumor necrosis factor-alpha (TNF). Phosphodiesterase 4 (PDE4) modulates inflammatory responses and its inhibitor can strongly reduce TNF release and inflammation. Additionally, PDE4 knockout mice were shown to be resistant to diet-induced obesity (DIO). The aim of this study was to investigate the role of central and peripheral effects of PDE4 in DIO. To attain this purpose, mice were treated with rolipram, a PDE4 inhibitor capable of crossing the blood-brain barrier, or YM-976, a brain-impermeable inhibitor. All experimental protocols were approved by the Ethics Committee for Animal Use of the Ribeirao Preto Medical School. Male C57Bl6 mice were fed with either chow or a high-fat diet (HFD; 60% fat) for 10 weeks and in the 8th week, they received daily subcutaneous injections of vehicle (VEH), rolipram (2mg/kg) or YM-976 (2mg/kg). During the experimental period, food intake and body weight were monitored and at the end of the study, inguinal, retroperitoneal, and brown fat pads were collected for analysis. Rolipram decreased the absolute value and change of body weight in the HFD group, which was associated with a decrease in epididymal and retroperitoneal fat pad weight, with no effect in the chow group. Remarkably, rolipram was able to decrease energy intake and energy efficiency, as well as to increase energy expenditure in HFD-treated animals. In addition, PDE4 inhibition decreased NF-KB translocation to the nucleus in the hypothalamus of HFD-treated animals, which is consistent with a reduction in neuroinflammation. In contrast to rolipram, the YM-976 inhibitor was unable to ameliorate the metabolic changes in DIO. These results indicated that the beneficial metabolic effects of PDE4 inhibitors on DIO occur through attenuation of central inflammation and reinforce PDE4 as a potential target for the treatment of obesity. Title: Insensitivity to the feeding response of exogenous ghrelin develops during pregnancy

Authors: *C. L. MURRELL[1], Z. B. ANDREWS[2], D. R. GRATTAN[1,3], S. L. LADYMAN[1,3]; [1]Univ. of Otago, Dunedin, New Zealand; [2]Dept. of Physiol., Monash Biomedicine Discovery Institute, Monash Univ., Clayton, Victoria, Australia; [3]Maurice Wilkins Ctr. for Mol. Biodiscovery, Auckland, New Zealand

Abstract: During pregnancy and lactation, the maternal body undergoes many metabolic adaptations, including increased food intake, to support the energy demands of the growing fetus and provide nutrition through milk production after birth. Ghrelin, an orexigenic hormone, activates agouti-related peptide (AgRP) neurons in the arcuate nucleus promoting rapid food intake. Here, we investigate the contribution of ghrelin in elevated maternal food intake. To determine whether increased sensitivity to ghrelin contributes to maternal hyperphagia, female C57/B6 mice were injected (i.p.) with either ghrelin (0.3mg/kg) or vehicle (saline) at four physiological timepoints: prior to pregnancy (virgin), day 8 (P8) and 15 of pregnancy (P15) and lactational day 10 (L10) then 2h food intake was measured. In virgin mice, ghrelin treatment (n = 16) acutely increased food intake compared to the saline-treated group (n = 16). Interestingly, during pregnancy (both P8 and P15) there was no difference in food intake between ghrelin and saline treatment groups (2-way ANOVA, interaction treatment x physiological state $p = 0.0482$, n = 8-18) suggesting a lack of sensitivity to the ghrelin-induced feeding response. By day 10 of lactation the food intake stimulating effect of ghrelin was restored (Mann-Whitney $p = 0.0223$, n = 10-12). *In vivo* GCaMP fibre photometry of the AgRP neuron population was used to assess if an attenuated response to ghrelin by AgRP neurons underlies the lack of ghrelin-induced food intake in pregnancy. Recordings of AgRP neuron population activity in response to ghrelin (0.3mg/kg i.p.) were collected from virgin, pregnant and lactating mice. At all timepoints, ghrelin treatment resulted in a well-established increase in AgRP neuron activity (n = 7 per time point). In a final experiment, female (groups of virgin, P15 and L10 n = 9-10) AgRP cre x Td-tomato mice were treated with either ghrelin (0.3mg/kg i.p.) or saline then perfused with 4% paraformaldehyde and brains were processed for c-fos immunofluorescent labelling. Ghrelin-treatment significantly increased c-fos expression in AgRP neurons, even in pregnancy (2-way ANOVA, effect of treatment $p = <0.0001$). Overall these results indicate that increased ghrelin sensitivity does not contribute to increased maternal food intake. In contrast to this hypothesis, a

temporary insensitivity to the ghrelin-induced feeding response develops during pregnancy, and this is not associated with a change in acute response of AgRP neurons to ghrelin. Therefore, it seems likely that this change in behavioural response to ghrelin develops downstream of AgRP neurons.

Title: Sirtuin1-induced deacetylation of TTF-1 is important in hypothalamic control of energy homeostasis

Authors: *D. KANG, B. LEE;
Univ. of Ulsan, Ulsan, Korea, Republic of

Abstract: When an animal is starving, thyroid transcription factor-1 (TTF-1) stimulates appetite by regulating the expression of agouti-related peptide (AgRP) and proopiomelanocortin (POMC) genes in the hypothalamus. However, the mechanism by which TTF-1 responds to a decrease in the body's energy level is not known. In this study, we present evidence that the NAD^+-dependent deacetylase Sirtuin 1 (Sirt1) plays a crucial role in mediating the actions of TTF-1 in response to energy deficiency. We discovered that energy deficiency enhances the expression of both Sirt1 and TTF-1, leading to the deacetylation of TTF-1 through increased interaction between TTF and Sirt1. Both energy deficiency-induced and resveratrol-induced activation of Sirt-1 resulted in an increase in the nuclear translocation of TTF-1. However, this effect was inhibited by treatment with a Sirt1 inhibitor. Notably, the action of TTF-1 on AgRP and POMC gene expression was hindered due to the inability of TTF-1 to undergo deacetylation, which was induced by a point mutation in a lysine residue of TTF-1. In summary, these findings indicate that energy deficiency-induced deacetylation of TTF-1 plays a crucial role in the overall regulation of whole-body energy homeostasis by TTF-1, particularly through the regulation of AgRP and POMC gene expression.

Title: Participation of P2 purinergic receptors in pilocarpine-induced water intake

Authors: *P. M. DE PAULA, P. A. A. GOIS, J. V. MENANI;
Physiol. and Pathology, Sao Paulo State Univ., UNESP Araraquara, Brazil

Abstract: Intraperitoneal (ip) injection of pilocarpine (PILO, muscarinic cholinergic agonist) induces salivation, water intake and changes in body temperature. These effects are due to a direct action on the salivary glands and central nervous system (CNS). ATP (adenosine 5-triphosphate) is a neurotransmitter in the peripheral and CNS and is responsible for activating P2 purinergic receptors located in various regions including the salivary glands. Preliminary results from our laboratory showed that ATP injected intraperitoneally (ip) reduced PILO-induced salivation, suggesting the participation of peripheral P2 purinergic receptors in salivary secretion. The aim of the present study was to investigate the effects of ip injection of ATP (a natural agonist of P2 purinergic receptors) on water intake and changes in body temperature induced by PILO also administrated ip. Male Holtzman rats (300-350 g, n=18) were used. The experimental protocols were approved by Ethical Committee for Animal Care and Use - CEUA from Dentistry School of Araraquara, UNESP (Proc. CEUA number 11/2019). A group of 10 rats received ip injection of PILO (1 mg/kg of body weight) to induced water intake. Ten minutes before, half of the group received an ip injection of ATP (200 mg/kg of body weight) and the other half received saline. Then water was offered in graduated burettes fitted with metal drinking spouts. The results showed that ip injections of ATP reduced PILO-induced water intake (0.2 +/- 0.1 mL/15 min, vs. saline + PILO: 2.2 +/- 0.6 mL/15 min, $p<0.05$). Another group of 8 rats was submitted to a median laparotomy for the placement of body temperature sensors in the abdominal cavity. The results showed that ip injection of PILO did not alter body temperature (0.3 +/- 0.1 °C, vs. saline: 0.3 +/- 0.1 °C) and the combination of ATP + PILO also did not change body temperature (0.2 +/- 0.1 °C). Thus, the results suggest that ip injection of ATP reduced PILO-induced water intake, but PILO alone or combined with ATP did not change body temperature in rats.

Title: Stimulation of sensory or motor vagal neurons produces opposite effects on glucose homeostasis

Authors: *L. A. LEON-MERCADO[1], S. DEJA[2], A. TINAJERO[1], B. CHEN[1], J. LEE[1], S. LEE[1], S. BURGESS[2], J. ELMQUIST[1];

Abstract: The parasympathetic nervous system contributes to the regulation of food intake, body weight and glycemia. In recent years, parasympathetic stimulation via the vagus nerve has emerged as a potential therapy to treat obesity and metabolic diseases. However, reports from different studies have shown dissimilar results, due by the complex mixture of sensory and motor fibers comprising the vagus nerve. To better characterize the mechanisms controlling the glycemic response to vagal stimulation, we decided to genetically target the sensory or motor vagal pathways individually. Using optogenetic techniques combined with transgenic mouse models, we stimulated the vagal sensory terminals in Nav1.8- Cre mice, parasympathetic motor neurons in Chat-Cre mice or both in Phox2b-Cre mice at the level of the brainstem. In addition, we performed optogenetic stimulation and various metabolic tests to evaluate hepatic glucose metabolism, glucose tolerance and insulin sensitivity in awake, freely moving mice. We found that stimulation of the sensory afferents in the NTS of Nav1.8-expressing neurons produced hyperglycemia accompanied by glucose intolerance and insulin insensitivity. On the other hand, optogenetic stimulation of the vagal motor Chat-expressing neurons increased both glucose tolerance and insulin sensitivity. Intriguingly, optogenetic stimulation of the dorsal vagal complex of Phox2b-Cre mice activated both sensory and motor vagal branches and produced hyperglycemia. Suggesting a predominant role of the vagal sensory input in the control of glycemia. Our results provide further insight into the complexity of vagal control of glucose metabolism by sensory and motor neurons. Moreover, vagal stimulation could be fine-tuned to address acute glucose fluctuations of hyper and hypoglycemia, both factors associated to diabetes.

Title: Characterization of nucleus of the solitary tract (NTS) neurons with direct inputs to the ventral tegmental area.

Authors: *C. R. RITCHEY, D. J. ROSSI, J. H. PETERS;
Integrated Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Goal-oriented behaviors, including food intake, are driven by evolutionarily ancient and extensive neurocircuitry that integrates internal and external cues. The midbrain ventral tegmental area (VTA) shapes these behaviors via dense dopaminergic projections to many key forebrain areas. In addition, the VTA serves as an integrator of neural inputs from throughout the brain that modulate VTA output to produce broad, state-dependent, changes that reflect the balance of internal and external considerations. While descending cortical and limbic inputs to the VTA are well characterized, the origins and mechanisms of hindbrain inputs to the VTA remain largely unknown. The brainstem nucleus of the solitary tract (NTS) is the primary site for integration of viscerosensory and taste information conveyed through the cranial nerves and is essential for the control of food intake. Importantly, the NTS has been shown to form direct connections with the VTA, but little is known about the anatomical and neurophysiological nature of these projecting neurons, or how they shape VTA output to influence appetitive feeding behaviors. The purpose of this study was to characterize the anatomical and neurophysiological properties of NTS neurons with direct projections to the VTA. Using VTA-targeted retrobead injections, we found that a subpopulation of NTS neurons form direct monosynaptic connections with the VTA that are distributed through all rostro to caudal levels of the NTS; with greater prevalence in the medial and caudal NTS. Further, immunohistochemical analysis for tyrosine hydroxylase demonstrated that a significant population of these VTA-projecting NTS neurons are catecholaminergic. Using patch-clamp electrophysiology, we assayed the relative prominence of glutamatergic and GABAergic synaptic contacts, connectivity to the solitary tract, and responsiveness to feeding peptides. We found that VTA-projecting NTS neurons respond to the peptides cholecystokinin and exendin-4 and receive predominately polysynaptic innervation by the solitary tract. These findings are the first step in characterizing the nature of NTS inputs to the VTA that may play a role in regulating the mesolimbic dopaminergic pathway to control appetitive feeding responses.

Med., [4]Physiol., [3]Univ. of Sao Paulo, Ribeirão Preto, Brazil; [5]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [6]Mol. and Integrative Physiol., Univ. of Michigan Neurosci. Grad. Program, Ann Arbor, MI; [7]Physiol., Ribeirão Preto Sch. of Med. - Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Decreased production of 17β-estradiol (E2) after menopause is associated with an increased risk of developing obesity and type 2 diabetes mellitus. In experimental animals, decreased circulating levels of E2 induced by ovariectomy leads to the development of hyperphagia and, obesity, which are reverted by hormone replacement. Ventromedial hypothalamus (VMH) has been considered one of the main regions of ovarian hormone action in the regulation of energy homeostasis. However, the intracellular mechanisms involved in E2 actions in the VMH to control body weight are still poorly understood. The aim of this study was to investigate the role of phosphoinositide 3-kinase (PI3K) signaling in VMH neurons that express the steroidogenic factor 1 (SF1) in ovariectomized females treated with E2. To assess the role of the PI3K signaling we used cre-lox technology to generate female mice with specific disruption of P110α catalytic subunit in SF1 neurons. All experimental protocols were approved by the Ethics Committee for Animal Use of the Ribeirao Preto Medical School. Food intake, body weight and energy expenditure were monitored and at the end of the study, inguinal, retroperitoneal, and brown fat pads were collected. Deletion of P110α catalytic subunit in SF1 neurons of VMH partially reduced the effects of E2 in OVX females on body weight gain. In addition, indirect calorimetry demonstrated that energy expenditure was increased in P110αflox/flox OVX mice that received E2 treatment, compared with respective vehicle group. However, E2 treatment did not increase energy expenditure in SF-1cre;P110αflox/flox mice . In addition, in this group there was a reduction of E2 effect to increase thermogenesis in the brown adipose tissue (BAT) which was associated with a decrease in sympathetic activity in this tissue . These results indicated that PI3K pathway in SF1 neurons is required to the estradiol effects on the energy homeostasis.

Title: Representation of bodily signals in the lateral parabrachial nucleus during natural feeding

Authors: *H. J. CHOH[1], R. A. ESSNER[1,2], K. RUDA[1], M. L. ANDERMANN[1,2];
[1]Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Program in Neurosci., Harvard Med. Sch., Boston, MA

Abstract: Interoception, the sensing of internal states, is vital for maintaining physiological homeostasis. For example, the proper regulation of food intake requires animals to perceive satiety signals related to stretch and/or nutrients within the gastrointestinal tract. These visceral signals are relayed to the brain via vagal, spinal, and hormonal pathways, which converge in the brainstem lateral parabrachial nucleus (LPBN) to drive associated changes in behavior and physiology through forebrain projections. Previous work has identified subpopulations of LPBN neurons based on gene expression, such as calcitonin gene-related peptide (CGRP)-expressing neurons in the LPBN that suppress appetite and process threat signals. Whether these subpopulations have dedicated functions or not is still unclear, preventing a comprehensive understanding of how the LPBN contributes to interoception during behaviors such as ingestion. In addition, several forebrain regions send feedback to LPBN, providing a basis to affect LPBN activity and associated feeding behaviors. For example, the insular cortex (InsCtx), which makes predictions about future energy states during feeding, sends a large feedback projection to LPBN. Thus, InsCtx may alter how LPBN processes interoceptive information. To understand how LPBN integrates autonomic signals and top-down modulation across physiological states, we recorded from CGRP neurons in LPBN using in vivo fiber photometry of bulk calcium signals. As expected, we found that CGRP neurons respond to liquid food (Ensure) consumption, mild tail shocks, and visceral malaise. We are also exploring the modulation of this activity by InsCtx inputs. Our preliminary data show that brief stimulation of InsCtx-LPBN axons drives robust responses in CGRP neurons, suggesting that InsCtx influences interoceptive processing in LPBN. To parse the sensory preferences of all LPBN neurons regardless of genetic subtype, we have further developed a novel method of chronic two-photon calcium imaging in awake mice during various visceral stimuli. Our data reveal a wave-like pattern of activation during ingestion of Ensure, which we hypothesize is indicative of a viscerotopic map of the gastrointestinal tract. These experiments reveal functional organization and diversity of representations of bodily signals in LPBN.

Title: Nociceptin Receptor Antagonism Modulates Dopamine Responses to Water in Thirsty Rats

Authors: *P. BAZZINO, M. LOH, M. ROITMAN;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Thirst, a powerful drive for fluid consumption to restore balance, recruits dopamine responses to water and water-predictive cues. We measured the activity of ventral tegmental area (VTA) dopamine neurons with fiber photometry during intra-oral infusions of water. In thirsty rats, dopamine responses are initially high but as the session proceeds and animals become satiated (400 microliters over 10 seconds per trial; 50 trials; 30-60s variable intertrial interval), dopamine responses diminish (slope of regression line: -0.03 z-score/trial), especially as rats begin to reject the intra-oral infusions. The mechanisms by which dopamine responses are modulated during thirst satiation remain unknown. Recent work (Parker et al. 2019) supports a role for nociceptin peptide and receptors within the paranigral VTA in limiting food reward-directed behavior during operant responding. Intra-oral delivery of fluids represents an ideal foundation to further examine a role for nociceptin in negative regulation of reward. This method provides an optimal platform for studying the ingestion or rejection of taste stimuli. Here, cre-dependent GCaMP6 and a fiber optic was targeted to the VTA of TH-cre+ rats. Following recovery, thirsty rats were pre-treated (t-15min) with different doses of the nociceptin antagonist J-113397 (0, 2.5, 5, or10mg/kg, i.p. treatment order counterbalanced across rats) and intra-oral infusions of water were made. Three days were inserted between treatment days. Interestingly, when administering 5mg/kg of nociception antagonist, there was a more shallow slope for dopamine across trials and this was correlated with increase in trials prior to rejection. These findings suggest that nociceptin signaling may contribute to the satiation of multiple motivational drives including thirst.

Title: An Open-Source Licking Box for Precise Measurement of Liquid Intake and Licking Microstructure

Authors: *A. KANAKAM, M. OLVERA-CALTZONTZIN, S. BRESLIN, D. MEYER, S. A. STERN;
Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: Title: “AnOpen-Source Licking Box for Precise Measurement of Liquid Intake and LickingMicrostructure”Liquidintake has proven invaluable in the exploration of various fundamental biologicalquestions, ranging from motivation and drug addiction to anhedonia, feeding behaviors,memory, and learning. However, researchers face a significant challenge in accuratelymeasuring liquidintake, as most existing methods fail to account for the intricate lickingmicrostructure. This oversight results in the loss of important information and an increasedmargin of human error. Additionally, commercially available options for measuring liquidintakeoften come with exorbitant prices,lack customization options, and possessrigid analysiscapabilities.To address these limitations, we have developedand validated an innovative,open-source, printable, and low-cost Arduino based licking box system. Each box contains twoliquid taps which are linked with anArduinosystem, which cankeeptrack of 10tapssimultaneously, thus allowing for the testing of upto5mice inasingle recording. This Arduinosystem is paired with auser-friendly interface which cananalyze the dataover acumulative,differential, and groupcomparisonformat. Tovalidate the functionality of our licking box weconducted astandard two-bottle conditioned taste aversiontask. During the habituationperiod,mice were allowed toacclimate tothe experimental setup, which had initially only containedwater inboth taps. Subsequently, the mice were introduced tothe same setup, but with sucroseinone of the taps. Following this session, mice were injected with lithium chloride toinducevisceral malaise or saline as acontrol. We thenconducted atest sessiontoexamine successfulaversionmemory tothe sucrose tap. We were able todemonstrate that the licking boxesaccurately kept track of licking events across all taps, allowing for reliable quantificationinthesubsequent dataanalysis. This novel experiment system has anumber of advantages, with itbeing much more precise thansome existing methods of quantifying intakes, such asmeasuring the volume of intake or manually observing licking events. By offering an accessibleand affordable solution, our novel licking system fills a crucial gapin the field of liquidintakemeasurement.

Title: Sodium appetite and thirst do not require angiotensinogen production in astrocytes or hepatocytes

Authors: *L. PELTEKIAN[1], S. GASPARINI[1], F. S. FAZAN[1], S. KARTHIK[1], G. IVERSON[1], J. M. RESCH[2], J. C. GEERLING[1];
[1]Neurol., [2]Univ. of Iowa, Iowa City, IA

Abstract: In addition to its renal and cardiovascular functions, angiotensin signaling is thought to be responsible for the increases in salt and water intake caused by hypovolemia. However, it remains unclear whether these behaviors require angiotensin production in the brain or liver. Here, we use in situ hybridization to identify tissue-specific expression of the genes required for producing angiotensin peptides, then use conditional genetic deletion of angiotensinogen (Agt) to test whether production in the brain or liver is necessary for sodium appetite and thirst. In the mouse brain, we identified expression of Agt (the precursor of all angiotensin peptides) in a large subset of astrocytes. We also identified Ren1 and Ace (enzymes required to produce angiotensin II) in the choroid plexus, and Ren1 in neurons within the nucleus ambiguus compact formation. In the liver, we confirmed that Agt is expressed in widespread hepatocytes. We next tested whether thirst and sodium appetite require angiotensinogen production in astrocytes or hepatocytes. Despite virtually eliminating expression in the brain, deleting astrocytic Agt did not reduce thirst or sodium appetite. Despite markedly reducing angiotensinogen in the blood, eliminating Agt from hepatocytes did not reduce thirst or sodium appetite, and in fact, these mice consumed the largest amounts of salt and water after sodium deprivation. Deleting Agt from both astrocytes and hepatocytes also did not prevent thirst or sodium appetite. Our findings suggest that angiotensin signaling is not required for sodium appetite or thirst and highlight the need to identify alternative signaling mechanisms.

Title: Brainstem neurons regulating energy balance

Authors: *A. NECTOW;
Columbia Univ., New York, NY

Abstract: The brainstem plays a key role in the sense-and-respond network regulating energy balance. However, the molecular, cellular, and circuit mechanisms through which the CNS achieves this goal is incompletely understood. In recent work, we have demonstrated a key role for the dorsal raphe nucleus (DRN) in regulating balance. Here, using single cell-resolved transcriptional and translational phenotyping, we further characterize the molecular composition of inhibitory and excitatory DRN neurons. We subsequently relate this molecular heterogeneity to their diverse behavioral and physiologic functions, further clarifying the DRN's diverse contributions to energy homeostasis. In particular, we find that these neurons track various aspects of ingestion and that these molecularly distinct populations use aversive drive states to suppress or augment food intake. These findings identify new strategies through which the brainstem regulates feeding. Together, this work represents an important step towards linking hunger to its physiologic and behavioral consequences.

Title: Pkc-delta neurons in the central extended amygdala regulate energy expenditure behaviors

Authors: *W. SCHNAPP, M. B. SCHMIT, C. JOHNSON, H. CAI;
Univ. of Arizona, Tucson, AZ

Abstract: Neurons expressing protein kinase C-δ (PKC-δ) in two specific regions of the central extended amygdala (EAc), namely the central amygdaloid nucleus (CeA) and the oval region of the bed nucleus of the stria terminalis (ovBNST), are known to regulate anorexigenic behaviors. Previous studies have demonstrated that acute activation of these neurons suppresses food intake and, correspondingly, they are necessary for anorexia induced by certain signals such as satiety or inflammation. However, recent findings from our lab have revealed that EAc-PKC-δ neurons are required for female C57BL/6 mice to develop increased running wheel activity during the light period, including food-anticipatory activity (FAA), that occurs under conditions of daily restricted feeding. PKC-δ-Cre mice with ablated EAc-PKC-δ neurons do not significantly increase light period wheel activity upon food restriction compared to ad libitum fed controls, in contrast to WT mice ($p<0.001$, $n = 10$ mice per group). To further test if EAc-PKC-δ neurons

also play a role in regulating energy output-related behaviors, we employed chemogenetic methods to investigate the impact of acute manipulation of EAc-PKC-δ neurons on mouse running wheel activity. Our results show that activation of EAc-PKC-δ neurons during the resting period (light cycle) resulted in elevated wheel activity compared to control mice, while silencing these neurons during the active period (dark cycle) showed a trend towards reduced wheel activity. Additionally, using miniaturized microendoscope calcium imaging in behaving mice, we demonstrated CeA-PKC-δ neurons respond to wheel running activity, and that these dynamics are modulated across days of food restriction. These findings directly link the activity of EAc-PKC-δ neurons to energy expenditure behaviors, indicating that their functional role in energy balance extends beyond energy intake.

Title: Noxious predator odorants cause activation of appetite-suppressing parasubthalamic nucleus (PSTN) neurons

Authors: Z. KAEGI, *M. CARTER;
Williams Col., Williamstown, MA

Abstract: Feeding and fear behaviors are important for promoting survival in animals. These behavioral phenomena are associated, as animals engaging in fear behaviors are not likely to seek food. Not surprisingly, brain regions that mediate fear responses also influence feeding suppression. One such appetite-suppressing brain region, the parasubthalamic nucleus (PSTN), has been demonstrated to be sensitive to odors and may mediate the suppression of feeding induced by fearful environmental stimuli such as predator odorants. However, it is unknown whether the PSTN is sensitive to a variety of odorants and whether this activation might cause suppression of feeding. We used fiber photometry to test the effects of exposure to eight aversive, attractive, and neutral odorants on activity in PSTN neurons in mice. We found that 2MT and TMT, odorants in predator urine that activate transient receptor potential ankyrin 1 (TRPA1) chemoreceptors in the vagal and trigeminal pathways, induced activation of PSTN neurons over several minutes. In contrast, odorants that engage other olfactory pathways did not cause PSTN activation. Consistently, only predator odorants caused a reduction in food intake. Taken together, these results indicate that appetite-suppressing PSTN neurons are activated by predator odorants.

Title: Leptin-evoked activation of distinct neuronal subpopulations in the centrally projecting Edinger-Westphal nucleus

Authors: ***S. L. HERNAN**, A. F. SVED, G. CANO;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: We have proposed that the centrally projecting Edinger-Westphal nucleus (EWcp) integrates signals from diverse central pathways involved in metabolic control and thermoregulation, and adjusts the sympathetic output to multiple organs, including adipose tissues, to help to maintain homeostasis after changes in energy status. The adipose-derived hormone, leptin, signals central targets to regulate energy balance. The EWcp expresses leptin receptors (LepR), and it is part of the central circuitry involved in the control of adipose tissues. It has been reported that the effect of leptin in EWcp on feeding behavior is mediated by peptidergic neurons, mainly containing urocortin-1 and cocaine-and-amphetamine regulated-transcript (CART). Nevertheless, the effect of leptin in non-peptidergic neurons in EWcp (mostly VGluT2 neurons) has not been examined. To characterize EWcp activation in response to leptin, rats were fasted for 24 hours and injected with leptin i.p. (400 ug/kg, n=4 or 800 ug/kg, n=3), and perfused 90 minutes later. Brain sections were processed immunohistochemically to label CART, Fos, and pSTAT3 (only expressed in neurons directly responsive to leptin, i.e., containing LepR). Fos and pSTAT3 expression were quantified in peptidergic (CART) and non-peptidergic (non-CART) neurons in EWcp. Brain regions that express pSTAT3 were also assessed. In situ hybridization (ISH) for LepR, VGluT2, and CART was performed to identify the phenotypes of LepR-expressing neurons in EWcp. There was no effect of leptin dose on the % of Fos-expressing CART ($p=0.71$) and % of Fos-expressing non-CART ($p=0.92$) neurons, so the data was compiled. EWcp activation in response to leptin i.p. induced Fos expression in CART neurons (43.4 ± 2.2%; % CART-Fos/Fos) and in non-CART neurons (56.6 ± 2.2%; % non-CART-Fos/Fos). Of the total CART neurons in EWcp, 30.7 ± 4.7% were activated in response to leptin i.p. (% CART-Fos/CART). pSTAT3 signal was not observed in EWcp but was present in other brain areas known to express LepR, such as the arcuate and ventromedial hypothalamic nuclei. ISH showed that LepR in the EWcp are mainly localized in glutamatergic (VGluT2) neurons (~80% of VGluT2 neurons express LepR), and to a much lesser extent in peptidergic neurons (~10% of CART neurons express LepR). This observation, combined with the Fos data in non-CART neurons, suggests that the glutamatergic subpopulation in EWcp is

substantially activated following leptin i.p. administration. Though most functional studies of EWcp focus on its peptidergic neurons, our results support that the glutamatergic, non-peptidergic population plays a role in leptin-mediated metabolic functions.

Title: Central mechanisms underlying MDMA induced hyponatremia in rats

Authors: *J. C. WYROSDIC, Z. S. THIROUIN, C. BOURQUE;
Neurol. & Neurosurg., Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Clinical studies have shown that hyponatremia can be induced by the ingestion of the recreational drug MDMA when combined with a water intake (Baggot et al., 2016). However, the mechanisms by which MDMA induces hyponatremia is unknown. Hyponatremia is a life-threatening condition that causes rapid swelling of the brain. Under the Controlled Drugs and Substances Act, MDMA is a schedule 1 drug and consumption usually occur at dance parties. With a prevalence of 3.5% of young adults 18-25 years old using MDMA in the United States in 2014 (Betzler, Viohl, &Romanczuk-Seiferth, 2017), along with the mainstream marketing of MDMA for PTSD, combined with very serious and potentially deathly side effects makes this substance worthwhile to investigate. Findings could not only aid in MDMA associated hyponatremia but could also provide the foundation clinically for fluid regulation during MDMA assisted psychotherapy. Clinically, ingestion of MDMA has been shown to cause an increase in the hormones vasopressin and oxytocin (Wolf et al., 2006). Therefore, we examined cFos activity in rats, we show that there is an increase in both cFos activation of vasopressin and oxytocin neurons of the supra optic nucleus. Despite the clinical literature, our data shows that an injection of MDMA does not increase in water intake in rats. Interestingly, in line with the human literature, when you combine MDMA with a gastric water load, it is sufficient to drop serum sodium levels to hyponatremic levels i.e. <135mmol/L. Indicating that a water load combined with MDMA is necessary for MDMA induced hyponatremia. Conventionally, MDMA has been shown to increase the amount of serotonin within the synaptic cleft (Oeri, 2021). To determine if MDMA is working via the release of 5HT we utilized whole cell patch clamp slice electrophysiology of double transgenic Wistar rats enabling fluorescent identification of

vasopressin and oxytocin neurons. Interestingly, at a bath temperature of a constant 30*C, a bath application of 5HT was sufficient in causing an enhancement of action potential firing, and this could be blocked by a 5HT receptor antagonist. Moreover, a bath application of MDMA also caused an increase in action potential firing, which too could be blocked by a 5HT receptor antagonist.

Title: Unraveling the Neural Circuitry of Energy Balance with Molecular Connectomics

Authors: *A. N. WEBSTER[1], D. C. SCHWALBE[2], E. N. GODSCHALL[2], A. D. GULER[2], J. N. CAMPBELL[2,1];
[1]Neurosci. Grad. Program, [2]Dept. of Biol., Univ. of Virginia, Charlottesville, VA

Abstract: Identifying neurons which are synaptically connected is a fundamental challenge in neuroscience, especially in the hypothalamus, a heterogeneous region which controls appetite and other functions through largely obscure neural circuits. One method for identifying synaptically connected neurons uses a fluorescent-labeling rabies virus, modified so that it can only infect a target population of neurons and their presynaptic partners. This method can anatomically and morphologically identify presynaptic partners but otherwise provides little insight into their identity. We therefore developed a method which leverages monosynaptic rabies with single-cell transcriptomics to molecularly identify connected neurons. To demonstrate its utility, we applied our method to neurons in the arcuate hypothalamus(ARC) that express Agouti-related peptide (AgRP) and regulate appetite and metabolism, but for whom only a few presynaptic partners are known. Following infection of AgRP neurons and their presynaptic partners with rabies-H2b-mCherry, we isolated mCherry+ cell nuclei from the ARC, dorsomedial hypothalamus, and paraventricular hypothalamus. We then profiled their transcriptomes by single-nuclei RNA-sequencing (5770 cells, averaging 2296 genes/cell) and mapped the ARC transcriptomes onto a previously published dataset made from uninfected ARC neurons. Rabies significantly altered expression of 328 genes in AgRP neurons, relative to those only infected with AAV. However, 75% of subtype specific genes were not significantly affected by rabies, supporting our ability to identify rabies-infected neurons. Overall, our results reveal 14

candidate afferent populations of AgRP neurons within the ARC. Our results confirm previously identified sources of synaptic input, including Kisspeptin-Neurokinin B-Dynorphin (KNDy) neurons and dopaminergic (*Th*+/*Slc6a3*+) ARC neurons. Our results also suggest 12 other ARC cell populations synapse onto AgRP neurons, 5 of which we validated using RNA fluorescence in situ hybridization. Among these are inhibitory neurons which express receptors for leptin and glucagon-like peptide 1 and so may couple those signals to satiety by inhibiting AgRP neurons.Identifying these afferent populations will shed light on the circuits and signaling pathways which shape AgRP neurons' role in energy balance. In addition, our method can be applied to any molecular neuron subtype to identify presynaptic partners in a versatile and genetically tractable way.

Title: Novel method for whole brain analysis of internal states reveals network interactions between hunger state and sensory cues

Authors: L. ROGERSON, *A. RAMIREZ, D. SALZMAN;
Columbia Univ., New York City, NY

Abstract: Neural circuits that have evolved to maximize food seeking behavior communicate extensively with the body to keep metabolism within a tight range. Consequently, sensory, motor, and reward pathways in the brain are modulated by internal states indicative of energy balance; notably, hunger and satiety. These distributed networks are challenging to isolate because they are spatially intermingled but functionally distinct. To overcome this challenge, we developed a novel method for achieving two timepoint labeling and statistical inference in rodents, allowing us to study whole brain activity at a single cell resolution. Building upon our previous investigation of whole-brain networks during fasting and refeeding, we now employ the same methodology to delve into the realm of palatable food perception. Our focus is on evaluating neuronal activity in response to food cues, specifically examining how hunger state modulates these responses within a single animal. Not only does this approach enable us to compare the intricate neural responses to palatable food after fasting and refeeding, but also the nuanced differences in responses between palatable food and regular chow. This knowledge may

offer valuable insights into the development of targeted interventions for obesity and metabolic disorders.

Title: Chemogenetic activation of a subset of VMHvl ERα-positive neurons co-expressing Mc4r increases energy expenditure and improves glucose tolerance

Authors: *G. DENG[1,2], Y. DENG[2], J. JIANG[2], U. SINGH[2], L. SCHMIDT[2], Z. ZHU[3], L. ZINGMAN[4], H. CUI[5];
[2]Neurosci. and Pharmacol., [1]Univ. of Iowa, Iowa City, IA; [3]Intrnl. Med., Univ. of Iowa, University of Iowa, IA; [4]Intrnl. Med., Univ. of Iowa, Iowa City, IA; [5]Neurosci. and Pharmacology, Iowa Neurosci. Institute,, Univ. of Iowa Roy J and Lucille A Carver Col. of Med., Iowa City, IA

Abstract: Obesity remains a pressing public health concern worldwide. The ventromedial nucleus of the hypothalamus (VMH) is a sexually dimorphic brain nucleus consisting of heterogeneous cell types that collectively play integral roles in metabolic regulation. Neurons in the ventrolateral region of the VMH (VMHvl) that express the estrogen receptor alpha (ERα) have been implicated in glucose and body weight homeostasis in a sex-specific manner. Notably, a subset of these VMHvl ERα+ neurons co-express the melanocortin-4 receptor (Mc4r), a well-known gene associated with obesity. Given the established role of both ERα and Mc4r signaling in metabolic homeostasis, we hypothesized that these Mc4r+/ERα+ VMHvl neurons sex-specifically contribute to metabolic control. To test this hypothesis, we crossbred male mice expressing Flp recombinase in ERα+ cells (ERα-Flp+) with female Mc4r-Cre+ mice, generating ERα-Flp+/Mc4r-Cre+ double transgenic mice for an intersectional chemogenetic approach. Subsequently, these double transgenic mice received microinjection of an AAV expressing an excitatory chemogenetic receptor (hM3Dq) in Cre- and Flp-dependent manner into the VMHvl, allowing us to specifically target and activate this specific subset of VMHvl ERα+ neurons chemogenetically for functional investigation. Following intraperitoneal administration of the chemogenetic ligand deschloroclozapine (DCZ), these double transgenic, but not wild-type, mice exhibited significantly increased brown adipose tissue temperature and locomotor activity compared to vehicle treatment, particularly in male mice. Follow-up whole-body indirect calorimetry and plethysmography confirmed that chemogenetic activation of these ERα+/Mc4r+

VMHvl neurons markedly increase energy expenditure (EE) and respiration, more profoundly in male mice. Additionally, consistent with the reported roles of VMHvl ERα+ neurons in glucose-sensing and glycemic control, we found that chemogenetic activation of Mc4r+/ERα+ VMHvl neurons significantly improve systemic glucose tolerance in both sexes. Collectively, our results identify this distinct subset of VMHvl ERα+ neurons expressing Mc4r as an important sexually dimorphic regulator of EE and glucose homeostasis.

Title: Gpr75 signaling isndispensable for reproductionbut involvedin high-fat diet-induced feeding and hyperglycemia in rats

Authors: *Y. OTSUKA[1,2], N. INOUE[2], M. HIRABAYASHI[3], H. TSUKAMURA[2], Y. UENOYAMA[2];

Abstract: A recent study showed that haploinsufficiency of G-protein coupled receptor 75 (GPR75) gene (*Gpr75)* caused lower body weight in humans, suggesting that GPR75 could be a potential therapeutic target to prevent obesity (Akbari et al., 2021). The present study aimed to examine the role of GPR75 signaling in controlling feeding, metabolism, and reproduction using newly generated *Gpr75* knockout (KO) rats. We found that *Gpr75* mRNA expression was highly detected in the hypothalamus, while the expression was limited in other peripheral tissues in female rats. Both female and male *Gpr75* KO rats exhibited significantly lower body weight and food intake compared to wild-type (WT) control rats. On the other hand, there were no differences in the timing of puberty onset or pulsatile luteinizing hormone secretion between

Gpr75 KO and WT groups in both sexes. Next, male *Gpr75* KO or WT rats were subjected to a high-fat diet (HFD) or control diet (CONT) feeding. The body weight and food intake of HFD-fed WT rats were significantly higher than those of CONT-fed WT rats, whereas the body weights and food intake of HFD- and CONT-fed *Gpr75* KO rats were significantly lower than those of HFD- and CONT-fed WT rats. Furthermore, the quantitative analysis of mRNA expression of some orexigenic and anorexigenic neuropeptides in the hypothalamus of male rats revealed that mRNA levels of hypothalamic agouti-related peptide (AgRP) were significantly higher in *Gpr75* KO rats than in WT rats regardless of types of diets, suggesting that GPR75 plays a role in the downstream of orexigenic AgRP signaling and that *Gpr75* KO may prevent AgRP-induced feeding. In addition, a glucose tolerance test revealed that plasma glucose and insulin levels were significantly lower in HFD-fed *Gpr75* KO rats than in HFD-fed WT rats. Regardless of type of diet, C-C motif chemokine ligand 2 (CCL2, an inflammatory marker) mRNA expression was significantly lower in the gonadal white adipose tissue (gWAT) of *Gpr75* KO rats compared to WT rats. Moreover, mRNA level of adiponectin, a peptide which promotes glucose uptake, was significantly lower in the gWAT of CONT-fed *Gpr75* KO rats compared to CONT-fed WT rats. These results suggest that GPR75 may mediate the orexigenic effect of AgRP signaling and then promote feeding, obesity, hyperglycemia, and insulin resistance induced by HFD. Therefore, drug discovery of antagonists targeting GPR75 may contribute to developing new therapeutic techniques that control feeding and body weight and improve insulin resistance without affecting reproduction.

Title: Activation of α7nAChR Modulates Body Weight, Anxiety-like Behaviors, and Nociception in Murine Diet-induced Obesity

Authors: *S. ALSHARARI[1], A. A. ALAMEEN[1], F. ALDAFIRI[1], F. A. ALOTAIBI[1], Y. SALAH[1], M. A. ALSHAMMARI[2], Y. SARI[3], M. I. DAMAJ[4];

Abstract: Background: Obesity becomes a major health issue of the current century and it has a detrimental effect on all physiological functions promoting disorders including anxiety and pain hypersensitivity. Several studies report that acute and chronic exposure to palatable diet induced obesity associated with neuro-inflammation. Cholinergic anti-inflammatory pathways relieve

inflammation via α7 nicotinic acetylcholine receptor (α7nAChR) signaling. Since the currently approved pharmacological drugs are linked to serious side effects, searching for novel targets is mandatory. In this regard, α7nAChR might serve as a promising therapeutic target in fighting against obesity and obesity associated disorders.**Objectives**: the present study aimed to assess body weight changes and anxiety-like behaviors associated with chronic exposure to obesogenic diet in male C57BL/6J.**Method**: Initially, mice (n=8/group) exposed to either standard chow alone in the control group or plus obesogenic diet in the obese group to for 7 weeks to induce obesity. Metabolic parameters were measured regularly then treatments [vehicle, PNU-282987 hydrate (α7nAChR agonist), and methyllycaconitine citrate (MLA, α7nAChR antagonist)] were given to examine changes in metabolic and behavioral parameters.**Results**: On day42, mice exposed to obesogenic diet showed significantly higher food intake over those administered standard chow (23.13 VS 9.77 Kcal/day, P-value= 0.0004) and they significantly gained more weight from initial (25.5 Vs 16.15 %, P-value= 0.0026). Treating obese mice with PNU-282987 normalized the food intake (P-value < 0.0001) while MLA block this effect. Moreover, anxiety-like behavior assessment showed significantly higher anxiety in obese mice in comparison to control group showed less time spent in open arms (26.06 VS 60.966 sec, P-value=0.0004) and lower time in light compartment (109.4 VS 130.97 sec, P-value= 0.0167) using elevated plus maze and light and dark paradigms, respectively. However, introducing PNU significantly alleviate anxiety-like behavior by increasing the time spent in open elevated arm and light compartment (up to 84.84, P-value=0.0002 and to 136.63, P-value= 0.0082), correspondingly.**Conclusion**: exposing male mice to obesogenic diet displayed gain weight, and anxiety-like behavior, while pharmacological activation of α7nAChR alleviate weight gain and obesity-associated disorders.

Title: Connections of the Edinger-Westphal nucleus with the central circuitry that controls the sympathetic outflow to adipose tissues

Authors: *G. CANO, S. L. HERNAN, A. F. SVED;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The centrally projecting Edinger-Westphal nucleus (EWcp) is anatomically and functionally distinct from the EW nucleus that contains parasympathetic preganglionic neurons

involved in pupillary constriction. We have proposed that EWcp contributes to the control of energy homeostasis via modulation of sympathetic outflow to multiple organs, including adipose tissues, after integrating multimodal signals from central systems involved in thermoregulation and metabolic control. To characterize the central pathways that link EWcp with adipose tissues, we injected combinations of viral tracers in EWcp and brown (BAT) or white (WAT) adipose tissues. Rats were injected with an anterograde herpesvirus expressing mCherry (stHSV) in EWcp and a retrograde transynaptic pseudorabies virus expressing GFP (PRV-152) in BAT (n=4) or WAT (n=3) to identify neuronal groups involved in fat control (PRV-infected) that receive afferent inputs from EWcp (stHSV-fibers). After appropriate survival times, rats were perfused. Brain sections were processed immunohistochemically to label infected neurons and fibers. There were afferent fibers from EWcp in apposition to BAT- or WAT-infected presympathetic neurons in the paraventricular hypothalamic nucleus (PVN), A5 group, locus coeruleus, ventromedial medulla (VMM), rostral (RVLM) and caudal (CVLM) ventrolateral medulla. In the forebrain, fibers from EWcp were observed on BAT- or WAT-infected neurons in regions involved in BAT-mediated thermoregulation, such as the preotic area (POA), lateral hypothalamus (LH), arcuate, dorsomedial hypothalamic, and tuberomammilary (TMN) nuclei. There were also a few anterograde stHSV-infected neurons in all these areas, indicating that EWcp neurons are synaptically connected to BAT- and WAT-infected neurons. Another group of rats was injected with a PRV expressing RFP (PRV-614) in BAT and PRV-152 in EWcp (n=6) to identify EWcp afferents that are also part of the circuit that controls the sympathetic outflow to BAT. Double-infected neurons were found in the POA, PVN, LH, habenula, TMN, A7 and A5 group, VMM, RVLM, CVLM and nucleus of the solitary tract. Our results demonstrate the existence of a complex circuit directly linking EWcp and its afferents with neuronal groups that control adipose tissue activity, with multiple reciprocal connections, suggesting a highly interconnected circuit. These data provide a neuroanatomic substrate for a putative role of EWcp as a hub that integrates multiple inputs from regions involved in the control of adipose tissues, and conveys the appropriate output to presympathetic groups that, in turn, modulate the sympathetic outflow to these tissues.

Abstract: Investigative exploration and foraging leading to food consumption have vital importance, but are not well-understood. Since GABAergic inputs to the lateral and ventrolateral periaqueductal gray (l/vlPAG) control such behaviors, we dissected the role of vgat-expressing GABAergic l/vlPAG cells in exploration, foraging and hunting. To investigate how l/vlPAG vgat cells encode exploratory approach towards food and eating, we injected the vector AAV-DIO-GCaMP6s in the l/vlPAG of vgat cre mice to express the genetically encoded calcium indicator GCaMP6s in l/vlPAG vgat cells. This approach allowed us to obtain calcium transients from these cells through miniaturized microscopes as freely-moving mice forage for both highly palatable food (walnut) and prey (cricket). Both approach and eating behaviors could be decoded above chance levels in cricket and walnut assays using calcium transient activity as model input (n=4; one-sample t-test, cricket t-statistics: approach=3.87, eat=5.59; walnut t-statistics: approach=4.75, eat=7.53). We then manipulated the activity of l/vlPAG vgat cells *in vivo* during foraging through expression of inhibitory opsin archearhodopsin (n=7) and excitatory channelrhodopsin (n=9) while control mice express YFP (n=6). Inhibition of these cells decreased the amount of walnut eaten and increased latency to predate; excitation decreased latency to eat walnut, increased amount eaten, and decreased latency to predate. Given this data, we hypothesized that the vgat l/vlPAG cells would be interconnected with other known feeding regions. Both retrograde and anterograde circuit mapping revealed dense interconnectivity between the PAG and feeding regions, such as the medial preoptic area, the central amygdala, the lateral hypothalamic area, the bed nucleus of the stria terminalis and the zona incerta (ZI); the strongest downstream projection was seen in the ZI. We now identify a previously uncharacterized monosynaptic GABAergic projection from l/vlPAG vgat cells to the ZI. Fiber photometry recordings show that both in the walnut and the cricket assay, this projection was more active prior to eating onset. Optogenetic manipulation of the axon terminals of this projection robustly increases foraging and predation, suggesting the existence of a novel, bottom-up midbrain mechanism controlling feeding.

Abstract: Signals from the gut and elsewhere act in the dorsal vagal complex (DVC) to promote meal termination and mediate aversive responses to gastrointestinal malaise. Of the DVC brain regions, molecularly identified neuron populations of the area postrema (AP, which lies dorsal to the *nucleus tractus solitarius* (NTS) and the dorsal motor nucleus of the vagus (DMV)) remain relatively unstudied due to the difficulty of stereotaxically targeting them in mice. To understand the circuitry and function of AP neurons that express the calcitonin receptor (*Calcr*), we generated a *Calcr*^{Cre} rat model. Intra-AP injection of viruses to cre-dependently express synaptic tracers in these animals revealed projections mainly to the NTS, DMV, and the lateral parabrachial nucleus (lPBN), where projections from AP *Calcr* neurons terminated in a region distinct from aversive CGRP cells. We also injected an AAV to cre-dependently express the activating (hM3Dq) Designer Receptor Exclusively Activated by Designer Drugs (DREADD) into the AP of *Calcr*^{Cre} rats to permit the activation of transduced *Calcr* neurons by the administration of CNO. *Post hoc* analysis revealed two classes of animals with transduced DVC neurons- those that expressed hM3Dq only in AP Calcr neurons (Calcr$^{AP\text{-}Dq}$ rats) and those in which some virus leaked into the NTS, as well (Calcr$^{AP+NTS\text{-}Dq}$ rats). CNO treatment decreased short-term food intake and delayed gastric emptying without provoking conditioned taste avoidance in Calcr$^{AP\text{-}Dq}$ and Calcr$^{AP+NTS\text{-}Dq}$ rats. However, multi-day CNO treatment of Calcr$^{AP\text{-}Dq}$ rats failed to reduce body weight. These results suggest that neither AP nor NTS *Calcr* neurons mediate aversive responses and that decreased gastric emptying does not necessarily provoke

aversive responses. Furthermore, while AP *Calcr* cells mediate short-term effects on feeding and do not impact body weight.

Abstract: Hypothalamic agouti-related peptide (AgRP)-expressing neurons are exclusively located in the arcuate nucleus of the hypothalamus and form the basis of the melanocortin system, a set of CNS circuits regulating energy homeostasis. Besides an important role in driving food intake, AgRP neurons are also involved in modulating complex, non-feeding behaviors. However, it is unknown how AgRP-dependent feeding influences general exploratory behavior. Using the $AgRP^{DTR}$ mouse model with impaired AgRP neuronal functions, we show here that perturbation of AgRP neuronal function leads to sex-dependent altered behavioral responses driven by calorie restriction (CR). Our findings highlight the pivotal role of the AgRP neurons during CR in the regulation of complex behaviors and show that AgRP neurons are critical for complex behavioral adaptations to CR.

Title: Eating behavior phenotype changes and treatment response to GLP-1 agonist for hypothalamic obesity patients: two prospective studies

Authors: *S. LEE[1], S.-S. PARK[2], M. LEE[3], M.-J. PARK[4], Y. KIM[4], J. KIM[2], H. CHOI[3]; [1]Seoul Natl. Univesity, Seoul, Korea, Republic of; [2]Pituitary Ctr., [3]Biomed. Sci., [4]Neurosurg., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: **Background(objective):**Hypothalamic obesity is a severe, intractable obesity that rapidly occurs when the hypothalamus is damaged by brain therapy. It is primarily known to be caused by craniopharyngioma among brain tumors. There have been attempts to predict the development of obesity by assessing the degree of hypothalamic damage. However, no method has yet been developed to predict and diagnose the development of hypothalamic obesity. Moreover, there is currently no treatment for this condition. We aimed to investigate various phenotypic changes associated with the development of obesity after tumor surgery and to discover the responding subtypes after GLP-1 agonist therapy.**Method:**We performed a prospective study with 50 patients (aged 19 yr or older) who have been diagnosed and treated surgically with a hypothalamic tumor or a nonfunctioning pituitary tumor. Several subscale results were collected with basic clinical information, tumor size, physical measurements, digital food diary, wearable device measurement, appetite/satiety/eating behavior assessments (questionnaires), cognitive behavioral task assessments, and biochemical test results related to obesity. Comparisons were statistically conducted between the patient's pre-operative and post-operative assessment to observe the development of postoperative obesity. In addition, we performed a prospective study with GLP-1 agonist (Saxenda) treatment in patients with hypothalamic damage (HD) (craniopharyngioma) to investigate treatment response.**Results:**Patients with hypothalamic damage and large tumor size showed higher post-operative weight gain than other patients. These patients had higher restrained eating behavior, emotional eating behavior, and higher average daily kcal intake after the surgery. The results of GLP-1 agonist administration and predictors of the treatment response are analyzed.**Conclusion:**These results suggested that tumor size is related to hypothalamic damage, post-operative weight gain, and eating behavior changes. This study identified factors associated with the development of obesity, which may provide a clinical basis for understanding the pathophysiological mechanisms of hypothalamic obesity.

Title: The Role of Cerebellum in Eating Behavior

Authors: *Y. ZHOU, G. THAPALIYA, L. CHEN, S. CARNELL;
Johns Hopkins Univ., Baltimore, MD

Abstract: Neuroimaging techniques such as functional Magnetic Resonance Imaging (fMRI) have provided valuable insights into the neurobiology underlying variation in eating behavior among humans. Food cues are one of the key environmental stimuli influencing eating behavior. Understanding altered food cue responsivity and resting state connectivity within neural systems subserving appetite in individuals with obesity and eating-related pathology may help inform the development of neurobehaviorally-targeted interventions. A recent reverse-translational study uncovered a role for anterior deep cerebellar nuclei in satiation, suggesting functioning in the cerebellum may contribute to eating behavior. We aimed to investigate the extent, range and nature of cerebellar activation to food cues, as well as functional connectivity of the cerebellum to other brain regions in the resting state, in published fMRI studies of obesity and eating disorders. Pubmed and Google Scholar were systematically searched up to September 2022 using keywords including cerebellum [and] food cue / go-no-go / obesity / eating disorders / appetite. Studies were eligible for inclusion if they reported outcomes of either a food cue fMRI task or resting-state fMRI. We identified 11 food cue fMRI studies reporting cerebellum effects. Of these, 7 reported food vs non food differences, 3 reported high vs low calorie food differences, and 1 reported a difference in food cue responses between fed and fasted states. 3 reported differences in cerebellum responses between individuals with obesity vs healthy-weight, 3 reported differences in cerebellum responses between individuals with eating pathology (1 Anorexia Nervosa, 2 Prader-Willi Syndrome) vs. healthy-weight, 1 reported differences in cerebellum responses post vs pre bariatric surgery, and 2 reported differences in cerebellum responses after leptin administration in leptin-deficient patients. We identified 6 studies reporting cerebellar functional connectivity findings. Of these 2 studies reported differences by weight status, and 4 reported differences by eating pathology (2 Anorexia Nervosa, 1 bulimia nervosa, 1 evening hyperphagia). Charting peak coordinates of implicated regions demonstrated effects throughout the anterior, posterior, and flocculonodular lobes of the cerebellum that were on the whole not consistent within type of study, likely due in part to methodological variation between studies. Our results support a role for the cerebellum in eating behavior, and argue for more rigorous research to investigate potential differentiation of function with relevance to eating behavior within the cerebellum.

Title: Disruption of Transient Receptor Potential Channel 5 Causes Obesity

Authors: *Y. XU[1], Y. LI[2], L. TONG[1];
[2]2207 S Braeswood Blvd 42G, [1]Baylor Col. of Med., Houston, TX

Abstract: Background: The prevalence of obesity has increased worldwide. More than one-third of the population is obese and therefore at risk of developing type 2 diabetes, which has a great impact on health and economy. Transient Receptor Potential Channel 5 (TRPC5) is a brain-expressed, membrane-spanning cation channel, which regulates the depolarization of neurons involved in energy homeostasis in rodents. **Methods:** We used CRISPR-Cas9 approach to generate a knock-in Trpc5 mutation mouse and examined the metabolic change. We also used designer receptor exclusively activated by designer drugs (DREADD) to inhibit POMC neuron activity and test the effect of Trpc5 activator in food intake. Lastly, we deleted Trpc5 in oxytocin neurons and examined the phenotype using Cre-LoxP system. **Results:** Knock-in male and female mice harboring a human loss-of-function *TRPC5* mutation exhibited obesity and hyperphagia. POMC neurons express abundant Trpc5 and BTD (Trpc5 activator) can reduce food intake in mice through activating POMC neurons. Importantly, chemogenetic inactivation of hM4Di-expressing POMC neurons with clozapine N-oxide (CNO) blocked BTD-induced anorexia. Meanwhile, we also found oxytocin neurons in paraventricular hypothalamic (PVH) express abundant Trpc5. Deletion of Trpc5 in oxytocin neurons significantly increased food intake and body weight, associated with hyperglycemia. Moreover, acute treatment with oxytocin decreases body weight and improves glycemic control in knockout mice. **Conclusions:** These results demonstrated that genetic disruption of TRPC5 in leads to intense food seeking and obesity, which suggesting that TRPC5 play a vital role in obesity and may become a novel target for human obesity treatment.

Title: Comparison of the inputs and outputs of the anterior subdivisions of the lateral hypothalamic area in the adult male rat using an open-access atlas framework

Authors: *L. SOTO ARZATE[1], M. QUINTANA[1], V. I. NAVARRO[1], K. NEGISHI[1,2], A. M. KHAN[1];
[1]Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]NIH/NIDA, Baltimore, MD

Abstract: Neuroanatomical tracing studies of the cytoarchitectonically-derived subdivisions of the lateral hypothalamic area (LHA) have yielded connectional differences that support the idea proposed by Swanson (2018; *Brain Maps 4.0* (*BM4.0*) *J. Comp. Neurol.*) for their existence as separately parceled cell groups. Our laboratory has previously conducted tracing studies that explored the hodological differences between the dorsal and anteroventral subdivisions of the LHA and found that each of these differs sufficiently to justify their separation. In an effort to add to these studies, we aimed to compare the labeling patterns produced by two cocktail injections of retrograde and anterograde tracers, cholera toxin B subunit and *Phaseolus vulgaris*-leucoagglutinin (PHAL), respectively, within the LHA ai/ad and LHAav, across levels 5-40 of *BM4.0* to visualize the connectional patterns between these subregions. Preliminary results suggest marked differences in their connectional profiles. Although anterograde transport of PHAL from both injections are very similar, they appear to contrast with each other's subregional distributions. One such instance of this is the lateral septal projections from LHAai/ad, which cover the rostral medial dorsal zone of that nucleus, whereas the injection in the LHAav demonstrates few fibers in this subdivision of the lateral septum. Overall, trends for LHAai/ad targets tend toward more lateral regional distribution, while LHAav targets stay within the medial regions. Some regions of overlap include the lateral habenula and medial septal nucleus. Additionally, a very noticeable feature that distinguishes these two experiments is that the LHAai/ad tends to favor ipsilateral regions for its anterograde projections while the LHAav communicates with regions on the contralateral side. Similarly, retrograde transport follows many of the above-stated trends, which overall underscores how these two regions have very distinct connectional profiles that merit subregional separation.

Title: Standardized mapping of glucagon-like peptide 1 (GLP-1) immunoreactive neuronal populations in the hindbrain: immunohistochemical studies in the adult male rat

Authors: *J. V. SALCIDO, Padilla[1], G. P. TAPIA[2], A. M. KHAN[2];
[2]Biol. Sci., [1]The Univ. of Texas at El Paso, El Paso, TX

Abstract: Glucagon-like peptide 1 (GLP-1) is a versatile molecule that is produced peripherally in the L-cells of the intestine and centrally in a population of neurons located in the nucleus of the solitary tract (NTS). A growing body of literature indicates that these neurons send widespread projections to distinct brain regions and that their location in the hindbrain (HB) suggests a role in feeding control and glucose homeostasis. In this study, fixed-frozen brain tissue sections of male Sprague-Dawley rats were processed using a commercially available polyclonal antibody raised against GLP-1, surveyed for GLP-1-like immunoreactivity, and mapped to a standardized open-access atlas of the rat brain (*Brain Maps 4.0* (*BM4.0*); L. W. Swanson, 2018, *J. Comp. Neurol*.) We employed fluorescence immunohistochemistry or 3,3'-diaminobenzidine (DAB) immunoperoxidase staining to visualize and map the precise locations of GLP-1+ neurons in the caudal nucleus of the solitary tract (NTS) within *BM4.0*. To assess validity of signal localization, we also performed control experiments using tissue sections harvested from select forebrain regions immunoreacted with the same antibody and compared our data with that of the existing literature. At *BM4.0* atlas levels 69 and 70, GLP-1 immunopositive cells were observed in the medial (NTSm), commissural (NTSco), and lateral NTS (NTSl). At atlas levels 71-73, GLP-1 immunopositive cells were mostly observed in the NTSco and NTSm. We observed few cells in the ventral medullary reticular nucleus (MDRNv) at this range of levels. Control experiments revealed GLP-1-ir neurites in the lateral hypothalamic area (LHA) and the ventral tegmental area (VTA). These atlas assignments place the GLP-1-expressing cell group within a defined spatial framework in stereotaxic space and will facilitate their precise targeting in future experiments.

Title: High-spatial resolution mapping of bidirectional connections between the lateral septal nucleus and the lateral hypothalamic anterior and dorsal regions in the adult male rat

Authors: *V. I. NAVARRO[1], K. NEGISHI[1,2], I. DELGADO[1], A. M. KHAN[1];
[1]Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]NIH/NIDA, Baltimore, MD

Abstract: The lateral hypothalamic area (LHA), once regarded as a relatively homogenous brain area, is known to have diverse cell groups involved in a variety of functions. One proposed model of LHA organization, furnished by Swanson, has subdivided the LHA into multiple zones, tiers, and regions based on cytoarchitecture (*Brain Maps 3.0*; 2004). Since then, several studies have shown that these parceled groups harbor cells with distinct connections, reinforcing their status as distinct structural entities. Our own ongoing efforts to independently test this spatial model of organization have led us to identify connections of the anterior and dorsal subdivisions of the LHA (LHAa and LHAd, respectively) using the anterograde and retrograde tracers, *Phaselous vulgaris*-leucoagglutinin and cholera toxin B subunit, respectively (Navarro et al., SfN Global Connectome Meeting abstract, 2020/2021; Toccoli et al., SfN Abstract, 2021). Here we report on studies investigating the neuroanatomical inputs and outputs of the LS and LHAa/d in male rats covering levels 5-40 of *Brain Maps 4.0* (*BM4.0*; Swanson, 2018, *J Comp Neurol*). These connections were mapped at high-spatial resolution within the atlas templates of *BM4.0* to analyze where these regions differ and overlap connections and to bring these data into spatial registry with those that have previously been generated. We found that the lateral septal nucleus (LS) rostral part medial zone ventral region rostral domain (LSr.m.v.r.) appears to not only send projections to the LHAa (as first reported by Risold and Swanson, *Brain Res Rev*, 1997), but also receives inputs from this subregion. Moreover, the LHAd projects to the more dorsal portions of the LS, and our work confirms and extends the findings of Risold and Swanson again by demonstrating bidirectional connections between the structures. These data add to the precise mapping of connections between these two extensively subdivided brain regions. Given the vital roles that the LS and LHA play in regulating reward and feeding, among other functions, our findings provide additional rationale for further detailed exploration of functional communication between these brain regions.

Title: Atlas-based spatial analysis of the distribution of feeding-associated neuropeptide immunoreactivities within the rat parabrachial nucleus

Authors: *G. P. TAPIA[1], L. LUCERO[2], A. BLAKE[1], S. BALIVADA[2], A. M. KHAN[2];
[2]Biol. Sci., [1]The Univ. of Texas at El Paso, El Paso, TX

Abstract: The rat parabrachial nucleus (PB) is located in the dorsolateral pons and consists of >10 distinct subregions that surround the superior cerebellar peduncle (scp). The PB is understood to play a significant role in the control of food intake and has previously been demonstrated to be activated after refeeding (G Zséli *et al*., *J. Comp. Neurol.*, 2016). Neuronal processes innervating the PB contain diverse feeding-associated neuropeptides, but the chemoarchitecture of PB neuronal populations has not been systematically mapped using an atlas-based approach. To begin addressing this deficit, we processed brain sections containing the PB for immunohistochemistry using antibodies against calcitonin gene-related peptide (CGRP), neurotensin (NT), cholecystokinin (CCK), or oxytocin-associated neurophysin (PS38), and mapped the immunoreactive patterns to an atlas of the rat brain (L. W. Swanson, *Brain Maps 4.0*, *J. Comp. Neurol.*, 2018). Photomicrographs of these sections were aligned with those of an adjacent series of Nissl-stained tissue that served as a cytoarchitectural reference, enabling the data to be mapped to atlas levels with PB representations (Atlas Levels 47-52). Fiber density distributions were plotted for each neuropeptide and the spatial distribution among the populations was compared. CGRP-immunoreactive fibers formed a cluster that wrapped tightly around the lateral scp and extended across the external lateral (PBle) and external medial (PBme) parts. CCK immunoreactive-fibers occupied a large portion of the ventral lateral (PBlv) and PBle parts and moderately overlapped the territory occupied by the CGRP distribution. NT-immunoreactive fibers were observed in ventral and medial areas of the PB, as well as the troughs of the scp that bridge these two divisions. PS38(OT)-immunoreactive fibers were the most sparse of the fibers we observed, and were located predominantly in the lateral subnuclei. The atlas assignments shown here are a first step towards anatomically locating PB areas with dense expression of neuropeptides associated with feeding control, and will facilitate precise targeting of the anorexigenic pathways of the PB in future experiments.

Title: A topographically-defined hypothalamic-thalamic-striatopallidal connectional motif that supports hedonic processes

Authors: *K. NEGISHI[1,2], V. I. NAVARRO[1], L. SOTO ARZATE[1], J. M. GUERRA RUIZ[1], D. SOTELO[1], A. TOCCOLI[1], A. M. KHAN[1];
[1]Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]NIH/NIDA, Baltimore, MD

Abstract: Connectional topography is increasingly recognized as a widespread feature of forebrain organization. Corticostriatal projections, for instance, form a highly ordered patchwork of segregated and minimally overlapping fields. Significant progress has been made toward elucidating corticostriatal projection patterns; however, it is unclear how these are connected with downstream regions such as pallidum and hypothalamus. We have previously used a bottom-up strategy to reveal a topographically-defined hypothalamic-thalamic-striatal axis that includes the lateral hypothalamic area (LHA), paraventricular thalamic nucleus (PVT), and a dorsomedial part of the nucleus accumbens (dmACB) (Negishi *et al*., SfN Abstract, 2022). Here, we show that the ventral pallidum (VP; alternatively, the "substantia innominata") is part of this connectional motif. We co-injected *Phaseolus vulgaris* leucoagglutinin (PHAL) and cholera toxin B subunit (CTB) into the mPFC to examine input and output connections of VP simultaneously. Tracers were immunodetected and an adjacent Nissl-stained tissue series was used to delineate boundaries with the cytoarchitectonic definitions of Swanson (*Brain Maps 4.0*, 2018; *J. Comp. Neurol.*). Localized signal was mapped to atlas templates from *Brain Maps 4.0*. We show that CTB injections into VP exclusively labeled neurons in the dmACB. PHAL-labeled VP axons predominantly terminated in the LHA, confirming that VP is a critical node in this network. Next, we further elaborate VP connections throughout the forebrain. Strong CTB labeling was found in the LHA, PVT, subfornical organ, and the central nucleus of the amygdala. VP projections were found throughout the LHA, and were notably present in the PVT, lateral habenula, and ventral tegmental area. The present work suggests that the VP, receiving inputs from the dmACB, PVT, and LHA, is a central component of this network. The Berridge lab, using μ-opioid receptor agonists, has identified the dmACB and LHA as "hedonic hotspots," whereas the VP described here was identified as a "hedonic coldspot." Our work describes a circuit motif that joins brain regions relevant to hedonic and motivational processes, and juxtaposing our connectional maps with functional maps leads to novel questions for future experiments.

Title: High-spatial resolution mapping and three-dimensional architecture of the C1, C2, and C3 putative adrenergic neuronal groups and their neurites in the medulla of the rat brainstem: A light sheet microscopic study of PNMT immunoreactive structures

Authors: *S. BALIVADA, G. P. TAPIA, J. V. SALCIDO PADILLA, M. J. KENNEY, A. M. KHAN;
Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX

Abstract: C1, C2, and C3 putative adrenergic neurons in the medulla are known for their role in autonomic control and their activation in response to hypoglycemia and hypoxia. Anatomical features of these putative adrenergic neurons and their neurites have been previously characterized in brainstem sections by immunostaining catecholamine synthesizing enzymes, especially phenylethanolamine *N*-methyltransferase (PNMT). However, their characterization at a mesoscopic scale has been limited to two-dimensional (2-D) medullary sections or three-dimensional (3-D) reconstructions of such sections with gaps. To our knowledge, the complete 3-D architecture of putative adrenergic neurons and their neurites in the medulla has not, to date, been visualized. To achieve this goal, we used tissue clearing combined with fluorescence immunohistochemistry and light sheet microscopy to produce volumetric renderings of the PNMT-immunostained brainstem. In tandem, we used atlas-based mapping methods on separate 2-D immunostained preparations of brainstem tissue to register the locations of PNMT-immunoreactive neurons to the open-access rat brain atlas of Swanson (*Brain Maps 4.0* (*BM4.0*), *J. Comp. Neurol.*, 2018), and to use these mappings as ground truth to register the 3-D dataset to *BM4.0*. Formaldehyde-fixed Sprague Dawley rat brainstems were protected using SHIELD hydrogel method and cleared through detergent based aqueous de-lipidation. These cleared rat brainstems were passively immunostained with PNMT primary and Alexa Fluor 647-tagged secondary antibodies, and scanned with a SmartSPIM light sheet microscope using a x3.6 objective lens. 3-D volume renders of the PNMT-positive neurons and their neurites were prepared using Imaris software. In addition, the spatial features of PNMT neurons and neurites from tissue sections were mapped onto *BM4.0* templates and their features compared to PNMT 3-D renders. In 3-D spatial exploration, we observed dense clusters of ventral C1 neurons and their interconnections with the dorsal C2 neurons on either side of the midline. These dorsal C2 neurons, in turn, were found to be interlinked by finely branched connections that crossed the midline of the brain, where the C3 neurons are, linking the two hemispheres in what appears to be a novel structural basis for coordinated and perhaps synchronized physiological control. In conclusion, complete volumetric renders allowed us to visualize and identify the mesoscopic-scale connectional network formed by the C1, C2, and C3 neuronal groups and their neurites. Future work could help determine the functional significance of these newly visualized network interactions.

Title: Pose tracking-based freezing detection reveals context-dependent features of fear response

Authors: *N. CANO ADAMUZ, R. DE LA VEGA RUIZ, C. REDONDO-ALAÑÓN, P. MENDEZ;
Dept. of Fundamental and Syst. Neurosciences, Inst. of Neurobio. Ramon y Cajal, Madrid, Spain

Abstract: Freezing is a threat defensive response characterized by complete immobility, except for respiration. It is a robust measure of associative fear memory in rodent contextual fear conditioning, where learning occurs when aversive foot-shocks (unconditioned stimulus, US) are presented within a context (conditioned stimulus, CS). Freezing can be restricted to the conditioning context or extended to a similar neutral context. To understand the neuronal underpinnings of discrimination and generalization, it is essential to reliably detect freezing in different contexts while monitoring the activity of different neuronal populations.
The accuracy of automated freezing detection by video image-based detection software is challenged by differences in experimental contexts or when mice wear head-mounted hardware. We have implemented BehaviorDEPOT (Gabriel et al. 2022), which uses pose tracking data obtained with DeepLabCutTM (Mathis et al. 2018), to reliably detect freezing without interference from environmental factors. We validated this method's detection on our data based on the biological properties of freezing: 1) it appears in response to shocks and not in their absence (US-dependent), 2) is maintained when mice are re-exposed to the context 3 or 25 days after shock (long-term persistence), 3) is facilitated by previous context exploration (CS-dependent), 4) decreases with repeated context exposure (extinction).
Using this method, we characterized the freezing response in conditioning and neutral contexts. We show that freezing is differently regulated in each context and can be expressed with distinguishable features (incubation, number of episodes and duration). Manipulations of learning conditions such as shock intensity, number of presentations or shock zone (center or periphery) differentially affect these freezing features in the conditioning or the neutral context. In addition, we recorded with fiber photometry the activity of hippocampal regions (CA1 and DG) responsible for conveying contextual representations during freezing in both contexts. Preliminary analysis reveals changes in the activity of defined neuronal populations associated to

freezing behavior in both contexts.
In summary, we contributed to the biological validation of an automatic pose estimation-based freezing detection method in rodent fear conditioning experiments. We successfully implemented this method with fiber photometry recordings of neuronal activity. As a result, we demonstrate context dependent adaptation of freezing features to changes in learning conditions and describe the neuronal activity correlates of freezing in the hippocampus.

Title: Study of Rodent Inequity aversion Revenge and the underlying Neural Mechanism

Authors: *Z. ZHANG, B. LIU, Z. WANG;
Inst. of Neuroscience, Ctr. for Excellence in Brain Sci. and Intelligence Technology, CAS, Shanghai, China

Abstract: Inequity aversion is an instinctive emotion that is constant in the comparison of social values. In human, this emotion is termed envy. There is little work in rodent and on the underlying mechanism. The negative social emotions of individuals will also lead to the retaliatory behavior against specific individuals in the subsequent social behavior. Besides, the social influence of inequity stimulation remains largely unknown. We design a new paradigm, and use rat as model animal to investigate the inequity aversion mechanism. A two screens- two nose pokes decision making task is first designed to explore whether rats prefer equity reward or not. Rats make decision by choosing vertical stripe or horizonal stripe which represent equity or inequity respectively. We find that rat prefers equal reward instead of inequity, which is proved after stripes swapped. In addition, we examine the influence of social after going through enforced inequity treatment. Social time between equity partner and inequity partner shows no difference. Meanwhile, rats are more aggressive when faced with individuals whose rewards are better than their own. This revealed that rodent animals also have inequity aversion and inequity changed their neuroplasticity. Aggression of rats suffered inequity aversion displays different behaviors for distinct individuals. This finding indicate that inequity stimulation can modulate rats' social behavior. Furthermore, we examine the influence of hippocampus CA2 on inequity aversion and find inhibition of CA2 affects rat inequity aversion and the resulted revenge behavior. Taken together, we establish a new paradigm, demonstrate that rats prefer equity reward, and find that inequity aversion results in aggression behavior in a CA2-dependent manner.

Title: Two-photon imaging of CA1 engram cells during memory retrieval

Authors: *A. MONASTERIO[1,2], S. COELLO[3], G. K. OCKER[4], B. B. SCOTT[3], S. RAMIREZ[3];
[2]Grad. Program for Neurosci., [3]Psychological and Brain Sci., [4]Mathematics & Statistics, [1]Boston Univ., Boston, MA

Abstract: Memories are believed to be stored in the strengthened connectivity between distributed networks of neurons after learning. This biophysical memory trace is often referred to as an engram, provisionally defined as cells that are active during learning, reactivated during memory retrieval, and causally linked to behavioral expression of fear memory recall. Inducible genetic strategies have identified putative populations of engram cells in the hippocampus that express c-Fos during fear learning, and can drive the behavioral expression of memory. The current model for engram formation predicts that CA1 engram cells will become coactive with each other after learning due to strengthened synaptic inputs from upstream CA3 engram cells. To test this model in vivo, we developed a novel approach to record from engram cells across learning by combining the inducible tet-Tag strategy with large scale two-photon calcium imaging. We previously found that spontaneous activity of engram cells did not become more correlated after contextual fear learning. Therefore, we sought to see if memory retrieval may influence the real time dynamics of engram cells. Here we evaluated if CA1 engram neurons were more correlated with one another than non-engram cells during memory retrieval. We utilized the c-Fos-driven tet-Tag system to label CA1 engram neurons during auditory trace fear conditioning with a tone conditioned stimulus (CS). Two days later, we recorded from CA1

tagged engram and non-tagged cells during 10 trials of CS presentation to test for memory retrieval (n=3 mice, 580 cells). Surprisingly, engram cells were not more correlated during tone presentation relative to non-engram cells (2-Way RM ANOVA, p=0.12). This result replicates our finding from spontaneous activity of engram cells, however these findings are not in accordance with a simulated model of engram formation in which learning results in stronger synaptic weights between all engram cells. Two possibilities for this discrepancy may be that a small subset of tagged engram cells become coupled after learning or that engram cell reactivation is distributed in time. Further analyses to evaluate these possibilities is warranted in order to characterize the in vivo dynamics of engram cells during memory recall.

Title: Age differentially affects behavioral outcomes in a murine model of frontal lobe glioblastoma

Authors: *H. LEBLANC[1], E. RUESCH[1], X. VARELAS[2], S. RAMIREZ[1];
[1]Psychological and Brain Sci., Boston Univ., Boston, MA; [2]Biochem. and Cell Biol., Boston Univ. Chobanian & Avedisian Sch. of Med., Boston, MA

Abstract: Glioblastoma is the most common malignant central nervous system (CNS) tumor in adults. This disease not only has a poor survival prognosis, but also poses a severe burden on a patient's quality of life (QOL) due to the high rates of tumor-induced cognitive impairments,

which can be further exacerbated by age-associated cognitive decline. Due to the high patient mortality rates of glioblastoma, past research has focused on the development of survival-prolonging therapeutics, but few studies have investigated the accompanying cognitive and psychiatric symptoms that may improve QOL. To better address this gap, we developed a frontal lobe model of glioblastoma by introducing murine, high grade glioma cells into the medial prefrontal cortex of young (6-7 week old) and aged (85-86 week old) mice, and subjected them to a battery of behavioral tasks including the open field, tail suspension, social interaction, y-maze, contextual memory recall, and elevated zero maze, to test the effects of tumor burden and age on cognition and behavior. We additionally investigated whether the brain-region specific spread of each tumor could predict the behavioral phenotypes observed in tumor-bearing mice. We found a shared, increased "risk-taking" phenotype between young and aged mice in the elevated zero maze, but conversely found diverging results in the tail suspension test, with young mice struggling more and aged mice struggling less than their age-matched controls. These results emphasize the need to consider the demographics of a disease population when developing small animal models of pathology in systems and behavioral neuroscience. Our ongoing work seeks to 1) understand the neural underpinnings of the differential phenotypes expressed in young versus aged mice, and 2) target these mechanisms through optogenetic and pharmaceutical approaches to rescue the behavioral deficits observed. Together, our observations provide new insight into the mechanisms underlying glioblastoma-induced cognitive and behavior alterations.

Title: Hippocampal Engrams Flexibly Generate Behavioral Responses and Brain-wide Network States

Authors: *K. E. DORST[1], R. A. SENNE[2], A. DIEP[2], R. SUTHARD[4], A. R. DE BOER[5], E. A. RUESCH[3], M. BUZHARSKY[6], A. PYO[3], S. RAMIREZ[2];

Abstract: Memory engrams are both necessary and sufficient to mediate behavioral outputs. Freezing behavior predominates when fear memory engrams are reactivated in constrained contexts, yet other experiments previously showed an avoidance behavioral phenotype when fear memory engrams were reactivated in spatially large arenas. How reactivation of a given fear memory engram engages the brain to produce various defensive behavioral strategies across contexts is relatively unclear. To address this, we first optogenetically reactivated a tagged fear memory engram in the dentate gyrus (DG) subregion of the hippocampus across three distinct contexts of various sizes. We found that there were differential amounts of within-animal light-induced freezing depending on the size of the context in which reactivation occurred: mice demonstrated robust light-induced freezing in the most spatially restricted of the three contexts but not in the largest. Next, we utilized graph theoretical analyses to identify brain-wide cFos co-activation patterns during engram reactivation across the smallest and largest contexts. We found that fear memory engram reactivation induced strong brain-wide correlation and regions spanning putative “fear” and “defense” systems were recruited as hub regions in the respective networks. Additionally, we show that fear memory engram reactivation and naturalistic fear memory retrieval are biologically degenerate (i.e., different configurations leading to the same behavioral outcome) network conditions to produce freezing behavior; there are shared hub regions across both experimental conditions, yet the mesoscale network composition had distinct structural features. By identifying and manipulating the circuits supporting memory function, as well as their corresponding brain-wide activity patterns, it is thereby possible to resolve systems-level biological mechanisms mediating memory’s capacity to modulate behavioral states.

Title: Reactivation of a dorsal dentate gyrus engram differentially engages neurons and astrocytes in ventral hippocampus

Authors: *A. PYO[1], M. BUZHARSKY[3], R. SUTHARD[4], R. A. SENNE[2], A. DIEP[2], S. RAMIREZ[2];
[2]Boston Univ., [1]Boston Univ., Boston, MA; [3]Boston Univ. Undergraduate Program In Neurosci., Boston, MA; [4]Boston Univ., Boston Univ. Grad. Program For Neurosci., Boston, MA

Abstract: Though traditionally characterized as support cells, glial cells play an integral role in modulating circuit activity and cognition. Astrocytes, in particular, have recently been implicated in learning processes, including contextual fear conditioning, although their real-time involvement in fear encoding and maintenance is less understood, and even less is known about how they interface with neurons. Here we investigated how astrocytes and neurons in ventral CA1 (vCA1) in male mice respond during natural and artificial reactivation of a fear memory. To accomplish this, we combined activity-dependent labeling strategies and optogenetics in the dorsal dentate gyrus (dDG) with simultaneous in vivo fiber photometry to record the calcium dynamics of neurons and astrocytes in vCA1 during contextual fear conditioning, 'natural' recall, and 'artificial' optogenetic reactivation of a fear engram'. Mice received viral injections to express channelrhodopsin-2 (ChR2) or eYFP in the dDG and the genetically-encoded calcium indicators, jRGECO1a and GCaMP6f in vCA1 neurons and astrocytes, respectively.We first find that both neurons and astrocytes in vCA1 respond robustly to aversive foot shock during fear conditioning as well during fear memory recall. To further characterize astrocytic and neuronal activity across sessions, our ongoing work is evaluating event metrics, including peak height , full-width half max,, area under the curve,and frequency. Our preliminary results indicate that astrocytes alone exhibit experience-dependent changes in calcium event metrics during fear conditioning and natural recall. However, optogenetic stimulation impacts event metrics in neurons but not in astrocytes. Lastly, we will perform peri-event analysis to study calcium dynamics of astrocytes and neurons around the onset and offset of freezing bouts. Together, our results suggest that astrocytes and neurons are differentially engaged across fear learning, natural recall and artificial reactivation of a neutral or fear memory.

Title: Ketamine enhances performance on a perceptual evidence accumulation task

Authors: *C. DELGADO SALLENT, S. A. AHMED, A. RATNAKAR, A. KHAWAJA-LOPEZ, J. GOMEZ, S. RAMIREZ, B. B. SCOTT;
Boston Univ., Boston, MA

Abstract: The use of psychedelics have proven to be effective in treating psychiatric disorders, often producing a sustained effect after a single dose. While the therapeutic effects of these psychedelics have been related with their ability to promote structural and neural plasticity, these interventions produce brain-wide effects, and the neural and behavioral mechanisms underlying these effects are poorly understood. In this study we focus on ketamine to characterize its therapeutic properties by combining two different approaches: elucidating ketamine's effects on flexible decision-making parameters in mice, as well as studying the brain-wide mapping of drug-responsive populations by using activity-dependent gene expression. To find the effects of different doses of ketamine on decision-making, we trained mice on a free-response, pulse-based perceptual integration task. We find that after ketamine administration at medium-high doses (30-50 mg/kg) mice slowed their response times (RT) and increased accuracy in the task. Subsequently, we fitted a drift diffusion model (DDM) that suggested that the slower decision time induced by medium-high dose ketamine administration is due to an increased boundary separation and non-decision time. RTs were well fit by the DDM, and parameter fits suggested that mice use a multi-flash accumulation strategy. To further characterize which brain regions are activated by ketamine administration (30 mg/kg), we combined whole-brain immuno-staining of the activity-dependent immediate early gene, c-fos, with the theoretical framework of graph theory. By measuring the difference in cfos expression between ketamine and saline and also applying topological measures of centrality to correlation networks we observed changes in several regions, particularly in specific thalamic areas, that we identify as key regions in our networks (hubs). To address the causal role of these network hubs our ongoing work plans to do targeted reactivation of cell populations active during ketamine administration to recapitulate ketamine's effects. Taken together, our results indicate that subanesthetic doses of ketamine improves perceptual evidence accumulation by raising the decision threshold and allowing the integration of more evidence before the decision.

Title: A hippocampal astrocyte ensemble is activated during fear learning and memory.

Authors: *R. A. SENNE[1], R. L. SUTHARD[1], E. A. RUESCH[2], A. H. MONASTERIO[1], M. D. BUZHARSKY[3], S. RAMIREZ[2];

Abstract: The dorsal CA1 (dCA1) subregion of the mammalian hippocampus has been well studied in the context of episodic memory, spatial coding, and navigation. Most published research on dCA1 focuses nearly entirely on its neuronal populations, but recent work has begun studying the glial counterparts present throughout dCA1-namely astrocytes. Astrocytes, once thought as supporting cells of the brain, have now been widely implicated as important choreographers in neuronal communication, releasing gliotransmitters, supporting metabolic needs during sustained neurotransmission, pruning synapses, and affecting synaptic plasticity. Recent studies have shown that the perturbation of dCA1 astrocyte populations has the capacity to both enhance and weaken fear memory at remote and recent timepoints and that these populations can even encode reward locations (Doron et. al., 2022; Adamsky et. al., 2018; Kol et. al., 2020). However, there has not been a systematic characterization of how these cells may be implicated in fear memory processing in the region and how stable these populations are across timepoints. To address this, we injected AAV-GfaABC1D-cyto-GCaMP6f-SV40 into the dCA1 of the hippocampus of male C57BL/6J mice to selectively express a genetically-encoded calcium indicator in astrocytes. We paired this with the implantation of a gradient-index (GRIN) lens to record freely-moving one-photon calcium imaging across a standard contextual fear

memory paradigm. We find that there is a small but stable population of hippocampal astrocytes that encode various aspects of the fear memory and that there are unique physiological signatures across this population. We further report that mice re-exposed to the original fear context show robust markers of memory recall in these populations compared to a group exploring a novel context. Our results demonstrate that astrocytes play a crucial, and equally important, role in learning and memory and that their physiological dynamics are intimately tied to the behavioral expression of fear.

Title: The role of positive and negative engrams in memory-guided decision making

Authors: *A. CABAN[1], M. SURETS[3], M. KAUFMANN[1], K. DORST[1], R. A. SENNE[2], C. DELGADO[1], R. SUTHARD[4], S. RAMIREZ[2];

Abstract: The ability to make flexible memory-guided decisions is fundamental to our daily lives. Such decision-making often requires a strategically balance between motivational drives including the pursuit of reward and avoidance of danger, which become impaired in pathological states such as addiction and anxiety disorders. Here, we aim to understand the underlying mechanisms that support such flexibility during memory-guided decision-making. To this end, we developed a novel decision-making task that allows animals to strategically combine the drive to approach a reward and avoid a footshock without compromising either goal. During training, mice learn that a 30s light cue indicates the availability of reward at a nose port (i.e. sucrose water), and a 30s auditory cue predicts the onset of a footshock which they can avoid by stepping onto a platform. After animals learn the reward and punishment contingencies, the light and auditory cues are delivered at the same time, creating a conflict between reward-seeking and punishment avoidance. Over the course of 7 days, we find that mice initially utilize unique sex-specific strategies that then converge over 7 days on the same resolution to this conflict. Initially, female mice are more risk-taking and opt to get the maximal reward at the expense of

footshocks. However, by day 7 all mice learn to balance both drives: seek reward early during the simultaneous cue presentations while then stepping on the platform towards the end of the cue presentations, thus avoiding the footshock without omitting reward seeking. To mechanistically study the brain regions recruited during this flexible decision-making process, we combined whole-brain inmuno-staining of the activity-dependent immediate early gene cFos with the theoretical framework of graph theory. By applying topological measures of centrality to correlation networks created from cFos expression we identified several regions (i.e. Hubs) in our networks, with the prelimbic cortex (PL) playing a key role. We next utilized population calcium imaging to record real-time calcium dynamics of both PL during memory guided decision-making and found the PL bidirectionally encodes avoidance and reward seeking behaviors. Additionally, we found that the PL differentially encodes trials in which memories were incorrectly balanced to maximize rewards and minimize punishment. Our ongoing experiments aim to chemogenetically perturb valance specific engrams to bias decision-making. Overall, our findings suggest the PL may play a critical role in arbitrating positive and negative memories during memory-guided decision making.

Title: The role of the ventral hippocampus in navigating predatory environments

Authors: ***X. LI**[1], M.-S. KONG[2], E. J. KIM[1], B. P. SCHUESSLER[4,5], J. J. KIM[1,3]; [1]Psychology, Univ. of Washington, Seattle, Seattle, WA; [2]Dept. of Psychiatry and Behavioral Sci., [3]Program in Neurosci., Univ. of Washington, Seattle, WA; [4]VA Northwest Geriatric Research, Educ. and Clin. Ctr., [5]VA Northwest Mental Illness Research, Educ. and Clin. Ctr., VA Puget Sound Hlth. Care Syst., Seattle, WA

Abstract: The hippocampus is posited to show functional segregation along its longitudinal axis, with the dorsal hippocampus (dHPC) and ventral hippocampus (vHPC) playing pivotal roles in cognitive and emotional processes, respectively (Fanselow and Dong, 2010; Strange et al., 2014). This view is corroborated by evidence demonstrating that selective lesions or inactivation of the dHPC impairs fear conditioning by affecting contextual and trace cues (e.g., Phillips and LeDoux, 1992; Chowdhury et al., 2005), whereas selective lesions/inactivation of the vHPC lead to generalized impairment in fear and anxiety by impacting innate or unconditioned fear

processes (e.g., Kjelstrup et al., 2002; Bannerman et al., 2003). Through an ecologically relevant "approach food-avoid predator" (AFAP) paradigm (Choi and Kim, 2010), we previously discovered that dHPC neurons also contribute to distance-gradient risky foraging decision-making (Kim et al, 2015). The present study investigated the function of vHPC using the same AFAP task. Long-Evans rats underwent either vHPC or sham lesion surgery and maintained 85% normal body weight to motivate food-seeking behavior during the baseline phase. On the test day, animals underwent pre-predator trials followed by predator exposure trials, with food pellets placed at various distances to the predatory robot. The findings suggest that animals with vHPC lesions showed diminished fear responses to the robot, evidenced by shorter latency to acquire pellets, including when placed in close proximity to the robot. Sham animals were comparably less successful at acquiring pellets and exhibited longer latencies. A subsequent study in C57BL mice also revealed heightened c-Fos expression in the CA1 region of the vHPC following predatory exposure in an AFAP task, compared to the foraging-only control group. Collectively, these results indicate that vHPC cells respond to predatory threats, thereby underscoring the potential significance of vHPC in natural fear behavior. Our ongoing research is employing electrophysiological techniques to study the activity of vHPC neurons in rats performing risky foraging tasks, aiming to deepen our understanding of this critical region.

Abstract: The consolidation of contextual fear memories requires the crosstalk among multiple brain regions, including the hippocampus and amygdala. Despite the advance in single cell transcriptomic techniques, tracing the dynamic gene expression across the hippocampal-amygdala circuit remains challenging. Here we integrated high resolution spatial transcriptomics with single nuclei multi-omics techniques to systematically investigate the spatiotemporally transcriptional programs across the hippocampal-amygdala circuit during the encoding and retrieval of contextual fear memory. It reveals brain region-specific gene expression changes during memory consolidation, especially in the subregions of hippocampus and amygdala. Furthermore, it showed cell-type specific epigenetic and transcriptional changes during the contextual fear memory consolidation. Our data provides new insight into the spatiotemporal and cell-type specific transcriptional programs during memory consolidation.

Title: Effects of stress on formation and retrieval of hippocampal ensemble representations of contextual fear memory

Authors: *D. PAREDES[1], M. R. DREW[2];
[1]Univ. of Texas at Austin, Austin, TX; [2]Univ. of Texas At Austin, Univ. of Texas At Austin, Austin, TX

Abstract: The stress-enhanced fear learning (SEFL) model recapitulates components of PTSD, such as stress-induced sensitization of fear learning. The SEFL procedure uses components of Pavlovian fear conditioning but generates a marked stress-sensitized fear response. The SEFL procedure entails exposing mice to footshock stress in context A (10 shocks, 2 s, 1 mA). On a separate day, mice receive a single shock at a lower intensity (0.75mA), in another context. 24 hrs later, mice are placed in context B and tested for fear recall. Stressed mice show higher freezing in context B. We used the SEFL model to investigate effects of stress on fear memory encoding and retrieval in the dentate gyrus and CA1. Fear memory representations in the hippocampus were investigated using activity-dependent neuronal tagging with FosTRAP/Ai6

mice, whereby cells activated during a discrete event are labeled using the IEG promoter elements to initiate the expression of a tag (zsGreen) following injection of tamoxifen. Prior research shows tagged fear engram cells are reactivated during fear memory recall, and the degree of reactivation of fear engram cells is correlated with the percentage of freezing during fear memory recall. We used the FosTRAP2/Ai6 system to investigate how prior stress exposure affects formation and reactivation of contextual fear ensembles. Male and female FosTRAP2/Ai6 mice received shock stress (or exposure to the context) on day 1. From days 2-5, mice were re-exposed to the stress context (context A) to extinguish fear of the stress context and reduce generalization to context B. On day 6, mice received conditioning in context B and immediately after received an injection of 4-OHT (55mg/kg). On day 7, mice were tested for fear recall and were perfused 90 minutes after. We examined the number of 1) zsGreen+ fear engram cells, 2) recall-activated cells (Fos+cells), and 3) fear engram cells reactivated during recall (Fos+ and zsGreen+) in the dentate gyrus and CA1. Our preliminary results show that prior stress increases the number of fear engram cells in the dorsal dentate gyrus, but does not change the number of activated cells (Fos+) during recall, the total number of reactivated engram cells (Fos+ and zsGreen+ cells/mm2), or the percent of reactivated cells. Thus, stress enhances the encoding of contextual fear, but does not affect the reactivation of a contextual fear memory. Ongoing experiments will determine if stress affects the number of cells in the fear engram, fear recall, or co-activated cells in CA1 and will examine differentiation along the dorsal-ventral axis. These studies are expected to reveal novel mechanisms for the stress-induced sensitization of fear learning.

Title: Role of the paraventricular thalamus in stress-induced fear sensitization

Authors: *K. NISHIMURA[1,2], D. PAREDES[2], N. A. NOCERA[2], M. R. DREW[2];
[1]Inst. for neuroscience, [2]Ctr. for Learning and Memory, Univ. of Texas at Austin, Austin, TX

Abstract: Stressful experiences can lead to long-lasting alterations in emotional fear responses. Excessive and disproportionate fear that extends beyond contexts or situations related to the traumatic event may resemble symptoms of hyperarousal, commonly observed in individuals with post-traumatic stress disorder. Although the neural circuitry underlying Pavlovian conditioned fear to a discrete stimulus has been well studied, the circuits recruited by a single stressful event to ubiquitously sensitize fear remain poorly understood. In the current study, we

characterized the behavioral and neural mechanisms of stress-induced fear sensitization using a novel mouse model. Mice were assigned to a “Stress” group that received four 1-mA foot shocks or a “No Stress” group that received equivalent context exposure. Following 24 hours, animals exposed to stress exhibit a persistent phenotype of fear sensitization characterized by (1) decreased exploration in the open field, (2) potentiated unconditioned fear of a novel tone, and (3) stress-enhanced fear learning (SEFL) in a novel context. Stress-induced fear sensitization to unconditioned tone and SEFL are resistant to extinction training in the stress context, indicating that non-associative learning facilitates this process. Next, c-fos analysis was performed to identify candidate brain regions that mediate fear sensitization. We identified several brain regions that were hyperactive in stressed animals including the paraventricular thalamus, dorsolateral periaqueductal gray, and the lateral parabrachial nucleus. Using fiber photometry, we confirm *in vivo* that stress leads to potentiated activity in the paraventricular thalamus in response to aversive or threatening stimuli. Finally, we used chemogenetic manipulations to show that the paraventricular thalamus is both necessary and sufficient for fear sensitization to unconditioned tone. Interestingly, silencing or activating the paraventricular thalamus had no effect on associative context fear conditioning. Overall, the data indicate that fear sensitization is not contingent on the initial associative fear memory and is likely acquired and maintained through dissociable neural mechanisms.

Title: The ventral hippocampus plays a critical role in habitual behaviors

Authors: *J. BHALERAO, E. SEO, A. G. ALLEN, S. L. GOURLEY;
Emory Univ., Atlanta, GA

Abstract: Habits are familiar actions that have been repeatedly performed and rewarded in the past, such that they manifest repeatedly and are triggered by cues in the environment rather than specific outcomes. While habitual responses are an important component of our behavioral repertoire, overreliance on them can lead to inflexible and maladaptive decision-making. The ventral hippocampus (vHC) appears to control the development of habitual behaviors, but its involvement in the *expression* of habits has largely not been explored. We used projection-specific G_q-coupled designer receptors exclusively activated by designer drugs (DREADDs) to stimulate vHC-to-central nucleus of the amygdala (CeA) projections in mice tested for their sensitivity to changes in action-outcome contingency. Stimulation of vHC-CeA projections

induced the expression of habits - that is, behaviors that were insensitive to action contingency. Next, we used schedules of reinforcement that induce habitual or non-habitual behaviors to examine neurobiological adaptations in the vHC to habit formation and execution. In conclusion, vHC-CeA connections exert control over the expression of habitual behaviors. Future experiments will reveal hippocampal-amygdalo-striatal connectivity by which familiar habits are executed, as well as substrates of vHC plasticity underlying habitual and non-habitual reward-seeking. These outcomes will serve as a platform by which to investigate vHC hyper-activity in disorders associated with persistent habitual behaviors, such as autism spectrum disorders.

Title: Emotional association enhances perceptual memory through amygdalo-cortical inputs during NREM sleep

Authors: *Y. SAITO[1,2], Y. OSAKO[1,3], M. ODAGAWA[1], Y. OISI[1], C. MATSUBARA[1], S. KATO[4], K. KOBAYASHI[4], M. MORITA[2], J. P. JOHANSEN[1], M. MURAYAMA[1];

Abstract: Long-lasting memories of perceived information associated with emotionally arousing experiences (e.g., sexual, threatening) are critical for animal reproduction and survival. Emotional arousal is thought to enhance the consolidation of associated memories by activating the basolateral amygdala (BLA) and its projections to memory-storing regions. Although the importance of both rapid eye movement (REM) and non-REM (NREM) sleep-state specific BLA activity for emotional memory processing has been proposed, how and when the BLA interacts with other brain regions to enhance memory consolidation remains unclear. Here, by adding emotional information to a tactile perceptual recognition task that relies on a top-down circuit from the secondary motor cortex (M2) to the primary somatosensory cortex (S1), we dissociated the perceptual memory consolidation and memory modulation. Anatomical experiments showed

that the BLA projects to M2, but not to S1, and may influence the top-down M2-S1 circuit underlying perceptual memory consolidation. Chemogenetic inactivation of the BLA-M2 circuit demonstrated that the BLA not only associates emotional information with perceptual information, but also enhances perceptual memory consolidation via BLA-M2 projections. Electrophysiological recordings revealed that emotional association increased the reactivation of coordinated activity across the BLA-M2-S1 during NREM sleep, but not during REM sleep. Notably, this inter-regionally coordinated reactivation during NREM sleep was entrained to the BLA high-frequency oscillations in the emotional condition, suggesting that the BLA triggers inter-regional interaction. Optogenetic silencing of BLA terminals in the frontal cortex during NREM sleep, but not REM sleep, disrupted the enhanced retention of the perceptual memory, but not the association itself or the emotional component of associative memory. These findings indicate that increased interregional reactivation via BLA-cortical inputs during NREM sleep is the neural basis for memory enhancement by emotional arousal.

Title: Examining the Role of Zn^{2+}-Releasing Neurons and Circuitry in Reward Related Regions

Authors: *F. P. CURRY, O. SOLÍS CASTREJÓN, M. MICHAELIDES;
Biobehavioral Imaging and Mol. Neuropsychopharm. Br., NIH, Natl. Inst. on Drug Abuse (NIDA), Baltimore, MD

Abstract: Vesicular or synaptic zinc (Zn^{2+}) is an essential element necessary for maintaining neurophysiological homeostasis. Previous literature has established that the striatum receives dense innervation from Zn^{2+}-releasing glutamatergic neurons. In addition, synaptic Zn^{2+} plays a critical role in modulating striatal dopamine neurotransmission, influencing cocaine's effect on synaptic transmission. However, little is known about the molecular profile of Zn^{2+}-releasing neurons in circuits related to reward and the proportion of Zn^{2+}-releasing neurons that project to the striatum. To characterize Zn^{2+}-releasing neurons, we performed RNAscope in situ hybridization (ISH) in reward related circuits (prefrontal cortex, orbitofrontal cortex, paraventricular thalamus, hippocampus, and amygdala) of male and female mice. We utilized mRNA probes that indicate the presence of glutamatergic neurons as well as probes that indicate the presence of GABAergic neurons (including parvalbumin, somatostatin, and VIP subtypes).

We then quantified the colocalization of these probes with ZnT3 mRNA, which represents Zn^{2+}-releasing neurons in our regions of interest. Through this colocalization analysis, we confirmed that there are notable numbers of Zn^{2+}-releasing neurons in these regions. Additionally, we discovered that Zn^{2+}-releasing neurons in these regions are primarily glutamatergic but also include a subset of GABAergic neurons. We also observed differences in the proportions of Zn^{2+}-releasing glutamatergic neurons between male and female mice, with female mice showing higher proportions of these neurons in the prefrontal cortex. Along with the molecular profile, we performed combined immunohistochemistry and RNAscope ISH using Fluorogold to identify the Zn^{2+} circuits projecting to the nucleus accumbens and dorsal striatum. Our preliminary results showed that there are Zn^{2+}-releasing projections from the previously stated regions of interest to the nucleus accumbens and the dorsal striatum, which suggests a role for synaptic Zn^{2+} in reward. Future work will use fiber photometry in awake mice during reward-related behaviors to study Zn^{2+} dynamics in the striatum.

Title: Sex dependent influence of early life adversity on reward circuits

Authors: *L. TANIGUCHI[1], M. T. BIRNIE[2], Y. CHEN[2], C. M. GOODPASTER[4], L. A. DENARDO[5], T. Z. BARAM[3];
[1]Anat. & Neurobio., [2]Pediatrics, [3]Anat. & Neurobiology, Pediatrics, Neurol., UC Irvine, Irvine, CA; [4]UCLA Neurosci. Interdepartmental Program, [5]Physiol., UCLA, Los Angeles, CA

Abstract: Rationale: Early life adversity (ELA) involves exposure to adverse, negative experiences during infancy and childhood. Humans with a history of ELA have an increased risk for depression, anxiety, and PTSD in a sex-dependent manner: women are more likely to be diagnosed with anxiety and depression than men. Disruptions in reward circuits may cause these disorders, but it is unknown how ELA directly impacts the development of this circuitry. Similarly to the human condition, ELA has contrasting effects on rodent male and female reward-seeking behaviors: adult ELA males are ‘anhedonic’ whereas females exhibit augmented reward behaviors. We identified a novel corticotropin-releasing hormone (CRH) expressing

GABA-ergic projection connecting the basolateral amygdala (BLA) to the nucleus accumbens (NAc) to be responsible for reduced reward-seeking behavior in adult male mice that experienced ELA. However, the functions of this projection in female mice are unknown. Here we investigate the role of this pathway in female mice and potential structural differences between males and females. Methods: We used chemogenetic approaches to investigate the function of the CRH/GABA BLA-NAc pathway in reward-seeking behavior in female mice. CRH-IRES-Cre mice raised in either control conditions or ELA conditions were injected bilaterally into the BLA with an excitatory or inhibitory Cre-dependent DREADD, followed by delivery of clozapine N-oxide (CNO) or vehicle through direct infusion into the medial shell NAc. Separately, mice were injected bilaterally into the BLA with a Cre-dependent channelrhodopsin. Using brain-clearing techniques, we mapped CRH projections from the BLA to NAc to determine whether the projection projects to different areas of the NAc or target cells in female and male mice. Results: Excitation of the CRH/GABA BLA-NAc projection did not influence reward behaviors in either control or ELA female mice, suggesting that the pathway is not involved in mediating reward behavior in females. Studies inhibiting the projection in female mice are ongoing. Studies mapping this projection in males and females are in progress to pinpoint structural differences. Conclusions: We characterized a novel CRH/GABA BLA-NAc pathway mediating the effects of ELA on reward circuits in male mice and are striving to determine if the neuroanatomy and cell-type specificity of the projection is the same in females. Investigating this projection will give us a deeper understanding of intrinsic sex differences in the organization of the reward circuitry and the effects of ELA on reward behaviors that underlie many mood disorders.

Title: Glutamate inputs send prediction error of reward but not negative value of aversive stimuli to dopamine neurons

Authors: *R. AMO, N. UCHIDA, M. WATABE-UCHIDA;
Mol. and Cell. Biol., Harvard Univ., Cambridge, MA

Abstract: Midbrain dopamine neurons are thought to signal reward prediction errors (RPEs). Typical circuit models assume that isolated components of RPE computation such as reward and expectation are carried by glutamate and GABA inputs to dopamine neurons, although the exact mechanisms remain poorly understood. Here we used a genetically-encoded glutamate sensor (SF-iGluSnFR) to examine the pattern of glutamate inputs to dopamine neurons in the ventral tegmental area. We found that glutamate input responses to reward-predicting cues positively correlated with associated value, while responses to water reward negatively correlated with reward expectation. Omission of expected reward reduced glutamate input activity below baseline. Thus, glutamate inputs to dopamine neurons convey a fully-formed RPE signal, in contrast to leading RPE models. Further, when animals were trained with sequential conditioning in which serial cues (distal, then proximal) signal reward probability, both dopamine and glutamate input activities at a rewarding proximal cue were suppressed when preceded by a distal cue predicting reward. The expectation-dependent suppression of cue responses supports a specific form of RPE, temporal difference (TD) error, in both dopamine neurons and their glutamate inputs. Notably, glutamate inputs were excited by aversive stimuli, while dopamine neurons were inhibited by the same aversive stimuli, suggesting competition between glutamate and GABA inputs. Opioid analgesics caused dopamine responses to aversive stimuli to become positive rather than negative, but did not change excitatory responses of glutamate inputs, and thus likely biased competition between glutamate and GABA inputs. Our findings uncover previously unknown mechanisms underlying RPE computations: dopamine responses are shaped by both synergistic and competitive interactions between glutamate and GABA inputs, with the nature of the interaction (synergistic or competitive) dependent on stimulus valence.

Title: Nucleus accumbens glutamatergic afferents integrate outcomes in reward-learning

Authors: *E. S. IYER[1], J. MUIR[2], R. C. BAGOT[3];
[1]Integrated Program in Neurosci., McGill Univ., Montréal, QC, Canada; [2]Integrated Program in Neurosci., McGill Univ., Montreal, QC, Canada; [3]Psychology, McGill Univ., Montréal, QC, Canada

Abstract: The ability to integrate information about reward over time is essential to reward learning. While the role of dopaminergic inputs to the nucleus accumbens (NAc) is widely studied, the role of accumbens glutamatergic afferents in reward learning is relatively unexplored. Using in vivo fiber photometry, we simultaneously record population-level activity of medial prefrontal cortex (mPFC) and ventral hippocampus (vHIP) projections to NAc in male and female adult mice performing a two-armed bandit task. We find that both mPFC and vHIP projections to NAc dynamically encode information outcome history, with subtle sex- and pathway-way specific differences. mPFC-NAc tracks the recent history of reward and loss in females but only the recent history of loss in males. In contrast, vHIP-NAc preferentially encodes recent history of loss, but not reward. To determine the precise information encoded in these neural signals, we manipulated task design to systematically degrade behavioral requirements. This revealed that outcome history is tracked preferentially when linking a behavioral response with an outcome. However, when action-outcome pairing is not relevant, mPFC-NAc encodes immediate outcomes but not outcome history and vHIP-NAc fails to encode any outcome information. Together, these findings establish that mPFC-NAc and vHIP-NAc integrate outcomes over time when outcomes are contingent upon behavior and reveal a neural mechanism for the propagation of reward-associated information over time.

Title: Involvement of the ventral tegmental area to central amygdala pathway in food consumption behavior

Authors: *D. KERSPERN[1], G. GABRIELSON[2], J. ISAAC[2], A. LUTAS[2];
[1]Diabetes, Endocrinology, & Obesity Br., NIH-NIDDK, washington, DC; [2]Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD

Abstract: Mesolimbic dopamine is known to be critically involved in food related reward processing and learning. The central amygdala (CeA) in the other hand, is one of the critical brain regions playing a significant role in various behavioral responses such as reward processing, energy valence and feeding behavior. Numerous studies describe the involvement of dopamine signaling and central amygdala in the associative learning, including fear and extinction learning, but little is now about how dopamine regulate the central amygdala during feeding behavior. In this study we evaluate the ventral tegmental area (VTA) → CeA pathway during food consumption. Using fiber photometry and a genetically encode calcium sensor (GCamP6) were able to monitor dopamine axon in the CeA in head fixe mice during Pavlovian feeding behavior. Interestingly we were able to demonstrate that dopamine signal was strongly

modulated by food consumption, but also that the same projection also responds to negative input. Our finding demonstrates that dopaminergic neurons projecting to the CeA might not encode reward prediction error but should be more involved in salience coding.

Title: Interrogating ventral pallidal circuits as a therapeutic target for diet-induced obesity

Authors: *J. WANG[1], T. THOMPSON[1,3], A. V. KRAVITZ[2];
[2]Psychiatry, [1]Washington Univ. in St. Louis, St. Louis, MO; [3]Psychology, The Col. of Wooster, Wooster, OH

Abstract: People with obesity experience physiological, neural, and behavioral changes resulting in decreases in metabolic rate and increases in appetite, making weight-loss extremely challenging. As to why obesity pathology is persistent, our overarching hypothesis is that obesity strengthens feeding neural circuits driving the continued consumption of palatable foods in excess of caloric requirement. To inform novel therapies for producing robust weight loss, it is critical to understand the mechanism for how these foods alter neural circuits involved in initiating and sustaining pathological overeating behavior. While many brain areas have been implicated in appetite control, this research focuses on the ventral pallidum (VP), a brain region involved in reward processing and incentive motivation. However, the potential of manipulating VP activity to suppress or reverse excessive body weight remains unknown. To test this, we used ad libitum high fat diet (HFD) access as a mouse model of diet-induced obesity. After 6 weeks, animals received bilateral injections of quinolinic acid into the VP, producing robust excitotoxic lesioning of neurons. We found that VP lesioning in both males and females promotes a lean phenotype characterized by reduced HFD consumption and enhanced energy expenditure, resulting in complete reversal of HFD-induced weight gain. Additionally, to test whether directly inhibiting the VP neural activity modulates high-fat consumption, we employed an optogenetic strategy through viral expression of the inhibitory opsin Arch3.0 in VP^{GABA} neurons. Based on previous research demonstrating that pharmacological manipulation of VP^{GABA} neurons modulated fat-specific intake, we reasoned that optogenetic inhibition of VP^{GABA} neurons would reduce consummatory behavior for fat-enriched rewards. Using a head-fixed liquid fat consumption task, we employed closed loop optogenetic stimulation on VP^{GABA} neurons to determine whether optogenetic inhibition of GABAergic cell bodies in the VP could produce similar effects seen in QA-lesioned mice. We performed licking microstructure analysis to evaluate the palatability of various fat-enriched liquid rewards and assessed whether changes and licking behavior were observed with and without optogenetic stimulation.

Title: The Role of Insulin Receptors on Striatal Cholinergic Interneurons in Weight Gain

Authors: *M. MAHBOOB[1], M. BOCARSLY[2];
[1]Pharmacol. Physiol. and Neurosci., New Jersey Med. Sch., Newark, NJ; [2]Rutgers NJMS, Newark, NJ

Abstract: Although prior literature once limited insulin to the peripheral nervous system, research on insulin receptors (IRs) in the brain is evolving. IRs are found throughout the brain, including the striatum, a brain region implicated in feeding behavior, motivation, and reward. There are 4 main cell types in the striatum that contain insulin receptors: cholinergic interneurons (CIN), medium spiny neurons, glial cells, and astrocytes. Although the presence of striatal IRs suggest the presence of insulin, the role of these IRs on CIN in the striatum remains under-researched. Because the striatum plays an integral role in food intake, we aimed to explore the function of IRs in maintaining body weight. To narrow our search, we focus on the IRs on CIN. We generated a transgenic mouse with a selective knockdown of IRs on the CIN (IR-KO) and littermate controls. To elucidate the role of striatal IRs in weight gain, body weights of 5-week-old male and female IR-KO (n = 10) and control (n = 9) mice were taken weekly for 28 weeks. IR-KO mice gained more weight compared to littermate controls. IR-KO mice also consumed more palatable food as evidenced by a sugar pellet consumption paradigm. Peripheral metabolic function is conserved in the IR-KO mice as there were no significant differences in basal glucose levels, and glucose and insulin tolerance between IR-KO and control mice. Performance in the novel object recognition test was not significantly different between IR-KO and control mice indicating that cognitive performance was not impaired. Collectively, the results highlight that this specific population of IRs on CIN in the striatum play a notable role in both feeding behavior and weight gain. The lack of untargeted peripheral changes support the importance of IRs in the central nervous system. Future considerations include testing for locomotor differences between IR-KO and littermate control mice. The function of striatal IRs are imperative to study as they may link obesity to certain genetic factors in a time where obesity is an epidemic.

Title: Alzheimer'S disease transgenic rats show altered prelimbic neurophysiological signatures to reward predictive cues following a change in expected outcome

Authors: T. J. SLOAND, B. DUNHAM, S. CORAGGIO, M. NIEDRINGHAUS, ***E. WEST**; Rowan Univ. SOM, Stratford, NJ

Abstract: Deficits in the ability to flexibly shift behavior in response to changing outcomes can have devastating consequences for one's decision-making. In Alzheimer's disease (AD) patients, behavioral deficits often precede the accumulation of neuropathological markers (Aβ plaques and tau pathology) and severe dementia. The Tg-F344-AD rat model expresses mutant amyloid precursor protein, overexpresses presenilin-1, and exhibits age-dependent AD pathology. At 6 months of age, AD rats show deficits in flexible behavior. Prelimbic cortex (PrL) neural encoding of reward-predictive cues during learning is both necessary for and predictive of a rat's ability to flexibly shift behavior following outcome devaluation. Here, we investigated if AD rats show aberrant PrL neural activity and/or behavioral responding to reward predictive cues following outcome devaluation. 6-month-old male and female AD rats (n=7) and wild-type littermate controls (n=8) were presented with two distinct cues as conditioned stimuli (CS+) predicting distinct rewards. A conditioned taste aversion to one reward was induced by pairing the reward with lithium chloride. Rats were then tested on the same Pavlovian task to evaluate the ability to avoid the devalued CS+. WT rats spent less time attending and had fewer phasic PrL neurons to the devalued (D) CS+ compared to the non-devalued (ND) CS+. In comparison, AD rats attended to both CS+ equally, and the number of phasic PrL neurons did not differ to either CS+. Phasic PrL neurons in WT rats were primarily inhibited to both CS+, especially to the D cue, while phasic PrL neurons in AD rats were primarily excited to both CS+ regardless of devaluation status. Further analyses revealed that in WT rats, more excited PrL neurons selectively respond to the ND cue and fewer neurons respond to both cues (ND: 80%, both: 20%, D:0%) suggesting that the PrL disengages during the D cue in WT rats. In contrast, AD rats do not show the same devaluation-induced dynamic PrL encoding, as AD rats show a similar number of excited PrL neurons that selectively respond to ND and D cues equally (ND: 38%, both: 31%, D: 31%). This hyperactive PrL encoding of the CS+ in AD rats is likely contributing to their impaired ability to shift behavior away from the D CS+. Additionally, AD rats' local field potential (LFP) power to both CS+ was significantly less than WT rats', particularly in the 8-12 Hz range. This study contributes to the overall understanding of neurobiological disruptions in AD before the neuropathology accumulation to inform future studies for potential therapeutic interventions such as noninvasive brain stimulation.

Title: Functional mapping of reward responses in the lateral septum along the dorsoventral axis

Authors: *S. KARKARE[1], J. ISAAC[1], M. MALAVIKA[2];
[2]Emory Univ., [1]Emory Univ., Atlanta, GA

Abstract: The lateral septum (LS) has been implicated in a wide range of behaviors, including aggression, reward-related behaviors, kin recognition, sexual behaviors, and social memory. While the specific role of the LS in mediating such a variety of behaviors is unclear, its anatomical heterogeneity has been suggested as a putative contributor to its functional diversity. Discrete LS compartments have been identified by specific properties, such as connectivity with the hippocampus and hypothalamus, as well as the differential expression of receptors and neuropeptides. Recent evidence suggests that subregions of the LS might play a role in modulating both approach and avoidance behaviors. In particular, there appears to be functional clustering of neurons along the dorsoventral (DV) axis within the LS, with approach behaviors modulated by neurons localized to the dorsal subdivision of the LS, while avoidance behaviors are mediated by neurons in the ventral LS. However, it is unclear how reward responses are organized along the DV axis of the LS. In this study, we performed monosynaptic rabies tracing experiments to characterize the patterns of inputs to different LS projection populations. Additionally, we performed cellular resolution calcium imaging in different positions along the DV axis of the LS during an operant reward task to determine how reward responses are organized along the DV axis of the LS. We did not find significant differences in proportions of input neurons to the projection populations in our tracing experiments suggesting that different LS projection populations receive similar patterns of inputs across various brain regions. We found interesting differences in the reward-related activity along the DV axis suggesting that dorsal and ventral populations of LS likely play different roles in reward-related behaviors. Future studies will be required to further ascertain the identities of the imaged neurons and the causal role they play in mediating behavior.

Title: Cortex-wide mechanism of reinforcement signaling via a cholinergic pathway

Authors: *Z. SZADAI[1], Q. CHEVY[2], L. POPARA[1], A. KEPECS[2], B. RÓZSA[3,1];
[1]BrainVisionCenter, Budapest, Hungary; [2]Washington Univ. Sch. of Med., Washington Univ. in St. Louis, St. Louis, MO; [3]Inst. Exptl. Med., Budapest, Hungary

Abstract: Reward and punishment powerfully inform ongoing behaviors and drive learning throughout the brain, including the neocortex. Yet it remains elusive how these global signals reach the cortex, how they are represented there and how they impact local cortical computations. To address these questions, we used 3D random-access two-photon microscopy to monitor neural activity in dozens of cortical areas while mice performed simple auditory decision tasks. We found that VIP and SOM interneurons were recruited differently by reinforcers during the initial learning procedure. The rapid, cortex-wide activation of most VIP interneurons upon reinforcement was mirrored in the acetylcholine release recorded at the vicinity of the VIP cells, implying that this neuromodulator may be responsible for the transmission of reinforcement signals. We suggest that this acetylcholine-dependent global response mode of VIP cortical inhibitory neurons provides a cell-type-specific circuit mechanism by which organism-level information about reinforcers regulates local circuit processing and plasticity.

Title: Dorsal hippocampus to nucleus accumbens projections drive reinforcement via activation of accumbens dynorphin neurons

Authors: *K. IBRAHIM[1], N. MASSALY[2], H.-J. YOON[1], R. SANDOVAL[1], A. WIDMAN[1], S. WILLIAMS[1], W. POST[1], S. PATHIRANAGE[1], T. LINTZ[1], A. ZEC[1], A. PARK[1], W. YU[3], T. KASH[3], R. W. GEREAU, IV[1], J. MORON-CONCEPCION[1];

Abstract: The hippocampus represents a key structure in the integration of emotional processing, learning and memory, and reward-related behaviors. While the ventral subdivision of the hippocampus (vHPC) is involved in processing emotional values of salient stimuli and goal-directed behaviors, the dorsal hippocampus (dHPC) plays a critical role in episodic, spatial, and associative memory. In addition, it has been shown that the dHPC is necessary for context- and cue-associated reward behaviors, including the expression of reward seeking. The nucleus accumbens (NAc), a central structure in the mesolimbic reward pathway, integrates the salience of aversive and rewarding stimuli and its activity is sufficient to drive aversive and appetitive behaviors. Recent evidence has demonstrated that dHPC->NAc pathway is necessary for the expression of a conditioned place preference. However, despite years of groundbreaking research and identification of direct projections from the dHPC to the NAc, the sufficiency for excitatory neurons in dHPC ($dHPC^{CaMKII)}$->NAc inputs to drive reinforcement and reward-associated behavior remains to be determined.
In this study, we used a wide range of complementary techniques including operant behavior, *in-vivo* manipulation using optogenetics, chemogenetics, and fiber photometry recordings to demonstrate that activation of $dHPC^{CaMKII}$->NAc pathway is sufficient to drive reinforcing behaviors via enhanced glutamatergic signaling in the NAcSh. Although stimulation of $dHPC^{CaMKII}$ neurons activates both enkephalin (Enk)- and dynorphin (Dyn)-containing medium spiny neurons (MSNs) in the NAcSh in male and female mice, only Dyn-containing MSNs mediates $dHPC^{CaMKII}$-induced reinforcing behavior. Our *ex-vivo* recordings in NAcSh slices determine the $dHPC^{CaMKII}$ neurons synapse directly to Dyn-containing neurons selectively in the dorsomedial part of the NAcSh, while they synapse into Enk-containing MSNs more broadly through the NAcSh. Our findings shed light on a novel pathway governing reinforcement and further extend the role of the dHPC on reward seeking.

Title: Charting the trajectory of impulsive and motivated behavior across adolescent development in mice

Authors: *R. ALBERT-LYONS, K. H. NG, K. M. NAUTIYAL;
Dartmouth Col., Hanover, NH

Abstract: Adolescence is a developmental phase that has been characterized by increased impulsive behavior, reward seeking, and maladaptive decision-making. The interdependence of these phenotypes and the trajectory of their maturation is not fully understood. Traditional behavioral and neural methods for studying adolescent development in rodents have limited our study to mostly static snapshots. Our approach for automated homecage behavioral testing allows for longitudinal assessment of complex phenotypes and their neural substrates throughout adolescent development in mice. Using our DIY-Nautiyal Arduino Modular Instrumental Conditioning (DIY-NAMIC) homecage behavioral system as well as additional commercial systems, we were able to test impulsive action, delay discounting, and reward and cue valuation on a time-scale consistent with the relatively short period of mouse adolescence. We measured these behaviors across the extent of mouse adolescent development ranging from post-weaning through adulthood to assess the trajectory of behavioral maturation of these different phenotypes to adult levels. We measured impulsive action using a two-choice serial reaction time task (2-CSRTT) as well as cue and reward-related behaviors through conditioned reinforcement, incentive salience, and hedonic drive. We found large increases in the hedonic response to rewards in adolescent mice, as early as postnatal day 34 (PN 34), compared to adults as measured by their increased preference for palatable rewards in a lickometer assay. Early adolescent mice also showed more incentive salience compared to adults displaying increased sign-tracking behavior, but no differences in learning or goal tracking behavior. Additionally, there was a small negative correlation between age and impulsive action from PN40 through adulthood, measured by premature responses in the 2-CSRTT. There were also no significant differences in conditioned reinforcement between adolescent and adult mice. Overall, we show that early adolescent mice have an exaggerated reward drive compared to adults, and more limited increases in impulsivity. Ongoing work is aimed at determining differences in the temporal patterns of the adolescent maturation of hedonic drive and impulsivity. Characterization of the trajectories and phenotypic interactions in adolescent mice is important for studies investigating the neural developmental changes that support behavioral maturation of impulsive and reward-related behavior.

Title: The role of serotonergic input to the paraventricular thalamus in reinforcement learning

Authors: *Y. KAJIHARA[1,2], P. GARCIA-ANDALUZ[1,3], K. MIYAZAKI[1], H. ASHITOMI[2], K. Z. TANAKA[2], K. DOYA[1];
[1]Neural Computation Unit, [2]Memory Res. Unit, [3]Synapse Biol. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Background: The paraventricular thalamus (PVT) serves as a hub that links hypothalamic and monoaminergic inputs to the amygdala, nucleus accumbens, and cortical areas for adaptive behaviors. PVT has been shown to receive strong serotonergic projections from the raphe nuclei. Since previous studies showed that serotonin neurons regulate the effects of prior choice-outcome experiences in future decision-making and PVT neurons predict values of outcomes, it is possible that the serotonergic input to PVT has an important role in decision-making from prior experiences. Here we investigate the roles of PVT and its serotonergic input in reinforcement learning by optogenetic manipulation. Method: We used a probabilistic reversal learning (PRL) task in which mice chose between the left and right nose-poke ports for a water reward. Reward probabilities changed in blocks; left good (left = 0.7/right = 0.1) and right good (0.1/0.7) blocks. Blocks were changed randomly within 1 - 10 trials after an exponential moving average (tau = 8 trials) of better choice reached 75%. We used wild-type mice with AAV-hsyn-Jaws injection (n=4) for optogenetic inhibition of PVT neurons, and Tph2-ChR2(C128S) transgenic mice (n=4) for terminal stimulation of serotonergic projections to PVT. Optogenetic illumination was applied from when mice poked the center nose-poking port for trial initialization until the end of a trial. Result: Neither optogenetic inhibition of PVT neurons nor activation of serotonergic projection to PVT alter the number of trials to achieve block change. We quantified the change of choice behavior by optogenetic manipulation using a logistic regression model of the probability of choice based on the rewarded and unrewarded choices in the last six trials. Optogenetic inhibition of PVT neurons significantly decreased regression coefficients for both rewarded and unrewarded choices in the last trials (18 manipulation sessions, 18 control sessions, 95% credible intervals comparison). Optogenetic activation of serotonergic projection to PVT significantly increased the regression coefficient for the rewarded choice in the last trial (23 manipulation sessions, 20 control sessions, 95% credible intervals comparison). Conclusion: The results suggest that PVT neurons support repetition of the previous choice, and serotonergic input to PVT enhances the effect of reward experiences for the next choice.

Title: Serotonin modulates habituation to novelty while drosophila explore

Authors: *G. ROMAN[1], **M. DE LA FLOR**[2], B. DAUWALDER[3], G. GUNARATNE[4], S. GARCIA[3], M. WANG[3], D. LE[3];
[1]Univ. of Mississippi, University, MS; [2]Univ. of Texas Hlth. Sci. Center, San Antonio, San Antonio, TX; [3]Biol. and Biochem., [4]Physics, Univ. of Houston, Houston, TX

Abstract: *Drosophila melanogaster* detect, learn about and respond to novelty in their environment. When introduced to a novel open field (OF), flies display initial robust levels of locomotor exploratory activity which decays over time. We hypothesized that the decreases in locomotor activity signifies habituation, a form of non-associative learning, in response to the novelty presented by the OF. To test this hypothesis, we employed a dishabituation assay that allowed us to detect not only habituation but also dishabituation and habituation to dishabituation in the OF, all of which are key characteristics of habituation. However, understanding of the underlying mechanisms involved in modulating locomotor activity during habituation to novelty in the fly brain remains limited. Serotonin (5-HT) is a known neuromodulator of important behaviors like arousal, attention, sleep, aggression, and learning and memory. Thus we hypothesized that 5-HT may play a role in habituation to novelty in flies. Our results show that pharmacological manipulation 5-HT signaling with 5-HTP or α-MTP increased and decreased habituation to novelty respectively. Moreover, we show that optogenetic and thermogenetic activation of neurons targeted by Trh-Gal4 was sufficient to increase habituation to novelty. We also show that optogenetic and thermogenetic activation or inhibition of the 5-HT secreting Dorsal Paired Medial neurons (DPMn) increased habituation to novelty. Further, through genetic rescue experiments we show that the 5-HT1A receptor is required in the α/β and γ neurons of the mushroom bodies (MB) for habituation to novelty to occur. Together, our work suggests a putative DPMn-MB 5-HT circuit that may regulate exploratory locomotor activity in response to learning and contribute to a broader understanding how behaviors are regulated.

Title: 5ht2c but not 5ht1b receptors in the nac constrain the rewarding effects of mdma

Authors: *S. VAILLANCOURT[1], M. POMRENZE[2], R. C. MALENKA[3], B. HEIFETS[1]; [1]Stanford Univ., Palo Alto, CA; [2]Stanford Univ., Stanford, CA; [3]Dept Psychiat, Stanford Univ. Sch. Med., Palo Alto, CA

Abstract: Intro: 3,4-methylenedioxymethamphetamine (MDMA) is a substituted amphetamine with prosocial and rewarding effects. These properties may be driven by efflux of serotonin (5-HT) and dopamine (DA) via action at their respective transporters, SERT and DAT, in the Nucleus Accumbens (NAc). While MDMA is considered a drug of abuse, it has less addiction liability compared to other psychostimulants. Understanding the distinct 5HTergic and DAergic mechanisms underlying MDMA's effects may lead to valuable insights for development of prosocial therapeutics in treating PTSD and other psychiatric conditions.
Methods: Behavior: Conditioned Place Preference (CPP; reward learning); 3 Chamber Test (3CT; social exploration). Drugs: MDMA (5, 7.5, 15 mg/kg), Fenfluramine (FEN, 10 mg/kg), Methamphetamine (METH, 2 mg/kg) Mouse lines: C57BL/6 (wild-type; WT); tamoxifen-induced conditional DAT and SERT-KO. Drug Microinfusions: SERT, 5-HTR1b, and (S)-citalopram (SCIT, 0.5 µg), NAS-181 (0.5 µg) or SB242084 (1 µM) respectively. Fiber Photometry: DA release in NAc was measured by viral fluorescent reporter (AAV-hSyn-GRAB-DA-4).
Results: Low-dose MDMA (7.5 mg/kg) and FEN promote social exploration but not CPP, whereas METH promotes CPP but not social exploration. High dose MDMA (15 mg/kg), which promotes CPP, and METH promote similarly large increases in GRAB-DA fluorescence in NAc, compared to MDMA 7.5 mg/kg and FEN. Conditional deletion of DAT significantly reduced MDMA-dependent (15 mg/kg) reward learning and MDMA-evoked DA release. Conditional deletion of SERT abolished MDMA-dependent (7.5 mg/kg) social exploration but promoted CPP at a subthreshold dose of MDMA (5 mg/kg) with minimal behavioral effects in WT mice. Blocking SERT and 5-HTR2c, but not 5-HTR1b, in the NAc enhanced CPP with subthreshold MDMA. NAc microinfusion of either SCIT or SB242084 significantly enhanced DA release evoked by subthreshold MDMA.
Discussion: These data support a model of MDMA action wherein 5-HT mediates acute social exploration and DA mediates nonsocial drug reward, but not acute social exploration. Several manipulations, including SERT cKO, intra-NAc infusion of SCIT, or a 5-HTR2c antagonist all converted a low, non-rewarding dose of MDMA into one that supports CPP, and these manipulations all enhance DA release in NAc evoked by low dose of MDMA. Interestingly, the mechanism of MDMA-mediated prosocial behavior, requiring 5-HTR1b, differs from the mechanism whereby MDMA-evoked 5-HT release constrains nonsocial MDMA reward. Altogether, our results suggest that MDMA-induced 5-HT release modulates DA release and MDMA CPP through activation of 5-HT2c receptors in the NAc.

Title: An investigation into the anatomical distribution and transcriptional heterogeneity of GABA neurons in the ventral tegmental area and rostromedial tegmental nucleus

Authors: *Z. J. HOUGH[1], B. HUGHES[2], C. COWAN[3], T. JHOU[1];
[1]Neurobio., Univ. of Maryland Sch. of Med. Program In Neurosci., Baltimore, MD; [2]Neurosci., [3]Med. Univ. of South Carolina, Charleston, SC

Abstract: Increasing evidence indicates substantial heterogeneity in the function and gene expression of ventral midbrain GABAergic neurons, which play a critical role in the regulation of motivated behavior. Accordingly, further elucidation of the molecular differences between distinct populations of GABA neurons and their topographical distribution is needed. In this study we focused primarily on two distinct regions of the midbrain known to regulate motivated behavior, the ventral tegmental area (VTA) and the rostromedial tegmental nucleus (RMTg, also known as the tail of the VTA). Importantly, nearly one third of the VTA is comprised of GABA neurons, which are increasingly recognized as heterogeneous. Interestingly, in situ hybridization (ISH) revealed a dense cluster of neurons that co-express *th*, *vgat* and *gad2*, but not *gad1*. Notably, *th* levels in this subpopulation was markedly lower than in *th* cells lacking *vgat* or *gad2*. In contrast to the VTA, RMTg neurons are almost entirely GABAergic, but less is known regarding their potential heterogeneity or whether they overlap with any subpopulations of VTA GABA neurons. Accordingly, we performed single nuclei RNA sequencing of VTA and RMTg tissue from four approximately 12-week-old male Sprague Dawley rat brains. Tissue from each region was isolated and processed independently to allow comparison of gene expression between cells of both brain regions. Preliminary analysis of these data sets corroborates previous findings of ourselves and others regarding heterogeneity of VTA GABA neurons, including the existence of a distinct subset containing *th* transcripts. Additionally, we confirmed that *foxp1* expression, found in over 90% of RMTg GABA neurons, distinguishes RMTg from VTA GABA neurons, consistent with prior immunohistochemical (IHC) and ISH findings. Ongoing analysis of these datasets, along with topographical characterization using IHC and ISH, will further elucidate distinct subtypes in these brain regions. In conclusion, RMTg GABA neurons are transcriptionally distinguishable from VTA GABA neurons, suggesting differing roles in the regulation of motivated behavior. Additionally, our findings further corroborate the heterogeneous nature of VTA GABA neurons and indicate the need for further investigation into their functional roles.

Title: Diversity and topology of inputs to the paraventricular thalamus associated with motivated behaviour

Authors: *S. R. GILCHRIST[1], E. CHOI[2], G. P. MCNALLY[2], J. M. POWER[3];
[2]Sch. of Psychology, [3]Translational Neurosci. Facility & Dept. of Physiol., [1]Univ. of New South Wales, Sydney, Australia

Abstract: Appetitive and aversive motivation are critical in our interaction with the environment. However, the neural circuitry underlying competition between these opposing motivations is not well understood. Recent studies have established a functional role of the paraventricular thalamus (PVT) in this competition. This has been linked in part, to inputs from multiple brain regions, including the periaqueductal gray (PAG) and the hypothalamus providing the PVT with interceptive and exteroceptive sensory information; inputs from the medial prefrontal cortex (PFC) providing possible control over these processes; and PVT projections to the nucleus accumbens shell. However, the nature of these projections to the PVT and their interactions with each other remain poorly characterised. We used whole-cell patch-clamp electrophysiology and optogenetic techniques in male and female Long Evans rat brain slices to map the characteristics and topographical organisation of PVT inputs. Retrograde tracer in the nucleus accumbens shell allowed for targeted recordings of PVT output neurons to build up a larger understanding of the circuitry. The GAD1 subpopulation of the hypothalamic input was also investigated with a combination of electrophysiology and RNAscope techniques to further understand this component. We found that inputs from the PFC were excitatory and topographically biased. Light evoked EPSCs were observed in 39 of 44 (89%) neurons in the posterior PVT and only in 4 of 12 (33%) neurons in the anterior PVT. Meanwhile, ascending inputs from the PAG and hypothalamus were mixed and showed no anterior-posterior topography. Light-evoked inhibitory currents from these inputs were recorded in 24% of 111, and 58% of 85 PVT neurons, while EPSCs were observed in 13% and 32% respectively. Crucially, this mixed excitatory/inhibitory input was preserved even when isolating PVT inputs from hypothalamic GAD1 neurons, though with a higher predominance of EPSCs (27 of 63; 43%) than IPSCs (16 of 63; 25%). RNAscope revealed a small population of GABA and Glutamate co-expressing neurons (0.7%) in the hypothalamus that may account for some of this mixed profile. The high rates of connectivity suggest convergence of diverse input pathways onto individual PVT neurons and possible integration prior to relay to ventral striatal regions for behavioural control. Moreover, heterogeneity in ascending pathways, and their convergence with

the descending PFC input suggests complexity in how these circuits drive behaviour and how they may be dysregulated following exposure to stressors or drugs of abuse.

Title: Ventral striatopallidal pathways to lateral hypothalamus in alcohol-seeking

Authors: *S. LUI[1], J. M. POWER[2], G. P. MCNALLY[3];
[2]Translational Neurosci. Facility & Dept. of Physiol., [3]Sch. of Psychology, [1]Univ. of New South Wales, Sydney, Australia

Abstract: The ventral striatopallidal system, consisting of nucleus accumbens and ventral pallidum (VP), is a key component of the reward system and plays a role in alcohol use disorder. We have previously shown that inhibitory projections from the nucleus accumbens shell (AcbSh) and the VP to the lateral hypothalamus (LH) have opposing actions: preventing and promoting relapse to alcohol-seeking respectively. The AcbSh also projects to the VP directly; however, the circuitry relationship between this connection and the VP to LH connection is poorly understood. To address this, we used channelrhodopsin (ChR2)-assisted circuit mapping and retrograde tracing techniques. Specifically, we used transgenic D1-Cre and A2A-Cre Long Evans rats (n = 9) with Cre-dependent ChR2 to target AcbSh neurons and retrograde labelled LH-projecting VP neurons with mCherry. Whole-cell patch-clamp recordings of VP neurons revealed light-evoked postsynaptic responses that were inhibitory and picrotoxin-sensitive in a subset of neurons. We showed that putative non-LH-projecting VP neurons received input from D1- and D2-AcbSh cells (36% and 24% respectively), whereas LH projectors predominantly received D1-AcbSh input with minimal D2-AcbSh connections (38% and 4% respectively). So, whereas D1-AcbSh neurons provide input to both LH-projecting and non-LH projecting VP neurons, D2-AcbSh neurons preferentially synapse with non-LH projectors. These results show an indirect disynaptic pathway connecting D1-AcbSh neurons to LH via VP neurons. Past work has shown a direct projection from AcbSh to LH. This bifurcation in ventral striatopallidal pathways may bidirectionally regulate alcohol-seeking behaviour and ongoing studies are assessing plasticity in these pathways.

Title: Central amygdala neurons are necessary for habit formation

Authors: *A. K. CRAWLEY[1], J. GIOVANNIELLO[2], M. MALVAEZ[3], K. M. WASSUM[4]; [1]UCLA Chapter, Los Angeles, CA; [2]Univ. of California Los Angeles, [4]UCLA, [3]UCLA, Los Angeles, CA

Abstract: When making decisions, we often consider possible future outcomes to help us make the best choice given our current circumstances. To do this, we rely on an internal model of our actions and their consequences. Such encoded **action-outcome (A-O) memories** support **goal-directed behavior**. Goal-directed decision making is, however, cognitively taxing. So, humans and other animals have another strategy for more routine behaviors: **habits**. Habits are formed with repeated practice and allow routine behaviors to be executed more automatically based on their past success, rather than forethought of their consequences. We balance goal-directed decisions and habits to allow behavior to be adaptive when needed, but efficient when appropriate. Disruptions to this balance can contribute to addiction and mental illness. There is much unknown about the neural circuitry that supports action-outcome goal-directed learning and habit formation. The central amygdala (CeA) is one brain region that has been implicated in habit. The goal of this project is to reveal how the CeA regulates habit formation. We hypothesized that CeA activity is necessary at the time of reward experience to form habits. To test this, we optogenetically inhibited CeA neurons at the time of reward delivery during each day of training on an instrumental lever press-food reward task in male and female rats. Rats were overtrained on a random interval schedule of reinforcement to promote habit formation. Whereas controls formed habits, as evidenced by insensitivity to post-training outcome-specific devaluation or omission contingency, inhibition of the CeA prevented habit formation, resulting in continued sensitivity to outcome-specific devaluation or omission contingency. Thus, the CeA is necessary for habit formation. Ongoing work is assessing how dopaminergic inputs into the CeA contribute to habit formation.

Title: Opposing amygdala-striatal pathways enable chronic stress to promote habit formation

Authors: *J. GIOVANNIELLO[1], N. PAREDES[6], A. WEINER[2], C. ORAGWAM[3], H. UWADIA[2], G. NNAMDI[2], M. SEHGAL[7], F. M. REIS[2], A. SIAS[3], M. MALVAEZ[4], A. ADHIKARI[4], A. SILVA[5], K. M. WASSUM[4];

Abstract: When making decisions, we prospectively evaluate our potential actions and their predicted outcomes to choose an appropriate behavior. This goal-directed strategy allows us to adapt when situations change but it is cognitively taxing. Habits are a more efficient but less flexible strategy whereby behaviors are executed without forethought of their consequences, based on past success. Balance between these strategies allows behavior to be adaptive when needed, but efficient when appropriate. Overreliance on habit is characteristic of many psychiatric conditions, including addictions. Stress is a major contributing factor to these conditions. It also promotes habits. Thus, we sought to uncover the neuronal circuits that permit stress to promote habits. We established a model of stress-potentiated habit formation in mice using chronic mild unpredictable stress and subsequent reward-seeking instrumental conditioning. Mice with a history of chronic stress formed habits prematurely, as evidenced by insensitivity to outcome devaluation or omission contingency. The dorsomedial striatum (DMS) mediates goal-directed behavior and the amygdala is a stress hub. Therefore, we next used a multifaceted approach to expose the contribution of amygdala-striatal projections to goal-directed learning and stress-potentiated habit formation. The basolateral amygdala (BLA) sends a direct excitatory projection to the DMS. We found that these neurons are activated during instrumental learning and that this activity is critical for the action-outcome learning that supports goal-directed behavioral control. Stress dampens this to disrupt action-outcome learning and promote habit formation. Activating this pathway during post-stress learning restores normal goal-directed behavioral control. A direct central amygdala (CeA) projection to the dorsal striatum was recently identified. We found that CeA neurons target DMS and inhibit striatal projection neurons. CeA-DMS projections are not typically robustly activated during goal-directed learning, but stress recruits activity in this pathway to promote habit formation. Inhibition of the CeA-DMS pathway during post-stress learning prevents habit formation. This establishes the first functional role for the CeA-DMS pathway in modulating behavior. Together,

these data reveal that stress disrupts the balance between two opposing amygdala-striatal projections to prevent the learning that underlies adaptive decision making and promote the formation of premature inflexible habits. Title: Cell-type specific contributions of striatal projection neurons to goal-directed and habit learning

Authors: *M. MALVAEZ, A. LIANG, J. GIOVANNIELLO, A. WIKENHEISER, K. WASSUM;
UCLA, Los Angeles, CA

Abstract: Optimal behavior relies on a balance between two distinct strategies. During goal-directed decision making the relationship between actions and their consequences is considered to enable adaptive choices. Habits allow routine tasks to be conducted more automatically, without forethought of their consequences. The balance between these systems allows behavior to be adaptive when needed and efficient behavior when appropriate. But disruption of this balance can lead to symptoms characteristic of several psychiatric and neurological diseases. Goal-directed behavior relies on the dorsomedial striatum (DMS). Little is known about the contribution of the two major striatal projection neurons (SPNs) subtypes: direct (characterized by D1 receptor expression) and indirect (characterized by A2A receptor expression) pathway projections. Using cell-type specific cellular resolution microendoscopic calcium imaging and chemogenetic manipulation coupled with instrumental lever press - food reward conditioning and outcome-specific devaluation tests, we characterized the function of these two DMS neuron subtypes in goal-directed learning. DMS D1 neurons are active throughout instrumental learning, especially around action initiation. The dSPN ensemble that represents action initiation is stable from early goal-directed learning through the transition to habit. Correspondingly, DMS D1 neurons are required for goal-directed learning and the expression of goal-directed behavior. DMS D1 neuron activity is also sufficient to promote goal-directed behavioral control even after overtraining, which would normally enable habit. DMS A2A neurons are also active during instrumental learning around action initiation. However, the A2A ensemble representing action

initiation shifts as behavioral control transitions from goal-directed to habitual. Accordingly, DMS A2A neurons are necessary for early goal-directed learning, but are insufficient to promote goal-directed behavior after overtraining. Thus, DMS D1 and A2A neurons have coordinated function to promote the action-outcome learning that supports flexible goal-directed behavioral control early in learning. But only D1 neurons maintain a representation of goal-directed actions as habits form, whereas A2A neurons lose such a representation and instead come to represent habitual behavior.

Title: Ventral pallidal GABAergic neurons drive consumption in a sex-dependent manner

Authors: *A. PAULSON, A. SCOTT, C. PRILL, B. NEWELL, J. RICHARD;
Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Food intake is controlled by multiple converging signals: hormonal signals that provide information about energy homeostasis, but also hedonic and motivational aspects of food and food cues that can drive non-homeostatic or “hedonic” feeding. The ventral pallidum (VP) is a brain region implicated in the hedonic and motivational impact of food and foods cues, as well as consumption of rewards. Disinhibition of VP neurons has been shown to generate intense hyperphagia, or overconsumption. While VP gamma-Aminobutyric acidergic (GABA) neurons have been implicated in cue-elicited reward seeking and motivation, the role of these neurons in the hyperphagia resulting from VP activation remains unclear. Here, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to activate or inhibit VP GABA neurons in sated male and female rats during chow and sucrose consumption. Long Evans rats (n = 62, 32 males [M], 30 females [F]) received bilateral infusions of a GAD1-cre virus mixed with a cre-dependent virus for either Gq DREADD (n=23, 12M, 11F), Gi DREADD (n=25, 13M, 12F), or mCherry control (n=14, 7M, 7F). Rats were habituated for three days to 1-hour access to sucrose or chow, and then tested with injections of a DREADD ligand, JHU37160 dihydrochloride (JHU; 0.05 and 0.5 mg/kg), and saline, on separate test days, counterbalanced for order. Following behavioral testing, a subset of rats was perfused following a ligand or saline injection and immunohistochemistry was performed to examine c-fos and DREADD colocalization. We found that activation of VP GABA neurons increases consumption of chow and sucrose in male rats, but not female rats. We also found that, while inhibition of VP GABA neurons tended to

decrease sucrose consumption, this effect was not significant. As expected, injections of DREADD ligand increased the proportion of DREADD-expressing cells that were cfos-positive. Together, these findings suggest that activation of VP GABA neurons can stimulate consumption of routine or highly palatable rewards selectively in male rats.

Title: Ventral pallidal encoding of expected outcome value evoked by Pavlovian cues

Authors: *A. SOOD[1], T. TRAN[2], M. CRISTOFORO[2], A. WALSH[2], J. M. RICHARD[2]; [1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Neurosci., Univ. of Minnesota, Twin cities, Minneapolis, MN

Abstract: Goal-directed behavior relies on accurate mental representations of outcomes and their expected value to guide decision making. Disruptions to this process are a core component of several neuropsychiatric conditions, including addiction. Understanding the neural mechanisms underlying expected value encoding is therefore key to developing effective long-term treatments for addiction. The Ventral Pallidum (VP) is a basal forebrain region that is important for motivation and reward processing. Cue-evoked activity in populations of VP neurons is known to encode the expected value of rewards. Yet, the impact of outcome (reward) devaluation on these neural responses to cues has not been assessed. Outcome devaluation involves reducing the value of the expected outcome and is a classic test of goal-directed behavior that can be used to test whether these neural responses to cues reflect the expected value or merely other factors that correlate with the expected value. In this study, we used *in-vivo* electrophysiology to record from single units in the VP of male and female Long Evans rats responding to Pavlovian reward cues before and after reward devaluation. Adult rats were trained with an auditory conditioned stimulus (CS+) that signaled the delivery of a 10% sucrose reward and a control cue (CS-) that never predicted a reward. They then underwent reward devaluation via sensory-specific satiety where they were allowed free access to either 10% sucrose or a control substance (maltodextrin) immediately followed by testing under extinction conditions. We recorded from the VP of these rats during training, free access, and testing under extinction. We found that many VP neurons were excited by the CS+ and that these neurons were more responsive to the CS+ than the CS-. Additionally, VP responses to the CS+ were reduced after free consumption of sucrose. Interestingly, free access to maltodextrin also reduced VP

responses to the CS+, suggesting that these changes in VP responding were probably not due to the encoding of the sucrose reward specifically. Behaviorally, both male and female rats displayed a reduced probability to enter the reward port during the CS+ after free access to sucrose, but only male rats showed a reduction in the latency to enter the port during the CS+ following devaluation. Future experiments will test whether cue-evoked excitations in VP neurons specifically reflect the expected outcome value or a general change in motivation due to the consumption of a sweet-tasting substance and whether encoding of the expected outcome value is sex-dependent.

Abstract
Alcohol use disorder is often characterized by compulsive alcohol use in the face of negative consequences. One model of compulsive-like alcohol seeking and consumption is aversion-resistant drinking, in which animals continue to drink alcohol despite its adulteration with quinine, a bitter substance. Cues associated with alcohol and other drugs have also been shown to increase craving, self-administration, and relapse-like behavior, but the effect of cues on aversion-resistant drinking has not yet been examined. Here, we assessed the influence of alcohol-paired cues on aversion sensitivity during alcohol self-administration in Long Evans rats (n=24; 12 males and 12 females). Following 4-6 weeks of intermittent access to 15% EtOH in their home cages, rats were trained to self-administer 15% EtOH in operant boxes for up to 17 sessions. During 1 hour self-administration sessions, presses on the active lever resulted in a delivery of 0.1 mL 15% EtOH to the reward port, and presentation of the alcohol cue, which

consisted of a white noise and stimulus light simultaneously presented for 5 seconds. Presses on the inactive lever had no programmed consequences. Following stabilization of responding, rats were tested under the following conditions for at least 4 days each: 1) 15% EtOH with cues, 2) 15% EtOH + 45 mg/L quinine with cues, 3) 15% EtOH without cues, and 4) 15% EtOH + 45 mg/L quinine without cues. When rats were tested with cues, we found that quinine failed to suppress both operant responding and consumption of alcohol. If anything, alcohol self-administration increased under the presence of cues. In contrast, when cues were removed, quinine reduced self-administration, as well as consumption. We saw a similar effect of cues on quinine sensitivity in male and female rats, though they differed in overall responding, with males completing more active lever presses as baseline. Overall, our data suggest that alcohol-paired cues can modulate sensitivity to aversive stimuli during alcohol seeking and consumption, potentially leading to compulsive-like alcohol seeking. Future work is needed to better understand the influence of cue-elicited appetitive motivation on behavioral and neural mechanisms governing the suppression of behavior by aversive stimuli.

Title: Ventral pallidal GABA neurons are necessary for the invigoration of reward-seeking by cues

Authors: *B. A. NEWELL[1], I. D. LIN[2], D. PALMER[3], A. SCOTT[4], A. PAULSON[1], P. MURUGANANDAN[3], P. REMDE[3], J. M. RICHARD[4];

Abstract: The ventral pallidum (VP) is an important target structure for the investigation of addiction and relapse due in part to its role in cue-elicited reward-seeking behavior. Prior research has demonstrated that VP GABA neurons are excited by reward cues and are necessary for context renewal of alcohol-seeking. Yet, their role in the invigoration of reward-seeking by discrete cues remains unclear. Here, we used optogenetics to assess the impact of phasic cue-paired manipulations of VP GABAergic neurons on reward-seeking behavior in a discriminative stimulus task (DS task). To target VP GABA neurons, male and female Long Evans rats received bilateral VP injections of a GAD1-Cre recombinase viral vector combined with a viral vector for cre-dependent expression of either inhibitory opsin, excitatory opsin, or non-opsin control

protein. After the rats recovered, they were trained in the DS task, in which presentations of an auditory DS cue indicated availability of 10% sucrose reward. Port entries during the DS (auditory) cue resulted in sucrose delivery, while port entries during a neutral stimulus (NS) auditory cue did not. Once rats learned to discriminate between the cues, they performed optogenetic test sessions in which 50% of DS and NS presentations were paired with either 1s or 10s of laser inhibition, excitation, or control manipulations. Inhibition for the duration of the DS (up to 10s) reduced response likelihood and increased response latency. In contrast, during sessions with brief 1s inhibition, port entry likelihood was reduced during the 1s inhibition, but rebounded afterwards. Similarly, port entry likelihood rebounded after inhibition offset during the NS, perhaps due to rebound excitation. Exciting VP GABA neurons did not significantly impact reward seeking on DS trials, but laser-paired NS excitation trials yielded higher response ratios and quicker responding for both 1s and 10s sessions. Altogether, our findings suggest that VP GABA neurons contribute to response invigoration by reward cues. Future experiments will examine the contributions of VP GABA neurons to the ability of reward cues to invigorate separately trained or novel reward-seeking behaviors.

Title: Elucidating the INS^{Nos1}-$CeA^{Pkc\ \delta/SST}$ circuit during non-homeostatic feeding behaviors

Authors: *A. L. RIVERA, S. STERN, M. OLVERA-CALTZONTZIN, Y.-S. HWANG;
Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: Feeding is pivotal for all living beings to survive, by maintaining bodily homeostasis. However, these behaviors can be disrupted and become maladaptive, resulting in various pathologies such as obesity and diabetes. Gaining a comprehensive understanding of how the brain regulates feeding behaviors and the impact of disruptions in this process is vital for our pursuit of potential treatments. The Insular Cortex (INS) is hypothesized to be important for the processing and regulation of internal signals and has a role in feeding behaviors. Previous results from the lab showed that nitric oxide synthase 1 (Nos1) neurons in the INS have an important role on appetitive non-homeostatic feeding behaviors, particularly overconsumption. Additionally, these neurons project to the central amygdala (CeA). By using retrograde tracing in

combination with fluorescent in situ hybridization, we found that INS^{Nos1} directly project to CeA, and particularly to two subpopulations, Protein Kinase C delta (PKC-δ), which are anorexigenic, and somatostatin interneurons (Stern et al., 2021). To gain a better understanding of this circuit we used a intersectional genetic and calcium recording approach to elucidate the functional connectivity between these two areas during feeding behavior. Using three transgenic mouse lines (Nos1-Cre/PKC δ -Flp or Nos1-Cre/SST-Flp), we injected a Cre-dependent Gq DREADD virus to target INS^{Nos1} neurons for activation and a Flp-dependent GCaMP6s virus with an optic fiber to simultaneously record neural activity of Pkc δ or Sst CeA neurons during a feeding behavior task. To first understand how this circuit works during eating, we fast mice and did calcium recordings during food presentation, then, we activate the INS^{Nos1} neurons, and record the calcium activity, once these two pathways where, separately, activated. We first observed, that the activation of INS^{Nos1} neurons increases food intake, in line with our previous observations that inhibition of these neurons prevents overconsumption. Additionally, activation of INS^{Nos1} may change calcium activity in the $CeA^{Pkc\ \delta/SST}$ neuronal populations before and after food approach. This suggests that the INS^{Nos1}-$CeA^{Pkc\ \delta/SST}$ circuit is important for appetitive feeding behaviors. Further experiments will determine the dynamic of both $CeA^{Pkc\ \delta}$ and CeA^{SST} and their possible connectivity. These experiments will provide valuable insights into the complex neural mechanisms underlying non-homeostatic appetitive behaviors.

Title: Deciphering Insula Ctx Circuits Governing Appetitive and Aversive Non-Homeostatic Feeding BehaviorsBehaviors

Authors: *M. OLVERA CALTZONTZIN[1,2], A. RIVERA[1], Y.-S. HWANG[1], K. HODUM[1], E. MIZRACHI[1], A. KANAKAM[1], S. A. STERN[1];
[1]Integrative Neural Circuits and Behavior, [2]Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: Although homeostatic feeding is vital for survival, nevertheless internal states or past experiences can disrupt this balance, leading to non-homeostatic feeding behaviors. Earlier studies have shown that the insular cortex (INS) has specific neural populations coding for appetitive and aversive stimuli. Yet, the mechanisms by which the INS regulates appetitive or

aversive feeding behaviors through different circuits remain unclear. Earlier work from the lab has shown that a glutamatergic population expressing nitric oxide synthase-1 (INS^{Nos1}) in the insular cortex is critical for non-homeostatic food overconsumption. Using chemogenetics, I confirmed that silencing INS^{Nos1} neurons decreases overconsumption, but, unexpectedly, the same manipulation enhances taste aversion. Notably, this inhibition did not affect anxiety-related tasks, memory formation, or homeostatic feeding, suggesting that there is no general impairment of function. To gain further insights into how INS^{Nos1} neurons regulate feeding behavior, we performed calcium recording using fiber photometry. Our results corroborated earlier findings, indicating that Nos1 neurons are responsive during overconsumption and play a significant role in aversive taste learning. Furthermore, our data suggest that these neurons may contribute to the detection of stimulus salience based on internal states (e.g., fed vs. fasted) and odor. To elucidate the upstream and downstream neural circuitry involved, we employed a combination of monosynaptic rabies tracing and in situ hybridization/immunohistochemistry. Our previous results suggest that INS^{Nos1} neurons project to both CeA-somatostatin and PKCd (protein kinase c-delta) neurons for appetitive behaviors such as overconsumption (Stern et al., 2021). Our new data suggest that INS^{Nos1} neurons receive inputs from the BLA and the hypothalamus, regions known to be involved in regulating aversive and internal state information, respectively. These findings indicate that the role of INS^{Nos1} neurons is primarily to regulate non-homeostatic feeding behaviors, perhaps based on the salience of food in the environment, particularly in non-homecage contexts. However, there is still a need for further experiments to fully understand the INS^{Nos1}-CeA and BLA-INS projections during non-homeostatic learning. In future studies, we aim to elucidate the precise mechanisms and functional implications of these projections. This knowledge will contribute to a deeper understanding of how the insula modulates appetitive and aversive responses, ultimately advancing our understanding of the neural basis of feeding behavior regulation.

Title: Mechanistic evidences of corticosterone-induced food overconsumption

Authors: *S. BULLICH, J. VO, D. LEWIS-SANDERS, S. STERN;
Stern Lab., Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: Eating disorders (ED) are very complex pathologies displaying strong comorbidities with a large variety of psychiatric disorders. Among them, major depression, anxiety and post-traumatic stress, are all largely associated with dysregulation of the hypothalamic pituitary adrenal axis. Indeed, this axis, also known as the stress axis, is over-stimulated leading to abnormal cortisol system activity. Yet, little is known about how stress, and more specifically cortisol, might contribute to feeding behavior alterations and possibly lead to eating disorders. Moreover, epidemiological studies reported higher prevalence of these disorders among women, suggesting sex differences regarding the physiopathology of ED. To that end, using subcutaneous releasing pellet as a chronic corticosterone administration (primary adrenal corticosteroid in rodents), we describe a food-overconsumption phenotype in both male and female mice accompanied with an increase in body weight. In order to better understand the different impact of corticosterone on the metabolic profile depending on sex, we studied both male and female metabolism in response to chronic corticosterone administration using metabolic chambers. Secondly, we aimed to identify which brain regions could be involved in corticosterone-induced overconsumption. The insular cortex (IC) is commonly known as a hub integrating multiple internal and external stimuli, and it has been shown to be involved in non-homeostatic feeding. As there is also growing evidence that IC is also involved in anxiety behaviors, we first focused our investigation on this structure. Using single cell sequencing, we identified mineralocorticoid and glucocorticoid receptor expressions within multiple IC cell types, supporting a direct effect of corticosterone on this structure. To probe the effect of corticosterone on the IC neuronal activity, we performed freely moving calcium imaging using IC synapsin-driven GCaMP7c expression and a prismatic lens allowing 90°-angled imaging from a median perspective, avoiding cumbersome cranial window procedure. Our preliminary data suggests a change in the global activity of IC neurons giving rise to a potential mechanistic pathway of corticosterone on feeding behaviors.

Title: Activity in auditory and reward-related structures shows an inverted U-shaped response to melodies that vary in complexity and rated pleasure

Authors: *G. FÀBREGA-CAMPS[1], A. ARA[2], M. DEOSDAD DIEZ[1], S. NICOLAOU[1], V. B. PENHUNE[3], J. MARCO-PALLARÉS[1];

Abstract: Musical pleasure depends on how well music meets or violates our expectations. Musical complexity, or how predictable or unpredictable a melody is, influences our preference and enjoyment. We tend to like melodies that are neither too simple nor too complex, but that balance familiarity and novelty. Previous studies have delineated the brain network involved in music pleasure, but the neural mechanisms behind the interaction between music reward and complexity is not yet well understood. In the current study, twenty-nine people participated in an fMRI study where they listened to musical excerpts of different degrees of predictability and rated how much they liked them. The melodies were artificially generated from the transitional probabilities of a natural Western grammar, and categorised into three levels of predictability according to the note-by-note information content. The use of grammar that mimics the conditional probabilities of musical notes to generate melodies allowed us to investigate in a controlled way how probabilistic expectations and subjective pleasure were related. Behavioural results replicated previous findings of an inverted U-shape relationship between predictability and liking. A consistent pattern of activation was also identified when performing a region of interest analysis (ROI) in areas of the reward network (including Nucleus Accumbens and ventromedial prefrontal cortex) and auditory cortex. These regions exhibited enhanced activity for intermediate predictability excerpts compared to both high and low complexity stimuli. These results suggest that the interaction between complexity of musical stimuli and musical pleasure arises from the activation of reward and auditory perception networks in the brain.

Abstract: The signed value and unsigned salience of reward prediction errors (RPEs) are critical to understanding reinforcement learning (RL) and cognitive control. Dorsomedial prefrontal cortex (dMPFC) and insula (INS) are key regions for integrating reward and surprise information, but conflicting evidence for both signed and unsigned activity has led to competing proposals for the nature of RPE representations in these brain areas. Recently developed RL models allow neurons to be differentially sensitive to positive and negative RPEs, a property with the potential to explain coding diversity in human INS and dMPFC. Here, we use intracranially recorded high frequency activity (HFA) to show that this asymmetric coding strategy captures RPE coding diversity in these regions. We found neural populations responding to valence-specific positive and negative RPEs, as well as unsigned RPE salience, which are spatially interleaved within each region. Furthermore, directional connectivity estimates suggest a leading role of INS in communicating positive and unsigned RPEs to dMPFC. These findings support asymmetric coding across distinct but intermingled neural populations as a core principle in RPE processing and reconcile long-standing theoretical debates on the role of dMPFC and INS in RL and cognitive control.

Title: Assessing the Impact of Social Decision-Making and Stimulus Expectancy on Pain Sensation

Authors: *A. DEHGHANI[1], C. BANGO[2], S. E. PRABHU[3], T. WAGER[4];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Dartmouth Col., Sharon, VT;

[3]Dartmouth Col., Hanover, NH; [4]Univ. of Colorado Boulder Dept. of Psychology and Neurosci., Hanover, NH

Abstract: How do people assess the negative utility of pain when choosing for themselves and others? And is the experience of pain altered by the social context of receiving it as a result of others' choices? We addressed both questions in a social decision-making study in which participants first made choices to accept a monetary payoff to cause pain to themselves or another person, and then experienced the outcome of other players' choices. Past studies have found that people are (a) hyper-altruistic, choosing more pain for themselves than others for a given payoff (Crockett et al., 2014), and (b) exhibit pain value curves with a characteristic nonlinearity, such that more extreme pain has increasing disutility (Coll et al., 2022). Effects of the choice context on pain experience are less clear. We hypothesized that pain may be experienced as more intense when another player chose a more intense stimulus (a stimulus expectancy effect) and when the monetary payoff for the other was higher (an unfairness effect). After an adaptive calibration to measure pain threshold and tolerance, participants (N=59) made a series of choices accept or reject heat pain paired with a monetary reward for themselves or for future participants (64 trials each, crossing 8 levels of pain based on their calibrated tolerance with 8 levels of monetary reward from $1-$8). To maintain incentive compatibility, participants received, at random, one of the choices. Then, they were told they would be receiving a random sample of decisions from previous participants' choices. In fact, choice cues and stimuli were experimentally randomized. Participants received a series of choice cues (intensity and monetary value, 48 trials) followed by painful thermal stimuli (high or low pain, randomly allocated). When making choices, participants accepted higher reward values for themselves vs. others ($t(177)= 2.364$, $p = 0.019$) but there was no effect by pain on decisions for self vs. others. When experiencing others' choices, higher intensity cues and higher monetary payoff for another player caused increases in perceived pain for a given stimulus (p-tolerance_cue = 2.434e-06, Cohen's d-tolerance_cue = 0.734, p-monetary = 0.00791, Cohen's d-monetary = 0.224). Overall, the study revealed a difference in participants' decisions to accept pain paired with monetary values for themself vs others. The findings demonstrate novel effects in stimulus expectancy and social cognition on pain experience.

Title: Serotonergic innervation of the nucleus accumbens and ventral pallidum are highly conserved among primates.

Authors: *H. N. SMITH[1], D. N. JONES[2], E. L. MUNGER[1], P. R. HOF[3], C. SHERWOOD[4], M. RAGHANTI[1];
[1]Anthrop., Kent State Univ., Kent, OH; [2]Flora Stone Mather Ctr. for Women, Case Western Reserve Univ., Cleveland, OH; [3]Icahn Sch. of Med. At Mount Sinai, New York, NY; [4]George Washington Univ., Washington, DC

Abstract: Serotonin is a phylogenetically ancient substance thought to regulate change in behavior and emotion over time through its actions in the brain's reward pathway. Modulating impulsivity, patience, and behavioral inhibition, serotonin affects behaviors such as personality style and sociability, which may buffer the emotional impact of group living. Humans and apes are known to have more serotonin than monkeys in the dorsal and medial caudate nucleus and dorsal putamen, contributing to the ability to select appropriate social interactions. The current study builds on earlier results by examining serotonergic axon innervation density in two important nodes in the reward system: the nucleus accumbens (NAcc) and ventral pallidum (VP). The present sample included humans (n = 6), bonobos (n = 4), chimpanzees (n = 6), gorillas (n = 4), olive baboons (n = 6), moor macaques (n = 6), Japanese macaques (n = 6), pigtailed macaques (n = 6), rhesus macaques (n = 6), capuchin monkeys (n = 6), owl monkeys (n = 4), tamarins (n = 6), and marmosets (n = 6). All individuals were adult and free of neuropathological alterations. Brain sections were immunohistochemically processed for serotonin transporter (SERT) (Millipore, MAB 5618), and stereological methods (Optical Fractionator and SpaceBalls probes, MBF Bioscience) were used to quantify the length density of SERT-immunoreactive axons and neuron densities from adjacent Nissl-stained sections. An Independent-samples Kruskal-Wallis test was used to evaluate differences of SERT-immunoreactive axon densities normalized by neuron densities among species in both brain regions. No differences among species were detected in the NAcc ($H(11) = 16.8$, $p = .114$). A species difference was detected in the VP ($H(11) = 30.7$, $p = .001$). Pairwise comparisons with adjusted p-values showed that moor macaques had higher innervation than owl monkeys ($p = .033$), marmosets ($p = .031$), and capuchins ($p = .047$). Moor macaques are considered an 'egalitarian' species and are isolated on the island of Sulawesi, Indonesia. More research needs to be done to explain their unique features. Based on the current results, the serotonergic system in the nucleus accumbens and ventral pallidum appears to be evolutionarily conserved among primate species, suggesting innervation levels that provide a baseline function to support social behavior. Title: Automated home-cage cognitive testing system for marmosets

Authors: *H. E. HARKINS, K. CHRISTOPHER, D. MATROV, I. INGRAM, Y. CHUDASAMA;
Section on Behavioral Neurosci., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: The common marmoset (*Callithrix jaccus*) represents a primate species of growing interest in cognitive-behavioral research largely due to their potential for study with optogenetic and related methods that are routinely applied to the brains of rats and mice. Similar to humans, marmosets live in close-knit families with a high degree of cooperative care and learn through social and vocal interactions. They also provide the advantage of being small, thereby reducing the need for large enclosures. In addition, critical features of the primate brain, such as the prefrontal cortex, hippocampus and thalamus, and their connections, are shared between the marmoset and more studied primates such as the Old-World macaque (Kaas, ILAR J. 2020; 61:260-273) and humans (Chaplin et al., J Neurosci. 2013; 33:15120-5). Thus, from the perspective of behavioral neuroscience, the marmoset represents an exceptional model of human cognition.

Many behavioral studies have used touchscreen operant platforms to examine high order cognitive functions (e.g., Clarke et al. Science. 2004; 304: 878-880). Typically, these tests are conducted in isolation, to enable experimental control while preventing distraction from the family unit. However, due to their social nature, marmosets prefer to be in close proximity to their family, and under these conditions, they work reliably over long time periods. With this in mind, some researchers have supported home-cage testing equipment (e.g., Takemoto et al., J. Neurosci. Methods. 2011; 199:82-86). Here, we report a novel, custom designed automated behavioral control testing system to assess complex cognitive-executive functions in freely behaving marmosets. The testing chamber, fitted with a touchscreen, stimulus lights, and food dispensers, was attached to the home-cage, and the monkeys could freely enter and exit as they pleased. Once habituated to the test box, monkeys worked for up to 3 hours completing many hundreds of trials (range 150-450). This approach, we found, allowed marmosets to work at their own pace and develop self-motivation to learn the task.

Thus far, we have trained 4 monkeys on a simple discrimination task in which two different stimuli were presented on the touchscreen. Touching the correct stimulus was rewarded with banana milkshake. The marmosets successfully attained over 80% accuracy in an average of 6 days (range 2-10) with fast response (2-5 s) and reward collection (< 3 s) latencies. Here, we report preliminary data on the effects of cholinergic manipulations on cognitive function using our home-cage behavioral control testing system.

Title: Roles of the nociceptin/orphanin FQ receptor in reward-related behaviors in mice

Authors: E. VAN DER RIJN[1,2], G. LIU[1,4], A. MERADIAN[1,4], A. PASQUALINI[1,4], M. A. ZAMBRANO[1,4], S. P. BROTHERS[5], K. J. RESSLER[1,3], *J. SUH[1,3];
[1]McLean Hosp., Belmont, MA; [3]Psychiatry, [2]Harvard Med. Sch., Belmont, MA; [4]Northeastern Univ., Boston, MA; [5]Univ. of Miami, Miami, FL

Abstract: The neuropeptide orphanin FQ/nociceptin receptor (NOR), the fourth member of the opioid receptor family, is widely distributed throughout multiple brain regions, including the amygdala. Although the NOR shares significant sequence homology with classic opioid receptors, emerging evidence suggests that the NOR system is involved in an anti-opioid action that suppresses the motivational effects of food and addictive substances such as alcohol. However, little is known about how NOR contributes to reward-related consummatory and seeking behaviors. To address this, we employed a battery of behavior tests combined with systemic administration of a non-peptide, brain-penetrant NOR agonist, SR-8993. To determine the effect of SR-8993 on consummatory behaviors, we first subjected male and female wild type adult C57BL/6 mice to a home cage binge-like drinking paradigm, Drinking in the Dark. We found that SR-8993 administration at doses of 1.0 and 3.0mg/kg BW significantly decreased both 20% ethanol (EtOH) and evaporated milk consumption. Next, we also investigated if SR-8993 affects seeking behaviors. In separate cohorts of mice subjected to EtOH conditioned place preference, we found that mice injected with SR-8993 (3.0 mg/kg BW) spent less time in EtOH-paired compartment during choice-test. In addition, we measured milk-seeking behaviors using Pavlovian and instrumental conditioning paradigms. We found that administration of SR-8993 at a dose of 1.0 mg/kg BW attenuated the number of pre-reward anticipatory nose-pokes responding to tone-cue in high performers in a Pavlovian conditioning task. Interestingly, in the instrumental conditioning task, SR-8993 at all doses did not significantly reduce milk seeking, yet 1.0 and 3.0 mg/kg BW both increased seeking behavior one day after the administration of SR-8993. Finally, we investigated if SR-8993 can alter behavioral structures including locomotion in an open field using Motion Sequencing (MoSeq), an unsupervised machine learning-based behavioral analysis method. Although MoSeq successfully parsed behavioral differences and similarities, we found that SR-8993 did not appear to affect stereotyped behaviors. In sum, these findings suggest that the NOR system is involved in consummatory and seeking behaviors, yet it appears to contribute to these behaviors in a dose-dependent, relatively selective manner, which depends upon the structure of tasks. Our results provide evidence that the NOR system may present promising targets for the development of novel pharmacotherapies for the treatment of alcohol use and eating disorders.

Title: Increased persistence for reward seeking in mice lacking NOP the receptor for nociceptin

Authors: *M. NISSENBAUM[1], S. WALPOLE[1], V. SOTIROV[1], D. HU[1], J. E. PINTAR[2], A. W. KUSNECOV[1];
[2]Neurosci. & Cell Biol., [1]Rutgers Univ., Piscataway, NJ

Abstract: The Nociceptin/Orphanin FQ (N/OFQ) precursor propeptide is linked to reward-seeking, and the nociceptin receptor (NOP) has been shown to oppose behavioral deficits due to inflammation. Here we report in 3-5 month old NOP-deficient (NOP KO) and wildtype (WT) mice the effects of the immune stimulus LPS on operant responding in a progressive ratio schedule (PR), as well as effects on cognitive flexibility. NOP KO (20F; 35M) and WT (18F; 30M) mice on a C57BL/6 background were trained to nose poke into a trough that lifted a liquid dipper containing a 4% sucrose reward. After successful training under FR1 and FR3 schedules, mice were subjected to a PR schedule for three sessions. At 90 mins before PR testing on day 2, mice were injected IP with saline or LPS at a high (200µg/kg) or low (40µg/kg) dose. One more PR day followed without further treatment. Subsequent to this, mice were entered into a second phase (Phase 2) of operant training, that involved a rule change, such that an adjacent operandum needed to be nose poked to activate the liquid dipper. This rule-change for receipt of reward was designed to assess the lingering effects of LPS on cognitive flexibility. RESULTS: Prior to LPS exposure, NOP KO mice showed more persistent nose poking throughout the PR task when compared to WT controls. In females, there was an interaction of genotype x time (RM 2-way ANOVA $F_{(59, 1593)}$ $p=0.0045$), but no interaction for males, only genotype and time main effects (RM 2-way $p=0.0012$ and $p=0.0001$, respectively). Therefore, NOP KO mice demonstrated increased motivation to seek reward. In response to high and low LPS doses, responding was reduced regardless of genotype or sex ($p<0.0001$). In the saline treated group, the persistent responding in NOP KO mice was maintained. To test for lingering sickness or a learned aversion, the progressive ratio task was repeated 24h later (day 3 of PR), and NOP KO mice previously given LPS showed significantly greater recovery and responding compared to WT-LPS controls ($p=0.02$). This suggests that NOP may be needed to dampen post-inflammation pursuit of reward. These mice were then given an alternate rule to obtain reward (Phase 2). An efficiency quotient was calculated to determine how well mice learned the new task. Interestingly, while all groups learned the new task, females previously given LPS had slightly

higher efficiency rates than saline controls regardless of genotype (p=0.06). Both LPS-treated and saline treated NOP KO males had higher efficiency compared to WT controls (p<0.005). These data suggest that the N/OFQ system, and NOP stimulation particularly, may modulate reward seeking and cognitive flexibility in a sex-dependent manner.

Title: Implications of Birth Route on Reward-Mediated Behavior in Adult Prairie Voles

Authors: ***K. ROGERS**[1], M. PARTIE[2], E. KIERNAN[2], N. FOLEY[2], W. M. KENKEL[2]; [1]Psychological and Brain Sci., Univ. of Delaware Grad. Program In Behavioral Neurosci., Newark, DE; [2]Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Accumulating evidence from clinical studies on the long-term impact of Cesarean delivery (CS) has found increased risk in offspring for developing obesity later in life. We have examined this using prairie voles and find that CS offspring weigh more across development compared to vaginally delivered (VD) counterparts. In this study, we explored the impact of CS on dopamine and reward-mediated behavior as a potential mechanism of increased weight gain. We used a conditioned place preference (CPP) paradigm and operant conditioning schedules to assess learning and motivation in adult prairie voles. Preliminary results from the CPP testing suggests the efficacy of sucrose does not differ between CS and VD voles when assessing context-dependent reward learning [$F(1, 13) = 0.004$, $p = 0.952$]. However, CS offspring demonstrate stronger acquisition of the FR1 schedule ($M = 38.8$, SD = 4.32; $M = 25.75$, SD = 13.96) measured by responses for an appetitive stimulus. To assess the role of DA in behavioral outcomes of CS, we intend to include analysis of tyrosine hydroxylase in the reward and appetite-regulating brain regions compared to VD offspring. These results will help us better understand the neurodevelopmental consequences of CS on dopamine and reward-mediated behavior as a potential mechanism for increased risk of obesity in adulthood.

Title: Discriminative properties of intracranial stimulation

Authors: *B. PACHECO GÓMEZ[1], W. ZEPEDA-RUIZ[1], D. VELAZQUEZ-LOPEZ[2], D. VELAZQUEZ-MARTINEZ[1];
[1]Facultad de Psicología, [2]Univ. Nacional Autónoma De México, Mexico City, Mexico

Abstract: Previous studies using electrical intracranial stimuli (ICS) as a discriminative cue, focused on estimating detection thresholds or on the discrimination between intensities. To our knowledge there is no direct comparison of the equivalence between variation of amplitude and variation of frequency on the discriminative functions. Seven Long Evans rats had an electrode aimed at the medial forebrain bundle (hypothalamus) and were trained to press a lever using a reinforcing intensity below motor alterations. Thereafter, rats were trained on a discrimination task where the previously used reinforcing ICS signaled a lever where a response was followed by sucrose reinforcer; on randomly alternating trials a -0.6 log ICS signaled an alternate lever where a similar response led to a reinforcer. After mastering discrimination, generalization tests were carried out varying intensity or frequency of ICS in ascending, descending or random order. Thereafter, rats had different doses of an apomorphine challenge while their intensity was varied in generalization tests. Rats learned the discrimination attaining discrimination indexes (DIs) of 90-98%. In generalization trials responding to the high-ICS was a function of the amplitude or frequency, but presentation order did not alter their DIs. After variations in the amplitude parameter, orderly generalization gradients were observed. Variations in the frequency parameter of ICS also produced orderly generalization gradients. Estimated DI_{50}s (expressed as charge of stimulation train) after frequency variations had a large coincidence with the DI_{50}s after frequency variations, in accordance with the counter model that posited that pulse frequency and amplitude of the stimulation train may be a tradeoff to determine the reinforcing properties of ICS. Although there is ample evidence of the involvement of DA receptors in the reinforcing properties of ICS, present results with apomorphine (that did not affect the generalization gradient after amplitude variations) and previous reports using DA antagonists indicate that administration of DA agents may be able to dissociate the reinforcing and discriminative properties of ICS.

Title: Melanin-concentrating hormone (MCH) receptor 1 mediates increased sucrose reward driven by opioid activation of the nucleus accumbens in female rats

Authors: *Y. CAM, C. G. KOCUM, E. R. KONRAD, T. A. SCHWEIZER, T. K. HOUSKA, C. A. SARDINA, S. K. SURI, M. J. WILL;
Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Melanin-concentrating hormone (MCH) projections from lateral hypothalamus to nucleus accumbens (Acb) have been shown to mediate feeding behavior, yet this has not been characterized in terms of homeostatic vs. hedonic feeding processes. Hedonic feeding is driven by palatability, rather than energy deficit, and can be modeled through intra-Acb administration of the selective μ-opioid agonist D-Ala2, NMe-Phe4, Glyol5-enkephalin (DAMGO), which enhances motivation for palatable preferred diets. Pharmacological activation of MCH 1 receptors (MCH1R) within Acb has been shown to promote general feeding of chow in males but not in intact females. However, the effects of MCH on hedonic feeding have not been explored. Here, we investigated the effects of an MCH1R antagonist on DAMGO-induced operant responding for sucrose pellets in females. After bilateral intra-Acb cannulae surgery and a 7-day recovery period, rats were trained on a fixed ratio to respond to a lever for a sucrose pellet in operant test chambers. Then, animals were trained and tested under a progressive ratio operant task following intra-Acb administration of DAMGO (0μg and 0.25μg/.5μl/side) immediately following administration of MCH1R antagonist (N-(3-{1-[4-(3,4-difluoro-phenoxy)-benzyl]-piperdin-4-yl}-4-methyl-phenyl)-isobutyramide (SNAP-94847; 0μg, 1.5μg and 15μg/.5μl/side) in a counterbalanced fashion. As expected, DAMGO significantly increased breakpoint and active lever presses. SNAP-94847 had no influence on breakpoint, compared to vehicle, however, SNAP-94847 significantly reduced the breakpoint produced by intra-Acb DAMGO following both 1.5 and 15μg doses of SNAP-94847. The results of the study demonstrate that MCHR1 within the Acb may be a critical contributor to the opioid model of palatability-driven feeding in female rats.

Title: Serotonin transients in the nucleus accumbens encode both appetitive and aversive stimuli

Authors: *R. WANG, T. JAMES, N. BALASUBRAMANIAN, C. MARCINKIEWCZ;
Dept. of Neurosci. and Pharmacol., Univ. of Iowa, Iowa City, IA

Abstract: The serotonergic (5-HT) circuitry from the dorsal raphe to the nucleus accumbens (NAcc) is involved in a variety of neural processes. But it remains elusive how 5-HT transmission in the NAcc changes in response to different sensory stimuli. In the present study, we expressed a 5-HT biosensor ($GRAB_{5\text{-}HT3.5}$) in the NAcc of male C57BL/6J mice via AAV infection, and performed wireless fiber photometry recordings while mice were being presented with different appetitive and aversive stimuli. First, when mildly food-deprived mice were offered palatable food (fruit loops) that they were previously familiarized with, we observed gradually increased fluorescent 5-HT transients in the NAcc, which remained elevated while mice were investigating the food but started to drop as food consumption began, suggesting that 5-HT transmission in the NAcc is associated with appetitive, but not consummatory, behavior. Interestingly, a small increase in NAcc 5-HT transients also emerged when mice were presented with the smell of the palatable food (from fruit loop fragrance oil) alone. Second, presentation of social stimuli, via a same-sex conspecific enclosed inside a corner cage in an arena, drove enhanced NAcc 5-HT transients, similar to the transients observed when mice were offered palatable food, indicating that 5-HT transmission in the NAcc encodes different appetitive stimuli with reinforcing values in a similar pattern. Finally, we assessed NAcc 5-HT response to aversive stimuli using an acute bright light exposure paradigm. In a dimly-lit (~ 20 lux) arena, a super bright white light (~1,800 lux) was unexpectedly illuminated, kept on for 2 min, and then turned off. We observed a sudden increase in 5-HT transients accompanying the bright light illumination, which sustained at the high level until lighting returned dim. During the elevation of NAcc 5-HT transients, fluorescent peaks with much greater amplitudes were also observed, suggesting the occurrence of synchronous cell firing upon acute stress exposure. In conclusion, 5-HT transmission in the NAcc encodes both appetitive and aversive stimuli, which drive enhanced 5-HT transients that may entail different neural processes. Our findings could help better understand the role 5-HT plays in the NAcc.

Title: Nmda receptor inhibition on rodent optimal decision-making in the diminishing returns task

Authors: *S. D. FOUST, M. MAINS, H. ABOUEICH, B. WELLS, B. GOH, H. DOBLE, E. MCCURRY, E. SANCHEZ, G. DELICH, E. JANCOLA, E. DAUGHERTY, P. M. BAKER; Psychology, Seattle Pacific Univ., Seattle, WA

Abstract: There has been growing interest in using N-methyl-D-aspartate (NMDA) receptor antagonists as treatments for mood disorders, but there is still much to learn about their cognitive effects. Specifically, some have reported impairments in working memory while foraging behavior remains intact. Others have demonstrated changes in choice behavior related to delay or risk in operant tasks. Research has shown NMDA receptors can affect decision-making, and the antagonist MK-801 has been found to have varying effects in rodents. We investigated the role of NMDA receptors in the specific paradigm of optimal decision-making to further confirm the effects of MK-801 and to explore whether inhibiting NMDA receptors alters optimal decision-making processes. The Diminishing Returns task (DRT) has been used to measure this process with rats placed in a chamber containing two levers that return a sugar pellet reward after a delay. One lever has a fixed delay (FD) that returns a reward after 10 s. The other lever has a progressive delay (PD) that increases by 1 s after each press starting at 0 s. The task includes two conditions: no reset and reset. In the no reset condition, pressing the PD lever continuously increases its delay. In the reset condition, the delay of the PD lever can be reset to 0 s by pressing the FD lever. In both conditions, there is an optimal response rate on the PD lever that returns the most rewards at the least amount of delay in a session. 12 male and 12 female Sprague Dawley rats aged 2 - 4 months were each injected with 3 doses of MK-801 (0.06 mg/kg, 0.1 mg/kg, 0.2 mg/kg) and saline as the control on a counterbalanced schedule before testing in the DRT. Their lever choices were analyzed with generalized linear mixed models for effects of the treatments and sex of the rats and were compared to optimal values. We hypothesized MK-801 would diminish the ability to make optimal decisions. In the no reset condition, rats on the 0.2 mg/kg dose made significantly more choices for the PD lever than the FD lever compared to the other treatments (56.9% ± 4.8%, n = 14). In the reset condition, females made significantly more PD lever presses than males after receiving saline (females: 93.8% ± 1.1%, males: 88.7% ± 1.8%, n = 24). It was found that males and females on the 0.2 mg/kg dose made more optimal sequences of lever choices (females: 3.38 ± 0.87, males: 6.48 ± 1.67, n = 16). These results reveal a complex effect of both sex and NMDA receptor effects on optimal foraging behaviors and overall task responsiveness. Therefore, the findings suggest inhibiting NMDA receptors may not detrimentally affect the cognitive mechanisms involved in optimal decision-making as it is measured in this task.

Abstract: A growing body of literature suggests that food seeking/taking and drug addiction overlap in neurobiology. For instance, many drugs of abuse, as well as palatable foods, recruit cortical neuronal ensembles. Unknown, however, is how neuromodulators, such as norepinephrine (NE) from the Locus Coeruleus (LC), perturb medial prefrontal cortex (mPFC) neuronal ensembles, and food-seeking. To investigate the relationship between food seeking, neuronal ensembles, and NE, female rats were required to lever press (FR1) for banana-flavored sugar pellets for ten days. To minimize stress to the animals, they were not weighed and lavaged (to determine the estrus cycle) until day 6 of the study. On day 10 of sugar pellet self-administration, the rats were injected with the selective Norepinephrine neurotoxin DSP-4 (50 mg/kg/.i.p) or saline and placed in home cages for ten days. On day 20, rats were given a single re-exposure session to the self-administration context (without sugar pellet delivery). Their responses were recorded for one hour. One and half hours following the start of this re-exposure session, rats were transcardially perfused, and the mPFC was sectioned for dual immunofluorescence (IF) for the immediate early gene Fos and dopamine beta-hydroxylase (DβH) (for confirmation of NE loss). Our preliminary results show comparable levels of lever pressing and body weight in female rats given saline or DSP-4. We are now replicating with male rats, analyzing the female estrus cycle, and performing IF in mPFC sections.

Abstract: (R,S)-methadone ((R,S)-MTD) is a μ-opioid receptor (MOR) agonist comprised of (R)-MTD and (S)-MTD enantiomers. (S)-MTD, thought to be the opioid inactive isomer, is being developed as an antidepressant and is considered an N-methyl-D-aspartate receptor (NMDAR) antagonist. Here we compared the pharmacology of (R)-MTD and (S)-MTD using in vivo, in vitro, and in silico methods. Broad receptor screening identified MOR as the main target for (R)-MTD and (S)-MTD. We use receptor occupancy autoradiography to show that racemic and both enantiomers ((R,S)-MTD: 4 mg/kg; (R)-MTD: 2 mg/kg; (S)-MTD: 30 mg/kg) produce near total occupancy MOR (over 90% for (R,S)-MTD and (R)-MTD and over 75% for (S)-MTD) at pharmacologically relevant doses. Additionally, we demonstrate here that, at these same doses, none of these drugs interact with NMDARs in vivo. Moreover, we performed [^{35}S]GTPγS and find that (R,S)-MTD, (R)-MTD, and (S)-MTD activate MORs, though (R)-MTD is the most potent. Using the hot plate assay, (R,S)-MTD (EC_{50}: 1.2 mg/kg), (R)-MTD (EC_{50}: 0.5 mg/kg), and (S)-MTD (EC_{50}: 17.9 mg/kg) produce full analgesia in rats. We next performed intravenous self-administration in rats and found that unlike (R,S)-MTD and (R)-MTD, (S)-MTD is a weak reinforcer. Additionally, (S)-MTD failed to induce locomotor stimulation in mice or to affect extracellular dopamine in the ventral tegmental area of rats. Furthermore, (S)-MTD antagonized motor effects of (R)-MTD. In bioluminescence resonance

energy transfer assays in transfected HEK-293 cells, (R)-MTD acted as a full efficacy agonist at MOR and the MOR-galanin$_1$ receptor heteromer (MOR-Gal$_1$R). By contrast, (S)-MTD acted as a partial agonist at MOR, with complete loss of efficacy at MOR-Gal$_1$R, a key mediator of the dopaminergic effects of opioids. We then utilize computer modeling to propose a novel molecular mechanism underlying the MOR-Gal$_1$R heteromer-dependent effects of (S)-MTD which will be useful in future drug development. Collectively, our results demonstrate that (S)-MTD is a novel prototype opioid with minimal abuse liability, most likely due to its lack of activity at MOR-Gal$_1$R sites mediating reinforcing effects of opioids.One-sentence summary (S)-MTD, like (R)-MTD, binds to and activates MORs in vitro, but (S)-MTD antagonizes the MOR-Gal$_1$R heteromer, decreasing its abuse liability.

Title: Muscarinic receptors in the basolateral amygdala act in synergy to impinge a hedonic value related to taste experience.

Authors: *E. RODRÍGUEZ NAVA[1], V. TORRES GARCÍA[2], R. ALCANTARA RIVAS[2], G. ROLDÁN ROLDÁN[3], O. PICAZO PICAZO[1], J.-P. MORIN[2];

Abstract: The basolateral amygdala (BLA) is a functionally heterogeneous brain area that encodes and stores valence-related information (Beyeler et al., 2018; Kim et al., 2016). This structure receives dense projections from the basal forebrain cholinergic system (Alexander J. McDonald, 2020), where its abundant muscarinic receptors (A. J. McDonald & Mascagni, 2011; Alexander Joseph McDonald & Mascagni, 2010) are thought to promote neuronal plasticity mechanisms underlying emotional learning and memory (Crouse et al., 2020). The attenuation of neophobia (AN) is an incidental type of taste learning in which the initial hesitation in ingesting a novel taste, due to a lack of knowledge regarding its post-ingestive consequences, attenuates upon repeated presentations (Chinnakkaruppan et al., 2014; Reilly & Bornovalova, 2005). Under laboratory conditions, in murine models, this is observed by an augmented intake of a taste as well as increased palatability (Lin et al., 2012), indicating that a valence switch occurs during the task. In the present study, we theorized that muscarinic receptor antagonism in the BLA, by bilateral microinfusions of scopolamine (SCOP) after novel taste presentation, would interfere with AN. As we showed previously (SfN 2022 poster 224.12), this treatment not only prevented AN but produced a robust aversion for the taste on subsequent presentations. We now present new data showing how intra-BLA SCOP infusions after novel taste affects taste palatability on the following day as showed by licking microstructure analysis. We also sought to determine whether this intra-BLA SCOP-induced taste avoidance was prone to latent inhibition by pre-exposing rats on four days before performing taste-paired scopolamine infusion on the fifth day. Here, a significant taste avoidance was produced as observed on the sixth day, albeit not as strong as when SCOP was administered after the novel taste. Moreover, specific M1-type or M3-type muscarinic receptor antagonism was performed after novel taste intake by intra-BLA microinfusions of pirenzepine or 4-DAMP, respectively. Although each treatment was able to prevent the increase in taste preference characteristic of the AN task -and observed in control animals-, they did not produce the strong avoidance that we observed with the SCOP treatment. Our data suggest that muscarinic receptors in the BLA work in synergy to impinge a hedonic value upon a taste experience, modulating the taste's valence upon subsequent encounters.

Title: Injections of gastrin releasing peptide into the rat medial nucleus accumbens cause a transient inhibition of the intake of a sweetened fat diet

Authors: *W. E. PRATT, R. B. COCHRAN, S. CHUANG, E. IRVIN, S. PATEL, L. WILSON;
Dept. of Psychology, Wake Forest Univ., Winston Salem, NC

Abstract: Gastrin releasing peptide (GRP) is a neuropeptide that is released in the gut following food ingestion. It has many peripheral digestive functions, such as stimulating gastrin release, regulating pancreatic secretions, and increasing gastrointestinal motility. Like many other gut-associated peptides released in response to energy metabolism, GRP has receptors distributed throughout the brain (Wolf & Moody, 1985). This includes heavy expression of its receptor within the hypothalamus and nucleus accumbens. These regions are involved in regulating food intake in response to energy deficit and the hedonic value of palatable foods. In the current experiments, we examined whether GRP injection into either the nucleus accumbens or paraventricular nucleus of the hypothalamus could affect intake of a sweetened fat diet. Two groups of male Sprague-Dawley rats were implanted with bilateral guide cannulas aimed at either the paraventricular nucleus of the hypothalamus (N = 6) or the medial nucleus accumbens shell (N = 8). These non-restricted animals were then habituated to daily 2-hr access of a high fat/sucrose diet consisting of 10% sugar in vegetable shortening. Diet intake, water intake, and locomotor measures were monitored throughout each session. Upon habituation to the diet and injection procedures, each rat received bilateral intracranial injections of 0, 100, 200, and 300 ng GRP/side in 0.5 microliters of isotonic saline directly into the paraventricular nucleus or the nucleus accumbens immediately prior to being placed into the feeding chambers. Each rat received all doses of GRP in a random order across multiple experimental days. Consistent with past research examining the effects of GRP on food intake when administered systemically or into the amygdala (e.g., Fekete et al., 2002; Ladenheim et al., 2002), GRP infusion into the nucleus accumbens caused a short-lived reduction in consumption of the sweetened fat diet early in the first hour of each session [effect of GRP: F (3,21) = 5.00, p = 0.009; GRP X time interaction: F (33,231) = 2.96, p = <0.001]. A similar trend was observed following injections into the paraventricular nucleus of the hypothalamus, although the inhibition did not achieve significance [effect of GRP: F (3,15) = 2.59, p = 0.091. GRP X time interaction: F(33,165) = 1.48, p = 0.06]. These data show, for the first time, that GRP may function to transiently impact the intake of palatable diets through actions within the nucleus accumbens and associated circuitry.

Title: Cannabinoid receptor-1 signaling promotes sensitivity to devaluation in male, but not female, sign-tracking rats.

Authors: *C. A. STAPF[1,2], S. E. KEEFER[3], J. M. MCINERNEY[2,3], D. J. CALU[3];
[1]Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [2]Program in Neurosci., [3]Dept. of Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Sign-tracking rats are insensitive to outcome devaluation but become devaluation sensitive after extended Pavlovian lever autoshaping (PLA) training. However, this finding was established using only male rats. Female rats are more likely to sign-track and show increased lever pressing compared to male rats, suggesting they may be less sensitive to devaluation even after extended training. Cannabinoid-1 receptor (CB1R) signaling in the dorsomedial striatum (DMS) regulates instrumental outcome devaluation suggesting this system may also be important for devaluation of Pavlovian behaviors like sign- and goal-tracking. To understand the contribution of DMS CB1R signaling to sex- or tracking-specific responses in outcome devaluation, we performed intracranial infusions of the CB1R inverse agonist, rimonabant, in the DMS before reinforced PLA sessions and outcome devaluation test sessions. We used a within-subject satiety-induced outcome devaluation procedure in male and female rats after extended training in PLA. We sated rats on training pellets (devalued) or home cage chow (valued) then tested rats in nonreinforced PLA sessions. During outcome devaluation tests, male sign-tracking rats were sensitive to devaluation while female sign-tracking rats were not. Inverse agonism of CB1Rs in the DMS with rimonabant reversed devaluation sensitivity in male sign-tracking rats. We saw no effect of DMS rimonabant injections on tracking behaviors during reinforced PLA sessions. Together, our results demonstrate that dorsal striatal endocannabinoid signaling has sex-specific effects on the devaluation sensitivity of Pavlovian behaviors in male and female rats.

Title: Methamphetamine Induces Conditioned Place Preference in a Sex and Strain Specific Manner in Adolescent Mice.

Authors: *L. NUNEZ SEVERINO[1], A. B. TOUSSAINT[2], G. MCKENNA[1], N. S. BURGHARDT[1,3];
[1]Psychology Dept., Hunter College, CUNY, New York, NY; [2]Zuckerman Inst., Columbia Univ., New York, NY; [3]Behavioral and Cognitive Neurosci., The Grad. Center, CUNY, New York, NY

Abstract: There are sex differences in the use and response to methamphetamine, with women initiating use earlier and transitioning to regular use faster than men. However, studies investigating the cellular basis of addiction often only test male rodents during adulthood. We used a conditioned place preference (CPP) paradigm to test whether there are sex differences in the rewarding effects of methamphetamine (1mg/kg) in mice of two strains (C57Bl/6 and 129Sv/Ev). CPP training began during adolescence (postnatal day 41), which is usually when substance abuse is initiated in humans. To evaluate the neural basis of methamphetamine-induced CPP, mice were perfused 90 minutes after the CPP test (drug-free) and immunohistochemistry was used to label cells expressing the neural activity marker c-Fos. Behaviorally-induced expression of c-Fos was quantified in the core and shell of the nucleus accumbens (NAc) using ImageJ software. In the C57Bl/6 strain, we found that methamphetamine only induced CPP in females ($n = 12$/group, $p < 0.05$), effects that were associated with increased c-Fos-positive (+) cells in the NAc shell ($n = 10$/group, $p = 0.05$**)**. Interestingly, when C57Bl/6 mice were on drug, methamphetamine stimulated locomotor activity in both sexes, with neither sex exhibiting locomotor sensitization. In the 129Sv/Ev strain, methamphetamine only induced CPP in males ($n = 12$/group, $p < 0.01$), which was also associated with an increase of c-Fos+ cells in the NAc shell ($n = 8$, $p < 0.05$). Overall, the effects of methamphetamine on locomotor activity were less dramatic in the 129Sv/Ev strain than the C57B/6 strain. In 129Sv/Ev mice, methamphetamine failed to increase locomotion in either sex until the fourth injection and sensitization was only detected in males ($p<0.01$). These findings clearly demonstrate sex and strain differences in the response to methamphetamine and are consistent with existing literature indicating that the NAc plays a pivotal role in driving the rewarding effects of drugs of abuse.

Title: Sensory-motor system and reinforcement learning

Authors: *Y. KYUNG, S.-L. KIM;
Yonsei Univ., Seoul, Korea, Republic of

Abstract: Reinforcement learning is a prominent and systematic technique in machine learning that involves deliberately modifying an agent's actions. By leveraging the agent's responses to the environment, it gradually improves its decision-making capabilities. However, traditional reinforcement learning models have limitations in capturing the intricate nature of sensory motor mechanisms. To address this challenge, we propose a novel framework grounded in statistical theory and control theory, aiming to overcome these limitations. Our framework incorporates the formulation of a cost function for action selection, serving as the foundation for developing an algorithm that estimates rewards and discount factors using biological data. This estimation process enables more precise predictions of escape behaviors. Moreover, our neuroscience-inspired model offers a strategic approach to decompose complex tasks into independent decision modules, facilitating the training of an artificial agent capable of emulating biological escaping systems.

Title: Dose-dependent effects of oral hormonal contraceptives on female gonadal function and amphetamine extinction.

Authors: *A. VASQUEZ, G. KIM, J. M. DOMINGUEZ, M. H. MONFILS, H. J. LEE; Univ. of Texas At Austin, Austin, TX

Abstract: Women are at an increased risk for developing substance use disorder (SUD), in part due to fluctuating levels of gonadal hormones, such as estradiol and progesterone, during the menstrual cycle. A common type of treatment for SUD in women is exposure therapy—an approach largely based on extinction. Changes in gonadal hormone levels across the menstrual cycle, as well as those induced by hormonal contraceptives (HC) among women of reproductive age, affect extinction, but are rarely considered. HCs work by suppressing hormonal fluctuations and levels of gonadal hormones in the body to prevent ovulation. Previous research in our lab has demonstrated that HC implants containing Levonorgestrel (LNG), a synthetic progestin commonly used in HCs, led to a rapid reduction in preference for amphetamine (AMPH)-associated context. Additionally, research on fear conditioning has shown that the timing of LNG administration may be important for extinction learning. The current experiment investigated whether oral administration of LNG, only during extinction, would lead to a reduction in AMPH-preference. Female rats underwent AMPH-conditioned place preference. They were then tested for their AMPH-preference either (1) over three sessions (ie., extinction learning sessions) while

receiving oral LNG (250µg/rat), or (2) during an estrous cycle stage associated with higher levels of gonadal hormones (i.e., proestrus/estrus). Both groups initially showed preference for the AMPH-associated context regardless of hormonal treatment. However, the LNG females showed no significant preference by the third extinction session, whereas naturally cycling females on proestrus/estrus stages still showed preference. Interestingly, estrous cycles of LNG females were not affected at the dose (250µg/rat) that influenced AMPH extinction. A higher dose (500µg/rat) of oral LNG still did not lead to persistent estrous stages associated with lower gonadal hormone levels (i.e., diestrus/metestrus), unlike what has been previously reported. Interestingly, uterine horn width, an index of prior exposure to high levels of estrogens, was significantly thinner in both high and low dose LNG rats as compared to proestrus/estrus rats, but not significantly different from diestrus/metestrus rats, suggesting that administration of the oral contraceptive was not without consequence. The findings are consistent with previous results from our lab and suggest a dose-dependent effect of LNG on gonadal function. Future work for this study will assess an optimal dose of LNG that leads to a persistent low gonadal hormonal state to assess conclusive effects of LNG on AMPH-extinction in females.

Title: Relationship between attention behaviors and prefrontal-parietal EEG synchronization in rats during proestrus-estrus

Authors: *C. A. DOMÍNGUEZ-ESTRADA[1], E. HERNANDEZ-ARTEAGA[2], A. Z. GÓMEZ-MÉNDEZ[1], M. HERNÁNDEZ-GONZÁLEZ[1];
[1]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico; [2]Facultad de Ciencias para el Desarrollo Humano, Univ. Autónoma de Tlaxcala, Guadalajara, Mexico

Abstract: Female rats display behavioral changes in response to differences in sex hormone levels that impact the functionality of certain brain areas, according to the stages of the estrous cycle. In this study, we characterized the electroencephalographic (EEG) activation and coupling between the medial prefrontal and posterior parietal cortices during antagonistic phases of the estrous cycle (proestrus-estrus vs. diestrous), as well as the attention that female rats paid to a sexually experienced male. The amount of nose pokes made while the rats were in a sexual incentive motivation box served as an index for the level of attention focused to the stimuli. Two situations—an awake-quiet state without a male rat present and an awake-quiet state with a male rat present—were used to record EEGs. The females displayed reduced latency with longer frequency and duration of nose pokes during proestrus-estrus. Regardless of the estrous cycle

phase, the females in both cortices presented increased absolute power in all EEG bands recorded in the presence of the male. Regardless of whether a male was present, the estrous females also showed higher EEG coupling between the medial prefrontal and posterior parietal cortices of the left hemisphere in all EEG bands. The greater attention focused to, and proper processing of the sexual signals released by the male may be related to the increased synchronization between prefrontal- parietal regions. Therefore, it is likely that a stronger functional connection between the prefrontal and parietal cortices is needed to display the proceptivity and receptivity behaviors that are specific of the proestrus-estrus phase.

Title: Influence of prenatal stress on prefrontal-accumbens electroencephalographic correlation during the first sexual interaction in male rats

Authors: *A. Z. GOMEZ MENDEZ, P. CORTES ESPARZA, C. DOMÍNGUEZ ESTRADA, M. HERNÁNDEZ GONZÁLEZ;
Univ. de Guadalajara, GUADALAJARA, Mexico

Abstract: The first sexual interaction in male rats plays a vital role in the development of their sexual behavior. The conjunct activity of two specific brain regions, the medial prefrontal cortex (mPFC) and the nucleus accumbens (NAcc), appear to be involved in processing sexually relevant stimuli during the acquisition of sexual experience. Any alterations in these structures could have a negative impact on sexual behavior. Previous studies have indicated that prenatal stress can have detrimental consequences for the development of the mPFC and NAcc. These effects may persist into adulthood and hinder the acquisition of sexual experience, especially during the first sexual interaction in male rats. Considering the forementioned context, the objective of this study was to analyze the impact of prenatal stress on the electroencephalographic correlation (rEEG) between the mPFC and NAcc during the first sexual interaction in male rats. To conduct the study, a sample of 16 male Wistar rats was used, divided into two groups: one group experienced prenatal stress, while the other did not. From the time of weaning, the male rats were exclusively housed with other males and were not exposed to female rats. At 90 days of age, the rats underwent surgery to bilaterally implant electrodes in the mPFC and NAcc. EEG activity was recorded under two conditions: 1) during the first interaction with an ovariectomized (OVX) female, and 2) during the first interaction with a receptive female (RE). The results showed that rats of the prenatal stress group exhibited an increased susceptibility to changes in interhemispheric correlation. When in the presence of a receptive

female, rats in the prenatal stress group showed a higher correlation between the NAcc in the fast frequencies, while for the correlation between the mPFC, such an increase was observed in the theta band. In contrast, the stress-free group showed higher susceptibility in intrahemispheric correlation. The presence of a receptive female was associated with an increase in the correlation between the left mPFC and NAcc in the beta band. These findings suggest that prenatal stress has a differential impact on brain electrical activity during the first sexual interaction, which may have implications for both the neurophysiological and behavioral aspects associated with sexual behavior in male rats.

Title: Monitoring progression of motivated behaviors during models of chronic female stress

Authors: *M. MCGRAW[1], C. CHRISTENSEN[2], A.-J. LI[3], E. QUALLS-CREEKMORE[2]; [1]Washington State Univ. Grad. IPN, Pullman, WA; [3]Integrative Physiol. and Neurosci., [2]Washington State Univ., Pullman, WA

Abstract: Exposure to stress has been shown to dysregulate motivated behaviors; while chronic stress commonly results in decreased motivated behaviors, as seen in depression, motivation has also been shown to increase with mild stress exposure. The bidirectional response to stress is not well characterized, especially in females. Chronic social defeat (CSD) is the standard protocol for psychosocial models of stress in mice as it is translationally relevant to the daily social and relationship stressors we encounter. However, this model has historically excluded female mice due to the model's reliance on territorial aggression which is typically absent in female mice. Additionally, most studies assess motivation after the fact, potentially occluding changes in motivation throughout the progression from acute to chronic stress. Our study seeks to compare and validate two proposed chronic social stress protocols that accommodate female cohorts. Model one introduces both a male and female C57 intruder into the home cage of a male CD1 mouse (Chronic Non-discriminatory Social Defeat Stress, CNSDS) to induce indiscriminate attack behavior. Model two replaces territorial aggression with social crowding (Social Crowding Stress, SCS). A female C57 mouse is exposed to daily prolonged investigation, vocalizations, and general contact with 8 unfamiliar female CD1 mice. Motivated behavior of controls (N=10) and experimental mice (N=10) are continuously monitored via an in-home operant feeding device (FED3) that dispenses sucrose pellets for trained nose pokes. Following 10-15 days of stress, we will use the standard social interaction assay to establish successful defeat and evaluate whether mice were susceptible or resilient to the stressors. We hypothesize

that there will be an initial increase in motivated behavior during the initial exposure to stress as a potential coping mechanism. However, as variations in exact stressor intensity and perception of stress for each mouse will occur, we anticipate that some mice will experience an overall mild-moderate stressor and others will experience severe stress. Preliminary data suggests mild-moderate stress will progressively increase their motivated behaviors while a severe stressor will alternatively decrease their motivated behaviors over time, resulting in anhedonia. Further, we aim to identify if resilient and susceptible populations correlate with differences in motivated behavior. Together, this study promotes the continued effort to compensate for the lack of female research in behavioral studies, as well as beginning to investigate the bidirectional switch in behavior as a product of stress over time.

Title: Sex Differences in the Renewal of Alcohol Seeking Rats

Authors: *T. A. SIMMONS[1], M. H. MONFILS[2], H. J. LEE[3];
[1]Psychology, Univ. of Texas at Austin, Austin, TX; [2]Univ. of Texas At Austin, Austin, TX; [3]Univ. of Texas at Austin Dept. of Psychology, Austin, TX

Abstract: Environmental cues become conditioned stimuli when associated with alcohol consumption, and facilitate alcohol-seeking, even during abstinence, leading to relapse. The gradual weakening of a conditioned response, or extinction, can reduce cue-conditioned responses by exposing discrete alcohol cues without alcohol consumption; however, extinguished cue-conditioned alcohol-seeking responses often return under certain conditions. One such phenomenon is renewal when the cue is presented in a different context than the extinction context. Existing research suggests sex differences whereby males exhibit more robust renewal of both appetitive and fear responses (Anderson and Petrovich, 2015; Binette et al., 2022); however, the presence of sex differences in renewal of alcohol-seeking behavior is not known. In the current study, we investigated the impact of contextual shifts and discrete environmental cues on renewal of alcohol-seeking behavior in rats. Male (n=5) and female (n=8) Long-Evans rats first underwent an induction phase: 15% unsweetened alcohol was provided MWF on a 24-hour schedule over a 5-week period. Then, Pavlovian conditioning took place in context A (standard conditioning chamber) where a 20-second light presentation was paired with a 10-second presentation of sipper containing 15% unsweetened alcohol (8 trials/session, 12

daily sessions). Subsequently, extinction (12 trial/session, 12 daily sessions) and testing (4 trials) occurred in context B which consisted of
smooth flooring, lemon scents, and black wall on the front and back of conditioning chambers. A 20-second light presentation was paired with a 10-second presentation of sipper without alcohol. Renewal testing (4 trials) occurred in context A. The results demonstrated successful extinction as measured by low levels of sipper contact (indicating reduced alcohol-seeking behavior) during extinction memory recall in context B. Notably, rats showed an overall increase in sipper contact when placed back in the original alcohol associated context (context A). While the renewal effect was only significant in males and not in females a larger cohort is needed to yield meaningful effect size estimates. Further research is warranted to explore potential factors contributing to the lack of renewal in females, including variability in the estrous cycle.

Title: The effects of prolonged social isolation in adulthood on alcohol-related behaviors in female and male Wistar rats

Authors: *A. COPPOLA, M. HEILIG, E. AUGIER;
Linköping Univ., Linköping, Sweden

Abstract: Social exclusion has been associated with the vulnerability to develop alcohol-use disorders in humans. However, how impoverished social conditions promote addictive behaviors is understudied and most preclinical works focus on rodent models in non-operant settings, that do not fully reflect the behavioral complexity of the human condition. We therefore aimed to investigate the role of social isolation in alcohol-related behavior using a rat model of operant

self-administration. For this purpose, we screened adult male (n = 32) and female (n = 32) Wistar rats for interindividual differences in a battery of alcohol-related behaviors, including choice of alcohol over a sweet reward and punishment-resistant alcohol drinking. Following this, animals were either individually housed or maintained group-housed for the rest of the experiment (n = 16 per group per each sex) and the effect of housing conditions on these alcohol-related behaviors was assessed. Behavioral screening indicated sex differences, with males being more motivated for alcohol than females ($p < 0.001$) but females being more resistant to contingent punishment than males ($p < 0.01$), despite equal intake of alcohol in unpunished conditions. However, we found no significant effect of prolonged social isolation at adulthood on any of the alcohol-related behaviors tested, in either male or female rats. Future studies will be required to assess whether social isolation at earlier developmental ages could instead affect addiction-like behavior in rats.

Title: Retrieval+extinction attenuates alcohol-seeking behavior in male and female rats previously exposed to chronic ethanol vapor

Authors: *M. OLVERA[1], M. RASKIN[2], R. U. COFRESI[3], R. GONZALES[4], M. H. MONFILS[5], H. J. LEE[6];
[1]Univ. of Texas at Austin, Austin, TX; [2]Univ. Of Texas At Austin Inst. For Neurosci., Univ. Of Texas At Austin Inst. For Neurosci., Austin, TX; [3]Psychological Sci., Univ. of Missouri, Columbia, Columbia, MO; [4]Univ. of Texas, Austin, TX; [5]Dept. of Psychology, Univ. of Texas At Austin, AUSTIN, TX; [6]Univ. of Texas at Austin, Dept. of Psychology, Univ. of Texas at Austin Dept. of Psychology, Austin, TX

Abstract: Environmental stimuli present during alcohol consumption can become conditioned cues that promote craving and relapse during abstinence. Extinction based therapy reduces conditioned response to the cue, but conditioned behavior may return under certain conditions. This may be due to the creation of a new competing inhibitory memory rather than modifying the original memory associated with cue. In contrast, the original memory may be modified if an extinction session is conducted after an isolated memory retrieval (retrieval+extinction; Ret+Ext) as initially shown with fear memory by Monfils et al., (2009). We recently showed that Ret+Ext was more effective than standard extinction (Ext) at reducing alcohol-cue reactivity in male rats

with moderate drinking history (Cofresi et al., 2017). In the current study, we tested the effectiveness of Ret+Ext using male rats (Experiment 1) and female rats (Experiment 2) with a history of alcohol dependence.Long-Evans rats were induced to drink 15% unsweetened ethanol (15E) on an intermittent 24hr schedule over 5 weeks. They then received chronic intermittent ethanol vapor (vapor group) over 10 days to induce physical dependence: controls received just air (air group). Rats were conditioned to associate a light cue with 15E delivered via a sipper over 12 sessions. They received one of two treatments, Ext or Ret+Ext, over 14 sessions. Lastly, rats were tested for return of alcohol seeking behavior in the presence of light alone (sipper site approach) and light with an empty sipper (sipper licks).Male and female rats that underwent Ret-Ext did not show significant return of sipper site approach regardless of their air or vapor exposure history (n=10-12 in each group). Rats that received Ext all showed significant return of sipper site approach with the exception of females in the air group (n=9-11 in each group). In the presence of an empty sipper, Ret-Ext was still effective at reducing sipper licks in male and female rats previously exposed to air or ethanol vapor. Among the rats that received Ext, only male rats showed significant return of sipper licks. This study replicated our previous work (Cofresi et al., 2017), which showed the effectiveness of Ret+Ext at reducing cue-reactivity in males with moderate drinking history, and now extended the findings to females. Importantly, we show that Ret+Ext can attenuate alcohol seeking behavior in male and female rats even with a history of alcohol dependence. Finally, our study suggests that Ext might influence alcohol seeking behavior (specifically sipper lick behavior) differently in male and female rats.

Title: Sex differences in pathological choice of alcohol over a healthy reward: role of GABAergic transmission in the CeA

Authors: *G. AUGIER, O. CONSOLER LYERE, L. XU, E. AUGIER;
CSAN, Linköping, Sweden

Abstract: Addiction leads to a progressively increased choice of drugs over healthy rewards. However, the choice of alcohol over alternative non-drug rewards has so far been largely overlooked as preclinical models of alcohol use disorder (AUD), and even less as a function of sex. We therefore aimed at investigating whether male and female rats would differ for choosing

alcohol over an alternative high-value reward and develop an addiction-like behavior. To address this issue, we applied a procedure in which about 15% of outbred male rats choose alcohol over an alternative high-value reward. We trained an equal number of male and female Wistar rats (n=32 per group) to self-administer a solution of 20% alcohol. Once stabilized, they were offered daily sessions of mutually exclusive choice between alcohol and 0.2% saccharin. We found that, although females tend to acquire 20% alcohol self-administration quicker than males during the first sessions of operant conditioning, males stabilized at higher levels of self-administration. While about 20 % of males chose alcohol over saccharin as previously observed, only about 8 % of females did. Importantly, alcohol choosing rats, whatever their sex, showed other traits reminiscent of clinical addiction, namely high motivation to obtain alcohol, and pursuit of alcohol despite adverse consequences. Finally, we investigated whether expression of the GABA transporter GAT-3 within central amygdala (CeA) was causal for alcohol choice over the sweet reward in females, as previously shown in male rats and translated to humans. For this, we injected independent groups of animals with an AAV-shRNAi targeting GAT-3, or a scrambled control vector, into the CeA and found that GAT-3 KD potently promoted pathological choice of alcohol over saccharin, and at an even higher extend in females. We finally assessed whether treatment with the $GABA_B$ PAM ADX71441 was able to reduce alcohol choice, as well as other alcohol-related behaviors in both male and females rats. All together, these results support a higher prevalence to develop addiction-like behaviors in male compared to female rats, which aligns with human epidemiological data. Furthermore, they indicate that decreased expression of GAT-3 within CeA is causal for pathological choice behavior in both sexes and that rescuing impaired GABA clearance due to suppressed GAT-3 expression might be a successful therapeutic mechanism in AUD.

Title: Alcohol consumption and alcohol seeking behaviors in rats based on biological sex and environmental light condition

Authors: *E. A. BREACH[1], A. VASQUEZ[2], R. AGARWAL[1], H. AJMAL[1], R. A. GONZALES[3], M. H. MONFILS[4], H. J. LEE[5];

[1]Col. of Natural Sci., [2]Dept. of Psychology, Univ. of Texas, Austin, TX; [3]Col. of Pharm., The Univ. of Texas at Austin, Austin, TX; [4]Dept. of Psychology, Univ. of Texas At Austin, Austin, TX; [5]Dept. of Psychology, Univ. of Texas at Austin, Austin, TX

Abstract: Current research aims to better understand the biological and environmental factors that contribute to alcohol use disorder(AUD). Intermittent access to alcohol in 2-bottle choice procedure (IA2BC) is a common model for alcohol consumption and binge-drinking behavior in a rat model of AUD. Research has shown that the majority of alcohol consumption during IA2BC occurs during the first 0.5-1.5 hours of the 24-hour access period; additionally, total alcohol consumption increases when the alcohol access period begins during the dark cycle rather than the light cycle. Even though females are generally known to drink more than males, no study has yet to compare how biological sex and environmental light conditions interact to affect binge-like alcohol consumption.Thus, this project examined alcohol consumption of male and female Long Evans rats under two different environmental light conditions(i.e., light and dark cycles). Rats were allowed to drink 15% (v/v in tap water) unsweetened alcohol under the IA2BC protocol (i.e., 24-hr access to alcohol on MWF) over the course of 5 weeks. The amount of alcohol consumed was measured in g per kg of body weight over the course of 30 min, 60 min, 90 min, 3 hr, and 24 hr intervals after the rats were presented with alcohol when the vivarium light came on (light cycle) or went off (dark cycle). After IA2BC, the rats that met threshold of sufficient alcohol consumption moved onto 2 weeks of Pavlovian conditioning (i.e., 20s light presentation with 10s sipper containing 15% alcohol) and 2 weeks of extinction (i.e., 20s light presentation with 10s empty sipper). Afterward, extinction memory testing was carried out along with spontaneous recovery testing two weeks laterResults showed no sex differences in alcohol consumption during the first 3 hrs of alcohol availability. However, at 24-hr time point, increased alcohol consumption was evident among females compared to males. We observed minimal binge-like drinking behavior, but rats in the dark cycle showed increased alcohol consumption at the 3-hr mark compared to the rats in the light cycle. No light or sex effect was found on conditioning or extinction as measured by sipper contacts. However, when testing for extinction recall and spontaneous recovery, an overall sex effect was observed. Females showed significantly greater response in alcohol seeking behavior ($p<0.05$); however, this effect was marginally modulated by the light condition ($p=0.09$) in which the sex difference was driven by females in the light cycle.Together, our study shows that biological sex and environmental factors play important roles in mediating drinking behavior.

Title: Early life stress produces sex-dependent differences in adult extinction learning in fear and motivational contexts

Authors: *M. J. MARTIN, C. A. BISHOP, J. B. TORRES, M. P. SADDORIS;
Univ. of Colorado Boulder, Boulder, CO

Abstract: A critical aspect of our understanding of mental health is understanding individual risk factors that may contribute to vulnerability to stress-related disorders such as PTSD or depression. One such factor is experienced during early development when the brain is rapidly developing. During this time, many people face adversity, with one CDC study indicating that approximately 2/3 of participants experienced at least one instance of severe stress during childhood. Furthermore, other studies have found that the risk of depression in females and drug abuse is positively correlated with the amount and severity of early life stress. Developmental stressors may also lead to disruption of appropriate behavioral responses to stress and reward in adulthood. Prior work from our lab using a brief wet bedding stressor around postnatal day 5 (P5) is sufficient to produce persistent fear in adults in a conditioned suppression paradigm along with fearful stimuli and motivated actions (Bercum et al. 2021; 2023). However, that prior study did not include both males and females nor did they separately compare the effects of reward versus fear extinction. Here, male and female pups were exposed to early life stress (ELS) from P2-P10 using a limited bedding approach (100g aspen shavings vs 300g controls), along with saturated wet bedding for 8h on P5. ELS rats were then returned to normal housing from P11 until wean. Meanwhile, control pups were left undisturbed until wean. As adults, all rats were trained to press a lever to obtain rewards up to VI60. Following a sequence of fear acquisition, extinction, and renewal in a novel set of contexts, rats were returned to the original reward context to again press for food. We then assessed suppression of pressing in the presence of the shock-paired cue versus a neutral cue for 3d, followed by 3d of instrumental extinction of the lever press. Males and females showed different vulnerability to the ELS stressor depending on the task features. During fear learning and extinction, female ELS rats showed elevated fear relative to female controls, but males in ELS and control groups were similar. In contrast, during the motivational components in conditioned suppression and reward extinction, male ELS rats were consistently different from male controls, while female ELS and controls were similar. Our data suggest that experiencing ELS may have distinct and sex-dependent impacts on adult vulnerability to stress and motivation disorders.

Title: Male and female rats exposed to a socially-paired context decrease preference for a sucrose-paired context in a conditioned place preference paradigm

Authors: *A. A. LACKAN[1], K.-C. LEONG[2];
[1]Psychology, [2]Dept. of Psychology, Trinity Univ., San Antonio, TX

Abstract: According to the United States Centers for Disease Control and Prevention (CDC), 73.6% of adults aged 20 and over were overweight from 2017-2018, with 41.9% of these individuals also suffering from obesity; additionally, about 1 in 10 Americans have diabetes, and more than 1 in 3 Americans are prediabetic. A major contributing factor to these disease states is the maladaptive preference of sugar reward. Social interaction and social support have been found to diminish drug-seeking behavior, suggesting that social reward may combat the reward of substance abuse. We hypothesize that the rewarding effects of sugar may also be contested by social reward. In order to examine the competing nature of sugar and social reward, male and female rats underwent a conditioned place preference paradigm in which one context was paired with sucrose (5 pellets every 10 minutes) and the other context was paired with a conspecific. In brief, all rats were first given 2 days of sucrose priming, and then were conditioned for 30 minutes for 8 consecutive days, during which they alternated between contexts each day of conditioning, and sucrose and social reward were counterbalanced within groups. Results revealed that in the absence of any conspecific context, rats showed a significant preference for the sucrose-paired context, but rats who were conditioned with both a sucrose-paired and a conspecific context did not display any preference for the sucrose-paired context. The results of the present study suggest that social reward may diminish sucrose conditioned place preference, and further research will focus on elucidating the specific structures involved in this effect. The neuropeptide oxytocin (OXT) is known to be implicated in both social processes and reward. As such, we investigate the role of OXT in modulating this shift in preference between sucrose and social reward.

Title: Carbon dioxide reactivity predicts extinction memory to fear and alcohol cues in rats

Authors: *M. RASKIN[1], M. OLVERA[2], N. KELLER[1], L. A. AGEE[3], J. D. SHUMAKE[2], R. GONZALES[4], H. J. LEE[2], M. H. MONFILS[2];
[1]Inst. for Neurosci., [2]Dept. of Psychology, [3]Dept. of Neurosci., [4]Col. of Pharm., Univ. of Texas at Austin, Austin, TX

Abstract: Maladaptive associations underlie persistent responding to previously neutral stimuli. For example, cues present during a traumatic event may result in fear responses, and cues that precede rewards lead to seeking behavior (e.g., in addiction). These responses can be attenuated through extinction learning, where cues are repeatedly presented without the previously learned outcome—a core component of exposure therapy. Exposure therapy is effective for some patients, but not all. Another method to attenuate conditioned responses, retrieval-extinction, modifies the original associative memory via distinct neural mechanisms. We recently demonstrated that CO_2 reactivity predicts fear extinction memory and orexin activation, and that orexin activation predicts fear extinction memory, suggesting that a CO_2 challenge may enable identifying whether an individual is a good candidate for an extinction-based approach. We then extended this to show that CO_2 reactivity predicts appetitive extinction memory to food cues. The purpose of the present study was to determine whether the predictive power of CO_2 reactivity can be replicated in fear cues, generalizes to alcohol cues, and is specific to extinction for both fear and alcohol cues. In experiment 1, male rats were fear conditioned, received either extinction (n = 30) or retrieval-extinction (n = 28), and then underwent a long-term memory test. In experiment 2, male and female rats with a history of alcohol dependence underwent alcohol conditioning, received extinction (n = 35) or retrieval-extinction (n = 39), and then underwent a long-term memory test. All rats then received a CO_2 challenge, as outlined in Monfils et al. (2019), and we used the best subset approach to linear regression to determine whether CO_2 reactivity would predict extinction phenotype. CO_2 reactivity predicted fear extinction memory, explaining 42% of the variability in the total sample and 28% of the variability in the cross-validated (CV) holdout samples. In the retrieval-extinction group, CO_2 reactivity predicted fear extinction memory, explaining 19% of the variability in the total sample and 9% of the variability in the CV holdout samples. In experiment 2, CO_2 reactivity and sex predicted alcohol extinction memory, explaining 17% of the variability in the total sample and 7% of the variability in the CV holdout samples. In the retrieval-extinction group, no reliable predictors emerged from our analysis. We thus find that the predictive power of CO_2 reactivity is replicated for standard extinction and generalizes to retrieval-extinction for fear cues, and generalizes to alcohol cues for extinction, but not retrieval-extinction.

Title: Neural Decoding of 15 Affective States from Imagined Emotional Scenarios

Authors: *N. MUNCY[1], Y. DING[2], L. FAUL[3], K. S. LABAR[3];
[2]Ctr. for Cognitive Neuroscience, Duke Univ., [3]Duke Univ., [1]Duke Univ., Durham, NC

Abstract: The representation and organization of specific affective states in the brain, such as sadness, anxiety, and craving, remain elusive despite significant investigative efforts. Prior work in this area has typically involved univariate analyses, small sample sizes, simple stimuli, and small numbers of emotions, that limit sensitivity, generalizability, ecological validity, and impact on emotion theory. To better understand how affective states are reflected in brain activity patterns, we trained a multivariate pattern classifier to decode fMRI responses during an emotion induction task to identify relevant voxels (features) for an array of 15 affective states, and to determine which states share off-diagonal elements. We developed and validated a large set of two-sentence descriptions of hypothetical, real-world scenarios presented in a second-person perspective that span the affective states of interest. During fMRI scanning, 85 healthy adults (with ongoing recruitment) read and imagined each scenario in blocks of 5 exemplars per intended emotion, determined which emotion the scenarios best represented per block, and rated how intensely they experienced the corresponding affective state. Behavioral results were consistent with ratings data from the normative sample. Partial least squares discriminant analysis was conducted on whole-brain gray matter beta-estimates with a nested validation scheme to prevent overfitting (8-fold outer for independent cross validation, 5-fold inner for optimization of latent space). This approach achieved significant above-chance accuracy in decoding the 15 states (mean accuracy = 14.5%, chance = 6.67%; $p < .05$, 95% CI=[12.5%, 16.5%]) with moderate mean AUC = 0.62 (CI = [0.6, 0.64]), sensitivity = 0.61 (CI=[0.57, 0.64]), and specificity = 0.61 (CI=[0.56, 0.66]). Voxel importance maps revealed distributed cortico-limbic networks for each affective state that overlapped with univariate analyses, and inspection of off-diagonal elements suggested that conceptually-related brain states (e.g. fear and horror) generally agreed with participant's behavioral similarity ratings. These results implicate brain regions that are active for specific and related affective states, giving insight into the neural representation of a relatively large number of emotions, and provide additional evidence for the organization of these emotions in a semantic space.

Title: Increased brain activity associated with enhanced maternal affection for infants after childbirth

Authors: *K. HISHIKAWA, M. ABE;
Natl. Ctr. of Neurol. and Psychiatry (NCNP), Kodaira, Tokyo, Japan

Abstract: Background: Pregnancy and childbirth lead to a reorganization of brain circuitry, resulting in heightened affection for the baby and nurturing behavior in women. Animal studies observed active dopaminergic or oxytocinergic circuit of the brain that parallel higher parental behaviors. While it is challenging to express affection on an objective scale, this study defines the brain activity of the dopaminergic or oxytocinergic circuit in response to infants as the neural activity associated with affection towards infants. This study aims to investigate increased brain activity in response to infants after childbirth using functional MRI (fMRI).
Methods: We recruited 27 women who have experienced a first episode of childbirth in less than recent 3 months (postpartum group) and 30 age-matched women who have not experieced pregnant events (control group). Participants' liking for unfamiliar babies was assessed using a visual analog scale (Baby like VAS). Using fMRI, we measured brain activity while the pohotographs of baby faces were visually presented to the participants: both of the postpartum and control groups saw the babies or adults whom all of the participants had never seen before (i.e. other person's babies or other adult persons), The reason for using photographs of unfamiliar babies is to avoid the influence of personal attachment that comes with interacting with one's own baby during caregiving. Furthermore, in the postpartum group, the brain responses to their own babies were compared with those towards unfamiliar babies.
Results: The postpartum group showed higher Baby-like VAS scores to the other person's babies than the non-mother group (postpartum group: mean 74.1 ± 21.8 vs. control group: mean 86.7 ± 12.8, $p = 0.02$). The postpartum group showed greater activity in the right orbitofrontal cortex, right anterior insular cortex, right angular gyrus, and right precuneus than the non-mother group (cluster level of family-wise error $p= 0.05$ with a voxel level threshold uncorrected $p = 0.001$). Analysis of the regions of interest revealed stronger brain activity in the ventral tegmental area (VTA) in the postpartum group compared to the control group. Furthermore, in the postpartum group, a greater increase in brain activity was found in the right anterior insula and VTA when participants viewed photographs of their own babies compared to unfamiliar babies.
Conclusion: This study demonstrates increased brain activity in the VTA and right anterior insula among the postpartum women, suggesting that these brain regions undergo changes following childbirth and are involved in the augmentation of maternal affection towards infants.

Title: Neural representation format in amygdala related to human memory for emotional faces

Authors: *T. LI, G. XUE;
Beijing Normal Univ., Beijing, China

Abstract: Human memory for emotional stimuli, such as emotional faces, are generally better than neutral stimuli, yet the neural representational mechanisms are not very well understood. In particular, although the amygdala has been consistently implicated in emotional face processing and memory, the information coding schema in this area and its contributions to episodic memory have not been systematically investigated. Here, we collected intracranial electroencephalography (IEEG) data from 14 epilepsy patients when they were encoding and recognizing negative, neutral and positive faces. We found clear behavioral evidence that patients have a higher d-prime rate when recognizing negative faces compared with neutral and positive faces. Using representation similarity analysis method, we further characterized the neural representations in the amygdala. We found stronger item-specific and category-specific representation for negative items than for neutral and positive faces in the amygdala, both of which were associated with subsequent memory. These results suggest the amygdala not only encodes emotional information, but also stimulus-specific information, and the stronger representations for negative faces could contribute to the better memory performances.

Title: Resilience-driven neural synchrony during naturalistic movie watching: an ultra-high field fMRI study

Authors: *S. YE[1], A. SALAMI[2], M. ZIAEI[1];
[1]Kavli Inst. for Systems Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway;
[2]Umeå Univ., Umea, Sweden

Abstract: Resilience, regarded as a capacity to effectively cope with adversities, could protect individuals against psychological distress induced by negative emotions. The way people perceive emotional cues is thus influenced by their level of resilience. It is still unclear, however, how the neural correlates of resilience can be measured in daily life. In this study, we examined

how resilience level is related to brain patterns across individuals. We presented two movies, one with negative and one with neutral emotional valence to 62 healthy younger (Mean age of 25.68 ± 4.30 years, 29 females) participants while in the 7T MRI scanner. We combined inter-subject correlation (ISC) with inter-subject representational similarity analysis (IS-RSA) to investigate the association between resilience level and brain-to-brain synchrony while watching movies. We further explore the modulation effect of intolerance of uncertainty (IU), a personality trait that may shape biased perception, on the association between resilience and brain synchrony. Results indicated resilience-driven brain synchrony of a wider set of brain regions in the negative movie (the prefrontal area, temporal lobe, and dorsal attentional network [DAN]) than in the neutral movie (mainly located in the DAN). The high-resilience individuals had similar neural activities to their peers whereas low-resilience individuals show more variable neural activities. Moreover, increased IU enhanced resilience-driven synchrony in the default mode network and dampened resilience-driven synchrony in the DAN. These results suggested that neural response to emotional stimuli is similar in high-resilience individuals but is idiosyncratic in low-resilience individuals, and such resilience-driven neural similarity is modulated by intolerance of uncertainty.

Title: The impact of emotional stimuli on arousal and task performance.

Authors: *B. WU[1], E. STEWART[1], B. BUTLER[2], D. MITCHELL[1];
[2]Physiol. & Pharmacol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: In times of emotional arousal, it is hypothesized that neural processes are triggered to "heighten" our senses to better respond to threatening stimuli. Some studies have tested this by exposing participants to emotional sounds to determine their impacts on visual acuity. However, the results have been mixed, sometimes showing improvements in vision, but other times showing detrimental effects or no effects at all. Previous studies have not investigated interactions between arousal induced by emotional sounds and visual acuity. Here, we aim to evaluate how emotional sounds influence arousal and performance in an orientation detection task. Participants viewed Gabor patches (sinusoidal luminance gratings) on the right or left side of fixation and indicated whether the Gabor patches were tilted left or right. To account for individual differences in baseline visual acuity, an orientation detection threshold task at the beginning of the experiment was conducted to select the orientation associated with 70% accuracy. The presentation of Gabor patches was presented concurrently with auditory stimuli selected from the International Affective Digital Sounds Database that varied in valence (negative or neutral). A no sound control condition was also included. Visual performance was measured by the proportion of correct responses for each condition as well as reaction time. Arousal was measured by tracking pupil dilation throughout the experiment using the EyeLink 1000 eye tracker. Preliminary results from (14, 36 more to be collected) participants showed significantly greater accuracy (5.72 percent difference ± 0.10 SE) and significantly faster reaction times (22 ms difference ± 0.45 SE) in the negative condition than the neutral condition and significantly greater accuracy (5.71 percent difference ± 0.1 SE) and faster reaction times (55 ms difference ± 0.24 SE) in the negative condition than the no sound condition. Additionally, pupil dilation from baseline during the presentation of the Gabor patches was significantly greater (0.02 mm difference ± 4.0×10^{-4} SE) in the negative condition compared to the neutral condition and significantly greater (0.20 mm difference ± 5.0×10^{-4} SE) in the negative condition compared to the no sound condition. Our findings provide evidence that negative sounds significantly increase visual acuity and arousal. These findings will delineate how changes in arousal due to environmental factors can alter sensory processing, leading to changes in human performance. In addition, they will pave the way for further work examining the neural mechanisms behind sensory enhancement in emotionally arousing contexts.

Title: Single-neuron amygdala activity during emotion recognition

Authors: *J. V. MACHNIK[1], R. N. TIEN[1], M. L. DARWIN[1], L. BASHFORD[3,1], S. G. OJEMANN[1], J. A. THOMPSON[1,2], D. R. KRAMER[1];
[1]Dept. of Neurosurg., [2]Dept. of Neurol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [3]Biosci. Inst., Newcastle Univ., London, United Kingdom

Abstract: The amygdala is known to process biologically relevant, emotionally valenced stimuli. Neuroimaging studies in humans have demonstrated that the amygdala responds to a wide range of stimuli, however fMRI is not well suited to characterize the precise neural response profiles. The required spatial and temporal resolution can be obtained from intracranial electroencephalography (iEEG). Previous iEEG research has identified both early and later responses in the amygdala during a range of face presentation stimuli, suggesting the amygdala plays an important role in the rapid evaluation of emotion. However, it remains to be elucidated how the time course of the response relates to the complexity of various emotions. Here we use iEEG with micro-contact depth electrodes to evaluate single neurons in the amygdala of human patients undergoing monitoring for seizure localization (N=6, M_{age}=39.6 years, SD_{age} =10.7, 1 male). A set of seven emotions (six basic and neutral) from a standardized set were presented to study participants for 2 seconds followed by a response period in which patients selected the emotion they saw. We divided the basic emotions into two categories for analysis: lower order emotions (happy, sad, and angry) and higher order emotions (disgusted, fearful, and surprised). Behavioral results demonstrated that within 250 ms of image onset, amygdala neurons significantly responded to sad, angry, neutral, fearful, and surprised emotions. Further investigations revealed the quickest responses overall were for the lower order emotions than the higher order ones. Furthermore, we found a significant misclassification of the higher order emotions (e.g., fear and surprise) and neutral, compared to the lower order emotions (e.g., happiness, sadness, and anger). Here we present initial evidence that the neural response in the amygdala is related to the complexity of the emotion being processed. Higher order emotions have more complex activation patterns which occur later than lower order emotions, suggesting a top-down processing role in emotion requiring a more nuanced understanding of emotional context. Further work should seek to simultaneously record from both cortical and deep areas to further understand emotional processing in the brain.

Title: Temporal dynamics of negative emotion and reappraisal in the amygdala

Authors: *K. BO[1], P. J. GIANAROS[3], T. D. WAGER[2];
[2]Dept. of Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH; [3]Univ. Pittsburgh, Univ. Pittsburgh, Pittsburgh, PA

Abstract: Reappraisal is an emotion regulation strategy that involves reinterpreting meaning and context to alter emotional experience. It is widely accepted that reappraisal can successfully down-regulate amygdala activation, a mechanism central to the affective generation process. However, some recent studies and meta-analyses have not confirmed this effect. To gain deeper insight, the current study further delves into the temporal dynamics of the amygdala's Blood-Oxygen-Level-Dependent (BOLD) time series in two large community samples (n=182 and n=178) who viewed and reappraised aversive and neutral images from the International Affective Picture System (IAPS) during fMRI scanning. Employing a smooth Finite Impulse Response (FIR) model, we estimated the amygdala's hemodynamic response during the cue, stimulus, and rating periods. Our findings reveal that both viewing (‘Look Negative’) and reappraising (‘Reappraise’) negative pictures evoked significant hemodynamic responses across laterobasal (LB), centromedial (CM), and superficial (SF) amygdala subregions. Responses occurred relatively late relative to picture onset, likely reflecting an extended image appraisal and comprehension process, and different subregions showed differences in the shape and latency of hemodynamic responses: BL and SF amygdala exhibited an earlier peak, at 10s post-stimulus onset, while CM peaked later, at 16s. However, evoked responses during Reappraise and Look Negative trials were equivalent. We also observed a habituation effect across trials during passive viewing (‘Look Negative’) that was absent in 'Reappraisal' trials, resulting in a significant condition x time interaction. These findings suggest that reappraisal does not significantly reduce amygdala responses to aversive pictures in this sample, and may interfere with habituation processes that are operative during passive viewing conditions.

Title: Mechanistic investigation of dyadic emotional connection: the emotional connection screen

Authors: *A. LAVALLEE[1], Q. J. MANNING[1], M. A. REIMERS[2], M. MOORE[2], M. KYLE[1], M. HUSSAIN[1], R. XU[1], M. MCKIERNAN[1], E. ARDUIN[1], M. KUROMARU[1], E. GREEMAN[1], D. DUMITRIU[1];
[1]Pediatrics, Columbia Univ., New York, NY; [2]Inst. Quantitative Hlth. Sci. and Engin., East Lansing, MI

Abstract: Human social connectedness is a complex phenomenon that stems in the early-life relationships with parents/caregivers. In pediatrics, promoting healthy early relationships, or the ability to form and maintain stable and nurturing parent/caregiver-child relationships, has been made a priority officialised in 2021 by a paradigm shifting statement of the American Academy of Pediatrics. Despite the importance of early parent-child relationships to child health, development and wellbeing, advances in systematic measurement of the quality of parent/caregiver-child dyadic interactions that can readily be used in clinical or research settings are scarce. With this in mind, the Nurture Science Program at Columbia University has developed an emotional connection screen; an observer-based assessment of dyadic interaction behaviors that translate emotional transfer between mother and infant. Here, we further investigate the mechanistic underpinnings of dyadic emotional connection using video-based data obtained from the 4-month relational health assessment as part of the COMBO Initiative. In a remote video visit, mothers were asked to interact face-to-face with their infant for 2 minutes, without using toys or pacifiers. A subset of 46 2-min videos was macro-coded with the emotional connection screen for a gestalt assessment of the dyad's global emotional connection (scores ranging from 0 to 100). The subset was also micro-coded using Boris, an open-source event-logging software, to gather timed-sequential data with millisecond precision on an array of maternal and infant interaction behaviors like gaze, touch (i.e., static, affectionate, caregiving, playful, attention seeking), reaching, leaning in, back arching, etc.The subset of 46 videos was composed of 32.21 (5.19) year old mothers and their 5.51 (2.33) month old infant, and 60% (n=28) of the infants were males. The mean score on the emotional connection screen was 50.48 (24.92), which represents 48% (n=22) of the dyads scoring high on emotional connection, 24% (n=11) scoring low on emotional connection, and the rest (n=13, 35%) with variable levels of emotional connection throughout the 2-min face-to-face interaction. At the micro-analysis level, preliminary results show a high correlation (r=0.82) between mother-infant mutual eye gaze and overall emotional connection scores. The contribution and patterning of microcoded maternal and infant interaction behaviors will be further investigated using sequential patterning mining techniques to identify the fundamental sequential patterns of multimodal behaviors during moments of high and low emotional connection.

Title: Description of the dimensions of burnout syndrome in medical students of the Universidad Veracruzana (2021-2023)

Authors: *S. SOSA ALVARADO[1,2], F. D. VÁZQUEZ-MARTÍNEZ[3], M. ACOSTA-FERNÁNDEZ[5], N. MATZUMOTO-BENÍTEZ[4], R. RAMOS-CASTRO[4], E. PEREDO-RIVERA[6];

Abstract: Burnout syndrome is an occupational phenomenon resulting from chronic work stress that has not been successfully managed. This syndrome has been identified in different professions, however it is more frequent and has greater repercussions in specialist doctors, presenting a prevalence range from 30 to 69% in general practitioners and specialists. Burnout syndrome is characterized by a lack of enthusiasm, a gradual loss of energy and general exhaustion, the presence of feelings of insensitivity and cynicism, and a tendency for the person to negatively evaluate their self-perception and job performance. A cross-sectional and descriptive study was carried out in last-year medical students who were doing their social service, from a public university in the state of Veracruz, Mexico; to evaluate the dimensions of the burnout syndrome by applying the Maslach Burnout Inventory. A convenience sampling was carried out, with a total of 218 participants. The results obtained show that the majority of the students 53.21% have a high degree of ocupational exhaustion, contrary to depersonalization where the majority 49.54% have a low degree. Regarding personal fulfillment, the majority 52.29% have high scores (more than 40 points) in this dimension. In addition to this, a multivariate analysis was applied with a cluster type grouping technique. Defining 5 Groups, characterizing Group 1 for presenting low scores of ocupational exhaustion and depersonalization, contrary to Group 5 who present high scores in these dimensions. These results are similar to those found by Álvarez et al. in 2019, where through a systematic review of the prevalence of burnout syndrome in Latin American doctors between 2012 and 2018, they identified that the majority present high levels of emotional exhaustion.

Title: Activity changes of the subthalamic region during emotional processing revealed by LFP data acquired from the Closed-loop DBS system

Authors: *T. MATSUHASHI[1], N. TANI[1], T. EMURA[1], Y. KIMOTO[1], K. HOSOMI[1], R. FUKUMA[2], S. OSHINO[1], T. YANAGISAWA[2], H. KISHIMA[1];
[1]Dept. of Neurosurgery, Grad. Sch. of Med., [2]Inst. for Advanced Co-Creation Studies, Osaka Univ., Osaka Univ., Suita/Osaka, Japan

Abstract: Introduction: The human subthalamic nucleus (STN) region is involved in the processing or transmission of emotional information. Recently, the DBS device equipped with a closed-loop system that measures and records local field potential (LFP) from electrodes implanted in the basal ganglia region and provides feedback on stimulus intensity in response to changes in LFP has been introduced into clinical practice. In the study of psychology, by collecting and analyzing emotionally stimulating data, such as videos that elicit various emotions, and human emotional response data to the stimuli, it has been shown that models using many emotion categories (high-dimensional emotion models) can explain human emotional responses better than conventional models based on a few basic emotions (AS Cowen et al., 2017). In this study, by using the Closed-loop DBS system, we attempted to obtain LFP changes in response to video stimuli with the labeling of emotional categories in a preceding psychological study.Methods: This study was performed on Parkinson's disease patients(n=18) who underwent implantation of the Closed-loop DBS system at our hospital. LFPs were recorded while watching a series of videos categorized into specific emotional categories. The participants were asked to select the emotional category corresponding to the videos and score on the degree of their emotion. Emotion labeling scores were normalized for each participant and treated as scoring intensity. We performed the frequency analysis of the LFP, and calculated the rate of change from the baseline at rest, in each band power in the delta, theta, alpha, beta, and gamma bands. Multiple regression analysis was performed between the band power change rates, and the emotion labeling scores intensity for each video category.Results: In viewing the category of videos that arouse appetite, the beta band power of the left STN was negatively correlated with the scoring intensity($p<0.05$), whereas the gamma band power of this location was positively correlated with the scoring intensity($p<0.05$). In viewing the category of videos that elicit fear, the Delta band power of the right dorsal STN was negatively correlated with the scoring intensity($p<0.05$), and the theta band power of this location was positively correlated with the scoring intensity($p=0.07$).Conclusion: Power changes in the frequency band of STN LFP may be informative as an indicator of the degree of emotional response to stimuli of Parkinson's patients

Title: Investigation of responsible molecules to control subjective well-being in humans

Authors: *Y. INADA[1], C. TOHDA[2];
[2]Inst. of Natural Medicine, Univ. of Toyama, [1]Inst. of Natural Medicine, Univ. of Toyama, Toyama, Japan

Abstract: Subjective well-being (SWB) is an important research topic being addressed from a variety of perspectives, including psychology, public health, and medicine. The fact that SWB is influenced by physical activity and cognitive activity, and vice versa SWB affects physical activity and cognitive activity, suggesting that the locomotor system and cognitive function closely relate to mental health. However, the molecular basis of these interactions has not been clarified at all. This clinical study aimed to investigate what are relating activities to SWB, and find molecules from the blood circulation, which are responsible for controlling SWB. Subjects were healthy elderly people aged 65 and over. Evaluation items were Happiness and Quality of Life as SWB scale, cognitive function (CF), motor function (MF) and daily physical activity (DPA). Based on all scores in those items, Structural Equation Modeling was conducted. The most fit model showed that CF, MF and DPA are sequentially needed to explain SWB. Next, to elucidate features of elder people with high SWB, subjects were divided by their SWB scores and other activities patterns. As a results, scoring patterns were divided into 4 groups. High SWB was associated with high scores in CF, MF and DPA. Plasma samples of typical subjects in those 4 groups were served for tandem mass tag-based quantitative proteomics. Comprehensive analysis indicated that the level of protein X was different depending on SWB level. Furthermore, the protein X level was significantly correlated with DPA, such as calorie consumption and moderate to vigorous physical activity. More analyses are ongoing. No molecular explanation has not been achieved why physical activity, cognitive activity, and social activity affect SWB. The present study has the potential to answer the question and to provide a new perspective for mental health.

Title: Altered autonomic balance by mood-congruent music in heart-broken people: an fMRI study

Authors: *L.-Y. CHIEN, W.-J. KUO;
Yang Ming Chaio Tung Univ., Taipei, Taiwan

Abstract: People can change their mood through music, which has been applied to individuals with certain clinical cases, such as Major Depressive Disorder (MDD). To investigate the neural relevance of mood changes induced by music, we organized pieces of music into two contexts based on the congruence between the music's valence (pleasant vs. unpleasant) and the listeners' mood state. In the congruent condition, there were five songs presented, starting with two sad songs and transitioning to three happy ones. In the other condition, all five songs were happy. The participants were females who had recently gone through a romantic relationship break-up. Resting fMRI sessions were conducted before and after the music sessions of the two conditions, on separate days. To evoke feelings of hurt and sadness, participants were shown a photo of their ex-partner during the resting fMRI sessions. Electrocardiogram (ECG) data was recorded while participants listened to the music, and based on this signal, we observed higher heart rate variability (HRV) in the congruent condition. Conversely, functional connectivity (rsFC) between the right anterior insula (rAIC) and anterior cingulate cortex (ACC) decreased after listening to music in the congruent condition. Overall, our findings demonstrate that mood-congruent music in the beginning, as indicated by higher HRV, may gradually promote a better balance between the parasympathetic and sympathetic systems, thus potentially disrupting the connectivity of the rAIC-ACC network (i.e., the salience network).

Title: Math Anxiety and its relationship with Arithmetic processing and Becks anxiety

Authors: *S. ZAMORA LUGO[1], T. CIBRIAN-LLANDERAL[2];
[1]Facultad de Psicología, [2]Inst. de Neuroetología, Univ. Veracruzana, Xalapa, Mexico

Abstract: Introduction: Among the most mentioned mathematical cognitive processing skills in the literature are abstract thinking and visuospatial processing. It has been suggested that

intellectual aspects such as poor abstract thinking or poor visuospatial processing may contribute to the development of Math Anxiety (In this regard, one study showed that people with high MA reported a worse sense of direction and obtained poorer performance on small- and large-scale behavioral tests of spatial abilities. Methodology: An observational, retrospective, descriptive and cross-sectional study was carried out. A questionnaire on the Prevalence of Mathematical Anxiety in university students was applied digitally through the Google Forms platform. 63 university students were evaluated according to the inclusion criteria to be part of the final sample, who had an average age of 23.38 (SD ± 5.5), 33.3% were male and 66.7% female. The instruments used were the Mathematical Anxiety Index, the Beck Anxiety Inventory) and a task of arithmetic processing. Results: The average Beck Anxiety Inventory score was 21.7 (SD ± 11.8). 11.1% obtained a Low rating, 44.4% Mild, 28.9% Moderate and 15.6% Severe. The average response time was 4.6 seconds (SD ± 1.8) and the average hit was 70.8 (SD ± 7.7). A correlation analysis was made between the IAM with the average Hits, Additions Hits, Subtraction Hits, Simple Operations Hits and Complex Operations Hits. Significant correlations were observed with the variables Hit (rho = -0.3, p = 0.02), HitS (rho = -0.4, p = 0.001) and HitCom (rho = -0.3, p = 0.01). A correlation analysis was also carried out between the AMI with the average Response Time (RT)0, RT of additions, RT of Subtractions, RT of Simple operations, and RT of Complex operations. Significant correlations were observed with the variables RT (rho = 0.42, p < 0.001), TRS (rho = 0.5, p < 0.001) and RT Com Complex (rho = 0.52, p < 0.001). Conclusion: It was observed that, in the simple additions, the participants required less time to generate the correct answer, which is related to the automatic recovery of the arithmetic facts, while in the complex subtractions the opposite happened. The observed response times coincided with what was reported, in that more difficult operations require more time to generate a response, for example, the participant will answer an addition faster than a subtraction or an operation with a digit compared to one. operation of more than one digit, this because it requires more time to make use of the work memory in operations with greater difficulty.

Title: Same emotion different stimuli: creating a contextually rich MRI paradigm for studying nostalgia

Authors: *H. S. DOSHI[1], C. KORNBREK[2], A. K. ANDERSON[1], M. GONZALEZ[1]; [1]Psychology, [2]Biomed. Engin., Cornell Univ., Ithaca, NY

Abstract: Advances in affective science show that emotions, especially those culturally and socially embedded, are deeply contextual. For example, though nostalgia is possibly a universal human emotion, what evokes nostalgia is rooted in one's individual experiences. However, neuroimaging paradigms usually involve the use of "universal" stimuli to evoke putative universal cognitive and affective phenomena. In this study, we developed a system for creating context-specific standardized stimuli that can be used in MRI paradigms to measure nomothetic phenomena (nostalgia) in an idiographic manner (culturally specific). We web-scraped 229 realistic images of foods commonly consumed in India (134) and the USA (95). Foods ranged from appetizers to festival meals, represented all macroregions within the nation, and were uniformly distributed across a low-high calorie range. Raw foods, sweet items, drinks, brands, and aesthetic images were excluded to create a collection of regular meals commonly found at home while controlling for glucose. In consideration of fMRI factors, images were standardized for size, color scale, pixels, grayscale, and hue. Saturation and texture could not be normalized so were measured to adjust our statistical models. 46 participants who currently live in the US, but grew up in either the US or India, rated each image on a 7-point Likert for familiarity, comfort, and nostalgia twice, with a gap of at least a month. Participants were significantly hungrier after completion of the paradigm ($t = 4.29$, $p = 0.00$), which replicated the second time ($t = 3.06$, $p < 0.01$). There were group differences in individual measures of nostalgia such that individuals tended to find developmentally consistent foods more nostalgic ($F(1,9068) = 1119.56$, $p = 0.00$). On an individual level, most developmentally consistent foods were highly familiar but differences in ratings of comfort and nostalgia emerged. That is, all participants demonstrated evidence of experience of nostalgia for different foods. Participants found an average of 46 food items, majority of which were culturally consistent, of the total set to be highly nostalgic (> 5). Test-retest reliability for familiarity, comfort, and nostalgia was $r = .762$, .764, and .780 ($p < 0.01$) respectively. Further testing for cross-validation with a new sample is underway. 27 items were removed overall, and ten new items were added to Indian foods to create a final set of 202 standardized, natural food images. This preliminary evidence suggests that our protocol can be used to create a culturally sensitive, but standardized image set, which can later be used in the MRI to elicit a universal experience.

Title: Neural decoding of 15 affective states from emotional movies

Authors: *Y. DING[1], N. MUNCY[2], L. FAUL[2], K. S. LABAR[2];
[2]Duke Univ., [1]Duke Univ., Durham, NC

Abstract: In this study, we investigatedthe relationship between discrete emotional states and patterns of brainactivity by experimentally inducing 15 emotions (amusement, anger, anxiety,awe, calmness, craving, disgust, excitement, fear, horror, joy, neutral,romance, sadness, and surprise) in participants during fMRI scanning.Previously-validated brief video clips (3-12 s long) were used for the emotioninduction and were presented in blocks of 5 clips per intended emotioncategory. One hundred and six healthy adult participants (73 female, mean age =30.8 (8.44)) were recruited from the local community. Analysis of participantin-scanner affective responses from 54 completers indicate successful emotioninduction, with a mean concordance of 73% ($p < 0.05$, CI [71%, 75.5%])between the participants' endorsement and the emotion labels assigned to thestimuli based on the normative ratings. We used a whole-brain general linearmodel to identify the block-level grey-matter beta-weights for subsequentlyclassifying the 15 emotional states with a partial least squares discriminantanalysis (PLS-DA). A nested cross-validation scheme (an 8-fold outer loop forsubject independent cross validation and a 5-fold inner loop for identifying anoptimal number of latent variables for classifying each emotion) was used whentraining the PLS-DA classifiers to improve their generalizability. The PLS-DAclassifiers achieved a significant above-chance level mean accuracy across the15 emotions (mean = 34.8%, $p < 0.05$, 95% CI [32.4% 37.2%]), wherechance-level accuracy is 6.67%. The area under the curve (AUC) (mean = 0.82, 95% CI [0.79 0.85]), sensitivity (mean = 0.76, 95 % CI [0.73 0.80]), andspecificity (mean = 0.74, 95 % CI [0.69 0.78]) also indicate good decodingperformance. The pattern classification results revealed unique, distributedpatterns of cortico-limbic activity for each of the 15 emotions, indicating ameaningful relationship between brain activity patterns and theexperimentally-induced emotional states. These robust findings indicate that itis possible to decode the specific emotional states that someone might besubjectively experiencing based on brain activation patterns alone across avariety of emotions.

Title: Time-invariant prefrontal activity patterns during repeated exposure to intense threat

Authors: *O. SYLTE, H. MUYSERS, H.-L. CHEN, M. BARTOS, J.-F. SAUER;
Albert Ludwig Univ. of Freiburg, Freiburg im Breisgau, Germany

Abstract: Intense threat elicits action in the form of active and passive coping. The medial prefrontal cortex (mPFC) executes top-level control over the selection of threat coping strategies, but the dynamics of mPFC activity upon continuing threat encounters remain unexplored. Here, we used 1-photon calcium imaging in mice to probe the activity of prefrontal pyramidal cells during repeated exposure to intense threat in a tail suspension (TS) paradigm. A subset of prefrontal neurons displayed selective activation during TS, which was stably maintained over days. During threat, neurons showed specific tuning to active or passive coping. These responses were unrelated to general motion tuning and persisted over days. Moreover, the neural manifold traversed by low-dimensional population activity remained stable over subsequent days of TS exposure and was preserved across individuals. These data thus reveal a specific, temporally and inter-individually conserved repertoire of prefrontal tuning to behavioral responses under threat.

Title: Lateral hypothalamus-dorsal raphe circuitry: anatomy and function in emotional behaviors

Authors: *R. SADRETDINOVA, Z. BENMAMMAR, C. D. PROULX;
CERVO Res. Ctr., Quebec, QC, Canada

Abstract: The dorsal raphe nucleus (DRN) regulates affective behaviors and energy balance. Emotional states might be encoded in DRN by neural inputs from numerous brain regions. Although one of the major reciprocal synaptic partners of DRN is the lateral hypothalamic area (LHA), the circuitry between LHA and DRN was not characterized yet. In the current study, we use anterograde and retrograde viral strategies to investigate the anatomical and functional reciprocal circuitry between the LHA and the DRN. Specifically, we targeted DRN cells receiving input from LHA (DRN input) and DRN cells projecting on LHA (DRN output) to express either fluorescent proteins or genetically-encoded calcium indicators. Our results show that DRN input and DRN output neurons are largely two distinct neuronal populations that have differential spatial distribution. LHA makes synaptic contact with 5-HT and non-5-HT neurons in the DRN, which is spatially biased to the ventromedial part and dorsolateral parts of the DRN, respectively. DRN output neurons appeared to be mostly non-serotonergic indicating the bias of the retroAAV-FlpO used. Both DRN input and DRN output neurons target a stereotypical set of subcortical regions while there were no terminals detected in cortical areas. Neural activity of

studied populations was increased in aversive stressful contexts such as air puff and tail suspension. Overall, these results show that 1) anterograde transsynaptic tracing can be applied to identify DRN neurons innervated by the LHA, 2) LHA targets specific DRN neuron populations with a spatial bias, 3) DRN input neurons projects mostly to subcortical limbic regions, 4) DRN input and DRN output neurons are involved in encoding aversive signals.

Abstract: Serotonergic psychedelics are emerging therapeutics for psychiatric disorders, yet their underlying mechanisms of action in the brain remain largely elusive. Zebrafish have evolutionarily conserved serotonergic circuits, including subcortical targets such as the brainstem regions and the cerebellum, making it a promising model for studying subcortical actions of serotonergic drugs. Here, we investigated the effects of psilocybin, a psychedelic serotonin receptor agonist, on larval zebrafish behavior and brain-wide neural dynamics. Using machine learning analyses of precise body kinematics, we identified two main behavioral effects of acute psilocybin treatment on free swimming behaviors: [i] increased rapid scooting in the absence of visual stimuli (stimulatory effect) and [ii] preventing changes in swim patterns after stress exposure (anxiolytic effect). We further explored the underlying neural mechanisms using c-*fos* mapping and whole-brain neural activity imaging. We identified several brain regions which respond to psilocybin treatment. These findings provide direct insights into how serotonergic psychedelics impact subcortical networks to affect animal behaviors.

Title: A competitive inhibitory circuit for selection of unpredictable threat response and anxiety induction

Authors: *S.-W. TENG[1,2], Z.-Y. CHEN[2];
[1]Shandong Univ. Sch. of Medicine: Shandong Univ. Cheeloo Col. of Med., Jinan, China; [2]Dept. of Anat. and Neurobio., Sch. of Basic Med. Sci. and Qilu hospital, Cheeloo Col. of Medicine, Shandong Univ., Jinan, China

Abstract: Anxiety is elicited by the excessive apprehension about possible unpredictable threats. Previous studies have identified the role of the bed nucleus of the stria terminalis (BNST) in regulating unpredictable threats and anxiety. However, the specific circuit links unpredictable threats to anxiety is still unclear. Here, we used Vgat-Cre mice combined with in vivo fiberphotometry and optogenetics technology to identify the selective vBNST circuit responsible for the defensive responses to unpredictable threat signal and anxiety. We found that vBNST Vgat neurons showed selective activation to unpredictable threat signals, which was necessary for the freezing behavior to unpredictable threats. Next, using activity-dependent neuronal circuit tracing combined with optogenetics technology, we found that insular cortex (IC) provides the excitatory inputs to vBNST, and the vBNST Vgat neurons which received the forward inhibition signal from the lateral nucleus of the amygdala (CeL) somatostatin (SOM) neurons showed selective activation in response to unpredictable rather than predictable threats. In addition, we further found that artificially activation of the circuits from vBNST unpredictable CS (CS-) activated cells to the median nucleus of the amygdala (CeM) or the ventral lateral periaqueductal grey (vlPAG) could elicit anxiety-like or freezing behaviors respectively, which suggest that the vBNST Vgat neurons are responsible for unpredictable threat signals induced anxiety-like and freezing behavior. Finally, we found that vBNST CS- responsible neurons showed increased activities to multi-unpredictable threat signals and inhibiting vBNSTVGAT-CeM circuits could rescue anxiety-like behavior in chronic unpredictable mild stimulation(CUMS) models. Our findings identify the specific neural circuits of vBNST Vgat neurons responsible for unpredictable threats and provide the neural circuitry basis for unpredictable threats induced anxiety behavior, which provide potential value in anxiety therapy.

Title: Two faces of anxiety: the differential efficacy of acute SSRI and ketamine to ameliorate anxiety-like behaviour in the marmoset induced either by ventromedial prefrontal overactivation or orbitofrontal inactivation

Authors: *K. G. MULVIHILL, L. MCIVER, A. C. ROBERTS;
Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Extensive individual variability in pharmacological treatment efficacy remains a persistent obstacle in ameliorating clinical anxiety. The most common first-line treatments are selective serotonin reuptake inhibitors (SSRIs), but these typically show anxiolytic action only following weeks of treatment; hence the growing interest in rapidly-acting agents like ketamine. However, there is also evidence in humans for short term actions of SSRIs to reduce aversive processing, although again there is marked variation in the response (Bhagwagar et al., 2004; Di Simplicio et al., 2014). Indeed, anxiolytic efficacy of acute SSRIs has been shown to be genotype dependent in marmoset monkeys (*Callithrix jacchus)* (Santangelo et al., 2016). We propose that novel insights into the heterogeneity of patient responsivity to anxiolytics may be obtained by comparing the efficacy of distinct classes of drugs (e.g. SSRIs and ketamine) on anxiety states with different aetiologies, but of known origin. Hence, we exploit our recent findings that a similar anxiety phenotype is induced by either *inactivation* of orbitofrontal cortex or *overactivation* of ventromedial prefrontal cortex (Stawicka et al, 2020, 2022) to compare the anxiolytic efficacy of citalopram and ketamine. In marmosets the human-intruder test measures the behavioural reactivity to an unfamiliar human; the human in this context being an uncertain stimulus provoking an anxiety-like response. Targeted intracerebral infusions were used to overactivate area 14 with dihydrokainic acid, a glutamate transporter (GLT-1) inhibitor, and to inactivate area 11 with the GABA-A/B agonists, muscimol/baclofen. The ability of an acute, systemic dose of 10 mg/kg citalopram or 1 mg/kg ketamine to ameliorate the anxiety induced by these two contrasting prefrontal interventions was then determined. Anxiety-like behaviour induced specifically by overactivation of area 14, but not that induced by inactivation of area 11, was ameliorated by citalopram. Preliminary findings demonstrate that this anxiolytic effect can be replicated by local application of citalopram into area 14. In contrast, systemic ketamine showed no systematic differences in anxiolytic efficacy between the two prefrontal manipulations, but individual variation was more prominent. We argue that these results inform our understanding of the neurobiological heterogeneity underlying anxiety. In addition, the evidence that different faces of anxiety are differentially responsive to distinct classes of anxiolytics offers potential for improved treatment strategies.

Title: Causal contribution of bilateral and left dorsolateral prefrontal cortex inactivation to heightened anxiety in the common marmoset

Authors: *R. BANAI TIZKAR[1], L. MCIVER[2], C. M. WOOD[2], A. C. ROBERTS[2];
[1]PDN, Univ. of Cambridge, Cambridge, United Kingdom; [2]Physiology, development and neuroscience, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Area 25 of subcallosal cingulate cortex (scACC-25) and dorsolateral prefrontal cortex (including area 46; dlPFC-46) are consistently reported by functional neuroimaging studies to be dysregulated in depression and anxiety. scACC-25 displays overactivity, whilst dlPFC displays reduced activity, particularly in the left hemisphere. Both regions have become targets for brain intervention therapies; scACC-25 a target for deep brain stimulation for treatment-resistant depression and dlPFC, especially on the left, for high frequency transcranial magnetic stimulation in both anxiety and treatment resistant depression. Moreover, success of the latter is predicted by the extent that activity between dlPFC and scACC-25 is negatively correlated. Recently we have provided direct causal evidence for the role of scACC-25 overactivation in the enhanced reactivity to uncertain threat in a non-human primate, the common marmoset, relevant to our understanding of anxiety (Alexander et al., 2018). However, any causal role for dlPFC in anxiety has not yet been established. Thus, our current objective was to determine the existence of such a relationship by investigating the effect of inactivating dlPFC-46 in the common marmoset on anxiety-like behaviour assessed by the human intruder test of uncertainty. Marmosets (n=7, 3 females) received cannulae targeting dlPFC-46 and temporary inactivation was induced by infusion of a cocktail of GABA-A/B agonists , muscimol/baclofen (0.1mM/1mM, 0.5ul). Not only were the effects of bilateral inactivation determined but also the effects of unilateral inactivation, given the evidence of asymmetry within this region in human emotion regulation and affective disorders. Findings reveal that, similar to overactivation of scACC-25, bilateral inactivation of dlPFC-46, as well as inactivation of area 46 in the left (but not right) hemisphere alone, increased anxiety-like behaviour. This provides causal evidence for reports in the clinical literature of reduced activity in particular in left dlPFC, and aligns with previous findings in our lab showing decreased activity in left dlPFC-46 following scACC-25 overactivation.

Title: Gabaergic inputs to pomc neurons are modulated by chronic unpredictable stress

Authors: *Y. CHEN, X.-Y. LU;
Dept. of Neurosci. & Regenerative Med., Augusta Univ., Augusta, GA

Abstract: Chronic stress exposure induces maladaptive behavioral responses and increases susceptibility for neuropsychiatric conditions. However, specific neuronal populations and circuits that are affected by chronic stress to drive maladaptive behaviors remain to be identified. We have recently shown that chronic unpredictable stress (CUS) for 10 days induces hyperactivity of proopiomelanocortin (POMC) neurons in the arcuate nucleus (ARC) and behavioral deficits such as anhedonia and behavioral despair (Fang, Chen et al., Mol Psychiatry 2021). The increased hyperactivity of POMC neurons is the result of a decrease in synaptic inhibition and an increase in intrinsic excitation. Neurons in the dorsomedial hypothalamus (DMH) provide a major source of inhibitory synaptic inputs to POMC neurons (Rau and Hentges, J Neurosci. 2019). The aim of the current study was to investigate the role of GABAergic neurons in the DMH in modulating synaptic inhibition of POMC neurons during chronic stress. Vgat-ires-Cre mice were injected with AAV-DIO-mCherry in the DMH to label GABAergic neurons. After 10 days of CUS, we recorded spontaneous firing rates and membrane potentials of GABAergic neurons in the DMH. Our data indicated that CUS decreases spontaneous firing of GABAergic neurons in the DMH. Furthermore, we have generated Vgat-ires-Cre;POMC-GFP mice to examine whether stimulation of GABAergic neurons in the DMH can attenuate the CUS-induced hyperexcitability of POMC neurons. By investigating the interactions between GABAergic neurons in the DMH and POMC neurons in the ARC, our study will identify the upstream inhibitory neurocircuits driving hyperactivity of POMC neurons during chronic stress.

Title: Characteristics of neuronal responses to complex visual stimuli in the monkey ventromedial prefrontal cortex.

Authors: *M. TOTSUKA[1], H. IWAOKI[2], N. KONOIKE[3,4], S. MIYACHI[4], K. NAKAMURA[4]; [1]Grad. Sch. of Sci., Kyoto Univ., Inuyama, Japan; [2]Natl. Inst. for Quantum Sci. and Technol., Chiba, Japan; [3]Hakubi Center, Kyoto Univ., Kyoto, Japan; [4]Ctr. for the Evolutionary Origins of Human Behavior, Kyoto Univ., Inuyama, Japan

Abstract: Appropriate evaluation of visual information about the external world is essential for survival. The ventromedial prefrontal cortex (vmPFC) has been focused on as an important brain region that links sensory information to emotional responses and processes reward or affective information. Anatomically, the vmPFC have reportedly rich reciprocal connections with the amygdala and the inferior temporal lobe. The amygdala is involved in emotional processing. In the primate species, the amygdala neurons respond to visual stimuli with emotional information. The inferior temporal lobe is the final stage in visual information processing. Given these anatomical insights, the vmPFC is considered important for integrating visual and emotional information. However, there are few studies on visual processing in the vmPFC, especially in areas 25, 14 and 10. Therefore its functions are still unclear. To elucidate how and what visual information the vmPFC neurons process, we recorded the activity of single neurons from two male Japanese monkeys (*Macaca fuscata*, both six years old). We examined the neuronal responsiveness to the complex visual stimuli while the monkey observed these stimuli. All experiments were approved by the Animal Experimentation Committee of the Center for the Evolutionary Origins of Human Behavior, Kyoto University. We prepared five categories of stimuli of behavioral significance to the monkeys; monkey faces, monkey hips, snakes, foods, and artificial objects. In total, the activity of 415 vmPFC neurons was recorded. Of these, 271 neurons (65%) showed a significant change in activity in response to the stimuli. Among these, about three-fourth (202 neurons) exhibited responses selective for certain stimuli. More than 40% of the selective neurons showed the maximal response to monkey faces or hips. The present results suggest that the vmPFC neurons conveyed visual information about conspecifics especially important for their social behavior.

Title: Distribution of Oxytocin and Vasopressin cells in the developing mouse brain and influence of early life stress.

Authors: *M. HABART[1], A. SOUMIER[2], G. LIO[3], C. DEMILY[5], A. SIRIGU[4];
[1]CNRS, 69500, France; [2]Inst. of Cognitive Sci. Marc Jeannerod, Bron, France; [3]Inst. of Cognitive Sci. Marc Jeannerod, Bron Cedex, France; [4]Inst. of Cognitive Sci. Marc Jeannerod, BRON Cedex, France; [5]iMIND, Bron, France

Abstract: Oxytocin and vasopressin are two neuropeptides involved in social behavior. Although the anatomy of these systems is known, few studies have focused on their maturation across developmental stages. We implemented a 3D developmental atlas based on 3D imaging of cleared and oxytocin and vasopressin immunostained mouse brains at 5 postnatal ages (P0, P3, P7, P14, P56). We found that the number of oxytocin cells doubles during development while no changes were observed for vasopressin neurons. We also found no sex effect during development. The increase of oxytocin cell number is expressed in selective regions such as the paraventricular and the periventricular nucleus and in a newly referenced oxytocin selective region, we named antero-lateral preoptic area. Cell density analyses in the PVN revealed the existence of two oxytocinergic clusters, one postero-dorsal present from birth and another located in the antero-ventral axis developing later. These results suggest that the wiring of the social brain relies on integrated communication between the activity of stable (vasopressin) and flexible, experience-dependent (oxytocin) neural networks. In a further study we investigated plasticity of oxytocin and vasopressin neurons in a context of early stress following maternal separation. We found a significant effect on oxytocin cell number only at a later stage of development (P14) and again no difference for the vasopressin system. All together these findings show that the hypothalamic oxytocin system develops in the postnatal life and that the impact of stressful events on this circuit appear at a later stage. Overall, these results show that the hypothalamic oxytocin system develops during postnatal life and that the impact of stressful events on this circuit appears at a later stage of brain maturation.

Title: Neurogenesis-dependent effects of electroconvulsive shock require mGluR2

Authors: *A. SANTIAGO[1,2], J. CASTELLO SAVAL[2], V. M. LUNA[2,3], H. CHUNG[2], R. HEN[2], W.-L. CHANG[2];
[1]Columbia Univ., New York, NY; [2]Columbia Univ. Irving Med. Center/ New York State Psychiatric Inst., New York, NY; [3]Temple Universty, Philadelphia, PA

Abstract: Therapeutic use of electroconvulsive shock (ECS) is 70%-80% effective for the remission of treatment-resistant depression. Yet the question of how ECS produces these powerful effects remains unanswered. Like other more common forms of antidepressant treatment such as fluoxetine, ECS has been shown to increase neurogenesis in the hippocampal dentate gyrus of rodent models. In human subjects, structural MRI of patients with depression reveals an increase in dentate gyrus volume after ECS treatment, as compared to volume before treatment, and the increase in dentate gyrus volume correlated with symptom improvement. Yet the question of how ECS-induced neurogenesis supports improvement of depressive symptoms remains unknown. Here, we show that ECS-induced neurogenesis is necessary to improve depressive-like behavior of mice exposed to chronic corticosterone. We then use slice electrophysiology to show that optogenetic stimulation of adult-born neurons produces a hyperpolarization in mature granule neurons. We identify that this hyperpolarization requires the activation of metabotropic glutamate receptor 2 (mGluR2). Consistent with this finding, we observe reduced expression of the immediate early gene cFos in the granule cell later of ECS vs sham subjects. Finally, we use conditional expression of mGluR2-shRNA virus to knockdown mGluR2 expression specifically in mature granule neurons. We find that mGluR2 knockdown prevents anti-depressant-like behavioral effects of ECS. Together, these findings reveal the importance of mGluR2 both in the suppression of mature granule neuron activity and in the therapeutic effect of ECS.

Title: Activation of the claustrum ensemble increases anxiety levels following stress exposure

Authors: M. TANUMA[1], Y. YOKOYAMA[1], K. MIYAJI[1], J. OHKUBO[1], R. YOKOYAMA[1], H. UENO[1], K. SEIRIKI[1], H. NOMURA[2], H. HASHIMOTO[1], ***A. KASAI**[1];
[1]Osaka Univ., Suita, Japan; [2]Nagoya City Univ., Nagoya, Japan

Abstract: A subpopulation of neurons in the claustrum (CLA ensemble) is responsible for mediating anxiety responses to acute psychological stressors that elicit negative emotional states. However, the precise mechanism in which the CLA ensemble controls stress-induced anxiety responses remains unclear. To address this question, here we conducted calcium imaging by expressing GCaMP6f in the CLA ensemble in freely moving mice during behavioral tests conducted before and after stress exposure. Prior to stress, we observed that approximately 10% of the neurons in the CLA ensemble display increased calcium levels when entering an anxiogenic center zone in the open field. In the open field test following social defeat stress, a significant increase in calcium levels was observed in 10% of the CLA ensemble when mice entered the center zone, while a marked decrease in calcium levels of the subset was observed after mice exited the center zone. Longitudinal tracking analysis revealed that approximately 25% of the neurons with increased calcium levels overlapped before and after stress. In addition, we observed a significant increase of pairwise temporal correlations within the CLA ensemble during the open field test following stress compared to those before stress. Furthermore, the mice showed reduced time spent in the zone where the CLA ensemble was optogenetically activated in the open field test. These results indicate that the activation of the subset of the CLA ensemble after stress contribute to increasing anxiety levels and anxiety-related behaviors.

Title: Monoaminergic modulation of the Dorsal Raphe Nucleus shapes the momentary release of serotonin at Dorsal Striatum-Amygdala circuits

Authors: *L. NAVA[1], Y. PELLOUX[1], L. BONTEMPI[1], A. LOCARNO[1], N. BARSOTTI[2], M. PASQUALETTI[2], Y. LI[3], R. TONINI[1];
[1]Inst. Italiano di Tecnologia, Genova, Italy; [2]Univ. of Pisa, Pisa, Italy; [3]Peking Univ., Beijing, China

Abstract: The dorsal striatum (DS) integrates sensorimotor circuits via cortico- and thalamic inputs, and motivational inputs from the substantia nigra pars compacta (SNc), thereby

regulating voluntary movements and goal-directed control of behavior. The DS is also indirectly connected via SNc to the Central Amygdala (CeA), a brain region involved in processing both positive and negative valence stimuli. The connectional hub, formed by the sensory DS and the CeA, is shaped by the temporal dynamics of the neuromodulator serotonin (5-HT) released by projections originating from the Dorsal Raphe Nucleus (DRN). In addition to serotonergic neurons ($DRN_{5\text{-}HT}$), the DRN contains dopaminergic cells (DRN_{DA}). DRN_{DA} neurons are anatomically placed in proximity to $DRN_{5\text{-}HT}$ cells, suggesting a modulatory functional crosstalk. Anatomical evidence also shows that the DRN receives projections from the noradrenergic locus coeruleus (LC). However, how the DRN processes different monoaminergic signals to shape striatal 5-HT release remains unexplored. In this study, we combined pharmacological and optogenetic approaches ex-vivo together with fiber photometry in-vivo to examine how DRN_{DA} neurons and LC projections to the DRN (LC→ DRN) modulate the activity of $DRN_{5\text{-}HT}$ cells and the release of 5-HT in both the DS and CeA. We found that exogenous DA application in the DRN boosted the firing activity of DS- and CeA-projecting $DRN_{5\text{-}HT}$ neurons ($DRN_{5\text{-}HT}$→DS and $DRN_{5\text{-}HT}$→CeA). While this DA-mediated increase in firing activity was insensitive to dopamine D1 or D2 receptor antagonism, it was prevented by the application of the adrenaline α1 receptor (α1R) antagonist prazosin. Accordingly, in tyrosine hydroxylase (TH)-CRE mice infused into the DRN with an adeno-associated viral (AAV) vector encoding the opsin Chrimson, we demonstrated that light-activation of DRN TH^+ neurons resulted in the α1R-mediated increase of $DRN_{5\text{-}HT}$→DS or $DRN_{5\text{-}HT}$→CeA firing rate. Furthermore, in dopamine beta-hydroxylase (DBH)-CRE mice injected with a Chrimson-expressing virus into the LC, we observed that LC→CeA projections preferentially activate DRN_{DA} neurons compared to $DRN_{5\text{-}HT}$ cells. By using genetically encoded sensors for monitoring the temporal dynamics of 5HT signal, we found that exogenous DA infusion in the DRN, as well as the optogenetic activation of either DRN_{DA} neurons or LC DRN, results in 5-HT release in the DS and CeA. In summary, our results indicate that monoaminergic modulation of the DRN microcircuit promotes concomitant 5-HT release in the DS and CeA, thus increasing our understanding of how emotional states can influence voluntary movement.

Title: The amygdala enkephalin system controls emotional recuperation following aversive experiences

Authors: *N. GUNGOR, Y. ISHIZU, N. JOSE, J. P. JOHANSEN;
RIKEN, Wako-shi, Japan

Abstract: Aversive experience and recuperation from it can be seen as interlinked processes which collectively define negative encounters inducing fear and anxiety. Despite this fact, the neural mechanisms mediating recuperation have not been studied. We define recuperation as an internal state, triggered by aversive experiences, which helps animals cope with dangerous environments by reconstituting their emotional well-being. Using a wide range of aversive behavioral assays combined with chemogenetic and in-vivo microendoscopic imaging, we examined the role of enkephalin expressing cells in the central nucleus of the amygdala (CeA-ENK) on recuperation in adult male and female mice. We discovered that chemogenetic inhibition of CeA-ENK cells reduces recuperation across different aversive behavioral assays. Single-cell in vivo calcium imaging showed that a proportion of CeA-ENK cells respond to aversive stimuli such as noxious hotplate, foot shocks and tail suspension. Importantly, separate populations of CeA-ENK cells are active during aversive events or homecage rest periods following these experiences. Furthermore, we studied the afferents, efferents as well as immuohistochemical characteristics of CeA-ENK cells. Cortical, hippocampal, olfactory and extended amygdala inputs dominate the afferents, whereas posterior brain regions located in midbrain, pons and medulla, as well the bed nucleus of stria terminalis are major targets of CeA-ENK inputs. We found that moderate and low proportion of CeA-ENK cells expresses calcitonin gene related peptide receptor and PKC delta, respectively. These results demonstrate the central role of the CeA-ENK system in facilitating recuperation from aversive experiences and suggest new treatment approaches for mitigating the effects of trauma.

Title: Single cell activity of serotonergic neurons in the dorsal raphe nucleus during emotional behaviors

Authors: G. E. PAQUELET, K. CARRION, C. O. LACEFIELD, P. ZHOU, R. HEN, ***B. MILLER**;
Columbia Univ., New York, NY

Abstract: The serotonin system regulates a vast array of emotional behaviors that span the spectrum from positive valence to negative valence. To determine the firing properties of serotonergic neurons during emotional behaviors, we adapted miniature microscopy to serotonergic neurons in the dorsal raphe nucleus (DRN-5HT). We imaged calcium activity in over 2,000 genetically identified DRN-5HT neurons across a range of emotional behaviors spanning positive and negative valence. These behaviors encompassed several modalities and categories including gustatory, auditory, innately threatening stimuli, foot shock, social interaction, and emotional learning. As comparators, we also recording DRN-5HT activity during exposure to neutral stimuli across several modalities. We found: 1. Across the population, DRN-5HT neurons are far more activated by valenced stimuli (positive or negative) compared to neutral stimuli. 2. Most DRN-5HT neurons have habituating responses over repeated presentations of valenced stimuli (but stable activity to neutral stimuli). 3. DRN-5HT responses to innately neutral stimuli increase after neutral stimuli take on valence through associative conditioning. 4. Within a given modality (eg gustatory), individual neurons respond to the intensity of the stimulus (salience) rather than the absolute valence of the stimuli. 5. Most DRN-5HT show mixed selectivity, responding to several emotional stimuli (but not all) across valence in combinations consistent with random assortment. 6. However, at the extreme ends of valence and modality (e.g. sucrose and shock) DRN-5HT neurons show more selectivity than expected by chance. 7. There are many ensembles of highly correlated DRN-5HT neurons, with tightly matched activity over long timescales even in the absence of specific extrinsic stimuli. We then investigated the single cell activity of DRN-5HT that project to specific targets (VTA and BNST). We found that: 1. DRN-5HT->VTA neurons and DRN-5HT->BNST neurons are non-overlapping and reside in different areas of the DRN. 2. Both projections include DRN-5HT cells that respond to all emotional stimuli we tested (there is no strict segregation between projections). 3. However, the proportion of cells varied, with the DRN-5HT->VTA projection containing more cells that respond to sucrose, and the DRN-5HT->BNST containing more cells that respond to threat. This large-scale study of DRN-5HT responses shows that the DRN-5HT system responds to emotional salience using ensembles with mixed selectivity and biases in downstream connectivity.

Title: Neuromodulation as a mechanism for lifelong learning in the prefrontal cortex

Authors: *K. BATRA[1,2], C. N. YI[1,2], T. ROY[1,2], M. G. CHAN[1,3], K. CHANG[1,2], A. BAKHTI-SUROOSH[1,2], J. YIU[1,2], C. R. LEE[1,2], R. WICHMANN[1], C. JIA[1,2], B. TSUDA[1,2], T. J. SEJNOWSKI[1,2], K. M. TYE[1,2,3,4];

Abstract: Cognitive flexibility allows the brain to adapt to different contexts by enabling complex phenomena like transfer learning, task-switching and lifelong learning. The prefrontal cortex (PFC) has been hypothesized to contribute to this flexibility, explained by various models (Miller and Cohen, 2001) describing the population ensemble dynamics during goal-driven tasks. Further, the PFC is innervated with an abundance of neuromodulatory circuits (Dembrow and Johnston, 2014) several of which have been implicated in guiding the PFC to modulate neural dynamics across task contexts (Vander Weele et al., 2018, Cools and Arnsten, 2022). Many attempts have been made to understand the PFC population level representation of task variables (Bocincova et al., 2022, Samboerska et al., 2022) and create models for this phenomena that switch between schema and enable meta-learning (Wang et al., 2018, Tsuda et al., 2020, Vecoven et al., 2020, Soltani et al., 2021), though they have not addressed ethological tasks and are engineering driven without experimental validation. Here, we take a hybrid approach to understand the population level computations in the PFC. Experimentally, we have designed a novel seasonal foraging behavioral task for freely-moving mice evaluating different reward and punishment pairings across multiple contingency contexts to dynamically modulate their behavior appropriately. The behavioral paradigm iteratively increases the complexity of the task so that both transfer learning and multi-task inference can be assessed. We observed differences in the reward retrieval behavior between distinct contexts ($n = 4$ mice, $F(1.08,3.240)= 30.37$, $p = 0.0094$; low cost vs no cost reward context: $p=0.0223$) and recovery of similar behavior between repetitions of the same context (low cost 1 vs low cost 2: $p>0.9999$) showing their adaptability. Complementarily, on the computational side, we are developing a novel deep learning architecture, modeling the context-dependent neuromodulatory routing of information through subpopulations of the PFC to learn multi-context tasks with a hierarchical decision-making component inspired by the Mixture of Experts framework. We are using the behavioral data to inform the model and then testing its capabilities using deep reinforcement learning simulations.

Developing a model informed by the biology of the PFC would not only help propel the world of artificial intelligence further but also be a good candidate to study neuropsychiatric conditions related to neuromodulatory dysfunction in the PFC as well as to distill through new experimental paradigms by narrowing the parameter space first using simulations.

Abstract: A critical issue within the mental health field is the lack of granularity in diagnostic practices. We speculate that many distinct pathologies are currently being diagnose as the same disease, and prescribed the same treatments - and that the key to developing effective antidepressants that work for everyone, we need to first identify a strategy to differentiate

between heterogeneous conditions. Anhedonia, described as the inability to experience pleasure, is linked to a dysregulation within the medial prefrontal cortex (mPFC), which is critical for valence processing. Dopamine (DA) tightly regulates mPFC cortical activity and associated behavior and is implicated in anhedonia. However, it remains unknown how DA modulates mPFC valence-specific neuronal population activity during anhedonia. *We hypothesize that mPFC valence-encoding processes are disrupted during stress-induced anhedonia.* To test this, we implemented learned helplessness (LH) and chronic mild stress (CMS) protocols to induce anhedonia in mice. Our findings showed a significant reduction in reward consumption and sociability in LH mice (Pearson Correlation, r=-0.69, p=0.03), but not CMS mice (r=-0.16, p=0.58). Using k-means clustering, we classified consummatory anhedonia, social anhedonia, severe anhedonia, and resilient mice (k=4). Our results showed that anhedonic groups display a significant decrease in sucrose preference (ANOVA, ($F(3,20)=13.11$, $p<0.0001$; Bonferroni's, Res/Cons, $p<0.0001$,) and social preference (ANOVA, ($F(3,20)=6.55$, $p=0.0029$; Res/Soc, $p=0.037$). Next, we performed longitudinal *in vivo* 2-photon endoscopic calcium imaging and photostimulated ChrimsonR-tdTomato VTA^{DA}-mPFC inputs while measuring mPFC population activity in mice exposed to LH (n=5 mice, N=366 neurons) and CMS (n=5, N=876). Using hierarchical clustering, we observed an increase in the proportion of non-responsive valence processing neurons in LH and CMS susceptible mice. During our longitudinal analysis, we observed a significant decrease in mPFC activity during aversive trials in susceptible mice compared to resilient groups following acute exposure to CMS (Wilcoxon Rank Sum test, $p<0.05$). Interestingly, susceptible mice revealed a significant increase in activity during reward trials compared to resilient groups ($p<0.0001$), and is decodable prior to stress. These results indicate the mPFC valence encoding properties are predictive of anhedonic states. Altogether, these experiments point to the need for increased granularity in the measurement of both behavior and neural activity, as these factors can decode the induction conditions of stress-induced anhedonia.

Title: Amygdalostriatal transition zone neurons encode sustained valence to direct conditioned behaviors

Authors: *F. MILLS[1], C. R. LEE[2,1], J. R. HOWE[2], H. LI[1], S. SHAO[3], M. N. KEISLER[1,4], M. LEMIEUX[1], F. TASCHBACH[1,2], L. KEYES[1,4], M. BORIO[1], H. S. CHEN[5], M. G. CHAN[1,4], G. P. Abstract: In order to respond appropriately to threats in the environment, the brain must rapidly determine whether a stimulus is important and whether it is positive or negative, and then use that information to direct behavioral responses. The amygdalostriatal transition zone (ASt) is anatomically poised to play a critical role in these processes by providing a shortcut between corticolimbic and basal ganglia circuitry to mediate behavioral responses to stimuli in parallel with the amygdala. Like the amygdala, the ASt receives converging sensory input from the thalamic and cortical pathways. However, the projections of the ASt are distinct from canonical outputs of the amygdala complex, and are integrated with striatal circuits involved in action selection. Despite this intriguing circuit connectivity, the function of the ASt is almost completely unknown.
From in vivo cellular resolution electrophysiology recordings, we find that ASt neurons show robust sustained responses to negative valence stimuli (Two-tailed t-test, $p = 0.00136$, n= 223 neurons paired, 89 neurons unpaired), which are distinct from responses observed in adjacent amygdala and striatum (One-way ANOVA, $p=0.0008$, n= 280 neurons TS, 223 neurons ASt, 25 neurons CeA). We further show that photostimulation of the ASt is sufficient to drive freezing and avoidance behaviors (Two-way ANOVA, group x laser interactions, $p = 0.0023$, $p = 0.0186$, n=8 mice ChR2, n=10 mice eYFP). Using single-nucleus RNA sequencing and in situ RNA labelling we generate a comprehensive profile of cell types and gene expression in the ASt, and find the ASt is genetically distinct from adjacent striatal and amygdalar structures (n=18-25 mice, >15000 cells per brain region, >50k unique molecular identifiers per cell). We also find that the ASt has a greater proportion of neurons expressing Drd2 than neurons expressing Drd1a (Chi-square test, $p=0.0032$, n=8 mice, >8 sections per group), a unique feature compared to other regions of the striatum. Using in vivo calcium imaging, we show that that this Drd2+ ASt neuron population robustly encodes stimuli of negative valence (Two-tailed t-test, $p = 0.0026$, n=4 mice paired, 4 mice unpaired), and in loss-of-function experiments find that optogenetic inhibition of Drd2+ ASt neurons causes a striking reduction in cue-conditioned fear responses (43% decreased freezing, Paired t-test, $p=0.0145$, n=8 mice NpHR, n=9 mice eYFP). Together, our findings

identify the ASt as a previously-unappreciated critical missing link for encoding learned associations and directing behavior.

Title: Unilateral mid-striatal deep brain stimulation improves cognitive flexibility in rats

Authors: *E. M. SACHSE[1], E. DASTIN-VAN RIJN[2], J. BENNEK[3], M. MENSINGER[3], F. IACOBUCCI[3], M. ESGUERRA[4], A. WIDGE[3];
[1]Dept. of Neuroscience, Dept. of Psychiatry, [2]Dept. of Biomed. Engineering, Dept. of Psychiatry, [3]Univ. of Minnesota, Minneapolis, MN; [4]Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN

Abstract: Neuromodulation of corticofugal circuits can ameliorate deficits in flexible decision-making. For example, deep brain stimulation (DBS) of the ventral internal capsule/ventral striatum (VCVS) in humans and DBS-like stimulation of mid-striatum (midSTR) in rats both improve cognitive flexibility, a component of healthy decision-making. Clinical DBS typically entails bilateral implantation of electrode leads. The rat midSTR DBS model was also developed using bilateral stimulation. However, recent work from our lab in humans suggests that unilateral DBS may be sufficient. To test this, we assessed how unilateral vs. bilateral DBS modulates cognitive flexibility. Unilateral DBS improved flexibility like bilateral DBS, with unilateral DBS being more effective in some cases. Long Evans rats (n=8) were implanted with bipolar stimulating electrodes in left and right midSTR. Rats were trained on an extradimensional set-shifting task that requires flexible decision-making to suppress prepotent responses and adjust to changing rules. After training, rats underwent a testing period where they received bilateral stimulation, unilateral stimulation (right or left) or no stimulation (OFF condition) for one hour in open field then throughout the duration of the task (eight sessions for each stimulation condition, 32 total). Reaction time (RT) and errors were quantified using a generalized linear mixed-effects model. Brains were sliced to confirm electrode placement. cFos+ neurons in

medial prefrontal cortex (mPFC) and midSTR were compared to determine regional involvement and correlations with behavior. Unilateral and bilateral midSTR DBS similarly reduced RTs without increasing errors, improving cognitive flexibility. Right unilateral stimulation resulted in the largest reduction in RTs compared to the OFF condition (~50ms, p = 5.47e-25). This was followed by bilateral stimulation (~40ms reduction, p = 2.52e-6) and left unilateral stimulation (~30ms reduction, p = 3.83e-10). These statistics are reported for rats that have completed testing at the time of the abstract submission (n=6). Further, we expect that the reduction in RTs from stimulation will correlate with cFos expression in mPFC subregions. Specifically, if stimulation delivered to one hemisphere is associated with a greater reduction in RTs compared to the other hemisphere, it is predicted that there will be more cFos+ cells in the mPFC ipsilateral to stimulation. The results of this work will clarify the circuitry involved in our midSTR DBS rat model of VCVS DBS. This model may allow optimization of stimulation parameters and brain targets to increase DBS's therapeutic efficacy.

Title: Unraveling the mechanistic link between repetitive mild traumatic brain injuries and maladaptive avoidance: Insights from neural synchrony

Authors: *C. J. LI, S. SIMPSON, L. BUHLER, M. R. ANGSTMAN, S. M. HU, J. L. CHANG, E. DASTIN-VAN RIJN, S. S. NAGRALE, D. J. TITUS, A. S. WIDGE;
Dept. of Psychiatry and Behavioral Sci., Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Mild traumatic brain injury (mTBI) is a prevalent health issue in the United States that can result in a wide range of outcomes, with some individuals experiencing long-term cognitive and behavioral deficits. Repetitive mTBIs (RmTBIs) have the potential to worsen this damage as the initial injury increases susceptibility to further traumas, compounding the behavioral, functional, and structural deficits associated with each injury. RmTBIs commonly lead to maladaptive avoidance (i.e., excessive avoidance in the absence of threatening stimuli) which can manifest in psychiatric disorders such as PTSD, Generalized Anxiety Disorder, and Major Depressive Disorder. However, the mechanistic link between RmTBIs and the development of these neuropsychiatric disorders is poorly understood.
We hypothesized that RmTBIs would alter the functional connectivity between the prelimbic (PL) and infralimbic (IL) cortices of the medial prefrontal cortex (mPFC) and the basolateral

nucleus of the amygdala (BLA), the main regions involved in the regulation of fear and avoidance, leading to increased avoidance behavior. To study this, we utilized the platform mediated avoidance (PMA) task, a behavioral paradigm that models the balance between avoidance and approach drives. Following 4 weeks of training, we induced RmTBIs (Days 0, 3, and 7) and implanted tetrode microdrives in adult Long Evans rats. For the next 4 weeks, we recorded neural activity in the PL, IL, and BLA simultaneously during the PMA task. RmTBIs persistently increased rats' avoidance behavior, both in the presence and absence of threatening stimuli. Even when the injured animals engaged in approach behavior, they were less effective in reward seeking than they were pre-injury. Additionally, there was diminished coherence in the IL-BLA and PL-BLA circuits during approach to the reward zone following RmTBIs when compared to non-injured animals. These post-injury behavioral and electrophysiological deficits will be correlated with structural changes which will be captured using polarization sensitive optical coherence tomography.
This study may yield valuable insights into the neural and structural attributes correlated with avoidance behavior following RmTBIs and could lead to the identification of biomarkers for diagnosis and treatment. Understanding the neural mechanisms underlying maladaptive avoidance after RmTBIs has the potential to improve the quality of life for those affected by this condition.

Title: Phase-locked transcranial magnetic stimulation over prefrontal cortex alters cortical excitability

Authors: *P. B. BUCHANAN, A. N. MCINNES, L. CAOLA, C. R. P. SULLIVAN, S. NAGRALE, D. M. LUNDTVEDT, A. S. WIDGE, S. WILSON;
Psychiatry, Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Transcranial magnetic stimulation (TMS) is an effective treatment for those suffering with treatment resistant major depressive disorder. However, 50% of TMS patients do not experience adequate improvement in depression symptoms. Adapting TMS by increasing the

engagement of target circuits may improve the outcomes for patients. One method to improve treatment protocols may be timing stimulation to endogenous alpha oscillations since this band is dominant in the prefrontal cortex. Closed loop TMS of this frequency band in the motor cortex has effects on corticospinal excitability, but it is unclear whether it has the same effect on the prefrontal cortex. Changes in excitability, and more specifically, inhibitory effects is relevant to neuromodulation therapies because dysfunction in intracortical inhibitory circuits is associated with mood disorders such as depression. The aim of this study is to examine the effect of TMS locked to negative peaks of alpha oscillations on cortical excitability within the prefrontal cortex. Seventy trials of single and paired pulse (100ms inter-pulse interval; long-interval intracortical inhibition; LICI) TMS at 120% of resting motor threshold were given to participants (n=11) before and after 5 minutes of phase locked stimulation . The Toolkit for Oscillatory Real-time Tracking and Estimation (TORTE) was used to lock to 180 degrees, and the stimulation was delivered in triplet bursts with a minimum interval of five seconds between phase-triggered bursts. Preliminary EEG data show an enhancement of single-pulse TMS evoked potentials (TEPs) post phase-locked stimulation, consistent with previously observed effects in the primary motor cortex. Phase-locked stimulation also increased LICI, as read out from paired pulse TMS. Thus, alpha phase-locked TMS may be more effective than non-phase-locked TMS at engaging intracortical inhibitory circuits, which may improve TMS' efficacy for the treatment of depression.

Title: Enhancing cognitive control through improved accuracy of deep brain stimulation (DBS) programming for optimal stimulation site selection

Authors: *S. NAGRALE[1], A. YOUSEFI[3], T. I. NETOFF[1], A. WIDGE[2];
[1]Dept. of Biomed. Engin., [2]Dept. of Psychiatry and Behavioral Sci., Univ. of Minnesota, Twin Cities, Minneapolis, MN; [3]Dept. of Computer Sci., Worcester Polytechnic Inst., Worcester, MA

Abstract: Precise programming of Deep Brain Stimulation (DBS) targeting the ventral internal capsule/striatum (VCVS) is critical for maximizing DBS' effectiveness in disorders such as

depression and OCD. Our recent study demonstrated the potential to replace the subjective trial-and-error method of VCVS DBS programming. We proposed an online closed-loop framework with an objective measurement obtained from the Multi Source Interference Task (MSIT), specifically using MSIT reaction time as a measure of cognitive control. We developed Bayesian optimization algorithms to systematically investigate various electrode contacts to identify those that significantly improved cognitive control. By implementing the Upper Confidence Bound (UCB1) algorithm over multiple days (in an ensemble) and selecting the optimal stimulation site using majority voting, we can recover a known optimum with an approximate accuracy of 80%. The current study presents an alternative to majority voting for ensembles, by better leveraging individual trials. We employ two primary strategies. Firstly, we implement arm pruning, which involves the removal of underperforming stimulation sites during the exploration-exploitation trade-off of the UCB1 algorithm at consecutive stages of the ensembles. Additionally, we use an A/B testing approach to compare the performance of the last two remaining stimulation sites in cases of unclear optimality. Secondly, we calculate a response surface for each individual stimulation site based on the data obtained from each stage of the ensemble. This enables the selection of the optimal stimulation site by considering the response surface, which incorporates more comprehensive information from the individual trials than the majority vote. By incorporating these strategies, we aim to achieve a more accurate approximation of the actual underlying distribution pertaining to the effectiveness of stimulating a specific site. The importance of this extended study lies in its potential to improve the accuracy and thus overall reliability of the selection process, instilling greater confidence in the selected settings for both patients and clinicians.

Title: Black-box optimization of cognitive control with electrical stimulation

Authors: *E. DASTIN-VAN RIJN[1], E. SACHSE[2], A. S. WIDGE[3];
[2]Neurosci., [3]Pyschiatry, [1]Univ. of Minnesota, Twin Cities, Minneapolis, MN

Abstract: Deep brain stimulation (DBS) of the ventral internal capsule/striatum (VCVS) is a promising therapy for treatment resistant psychiatric disorders. However, effective treatment depends on correct programming of stimulation parameters. This process is currently iterative, time-consuming, and reliant on noisy, subjective measures leading to inconsistent patient outcomes and months to clinical benefit. Prior work from our lab has shown that effective VCVS DBS can acutely improve cognitive control. Using psychophysical tasks, cognitive control can be estimated through trial-to-trial measures like reaction times, presenting a potential objective, rapid optimization target. Further, in unpublished work, we reverse translated this effect to Long-Evans rats performing an extradimensional set-shifting task. To use this rodent platform to demonstrate DBS optimization for cognitive control, we developed a real-time Bayesian optimizer to minimize rat reaction times on the set-shift task (n=1). In this task, rats had to shift between selecting stimuli based on side or light to receive rewards. As with prior human work, this task requires cognitive control and is thought to engage analogous circuitry. On each trial, the optimizer selects a new stimulation amplitude between 0 and 300 μA (130 Hz, 100 μs pulse-width, bilateral mid-striatum) based on a Gaussian process model with a softmax acquisition function. Within 5 sessions, the optimizer identified 150 μA as the optimal stimulation amplitude, balancing between under and overstimulation. Further offline analyses showed that the same optimal amplitude additionally minimized delays in initiating trials and maximized accuracy. These results support the feasibility of using cognitive metrics as a control signal for stimulation programming. With further development, this approach could provide a path for streamlining and expanding access of DBS and other neuromodulation therapies in psychiatric and non-motor applications.

Title: Deep brain stimulation does not affect impulsivity but increases inter-trial behaviors in a rodent 5-choice serial reaction time task

Authors: *M. MENSINGER[1], A. WALD[2], E. M. SACHSE[3], E. M. DASTIN-VAN RIJN[4], A. E. REIMER[2,5], A. S. WIDGE[1];

Abstract: Deep brain stimulation (DBS) may be effective for treating severe treatment resistant psychiatric disorders. DBS-responsive disorders, such as major depressive and obsessive-compulsive disorder, often involve disruptions in cortical-striatal circuitry which can affect flexible decision-making. Previously, our lab evaluated the effect of DBS delivered to the mid striatum in rats performing an extradimensional set-shifting task. Rats exhibited a decrease in reaction time without an increase in errors, attributed to increased flexibility. Additionally, stimulation increased inter-trial behavior across all response types. It can be argued the decrease in reaction time was due to impulsivity. To elucidate this, rats performed a 5-choice serial reaction time task (5-CSRTT). Long-Evans rats (n=7) were trained on a 5-CSRTT and then implanted with bilateral bipolar Plastics1 stimulating electrodes in the mid striatum. Next, rats underwent 16 experimental sessions, evenly divided between interleaved sessions of active (current-controlled biphasic stimulation, 300 µA, 130 Hz) and sham stimulation. For each session, rats were placed in an open field for one hour to allow full onset of stimulation effect, followed by performance of the 5-CSRTT. Performance was quantified by number of premature responses, and we employed a generalized linear mixed-effects model for statistical analysis. No significant differences were found between active and sham conditions regarding premature responses ($p=0.764$). Inter-trial behavior was quantified by premature, correct, incorrect, and omission response types. Significant increase in inter-trial behavior with stimulation was found across all response types ($n=3$, $p<0.001$). Mid striatum DBS during the 5-CSRTT does not increase the number of premature responses, indicating no increase in impulsivity. Therefore, increased impulsivity does not explain decreased reaction time in the extradimensional set-shifting task, supporting increased flexibility. Inter-trial behavior results also show preserved effects across tasks. These findings help to elucidate therapeutic mechanisms of DBS in cortical-striatal circuitry.

Title: Characterization of spike activity and local field potentials in the cortico-striatal pathway during set-shifting behavior

Authors: *Z. SONG, E. HOSKINS, J. MAJOR, F. IACOBUCCI, S. MILLER, A. ALPERS, K. WARNER, A. S. WIDGE;
Dept. of Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: The ability to make decisions appropriate to continuously changing environments is impaired in a wide range of psychiatric disorders, including depression and obsessive-compulsive disorder. Extradimensional set shifting is commonly used as a behavioral model to study that capability, in both animals and humans. The present project aimed to characterize electrophysiological activity in the prefrontal cortex (PFC) and the striatum, and then examine the associations between the spike activity, the local field potential (LFP), and the behavior while rats performed an extra-dimensional Set Shift task. Three rats were implanted with dual Neuropixel probes, covering both the dorsal and ventral sub-regions of the medial PFC and the striatum. Electrophysiological data were obtained while rats shifted between a cue-driven Light rule and a spatial Side rule to obtain food rewards. The task required five consecutive correct responses to proceed to the next rule and one test session had a total of eight rules (alternating between Light and Side rules). Spike and LFP data were compared while rats were in different cognitive states including the decision-making periods that led to correct responses versus those that led to incorrect ones. Additionally, the data were compared between the time when the rule was just changed (thus rats were uncertain of the rules and had to explore) versus the time towards the end of rule change (when rats knew the current rule). The pattern of the LFP oscillation power appeared to be distinct between the correct trials and the incorrect trials, particularly in the theta, low gamma, and high gamma bands. For instance, the power in the low gamma band increased in the PFC around the response time during the incorrect trials, while the power of the same band remained largely unchanged in the correct trials. Putative neurons that had reward outcome-dependent firing rates were also identified. Interestingly, these putative neurons coupled with the high gamma band oscillation and strongly preferred to fire action potentials during the negative phase of those oscillations. The present study should help better understanding the role of LFPs and spikes in regulating decision-making and provide insightful information on the ongoing treatment development via neuromodulation.

Title: Whole-brain correlates of emotion processing in mice using functional ultrasound imaging

Authors: *B. EDELMAN[1,2], E. CHO[1], N. GOGOLLA[1], E. MACE[2,3];
[1]Emotion Res. Dept., MPI for Psychiatry, Munich, Germany; [2]Brain-Wide Circuits for Behavior Res. Group, Max Planck Inst. for Biol. Intelligence, Martinsried, Germany; [3]Dept. of Ophthalmology, Univ. of Gottingen, Gottingen, Germany

Abstract: Emotion states are important motivators of individual experience and behavior, and identifying their neural correlates has been the subject of affective neuroscience for many years. Human imaging studies have identified brain regions implicated in subjective emotional experiences yet remain correlative in nature. Research in animal models provides insights into the precise neuronal circuit mechanisms underlying diverse emotions, but often focuses on pre-selected brain regions and individual states. Recent advances in functional ultrasound (fUS) imaging enable the investigation of whole-brain functional activity in awake and behaving mice with limited animal disturbance. In parallel, machine vision-based facial expression analyses now allow for the quantitative and dynamic tracking of emotion state in mice. Here, we combined these two pioneering techniques to start identifying whole-brain correlates of emotion states in behaving mice. We administered a variety of emotion-evoking stimuli across different sensory and contextual domains to head-fixed mice. We examined whole-brain fUS activity during emotion states such as pleasure, disgust, pain, and fear using a general linear model and multivariate pattern analysis. Emotion-related brain activity maps were distinct from those observed during periods of stimulus delivery, suggesting separate neural correlates for sensory and emotion processing. Furthermore, machine learning and latent space embedding of whole-brain fUS patterns revealed a separation of emotion state categories, and also potential dimensional representations of valence. We also identified unsolicited emotion states, defined as spontaneous occurrences of facial expressions outside the expected stimulus environment, that elicited brain activation patterns similar to evoked emotion states. Importantly, when comparing brain activity maps across diverse emotion states, we found regions selective to individual emotion states as well as regions that were involved in all emotion states. As validation of our approach, we observed strong correspondence between the fUS signal and bulk calcium activity from fiber photometry recordings in key emotion-related brain regions such as the insular cortex and amygdala. Overall, we demonstrate that the combination of facial emotion readouts with whole-brain fUS imaging in mice represents a powerful approach to revealing the neuronal correlates of emotion, which will help guide the in-depth dissection of the underlying neural mechanisms.

Title: Social Exclusion Modifies the Neural Representation of Physical Pain

Authors: *C. JIA[1,2], A. TRAN[1,2], F. ALOBOUDI[1,2], K. BATRA[2,1], C. R. LEE[2,1], A. BAL[2,3], A. NGUYEN[2,1], J. DELAHANTY[2,4], M. CHAN[2,4], E. SAY[2,1], R. PATEL[2], R. WICHMANN[2], L. Studies, La Jolla, CA; [3]Johns Hopkins Univ., Baltimore, MD; [4]Salk Inst. for Biol. Studies, Howard Hughes Med. Inst., La Jolla, CA; [5]Peking Univ., Peking Univ., Beijing, China

Abstract: Social pain, the emotional pain caused by aversive experiences with one's social group, can have deleterious effects on both mental and physical health. The "pain overlap theory" proposes that the experience of social pain can overlap with and modulate physical pain. However, we do not know if a neural substrate exists where social and physical pain overlap. To address this gap, we have designed a novel Social Exclusion paradigm, in which mice are separated from their cagemates by a switchable glass divider and observe their cagemates collectively consume a reward. To control for the tones and reward delivery, we have the Tone Only control, in which there are no mice on the reward collection side of the chamber. To control for visualizing another mouse consume a reward, we have the One Mouse control, in which mice are excluded with one mouse on the other side. For the 180 mice we have included in these paradigms, each of the 60 trials for Social Exclusion, Tone Only, and One Mouse are separated into two categories (FOMO vs Fine) using a new supervised machine learning algorithm, AlphaClass, and k-means clustering. Fear Of Missing Out (FOMO) behavior, is operationally defined by mice climbing to, rearing near, or oriented towards the social group. Trials during which mice did not orient towards the social group during reward collection are termed "Fine" trials. We found that FOMO behavior is significantly elevated during Social Exclusion, compared to the Tone Only control (*P = 0.0108). After experiencing Social Exclusion, social rank is negatively correlated with a lower latency to lick, suggesting increased affective pain behaviors in dominant mice (*P = 0.004). To find the neural substrates that might mediate social exclusion-induced hyperalgesia, we are looking in the anterior insular cortex (aIC). Using microendoscopic calcium imaging with GCaMP7f, we have discovered the aIC contains neural ensembles responsive to social and physical pain. Decoding analyses reveals that after Social Exclusion, the representation of physical pain is enhanced (***P = 0.0004). To explore the role of neuromodulators in mediating a prolonged negative affective state after social exclusion, we used a fluorescent endocannabinoid sensor ($GRAB_{eCB2.0}$) during social exclusion and pain behavior. We found that during Social Exclusion only, there is a significant increase in fluorescent activity (*P = 0.0134) during Fine trials, but not during FOMO trials, or any control condition trials. Together these findings suggest social exclusion enhances the neural

representation and behavior of physical pain and the endocannabinoid system can potentially be a mechanism to bind these two types of pain.

Title: Investigating the mechanisms of precise predictive timing: simulation and intracranial EEG

Authors: *S. SMITH[1], B. VOYTEK[2,3,1,4];
[1]Neurosciences Grad. Program, [2]Cognitive Sci., [3]Halıcıoğlu Data Sci. Inst., [4]Kavli Inst. for Brain and Mind, Univ. Of California San Diego, La Jolla, CA

Abstract: Our sensory environment is rich with repetitive stimuli that we can perceive and use to predict upcoming events. Our brains can accomplish this via temporal predictive coding, one example of which is oscillatory entrainment, in which ongoing, low frequency cortical oscillations in human EEG and MEG can become synchronized to a rhythmic stream of sensory inputs. Previous investigations have observed instances of entrainment of low frequency oscillations in the delta (1-4 Hz) band, often coupled to activity in the higher frequency beta (13-30 Hz) band. However, observations of cross-frequency interactions have recently been shown to also potentially be caused by nonsinusoidal oscillations. Here, we hypothesize that cross-frequency delta-to-beta coupling in anticipatory perception might be better explained by nonsinusoidal oscillations. Furthermore, we hypothesize that the nonsinusoidal waveforms of these oscillations are driven by the temporal coincidence of excitatory top-down and bottom-up postsynaptic currents converging onto auditory cortex. That is, these nonsinusoidal oscillations could be the product of top-down modulation of neural excitability in the auditory cortex, serving a potential mechanistic role in the precision of temporal predictions. To investigate the possible occurrence of nonsinusoidal entrained oscillations in temporal predictive coding, we designed a novel anticipatory perception task. Here, we analyze intracranial EEG data from 8 epilepsy patients performing this task. We use simulated, hypothesized top-down and bottom-up signals to select electrodes of interest. Then, we compare our cycle-by-cycle approach with traditional phase-amplitude coupling methods to investigate neural mechanisms of precise predictive timing.

Title: A thalamic ventral hippocampal pathway that supports anxiety-related behavior

Authors: *M. M. GERGUES, J. BRATSCH-PRINCE, S. HASSAN, M. LI, A. KOLANJIAN, V. S. TURNER, M. A. KHEIRBEK;
Psychiatry & Behavioral Sci., Univ. of California San Francisco, San Francisco, CA

Abstract: The hippocampus (HPC) plays an important role not only in spatial memory, but in the encoding emotionally charged environments and generating appropriate behavioral responses. Yet how and which inputs are involved in the generation of anxiety-related representations in the HPC remain unknown. Using a whole-brain, cell-type specific, anatomical screen, we identified the anterior portion of the paraventricular nucleus of the thalamus (PVT), an area implicated in the processing of salient emotional stimuli, as a putative source of anxiety-related information to the HPC. In this study, we dissect the anatomical organization of the PVT-vHPC circuit and its contribution to anxiety-related behavior using advanced tracing methods and optical approaches. We used high-throughput sequencing of genetically barcoded neurons to map the axonal projection pattern of aPVT neurons and determined the organizational principles that govern output patterns of PVT-vHPC projection neurons. In optogenetic and chemogenetic studies, we find that modulation of PVT-vHPC pathway resulted in reduced avoidance of anxiogenic compartments of conflict-based anxiety tests. Using calcium imaging, we recorded the response patterns of aPVT-vHPC neurons while also monitoring BLA-vHPC neurons, a known input that modulates anxiety-related behavior. These recording revealed differential recruitment of these two pathways during exploration of anxiogenic environments. In sum, we identify a novel role for PVT-vHPC projections in modulating anxiety-related behavior, including its anatomical architecture and how its activity compares with other known inputs to the vHPC.

Abstract: Emotional well being requires the ability to identify and accurately interpret positive and negative stimuli in the environment. How emotionally charged stimuli are processed and encoded by the brain, however, is not well understood. The ventral hippocampus (vHPC) plays a key role in orchestrating emotional responses, including processing stimuli with innate valence, as well as learned cues predictive of emotionally salient outcomes. Moreover, dysfunction of vHPC and its outputs is associated with a variety of mood disorders, including anxiety, depression and post-traumatic stress. Thus, understanding how emotionally charged stimuli are processed by the vHPC can provide insight into the etiology of maladaptive emotional states. Here, we used 2-photon calcium imaging to record the activity of vCA1 neurons while exposing mice to a battery of stimuli with innate or learned valence. Although neuronal activity tagging studies in vCA1 and related areas show significant overlap for neurons responsive to stimuli belonging to the same valence class, but not across valence classes (ie, valence encoding), we found little evidence for such valence encoding when stimuli from distinct sensory modalities were presented (eg, sucrose, shock, predator odor, female conspecific urine). Instead stimulus identity dominated neural representations during this time. Conversely, for stimuli within the same modality (appetitive chocolate or vanilla milk, aversive quinine or high salt solution), valence encoding was present, in addition to identity, suggestive of modality-specific processing in vCA1. Finally, as recent findings suggest that neural representations of neutral cues come to

mimic the innate representations of paired outcomes, we examined how neutral odor cues predicting sucrose, low amplitude shock or high amplitude shock were transformed in vCA1 with learning. Indeed, we found an increase in the similarity of population activity for a cue and its associated outcome following training. Notably, representations of odor cues also became more similar to one another, indicating a general salience signal is also embedded in stimulus representations. Thus, vCA1 encodes a rich repertoire of information about encountered stimuli that includes stimulus identity, associated outcome, salience/arousal, and in the case of stimuli within the same modality, valence. This multitude of information may help animals to identify, interpret and react to stimuli in an appropriate manner.

Title: Control of anxiety states and underlying neural dynamics by respiratory rhythms

Authors: *A. S. KLEIN, M. KHEIRBEK;
Psychiatry and Behavioral Sci., Univ. of California, San Francisco, San Francisco, CA

Abstract: An animal's emotion state is strongly influenced by the state of its body. For example, changes in heart rate or breathing rhythms can influence how the brain responds to emotional stimuli and generates adaptive behaviors. In humans, it is well documented that changes in respiration occur during high anxiety states, and that individuals suffering from certain types of anxiety disorders experience altered sensations of breathing-derived signals. Furthermore, accumulating scientific evidence supports the idea that controlled breathing can have a positive influence on an individual's mental and physical well-being. However, the underlying neuronal circuits mediating this tight coupling between the control and sensation of respiration and anxiety-related behaviors remain unknown.
To determine how respiration influences anxiety-related behaviors and their underlying neuronal dynamics, we have identified how breathing rhythms are correlated with specific behavior motifs in tests of aversive behaviors in mice. This allowed us to predict an animal's location in safe or aversive compartments based on individual breathing rates alone. In addition, calcium imaging experiments revealed that dynamic changes in breathing rates during exploration of anxiety provoking arenas were tightly correlated to activity in the central nucleus of the amygdala. Moreover, direct control of breathing patterns using chemogenetic manipulations of neuronal subpopulations in the brainstem breathing center revealed that slowing down of respiration

acutely reduces an animal's fear-related behavior. Currently we are using high-density electrophysiology (Neuropixels) to record from limbic brain regions to determine how breathing impacts the neuronal dynamics underlying distinct anxiety states.

Title: Shifting balance of local inhibitory interneurons in ventral hippocampus controls approach and avoidance behaviors.

Authors: *J. BRATSCH-PRINCE[1], A. KWON[1], M. KHEIRBEK[2];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Psychiatry, UCSF, San Francisco, CA

Abstract: The ventral hippocampus (vHPC) plays a critical role in mood and anxiety-related behaviors. Information regarding the salient nature of an environment, arising from input from cortical and subcortical regions, converge in vCA1 where an output signal is routed to specific downstream targets to support appropriate behavioral selection. Indeed, activity in projection-defined vCA1 excitatory pyramidal neurons (PNs) has been shown to influence approach or avoidance behaviors depending on the target structure. At the local circuit level, activity in hippocampal PNs is regulated by a diverse pool of local inhibitory interneurons (INs), including those expressing parvalbumin (PV), somatostatin (SST), or vasoactive intestinal polypeptide (VIP). These INs differ in their electrophysiological and local connectivity patterns, placing each class in a unique position to influence vCA1 circuit output and ultimately behavior. Yet, it is not understood how these IN populations shape vCA1 output in a behavior-specific manner. Here, using a combination of population and single cell in vivo calcium imaging and optogenetics in mice, we show that PV, SST, and VIP INs are differentially modulated during multiple tests of anxiety-related behavior. High-resolution analysis of mouse behavior found that during exploratory-approach behaviors, PV and VIP IN networks were recruited, while SST IN activity decreased. Conversely, during avoidance behaviors SST INs were uniquely recruited with decreased PV and VIP IN network activity. Interestingly, increases in activity of SST INs prior to approach-avoidance decisions could be predictive of future avoidance behavior, suggesting a uniquely critical role of SST INs in shaping network activity in vCA1 to guide avoidance behavior. Consistent with this, closed-loop optogenetic silencing of SST INs during simultaneous calcium imaging of vCA1 neurons revealed that inhibiting SST INs decreased avoidance behavior and altered vCA1 network activity during approach-avoidance decisions. Together, these data reveal the competitive balance between vCA1 IN populations guides vCA1

output to drive appropriate behavioral selection during anxiety-related behaviors, highlighting unique contribution of these different inhibitory networks to behaviorally-relevant vCA1 circuit function.

Title: Understanding the mechanisms by which vCA1 orchestrates avoidance behavior

Authors: *R. O. O'SULLIVAN[1], J. X. BRATSCH-PRINCE[1], M. A. KHEIRBEK[2];
[2]Psychiatry, [1]UCSF, San Francisco, CA

Abstract: The decision to approach or avoid an external stimulus is not trivial, and execution of the appropriate action is often essential to an animal's survival. Consider the competing drives to explore a new environment in order to attain food or to stay hidden in order to avoid predation. These conflicting motivations must be weighed, and their outcomes considered so that the correct behavior is selected. The vCA1 subregion of the ventral hippocampus plays a central role in this approach-avoid calculation, as it represents experiences imbued with motivation to avoid; and manipulation of vCA1 can drive avoidance. However, while a role for vCA1 in representing salient stimuli is well documented, how it is involved in appropriate behavioral selection remains unclear. For example, we currently lack an understanding of how vCA1 orchestrates avoidance of learned cues that predict aversive outcomes. Here, we use a visually guided two-way active-passive avoidance task, to dissect the contributions of vCA1 to distinct avoidance behaviors. Using circuit manipulation tools, we demonstrate that inhibition of vCA1 improves avoidance learning. However, silencing vCA1 projections to basal amygdala, is detrimental to avoidance learning suggesting differential control of avoidance learning by distinct vCA1 output streams. Using *in vivo* calcium imaging, we are now exploring what task-relevant features are encoded by vCA1 and specific vCA1 projections, and how this information is used by downstream targets to control avoidance behavior.

Title: Reorganization of thalamocortical functional connectivity underlies loss of consciousness

Authors: *Z. HUANG, A. G. HUDETZ;
Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: Background. Understanding the neural basis of consciousness and the mechanism general anesthesia are two interrelated problems. The cellular-molecular action of general anesthetics has been thoroughly studied; however, their effect on consciousness at systems level remains incompletely understood. Two mechanistic hypotheses of anesthetic-induced unconsciousness have been proposed: the disruption of corticocortical loops and the disruption of thalamocortical loops. To better understand the differential roles of the two loops, we devised a method to pinpoint the thalamic counterparts of the cortex's unimodal-transmodal functional axis. Through this approach, we examined how these counterparts undergo changes during anesthesia in comparison to the conscious awake state. **Methods.** Thirty participants (18-38 ys, 20 women) underwent fMRI during conscious baseline, loss of behavioral responsiveness induced by propofol sedation, and recovery of responsiveness. We expanded the cortical gradient analysis to identify the subcortical correlates of the principal cortical gradient. Specifically, pair-wise correlations were computed between the subcorticocortical connectivity values of each subcortical voxel and the cortical gradient values, generating a topographical map of the subcortical correlate of the cortical gradient. **Results.** Propofol-induced loss of consciousness was associated with a reorganization of thalamocortical functional connectivity along the unimodal-transmodal functional axis of the cortex, where the transmodal thalamocortical connectivity was preferentially suppressed. **Conclusions.** The results suggest that both thalamocortical and corticocortical functional connectivity are disrupted in propofol sedation, supporting the importance of both mechanisms in causing unconsciousness in humans.

Title: Functional dissociation of the individual regions involved in the hippocampal-cortical network

Authors: *X. WEI[1], P. A. ANGELI[1], R. L. BUCKNER[1,2,3];
[1]Harvard Univ., Cambridge, MA; [2]Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Human neuroimaging has identified a hippocampal-cortical network that includes the hippocampal formation and distributed cortical regions (here labeled DN-A based on within-individual precision network estimation; Braga & Buckner 2017 *Neuron*). DN-A comprises multiple regions established to play a role in spatial cognition (e.g., parahippocampal cortex, PHC; retrosplenial cortex, RSC) as well as distributed association regions whose roles are less clear (e.g., a specific region of dorsolateral prefrontal cortex, DLPFC). Anatomical studies in monkeys suggest that the distributed network likely arises from direct projectional anatomy including a local zone of DLPFC. Interestingly, DN-A responds when individuals are imagining spatial scenes (DiNicola et al. 2023 *J. Neurophysiol.*), raising questions about how mentalizing scenes relates to perceiving scenes and whether the multiple regions within DN-A similarly respond. Here we contrasted the response of DN-A regions to perceiving versus mentally constructing scenes. A multisession hierarchical Bayesian model estimated DN-A within 11 intensively studied individuals. Separate DN-A regions were then defined (DLPFC; inferior parietal lobule, IPL; ventromedial prefrontal cortex, VMPFC; PHC; RSC). Responses were measured during Scene Perception in a low-level 0-Back task and during effortful Scene Construction by isolating trials of an Episodic Projection task that possessed the highest levels of imagined spatial content. Result suggested that DN-A responded to both Scene Perception and Scene Construction, but subregions displayed a functional dissociation. Specifically, while PHC and RSC demonstrated preferential response to both Scene Perception and Scene Construction, the higher-order regions of association cortex (IPL and DLPFC) showed relatively higher response to Scene Construction when participants effortfully mentalized scenes. These higher-order regions were scene preferential and dissociable from control regions with domain-flexible response properties. These findings indicate a potential specialization of DN-A regions with domain-specialized higher-order association regions becoming most active when scene content is mentalized.

Title: The hippocampus sends perceptual predictions to the cortex

Authors: *O. WARRINGTON, N. N. GRAEDEL, M. F. CALLAGHAN, P. KOK;
The Wellcome Ctr. for Human Neuroimaging, UCL Queen Square Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: The brain must use prior knowledge to overcome the limitations of our sensory machinery and infer the cause of incoming sensory information. This knowledge generates predictions of future sensations formed by extracting statistical regularities from the environment, including rapidly learnt associations between arbitrary stimuli. While the effects of predictions on sensory processing can be seen in the early sensory cortex (Aitken et al., 2020; De Lange et al., 2018), the mechanisms underlying the generation and communication of these predictions remain unclear. The hippocampus (HC) has been suggested as an essential region coordinating learning and exploitation of predictive relationships for perceptual inference (Barron et al., 2020; De Lange et al., 2018). Representations of predicted stimuli have been found in the HC (Clarke et al., 2022; Kok & Turk-Browne, 2018), emerging after an implicit association has been learnt (Aitken & Kok, 2022). One possibility to link these findings is that the HC generates and communicates predictions to the sensory cortex via mechanisms used in episodic memory, such as pattern completion and cortical reinstatement (Hindy et al., 2016; McClelland et al., 1995; Rolls, 2013; Treves & Rolls, 1994). Indeed, predictions could exploit the reversal of information flow between the sensory cortex and the medial temporal lobe that has been found for internally-generated information in memory (Linde-Domingo et al., 2019; Staresina & Wimber, 2019; Treder et al., 2021) and mental imagery (Dijkstra et al., 2017, 2019). However, previous studies could not determine whether the HC was responsible for passing these predictions to the cortex.
Here we collected submillimetre 7T fMRI data to measure layer-specific activity in the entorhinal cortex (EC). Layer-specific fMRI allows one to infer the direction of communication between the HC and EC, as EC layers II & III project to the HC, while layer V & VI receive feedback projections from HC. Participants performed a task in which an auditory cue predicted shapes in 75% of trials. Crucially, we omitted the expected shape on 25% of trials, thus isolating the prediction signal from the bottom-up input and allowing us to ask: In which direction are predictions communicated between the HC and neocortex? Using layer-specific informational connectivity analysis, we find that the posterior subiculum sends information specific to the predicted but omitted shapes to the deep layers of the EC. These findings demonstrate that the HC sends prediction signals to the neocortex, adding weight to the suggestion of its pivotal role in generating perceptual predictions.

Title: Illusory surface representation in visually responsive thalamic nuclei

Authors: *A. ARSENOVIC[1,2], M. KREIS[1,2], A. ISCHEBECK[1,2], N. ZARETSKAYA[1,2];
[1]Univ. of Graz, Graz, Austria; [2]BioTechMed-Graz, Graz, Austria

Abstract: Kanizsa figures are visual illusions that induce perception of an illusory surface, which is defined by emerging illusory contours. Responses to illusory Kanizsa shapes can be observed not only in the temporal and parietal cortical areas, but also in early visual cortical areas such as the primary visual cortex (V1). Specifically, there is a signal increase within the topographic representation of an illusory surface. Predictive coding theory explains this signal enhancement through a mismatch between the bottom-up sensory input and the top-down prediction, termed prediction error. Here, we investigated whether visual subcortical regions are also capable of representing illusory content by examining the topographically specific responses to illusory shapes in the lateral geniculate nucleus (LGN) and the inferior pulvinar nucleus of the thalamus using functional MRI. 32 healthy human participants (male = 20, female = 12; age: 18-33, $M = 23.59 \pm 3.04$) took part in the experiment. Participants were instructed to perform one of the two symbol detection tasks (color or symbol identity), during which six flickering circle segments appeared on the screen. The circle segments were oriented such that they either formed an illusory square on one side of the central fixation task or did not form an illusory figure (inverted outwards). Additionally, we presented participants with a functional localizer experiment consisting of a flickering checkerboard located either at the surface representation of the illusory squares or at the background surrounding the squares. This allowed us to define voxels in each area representing illusory surface only. We tested for the presence of illusory surface responses, their topographic specificity and their modulation by task difficulty in the LGN and the inferior pulvinar, including V1 for comparison. Similarly to V1, regions representing the surface of the illusory squares in the LGN as identified by the localizer showed an increased response to illusory Kanizsa squares. This response was contralateral to the illusory surface presentation. Pulvinar also showed an overall increased response to illusory Kanizsa squares, but no spatial specificity with regard to laterality of illusory surface. Illusory responses of all three areas were not affected by task difficulty. These results demonstrate that visually responsive thalamic nuclei can represent illusory shapes in a way that is consistent with predictive coding theory. They are also in line with previous studies showing LGN's contribution to higher-level visual processing.

Title: Sources of monosynaptic input to neurons of the paraventricular nucleus of the thalamus that project to the shell of the nucleus accumbens and central extended amygdala

Authors: S. LI, S. LI, *G. J. KIROUAC;
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: The paraventricular nucleus of the thalamus (PVT) sends dense projections to the shell of the nucleus accumbens (NAcSh) and the central extended amygdala composed of the dorsolateral region of the bed nucleus of the stria terminalis (BSTDL) and the lateral region of central nucleus of the amygdala (CeL). Projection specific modulation of these efferent pathways has been shown to regulate appetitive and aversive behavioral responses. The present investigation applied an intersectional monosynaptic rabies tracing approach to quantify the brain-wide sources of afferent input to PVT neurons that primarily project to the NAcSh, BSTDL and CeL as identified by microinjections of an adeno associated virus that transduces Cre recombinase in the retrograde direction. The prefrontal cortex and the ventral subiculum of the hippocampus were major sources of input to the PVT projection neurons. A number of hypothalamic and brainstem regions associated with homeostasis and regulation of body state were also found to be significant sources of input to the projection neurons. These included the dorsomedial, ventromedial, and arcuate nuclei of the hypothalamus and the periaqueductal gray matter, lateral parabrachial nucleus, and nucleus of the solitary tract of the brainstem. Other important sources of input were the thalamic reticular nucleus, lateral septal nucleus, medial preoptic area, and subfornical organ. Analysis of regional sources of afferent input shows that PVT neurons that project to the NAcSh, BSTDL, and CeL receive the largest proportion of its inputs from the limbic cortical areas and the hypothalamus. Neurons in limbic cortical areas are postulated to transmit signals related to the saliency of stimuli and their context to PVT projection neurons that regulate behavior. In addition, hypothalamic and brainstem inputs are proposed to transmit signals related to homeostasis and body state to these same neurons. Recent observations that PVT neurons have axons that bifurcate extensively to divergently innervate the NAcSh, BSTDL and CeL in addition to limbic cortical regions and the hypothalamus suggest that the PVT broadly coordinates neural activity in brain regions that mediate behavioral responses. A convergence-divergence arrangement of inputs and outputs underscores the accumulating evidence that the PVT regulates many types of behavioral responses.

Title: The dorsal hippocampus-medial prefrontal cortex circuitry regulates behavioral despair

Authors: S. YOON, G. CHUNG, W. SONG, S. KIM, ***M.-H. KIM**;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Despair is a core symptom of depressive disorders. However, little is known regarding neural circuits mediating despair and their modulation by antidepressants. Here, we show that neural activity in the dorsal hippocampus (dHP) affects behavioral despair through the projections to the medial prefrontal cortex (mPFC). The antidepressant ketamine rapidly induced anti-despair-like behaviors and enhanced c-Fos expression in both the dorsal and ventral hippocampi. Knockdown of $GABA_A$ receptor gamma 2 subunit gene (Gabrg2) or DREADD-mediated suppression of interneurons in the dHP CA1 area induced anti-despair-like behaviors in mice. Conversely, pharmacological and chemogenetic potentiation of GABAergic transmission in dHP CA1 neurons induced despair-like behaviors. Trans-synaptic tracing of dorsal CA1 neurons with wheat germ agglutinin (WGA)-Cre revealed a monosynaptic connection between the dorsal hippocampus and mPFC. Optogenetic stimulation of CA1 neurons in the dHP induced spike firing and increased c-Fos expression in the mPFC neurons. In addition, the chemogenetic activation of mPFC neurons in the dHP-mPFC circuitry reversed the behavioral despair induced by the activity suppression of the CA1 pyramidal neurons in the dHP. Collectively, these results indicate that neuronal activity in the dHP modifies behavioral despair and contributes to the antidepressant effects of ketamine through the dHP-mPFC circuitry.

Title: Connectional architecture of a mouse hippocampal circuit node controlling stress-induced anxiety responses

Authors: *J. SUN, I. BOWMAN, D. LO, T. BOESEN, M. RUDD, L. GOU, C. CAO, J. GONZALEZ, B. ZINGG, L. GARCIA, S. YAMASHITA, K. MORADI, S. NANDA, Q. ZHAO, N. FOSTER, H. HINTIRYAN, H. DONG;
Neurobio., UCLA, Los Angeles, CA

Abstract: The role of the ventral subiculum (SUBv) in mediating psychological stress coping has been widely acknowledged. However, it still remains unclear for how different neuron types in the SUBv are affected by psychological stress. To address this long-standing question, we inject fluorescent retrograde tracers into different projection targets of the SUBv to label its different populations of projection neurons (PNs). Thereafter, the same group of mice were exposed to acute restraint stress. Using c-fos as neuronal activation marker, we found that PNs neurons in the SUBv activated by acute restraint stress projected to various regions, including the nucleus accumbens (ACB), anterior hypothalamic nucleus (AHN), lateral septal nucleus (LS), and bed nuclei stria terminalis (BST). To validate these findings, we employed a knock-in mouse model featuring activity-dependent genetic labeling (TRAP2) and confirmed the engagement of ACB- and AHN-projecting PNs during acute restraint stress. Additionally, through unbiased collateralization mapping experiments, we found that a subset of SUBv neurons concurrently targeted multiple areas, such as the ACB and AHN. Furthermore, we also characterized neural inputs to stress-activated neurons in SUBv, such as the medial septal nucleus (MSN) and lateral preoptic area (LPO). Finally, in TRAP2 mice, we conducted chemogenetic activation of the SUBv neuronal ensemble, which was tagged by acute restraint stress, leading to the elicitation of anxiety-related behaviors. Conversely, silencing the SUBv ensemble attenuated anxiety-related behaviors induced by restraint stress. These findings highlight the significance of the stress-responsive inputs and outputs of SUBv in unraveling the neural circuitry underlying stress-induced anxiety responses.

Title: Deviance detection in subthalamic neural population responses to natural stimuli in bats

Authors: *J. WETEKAM, J. HECHAVARRIA, L. LÓPEZ-JURY, E. GONZÁLEZ-PALOMARES, M. KÖSSL;
Goethe-University Frankfurt, Frankfurt am Main, Germany

Abstract: Deviance detection describes an increase of neural response strength caused by an improbable acoustic stimulus. This ubiquitous phenomenon has been reported for multiple species, from subthalamic areas to auditory cortex. While cortical deviance detection has been well characterised by a range of studies covering neural activity at population level (mismatch negativity, MMN) as well as at cellular level (stimulus-specific adaptation, SSA), subcortical deviance detection has been studied mainly on cellular level in the form of SSA. Here, we aim to bridge this gap by using noninvasively recorded auditory brainstem responses (ABRs) to investigate deviance detection at population level in the lower stations of the auditory system of a hearing specialist: the bat *Carollia perspicillata*. Our present approach uses behaviourally relevant vocalisation stimuli that are closer to the animals' natural soundscape than artificial stimuli used in previous studies that focussed on subcortical areas. We show that deviance detection in ABRs is significantly stronger for echolocation pulses than for communication calls or artificial sounds, indicating that subthalamic deviance detection depends on the behavioural meaning of a stimulus. Additionally, complex physical sound features like frequency- and amplitude-modulation affected the strength of deviance detection in the ABR. In summary, our results suggest that at population level, the bat brain can detect more complex violations of regularity than simple frequency changes already in the brainstem. To achieve this, neural populations integrate different features of the input, exhibiting more complex forms of deviance detection than single neurons in subthalamic brain areas.

Title: Encoding valence and arousal in the human brain; amygdala stimulation drives a circuit activating the anterior cingulate cortex

Authors: *P. M. KASKAN[1], S. BEKER[1], J. I. BERGER[3], C. K. KOVACH[4], E. N. ESKANDAR[2], H. OYA[5];
[2]Neurosurg., [1]Albert Einstein Col. of Med., Bronx, NY; [3]1800 JPP, 200 Hawkins Drive, Univ. of

Iowa, Iowa City, IA; [4]Neurosurg., Univ. of Iowa, Iowa City, NY; [5]Univ. of Iowa Hosp. and Clinics, Univ. of Iowa Hosp. and Clinics, Iowa City, IA

Abstract: Using intracranial electrical stimulation of the amygdala in humans to drive a circuit including the anterior cingulate cortex, we sought to experimentally determine how the amygdala and cingulate interact during the appraisal of, autonomic responses to, and choices between alternative affective stimuli. Human subjects undergoing intracranial recordings for the treatment of drug-resistant epilepsy viewed and rated a luminance-balanced set of affective images on scales of valence and arousal. Valence ratings were used to curate 2-alternative, forced-choice trials per-subject that varied parametrically by valence difference (i.e. conflict). We collected eye movement data and pupillometric responses during the Viewing and Rating task and the Affective Choice task during neural recordings. In the Affective Choice task, choice reaction times (RTs) varied as a function of conflict (i.e. valence difference). Choice RTs on conflicting trials were significantly slower than those on non-conflicting trials. We found a weak effect of the overall valence of the choice pair on RT, with low valence offers slowing RT to a greater degree than high valence offers. To pursue the role of the amygdala in the appraisal of, autonomic responses to, and choices between alternative affective stimuli, we used an electrical stimulation fMRI (es-fMRI) database to identify areas activated by amygdala stimulation, and to confirm the amygdala's role in driving inputs with the identified stimulation parameters. fMRI analyses indicated amygdala stimulation increased blood-oxygen level dependent (BOLD) responses in large portions of the anterior cingulate, and to a lesser spatial extent, the orbitofrontal cortex. Using the same amygdala stimulation parameters, we delivered stimulus-locked and decision-locked stimulation to the amygdala during the Viewing and Rating task and the Affective Choice task to determine the role of the activated amygdala-cingulate circuit on the appraisal of affective stimuli and how such stimuli influence action control during decisions.

Abstract: Introduction: The positive effects of exercise and meditation on mental health are widely recognized. Previous studies in adult and animal models have indicated that acute exercise leads to increased levels of circulating endocannabinoids (eCBs), potentially explaining the observed mental health benefits such as anxiety reduction. However, the impact of acute exercise and meditation on eCBs in youth remains unexplored. Given that mental health issues often emerge during childhood and adolescence, which coincides with developmental changes in eCB signaling, investigating this relationship is crucial.
Methods: In this randomized controlled trial, data were collected from 36 youth (50% female, aged 9-17) as part of an ongoing study in the Metro Detroit area. Participants were randomly assigned to one of three 30-minute conditions: (1) moderate-intensity treadmill exercise (N=15), (2) light-intensity stretching (N=12), or (3) seated meditation (N=9). State anxiety and circulating eCB concentrations were measured before and after the condition.
Results: Significant reductions in anxiety scores were observed from pre-session to post-session across all three conditions ($p<0.002$). However, there were no significant main effects of condition, nor significant time by condition interaction on anxiety scores ($p=0.82$). While anandamide, an eCB, exhibited higher concentrations after the treadmill exercise, these differences did not reach statistical significance ($p>0.05$).
Discussion: Our findings highlight that both light and moderate-intensity exercise, along with meditation, are associated with decreased state anxiety in youth. While the differences in circulating eCBs did not reach statistical significance, preliminary analyses suggest a potential elevation in eCB levels following moderate-intensity exercise. Physical activity and meditation could serve as low-cost, low-risk behavioral interventions in conjunction with pharmacotherapy or psychotherapy for addressing mental health issues in young individuals.

Title: The effect of a psychoeducational session on stress and treatment adherence in patients with breast cancer.

Authors: A. RODRIGUEZ-MONTERO[1], R. CASTILLO-LÓPEZ[2], **T. CIBRIAN-LLANDERAL**[1], O. GALINDO-VASQUEZ[3], *S. MORALES[2];
[1]Inst. de Neuroetologia, [2]Univ. Veracruzana, Xalapa, Mexico; [3]Inst. Nacional de Cancerologia, CDMX, Mexico

Abstract: Cancer is one of the most relevant diseases today, due to its incidence, prevalence, and mortality. The diagnosis of breast cancer often presents significant challenges in various areas of life. The disease itself, events following the diagnosis, and treatments can have an impact on physical, psychological, economic, and social levels. These effects can manifest as family problems, financial difficulties, stress, anxiety, depression, fear of recurrence, among others. Additionally, it has been reported that because of the physical and emotional events faced by cancer patients, stress response mechanisms are activated, mainly in the hypothalamic-pituitary-adrenal (HPA) axis, which is responsible for releasing certain catecholamines, including cortisol. The objective of this project is to design and implement a psychoeducational session that allows for the reduction of stress levels in patients, provides them with the necessary tools to develop behaviors that promote adherence to oncological treatment, to identify the most vulnerable patient groups to prioritize their care. A descriptive, quasi-experimental study with pre-test and post-test will be conducted, consisting of two randomly assigned groups: an intervention group and a control or waitlist group. The Perceived Stress Scale (PSS-10), Measure of Current Status Scale (MOCS), and the Therapeutic Adherence Scale for Breast Cancer Patients (EAT-CaMa) will be used as evaluation instruments.
30 participants were evaluated, of which 2 were excluded because they did not meet the inclusion criteria. The Kolmogorov-Smirnov test for normality was used, and non-normal data were obtained, so the Spearman correlation test was used. The dimensions of treatment adherence from the EAT-CaMa Scale were correlated with perceived stress and the dimensions of the Measurement of Current State (MOCS) scale. The results were statistically significant between ease of relaxation and treatment side effects and physician-patient communication (P=0.048). Similarly, perceived stress showed significant relationships with coping strategy dimensions (P=0.002), self-efficacy (P=0.021), perception of social support (0.032), and assertiveness regarding needs (P=0.036). The perception of attention from others showed significant results in relation to self-efficacy (P=0.010). These results provide important information about the relationships between the evaluated dimensions in your study and may have implications for treatment adherence and stress management in the participants

Title: Novelty-based fear extinction in people with social anxiety

Authors: *L. BUDGE[1], S. SKLENARIK[1], P. LONG[1], L. KLIN[1], M. SHRESTHA[1], M. ASTUR[1], H. POSADA-QUINTERO[1], K. TREADWELL[1], D. F. TOLIN[3], R. S. ASTUR[2]; [2]Dept. of Psychological Sci., [1]Univ. of Connecticut, Storrs, CT; [3]Anxiety Disorders Ctr., Inst. of Living, Hartford Hosp., Hartford, CT

Abstract: Social anxiety disorder (SAD) has one of the highest lifetime prevalence rates of all psychological disorders (~12% in the general population; Kessler et al., 2005). If left untreated, SAD follows a chronic and debilitating course (Grant et al., 2005). Exposure, which is a key component of cognitive behavioral therapy (CBT) for SAD, has benefited greatly from our understanding of fear extinction protocols. Importantly,, not all individuals experience reduced social anxiety following the extinction phase of exposure therapy. Recent research has focused on improving extinction practices for the better long-term elimination of conditioned behaviors. One such study demonstrated that extinction efficacy could be increased by replacing a shock with a novel innocuous tone (Dunsmoor et al., 2015). However, novelty-based extinction has not been tested in populations with SAD. Accordingly, the purpose of the current study is to determine the efficacy of a novelty-based extinction model in reducing acquired fear in individuals with moderate to severe social anxiety. Twenty-seven undergraduates with moderate to severe social anxiety were recruited. Participants were conditioned to fear one of two angry faces (adapted from Dunsmoor et al., 2015) by pairing one of the faces with aversive electrical stimulation to the forearm. Participants then underwent a standard extinction protocol (shock omission) or an augmented extinction protocol (shock omission + novel tone). Reinstatement was tested after extinction. Physiological fear measures were obtained via electrodermal response and psychological aversion to the faces were obtained via a visual analogue scale. Initial analyses indicate that participants in both groups underwent similar extinction. However, during reinstatement, participants in the novelty-based extinction condition showed significantly enhanced fear reduction to the fearful face compared to participants in the standard extinction condition ($p < 0.001$). We will also report how severity of SAD correlates with these fear reductions and describe sex differences in extinction efficacy. Subsequent studies will focus on the longevity of the extinction effects and clinical implications of a novelty-based extinction process within exposure therapy procedures.

Title: Functional Connectivity of the Locus Coeruleus with Bilateral Insula is associated with increased Anxious Arousal in Anxiety Disorder and PTSD

Authors: *P. T. NEUKAM[1], S. BOUKEZZI[1], Y. JACOB[1], Y. I. WHITAKER[1], P. BALCHANDANI[2], L. MORRIS[1], J. MURROUGH[1];
[1]Psychiatry, [2]Diagnostic, Molecular, and Interventional Radiology, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Anxiety and stress related disorders are among the most prevalent neuropsychiatric conditions in the United States, with pathological anxiety symptoms such as anxious arousal and fear being core features. Preclinical studies suggest that increased tonic activation of locus coeruleus (LC), a brainstem nucleus primarily responsible for the synthesis of norepinephrine in the brain, together with other brain regions is related to anxiety related behaviors. In humans, establishing a role for the LC in pathological anxiety and linking it to clinical measures of anxiety remains a challenge due to the technical limitations of 3-Tesla MRI. Therefore, the aim of this study was to use ultra-high field 7-Tesla (7T) imaging and seed-based resting-state functional connectivity (RSFC) from the LC to the whole brain and relate the connectivity measures to anxious arousal (AA), a core feature of pathological anxiety and PTSD. Data were collected using a 7T Siemens Magnetom MRI and consisted of patients with anxiety-related (ANX) disorders (N=20), PTSD (N=13), and healthy controls (N=27). Individual LC masks were created from a magnetization transfer scan with 400μm³ resolution using an in-house developed unsupervised Gaussian mixture model machine learning algorithm for segmentation. Resting-state data were collected with 1.5 mm³ (16 subjects with 2.5 mm³) resolution, preprocessed and denoised using multi-echo independent component analysis implemented in *afni*. The LC masks were coregistered to EPI space and voxel wise Fisher-Z correlation coefficients from the LC mask to whole brain were computed for a seed-based RSFC analysis using *afni*. AA was measured with the Mood and Anxiety Symptom Questionnaire. A one-sample t-test was conducted on the group level on the correlation maps with SPM12 that included AA, gender and age as regressors. We found significant bilateral clusters RSFC of the LC with the insula (left: $p < 0.001$ k(FWE corr.); right: $p < .05$ k(FWE corr.)) that positively correlated with AA (left insula $r = 0.572$, $p = .001$, right insula $r = 0.484$, $p = .004$) in ANX and PTSD patients. There was no difference, however, between the anxiety and PTSD groups for both insula regions. This is the first study using 7T imaging to show that the strength of the functional coupling between the LC, a crucial region implicated in anxiety, and the insula, a region that has been suggested to represent anxiety sensitivity and individuals having high anxiety sensitivity may be susceptible to anxiety disorders. Our results provide a biological mechanism for this perspective in a way that the functional coupling between the LC and insula is related to AA, a core feature of pathological anxiety.

Title: Structural insights into human brain-gut peptide cholecystokinin receptor-1

Authors: *Y. DING;
Zhejiang Univ., jiangsu, China

Abstract: Cholecystokinin (CCK) receptor family belongs to class-A sevenfold transmembrane G protein-coupled receptors, and is divided into CCK1 receptor (CCK1R) and CCK2 receptor (CCK2R). CCK1R is mainly distributed in the gastro-intestinal tract, peripheral nervous system, and some regions of the brain, e.g., the area postrema, the nucleus tractus solitarius, and the hypothalamus. This paper, we reported 2 high-resolution cryo-EM structures of CCK1R signaling complexes. The structures, together with mutagenesis studies, revealed distinct features of the CCK1R ligand-binding pockets that determine CCK1R selectivity for sulfated CCK-8 and SR146131.

Title: Examining error-related negativity as a neural marker for anxiety among college students

Authors: A. BARSEGYAN[1], **G. GUZMAN**[1], *J. SCHINDLER[2], L. APAR[1], S.-M. KANG[1];
[1]Psychology, [2]California State Univ. Northridge, Northridge, CA

Abstract: Making mistakes can induce anxiety and is inevitable throughout human nature. Accordingly, Error-Related Negativity (ERN) is an event-related potential component that appears when an individual makes erroneous responses. Previous literature suggests that ERN is a neural marker for anxiety and is measured through electrical impulses of brain wave activity. There is a notable difference between the ERN and the neural potential to correct responses, known as the Correct-Response Negativity (CRN). This response to error commission is associated with an adaptive, evolutionary mechanism that allows humans to allocate more cognitive resources for future responses. We hypothesized that students who exhibited an enhanced ERN would be associated with reporting more anxiety-related symptoms. To further elucidate on the relationship between heightened ERN amplitude and anxiety, a total of 22 college students with diverse ethnic backgrounds were asked to fill out stress and anxiety measures and then take the flanker task while their brain waves were recorded. The effects of non-interpersonal stressors such as academic performance and financial hardships were also surveyed to potentially interact with ERN. The results showed that the participants with higher ERN over CRN tended to report more achievement-related stress and panic symptoms, suggesting that this neural marker is associated with anxiety symptoms among college students.

Title: Anxiety prevalence between nurse students of 6th grade and 8th grade

Authors: R. B. GONZÁLEZ-GARCÍA[1], M. D. VALLECILLOS BANDA[1], M. E. BARRETO-ARIAS[1], M. FERNÁNDEZ-MOYA[1], *O. JARAMILLO-MORALES[2];

Abstract: Anxiety levels in students are related to various factors that surround the social, emotional, family and academic environment. The objective of this article was to know the prevalence of anxiety that exists among nursing students of the last two years of the Life Sciences Division. The study was carried out in a sample of 60 students: 30 sixth-semester students and 30 eighth-semester students, to whom the STAI questionnaire was applied: Anxiety-Trait Inventory to assess transitory emotional state, and the Hamilton Scale to assess physical symptoms. Data collection was obtained through the Google Forms platform. The results reveal that eighth-semester Nursing students have high anxiety rates compared to sixth-semester students, despite the fact that they also have moderate anxiety. These results suggest that the last year of the Nursing Degree is related to higher levels of anxiety, hence it is

necessary to analyze the implementation of counseling and workshops to teach students to deal with stressful situations

Title: Supplementation with whey peptide rich in β-lactolin improves mood states in healthy adults: A randomized, double-blind, placebo-controlled study.

Authors: *T. AYABE[1], M. SHINOHARA[2], J. SAITO[3], T. FURUYASHIKI[2], K. TOBA[4], S. UMEDA[5], Y. ANO[1];
[1]Kirin Holdings Company, Limited, Fujisawa, Japan; [2]Kobe Univ., Kobe, Japan; [3]Med. Station Clinics, Tokyo, Japan; [4]Natl. Ctr. for Geriatrics and Gerontology, Tokyo, Japan; [5]Keio Univ., Tokyo, Japan

Abstract: Background: Mental disorders have become one of the most burdensome health concerns, and thus preventive approaches to support mood states in daily life have recently gained attention. We have previously demonstrated that whey-derived glycine-thereonine-tryptophan-tyrosine tetrapeptide, designated as β-lactolin, improves cognitive and psychiatric functions in rodents via activation of dopaminergic system. We have also performed clinical trials and found that supplementation of β-lactolin improves memory function in healthy older adults. However, the effects of β-lactolin on human mood states have not been investigated. **Objective:** The aim of this study was to evaluate the effects of β-lactolin-rich whey peptide supplementation on mood states in healthy adults in a randomized, double-blind, placebo-controlled study. **Methods:** Sixty healthy adults (aged 45 to 64) with relatively low mental health were randomly allocated to receive either whey peptide tablets (containing β-lactolin 1.6 mg/day) or placebo tablets for 6 weeks. Mood states (primary outcomes) were evaluated using self-reporting questionnaires. Health related quality of life (QOL), salivary stress markers and lipid mediators were evaluated as secondary outcomes. **Results:** Compared with placebo, supplementation of β-lactolin for 6 weeks significantly improved the changes in trait anxiety (p = 0.046) assessed by state-trait anxiety inventory and in subjective stress (p = 0.043) assessed in perceived stress scale. In QOL assessment, score changes in vitality subscale (p = 0.033) and mental health summary score (p = 0.039) in 36-Item Short-Form Health Survey were improved in β-lactolin group. The levels of salivary immunoglobulin A were significantly higher in β-lactolin group (p = 0.045). In subgroup analysis by median age (54.5 years), subjective stress and salivary prostaglandin levels were significantly decreased by β-lactolin supplementation in 45-54 years old subgroup. **Conclusions:** Supplementation of β-lactolin improves mood states such as

trait anxiety and subjective stress and psychological QOL, which may be detected by immunological stress markers assessed in salivary analysis.

Title: Music presentation alters the metabolic and physiologic profile in normal subjects and patients within the ICU

Authors: J. MILLARD[1], A. PERELMAN[1], M. D. HANZA[5], A. SCHULMAN[1], P. KOTA[2], A. PATEL[3], J. LANGLEY[1], *J. S. KANWAL[4];
[1]Georgetown Lombardi Arts and Humanities Program, [2]Psychology, [3]Biol., [4]Neurol., Georgetown Univ., Washington, DC; [5]MedStar-Georgetown Transplant institute, MedStar-Georgetown Hosp., Washington, DC

Abstract: Listening to music can either lead to arousal or promote a state of relaxation. Yet, the acoustic, neural, and physiologic parameters and processes that facilitate these effects are not well understood. Here, we tested the hypothesis that a custom music composition can promote healing in patients recovering from liver transplant surgery within an intensive care unit (ICU) in a hospital setting. We also presented music to normal subjects (ages 20 to 50 years) to delineate patient-specific effects from the relatively well-established calming effects of music. The music presented to all consisted of custom,15-minute music sets curated and recorded by an experienced medical musician to promote well-being. Participants' musicality, motivation for music use, and anxiety levels were assessed to evaluate if and how musicality and mental state correlates with individual physiologic changes. Musicality was scored using the standardized music background questionnaire (MUSEBAQ). We obtained cortisol samples from saliva samples ~15 minutes before and after music presentation, and also captured autonomic activity by recording electrocardiography, respiration, photoplethysmography, temperature, and electrodermal activity for 5 minutes before, during, and 5 minutes after music presentation in normal subjects and patients. Results showed a significant decrease in cortisol production in normal subjects ($P < 0.05$; $n = 11$) after music presentation. Music-mediated increases in heart rate variability (HRV), calculated via triangular interpolation of NN intervals (TINN), correlated with the subject's change in cortisol production during music presentation ($n = 7$, $P = 0.0087$).

Individual changes in cortisol production over the course of music presentation were significantly correlated with self-reported use of music as a tool for cognitive regulation (n = 7, P = 0.0218). Detailed analysis in a single patient showed significant changes in multiple cardiac parameters, including HRV, similar to that of normal, healthy subjects. Multidimensional scaling of twenty-five parameters related to HRV in a patient mapped all five instances of the music presentation condition outside of the mixed cluster of baseline conditions before and after music presentation. We propose that listening to music promotes homeostasis by transiently shifting physiological parameters towards a state of recovery that may stabilize over time.

Title: Effects of childhood trauma on brain multiregional transcriptomics in subjects with posttraumatic stress disorder and major depressive disorder.

Authors: *M. SOLIVA ESTRUCH[1,2,3], C. CHATZINAKOS[1,2], C. SNIJDERS[1,2], C. PERNIA[1,2], C. DIPIETRO[1], A. IATROU[1,2], G. KENIS[3], B. RUTTEN[3], C. B. NEMEROFF[4], J. KLEINMAN[5], K. RESSLER[1], N. DASKALAKIS[1,2];
[1]McLean Hosp., Belmont, MA; [2]Broad Inst., Boston, MA; [3]Maastricht Univ., Maastricht, Netherlands; [4]Psychiatry and Behavioral Sci., Univ. of Miami Miller Sch. of Med., Miami, FL; [5]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Background. Childhood trauma (CT) is known to have long-term effects on mental health by altering the development and plasticity of the neural circuitry, which can precipitate the onset of Major Depressive Disorder (MDD) and Posttraumatic Stress Disorder (PTSD). However, the long-term effects of CT on the molecular profiles in human brains remains largely unknown. **Methods and Results per aim.** Using human postmortem brain tissue, our first aim studied the effects of CT on bulk transcriptomic profiles of subjects with MDD and/or PTSD in three stress-processing regions [dorsolateral (dl)PFC, medial (m)PFC, and central amygdala (CeA)]. We compared bulk RNA sequencing (RNAseq) data between subjects with MDD/PTSD without CT (MDD/PTSD-*CT*; n= 92 for dlPFC and 87 for mPFC and CeA) or with CT (MDD/PTSD+*CT*; n= 64 and 67, respectively) and controls (CTR) (n=77 and 74) using *limma differential expression* analyses. We obtained differentially expressed genes (DEGs) between MDD/PTSD-CT vs CTR and MDD/PTSD+CT vs CTR and compared the DEGs with *Rank-Rank Hypergeometric Overlap test*. DEGs were the least overlapping in the dlPFC (rho = 0.534) followed by CeA (rho= 0.639) and mPFC (rho= 0.738). Due to the high variability of cell types within these brain regions, our second aim explored how changes in gene expression in

excitatory (Ex) and inhibitory (In) neurons in subjects with PTSD related to our bulk findings. We *correlated* our bulk dlPFC results with single nucleus RNAseq data from Chatzinakos et. al. (AJP, in press) on the dlPFC transcriptomic profiles of subjects with PTSD (n= 11) vs CTR (n= 11). Results showed negative correlations between MDD/PTSD+CT signatures and PTSD Ex (r= 0.204; p-val= 0.0016) and In (r= 0.335; p-val= 1.620e-5) neurons, and positive correlations between MDD/PTSD-CT and these cell types (r= 0.386; p-val= 0.002 and r= 0.104; p-val= 0.123, respectively). Our last aim studied the involvement of glucocorticoid receptor (GR)-dependent pathway on CT effects in bulk tissue. We *correlated* our bulk results from dlPFC, mPFC and CeA with RNAseq data from human induced pluripotent stem cells (iPSC)-derived neurons exposed to dexamethasone (DEX, a synthetic glucocorticoid with high GR-affinity) by Chatzinakos et. al. Results showed that the dlPFC bulk MDD/PTSD+CT signature is the only negatively correlated with GR-mediated transcriptomic changes in DEX-exposed iPSC-derived neurons (r= 0.189; p-val= 0.0029). **Conclusions.** Based on these results, we concluded that exposure to CT in the context of MDD/PTSD has a specific effect, distinct from the overall disorder, in the transcriptomic profile of PFC subregions and amygdala, which is more prevalent in the dlPFC.

Title: Prospective memory deficits predicted by depression and PTSD severity in treatment-seeking veterans

Authors: D. STALEY[1], S. KUNRATH[2], R. ASARNOW[3], D. THRASHER[2], ***B. J. KNOWLTON**[1];
[1]Psychology, [2]Operation Mend, [3]Dept of Psychiatry and Biobehavioral Sciences, Semel Inst. for Neurosci. and Human Behavior, UCLA, Los Angeles, CA

Abstract: Treatment-seeking veterans often present comorbidities that may contribute to the cognitive deficits they experience, including prospective memory (PM) deficits. Failures in PM contribute to everyday functional impairments and many veterans demonstrate low performance in PM tasks, making it a worthwhile target for intervention. This study investigates the predictive value of common comorbidities: depression, PTSD, and traumatic brain injury (TBI) to PM deficits. Data was collected from 66 treatment-seeking veterans prior to their participation in

UCLA Operation Mend: a two-week intensive treatment in which they will receive individual training sessions to address their cognitive deficits as well as other mental health and TBI-related treatment. This study contains data from 51 males and 12 females (3 no response/decline to answer) between the ages 25 and 63, with an average age of 43.5. Veterans completed the PM concerns questionnaire (PMCQ), Patient Health Questionnaire (PHQ-9), PTSD Checklist (PCL-5), and self-reported traumatic brain injury history. A stepwise regression procedure was conducted, in which age, depression symptomatology (PHQ-9), PTSD severity (PCL-5), and self-reported history of TBI were used to predict PM deficits, measured by scores on the PMCQ. Only depression and PTSD severity were found to predict PMCQ scores, while TBI history and age failed to significantly predict PM deficits. There was a significant positive Pearson correlation between the PM deficits and PTSD symptom severity $r(64)= .46$, $p <.001$ and a significant positive Pearson correlation between PM deficits and depression symptom severity, $r(64)= .47$, $p<.001$. As a follow up to these findings, a series of stepwise regressions were conducted to investigate which domains of symptomology in PTSD and depression are predictive for PM deficit severity. For PTSD, only the Criterion E: Arousal and Reactivity sub-score was found to be significantly predictive of PMCQ scores. Specifically, the symptoms, both within the arousal domain, of "taking too many risks or doing things to cause themselves harm" and "having difficulty concentrating" were predictive of PM deficits. For depression, only items querying fatigue and psychomotor agitation, or retardation were significantly predictive of PMCQ scores. This study demonstrates that PTSD and depression symptom severity are possible predictors of PM deficits in treatment seeking veterans and provides specific symptoms as possible targets for intervention to reduce PM deficits. This reinforces the value of an integrated, multi-disciplinary treatment approach to improve cognitive problems, in particular PM.

Abstract: Military veterans and service members are uniquely susceptible to a variety of mental health disorders, with post-traumatic stress disorder (PTSD) being the most prevalent. It is estimated that 11-23% of veterans will experience PTSD in a given year. Additionally, it has been observed that up to 53% exposed to combat will have a dual diagnosis of PTSD and alcohol use disorder (AUD). The effects of PTSD and SUD individually are well established; however, effects of the co-occurring condition are not understood as clearly. The present study examined brain function in individuals completing an intensive substance use treatment program. We hypothesized that co-occurring PTSD and AUD would have both unique and interactive effects on brain function.
Study participants consisted of 47 veterans undergoing substance use disorder treatment at the Salisbury VA Healthcare System (SVAHS), specifically recruited from either a resident or intensive outpatient treatment program. Participants were diagnosed with PTSD via the Clinician Administered PTSD Scale -5 (n-28). All participants were diagnosed with substance use disorder (37 with AUD). Participation in the study occurred in the two weeks following treatment. Functional connectomes were constructed using resting-state brain activity via magnetoencephalography (MEG) whole-head CTF neuromagnometer system. Linear regression determined variables responsible for the variability between outcomes. Variables in the model consisted of PTSD diagnosis, time since last drink, and number of drinks in the two weeks preceding treatment.
Preliminary results indicated several factors that were associated with various features of the connectome. Time elapsed since the last drink was associated with the number of nodes in the connectome, Average Degree of nodes, distribution of frequencies at which connections occur across the connectome, and the proportion of connections in the gamma band. Interestingly, no significant effects of PTSD on the connectome were detected. Overall, the results suggest that recent heavy use of alcohol has the most significant effect on the connectome at the end of a treatment episode.

Title: Posttraumatic Stress and Whole-brain Magnetic Resonance Spectroscopy

Authors: *A. BOLARAM[1], J. B. PURCELL[1], H. E. DARK[1], D. K. GREY[1], A. J. KNIGHT[2], D. C. KNIGHT[1];

Abstract: Posttraumatic stress disorder (PTSD) develops following exposure to a traumatic event and has a negative impact on cognitive and affective processes. Neuroimaging studies suggest the symptoms of PTSD are associated with structural and functional alterations in brain regions that support important emotional processes. H^1-Magnetic resonance spectroscopy can advance our understanding of PTSD by identifying brain metabolites that are associated with PTSD symptoms. Therefore, the present study assessed neurometabolite concentrations among participants who reported PTSD symptoms (n = 25, [23 female], Mean Age = 22.7) and healthy controls (n=20, [15 female], Mean Age = 27.55) determined by the Clinician administered PTSD scale for DSM-5 (CAPS-5). Whole brain magnetic resonance spectroscopy and high resolution T1-weighted anatomical images were collected using a 3T Siemens Prisma scanner. Whole brain magnetic resonance spectroscopic imaging was performed using a 3D-echo-planar spectroscopic imaging sequence. Neuroimaging data were processed using a fully automated pipeline, which included spatial and spectral reconstruction, field inhomogeneity and eddy current correction, tissue segmentation, registration to the Montreal Neurological Institute template, and voxel-wise spectral fitting using LC-Model followed by intensity normalization of the spectral peaks. The resulting whole-brain data included metabolite maps of N-acetylaspartate (NAA), glutamate/glutamine (Glx), total creatine (tCr), total choline (tCh), and myo-Inositol (MINO). Differences in neurometabolite concentrations were assessed between the PTSD and control groups. Results revealed greater Glx in the putamen, parahippocampal gyrus (PHG), and superior temporal gyrus in the PTSD group compared to healthy controls. Lower levels of Glx were observed in the inferior parietal lobule (IPL) and dorsolateral prefrontal cortex (PFC) in the PTSD group. Further, compared to healthy controls, the PTSD group showed elevated levels of NAA in the posterior cingulate cortex (PCC), IPL, thalamus, PHG, and dorsomedial PFC. In addition, the PTSD group showed higher levels of tCr and tCh in PCC, putamen, and insula. The PTSD group also showed higher levels of MINO in the IPL, PCC, and dorsolateral PFC than healthy controls. Lower MINO was also observed within the superior parietal lobe in the PTSD group. These results suggest that variations in neurometabolites may underlie the symptoms of PTSD.

Title: Transgenerational impact of maternal early life adversity on cortical structure and epigenetic age acceleration

Authors: *L. FLEMING[1], A. PROFETTO[1], K. OHASHI[1], S. KATRINLI[2], A. SMITH[2], T. KLENGEL[1], K. J. RESSLER[1], K. LYONS-RUTH[3], M. TEICHER[1];

Abstract: Adversity experienced early in life can produce long-lasting effects on the brain and behavior. For example, previous work shows that childhood maltreatment can lead to compromised structural integrity in sensory regions, as well as regions directly associated with threat-responses. Studies suggest these changes may be partially related to accelerated patterns of aging due to increased allostatic load. Evidence in recent years suggests that these effects have the potential to be intergenerationally transmitted between parents and offspring. However, studies of the intergenerational effects of childhood maltreatment on epigenetic aging have produced varied results, suggesting an importance for understanding the factors that drive variability in the relationship between maltreatment, age acceleration, and brain structure. Here, we investigate this relationship in a deeply-phenotyped cohort of mothers and infants at 4 months and 15 months of age. Structural MRI scans, childhood trauma history, and saliva samples were collected from (n=93) mothers with history of childhood maltreatment and their infant offspring. Individuals who had witnessed multiple episodes of interparental and sibling violence showed lower cortical thickness in inferior occipital cortex and fusiform cortex compared to controls. Epigenetic age acceleration in mothers, calculated from saliva-derived DNA methylation measurements, was significantly associated with that of their infants at 15 months of age. Additionally, we saw significant associations between epigenetic aging and post-natal depression, overall PTSD severity, and a particularly strong association with measures of abuse. These findings serve as indicators of both macroscale brain effects and microscale epigenetic effects of early life adversity. Together, these results demonstrate the long-lasting impact of childhood maltreatment on underlying biology and point toward potential intergenerational transmission of these effects.

Title: Topological data analysis reveals the impact of sleep, pain, and social function on persistent PTSD symptoms in veterans from the Mind Your Heart study

Authors: *A. E. INGEBRETSON[1,2], T. KIRSH[1,3], S. MA[1,3,4], E. KUMMERFELD[1,3], A. R. FERGUSON[5,6,9], T. C. NEYLAN[5,9,7], B. E. COHEN[5,9,8], J. L. NIELSON[1,3,2];

Surgery, [7]Dept. of Psychiatry & Behavioral Sci., [8]Dept. of Med., [5]Univ. of California San Francisco, San Francisco, CA; [9]San Francisco VA Med. Ctr., San Francisco, CA

Abstract: Introduction: Posttraumatic stress disorder (PTSD) affects up to 5% of the US population. Heterogeneity and evolution of PTSD symptoms over time requires identifying complex patterns and subtypes in large-scale clinical datasets, which can be computationally intense. Topological data analysis (TDA) is a topological and geometrical approach for reducing complex, high-dimensional data into its fundamental structure, which leads us to generate new hypotheses about what impacts persistent symptoms in chronic PTSD. **Methods**: Data were mined from the Mind Your Heart study, a longitudinal prospective cohort study of US military veterans consisting of multidomain data collected at baseline and 10 years of annual follow up (N = 746). Using a subset of data comprising measures of PTSD, depression, alcohol consumption, overall health, general physical functioning, and quality of life across all years (n=208), dimension reduction was performed using the non-linear Isomap algorithm with persistent homology. A network graph was then extracted from this low-dimensional space, forming five patient clusters. Variables collected across all 10 years were assessed for differences between selected clusters using ranked Kolmogorov-Smirnoff (KS) tests to identify features with potential clinical relevance to chronic PTSD. **Results**: From these five patient clusters we observed two clusters with high PTSD symptom severity at baseline, where one cluster had clinically significant improvement in depression and PTSD whereas the other did not at year 10 follow up. From the list of rank sorted KS results, given the known impact of poor sleep quality, pain, and social dysfunction on PTSD symptomology, we compared patients in these clusters on self-reported measures of these domains. Patients with persistent PTSD showed an interaction between sleep quality and pain which interfered with social relationships and mood at year 10. In contrast, patients with improving PTSD had a greater influence of social function across years 8 - 10 of the study while reporting greater social support resources. Following correction for multiple
comparisons, only pain interference with social relationships at year 10 and variables already used to define the TDA network differed significantly between these clusters, indicating that the impact of pain on social relationships may be an important factor in chronic PTSD. **Discussion**: In this study we show that chronic PTSD is exacerbated by sleep, pain and availability of social support; however this is more of a factor in the years preceding symptom progression, rather than earlier symptoms predicting those that occur many years later.

Title: Examining multimodal magnetic resonance imaging features for symptom assessment and prediction in veterans with chronic multisymptom illness

Authors: *M. MOORE[1,2], Y. ZHANG[1], P. J. BAYLEY[1,2], J. W. ASHFORD[1,2], A. J. FURST[1,2]; [1]War Related Illness and Injury Study Ctr., Veterans Affairs Palo Alto Hlth. Care Syst., Palo Alto, CA; [2]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The neural correlates of many health conditions veterans experience post-deployment, such as chronic multisymptom illness (CMI), post-traumatic stress disorder (PTSD), and traumatic brain injury (TBI), remain unclear. Multimodal brain imaging approaches allow for the possibility of investigating the neural correlates of complex, and potentially coexisting, health conditions in comprehensive ways by jointly characterizing features of the brain. Therefore, the present study examined multimodal features of structural and diffusion magnetic resonance imaging data from veterans and healthy controls (HC). Veteran data were acquired at the War Related Illness and Injury Study Center (n = 181), and HC data were acquired from a public research database (n = 122). Targeted examples of veteran-relevant health conditions, including CMI, PTSD, and TBI symptoms, were assessed based on screening information obtained from participants. Among veterans who met criteria for CMI, subgroups endorsed symptoms of PTSD, TBI, both PTSD and TBI, or neither. Multimodal data fusion was performed to integrate gray matter volume and fractional anisotropy maps. Results identified components consistent with cortical and subcortical systems in veterans and HC across imaging modalities. Anatomical patterns revealed by components indicated that veterans who endorsed symptoms showed modulated regions within distributed brain systems. Further analyses expanded on these findings using machine learning to predict health condition symptoms. Together, the present results support the idea that multimodal biomarkers of conditions such as PTSD and TBI, comorbid with CMI, can be captured and characterized to better elucidate the neural correlates of chronic health conditions in veterans.

Abstract: Posttraumatic stress disorder (PTSD) is a mental health disorder caused by experiencing or witnessing traumatic events. PTSD symptoms include intrusive memories, avoidant behaviors, anxiety, flashbacks and negative changes in mood and cognition. Symptom severity is measured using the Clinician-Administered PTSD Scale for DSM-5 (CAPS-5). Recent studies show that patients with PTSD have an increased risk of developing Alzheimer's disease (AD), but there is currently no way to predict which patients will go on to develop AD. We previously developed a machine learning-based AD designation (MAD) algorithm to objectively distinguish neural activity between AD patients and healthy controls (HC) using neuroimaging modalities.[1] The objective of this study is to identify brain anatomical and activity markers in PTSD that may relate to potential increased risk of developing AD. 67 participants were recruited from a clinical trial performed by our lab for treatment-seeking PTSD individuals and age-matched HC (PTSD: n = 40; 14M:26F; age = 40.0 ± 3.6; HC: n = 27; 11M:16F; age = 35.4 ± 5.2). We calculated MAD scores for each participant using pseudo-continuous arterial spin labeling (pCASL) data. We assessed grey matter (GM) volume using voxel-based morphometry of structural MRI data. Correlations between MAD scores, CAPS-5 scores, and GM volume were assessed using SPSS. A significant reduction of GM in the temporal lobe was observed in the PTSD group compared to HC (pFWE= 0.006). Additionally, MAD scores significantly correlated with CAPS-5 scores in the PTSD group (Pearson's r = 0.363, p = 0.021). GM volume inversely correlated with CAPS-5 scores in the PTSD group (Pearson's r = -0.428, p = 0.006). PTSD participants who demonstrated increased symptom severity correlated with increased GM atrophy and increased AD-like brain activity. PTSD patients demonstrated significant GM atrophy in the medial temporal lobe, one of the earliest markers for AD progression.[2] These results show promising potential for early diagnosis of AD in an at-risk population, in the hopes for allowing for an early treatment method. 1. Title: White matter microstructure in posttraumatic stress disorder

Authors: *C. A. SANDERS[1], A. BOLARAM[1], D. K. GREY[1], H. E. DARK[1], J. B. PURCELL[1], A. J. KNIGHT[2], D. C. KNIGHT[1];
[1]Psychology, [2]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Posttraumatic Stress Disorder (PTSD) is associated with the dysfunction of emotion expression and regulation processes. These emotional processes are associated with a neural network that includes the prefrontal cortex, inferior parietal lobule, hippocampus, amygdala, and hypothalamus. These brain regions are connected by white matter tracts that include the superior longitudinal fasciculus, cingulum bundle, uncinate fasciculus, and stria terminalis/fornix. Therefore, determining the relationship between posttraumatic stress and the microstructure of these white matter tracts may offer new insight into the neurobiological processes that underlie PTSD. The present confirmatory study examined the relationship between white matter microstructure and posttraumatic stress. Forty five participants (PTSD = 15; Controls = 30; M_{age} = 26.7 years; SD = 11.8) were recruited for this study. Participants completed the Life Events Checklist and Clinician-Administered PTSD Scale for DSM-5. Diffusion-weighted magnetic resonance imaging (TR = 3230 ms, TE = 89.2 ms, FOV = 210 mm^2, matrix size = 140 x 140, 1.5 mm isotropic resolution) was acquired in 98 directions (b = 0, 3000 s/mm^2). Voxel-wise cross-subject analysis of white matter fractional anisotropy (FA) data was completed using Tract-Based Spatial Statistics. We hypothesized that FA would be greater within the stria terminalis/fornix, but lower in the superior longitudinal fasciculus, cingulum bundle, and uncinate fasciculus in participants with PTSD compared to healthy controls. We also hypothesized that FA would vary with PTSD symptom severity (positively: stria terminalis/fornix; negatively: superior longitudinal fasciculus, cingulum bundle, and uncinate fasciculus). Results showed greater FA in the uncinate fasciculus and stria terminalis/fornix in participants with PTSD compared to healthy controls. In addition, PTSD symptom severity was positively related to stria terminalis/fornix FA and negatively related to cingulum bundle FA. These results suggest that differences in the white matter of the cingulum bundle, uncinate fasciculus, and stria terminalis/fornix may underlie symptom expression in PTSD.

Title: Predicting resiliency and vulnerability factors of post-traumatic stress disorder using long term mirna changes in a large military cohort - millennium cohort study

Authors: *N. GARY[1,2], A. LAWRENCE[1,3], R. YANG[1], A. GAUTAM[1], C. J. DONOHO[4], T. M. POWELL[4], A. HOKE[1], G. DIMITROV[1], M. JETT[1], R. HAMMAMIEH[1];

Abstract: Post-traumatic stress disorder (PTSD) can be a debilitating disorder associated with considerable morbidity; therefore, it is critical to determine resiliency and vulnerability factors for long-term outcomes associated with PTSD including comorbidities (depression, substance abuse, pain syndromes) as well as functional health status. The purpose of this study is to discover microRNA (miRNA) signatures corresponding to different trajectories of PTSD symptoms and associated comorbidities. This study investigates whether the use of miRNA profiles can have a predictive effect on the changes in symptom severity (i.e., physical, social, emotional functioning) across individuals, as well as also differentiating between individuals who screen positive for PTSD versus those who do not. The Millennium Cohort Study is a large military prospective study conducted since 2001, with the goal of assessing the health of military personnel. 352 participants were screened for PTSD using the PTSD CheckList - Civilian Version (PCL-C). Blood samples (N = 1036) were collected and assayed for miRNA profiles using next-generation sequencing (NGS) techniques. Four differential analyses were conducted to compare post-deployment PTSD and healthy controls using pre-deployment samples between those who developed PTSD after deployment and those did not, and to identify the miRNA profiles associated with the PTSD symptom changes. Our data showed that certain miRNA changed over time in response to the physical and psychological stressors during the deployment of active-duty personnel. Data shows a significant dysregulation of miRNA genes involved in the stress response, inflammation, and oxidative stress were observed between post-deployment PTSD and control groups. The two miRNA that distinguished the groups the most before deployment were hsa-miR-9-5p and has-miR-127-3p. In addition, using PCL-C score, six miRNAs correlated with the changes of measured PTSD severity. Our findings help provide important insights into the impact that psychological and physical stressors experienced by active-duty personnel have on the molecular changes that occur at the miRNA level. These data may be used to inform the development of new therapeutic interventions to prevent or mitigate the effects of these stressors on the health and well-being of military personnel. To confirm and extend these findings, and to examine the resiliency and vulnerability factors for long-term outcomes associated with PTSD including comorbidities, further studies will be required.

Abstract: Post-traumatic stress disorder (PTSD) is a common and disabling psychiatric disorder. Here we present findings from the first proteome-wide study of the postmortem PTSD brain. We performed tandem mass spectrometry on large cohort of donors (N = 66) in two prefrontal cortical areas and found differentially expressed proteins and co-expression modules disturbed in PTSD. Integrative analysis pointed to hsa-mir-589 as a regulatory miRNA responsible for disruptions in neuronal protein networks for PTSD, including the GABA vesicular transporter, SLC32A1. In addition, we identified significant enrichment of risk genes for Alzheimers Disease, major depression, and schizophrenia within PTSD co-expression protein modules, suggesting shared molecular pathology. Our findings highlight the altered proteomic landscape of postmortem PTSD brain and provide a novel framework for future studies integrating proteomic profiling with transcriptomics in postmortem human brain tissue.

Abstract: Posttraumatic stress disorder (PTSD) is a debilitating psychiatric disorder occurring in the aftermath of a highly traumatizing event. The hippocampus is a key component in the "fear" circuitry of the brain, and previous studies have implicated structural and molecular dysfunction in PTSD patients. PTSD is highly comorbid with major depressive disorder (MDD), and the two disorders share genetic, molecular and neurobiological alterations in the frontal cortex and subcortical regions of the brain. Previous work from our lab has identified changes in DNA methylation in the PTSD hippocampus, suggesting epigenetic changes after psychological trauma that may affect gene expression. We therefore endeavored to identify gene expression patterns within the PTSD and MDD hipppocampus. We performed bulk-tissue RNA-sequencing on three hippocampal subfields (dentate gyrus, CA, and subiculum) dissected from postmortem brains of 132 donors (49 PTSD, 43 MDD, 40 non-psychiatric controls). Our analysis reveals distinctive patterns of differential expression and splicing between PTSD and controls. Transcript co-expression analysis identifies hub genes and novel candidates specific to each subregion. Our findings highlight the regional diversity of brain gene expression and provide insights into the molecular mechanisms underlying PTSD and hippocampal function.

Abstract: Post-traumatic stress disorder is a multigenic disorder occurring in the aftermath of severe trauma exposure. Recent studies have begun to detail the molecular biology of the postmortem PTSD brain using bulk-tissue transcriptomic and epigenetic analyses. However, given the array of PTSD-perturbed molecular pathways identified thus far, it is unlikely that a single cell type is responsible. It is therefore necessary to uncover the individual cell types contributing to the molecular pathology of PTSD. We isolated ~1M nuclei from human postmortem dorsolateral prefrontal cortex from cases and controls for single nucleus RNA sequencing (snRNA-seq) across three diagnostic cohorts: PTSD, MDD (Psychiatric control), and neurotypical controls to identify neuronal and non-neuronal cell type clusters and cell type-specific gene expression changes. We tested whether differentially expressed genes and their pathways are enriched for specific biological functions in each cell population. We then performed single cell ATAC-sequencing on nuclei from the same donors as our snRNA-seq, to measure chromatin assembly dynamics in PTSD. We also test whether genome-wide significant SNPs identified from the MVP GWAS of PTSD are associated with gene expression within specific cell types of the DLPFC and whether open chromatin regions were enriched for PTSD risk variants. From 14 distinct cell type clusters we identified over 1100 FDR significant differentially expressed genes and confirmed expression changes of several genes implicated in PTSD pathophysiology by FISH. We found PTSD specific cis-regulatory elements for several genes including *ELFN1*, *MAD1L1*, *CRHR1* and *UBA7*. Integration of large GWAS data from MVP with our snATAC dataset showed enrichment of variants for PTSD and its quantitative clinical traits (hyperarousal, re-experiencing and avoidance) within excitatory and inhibitory neurons. Taken together, this work is the first step in the creation of a cell type-specific atlas of stress disorders. Annotating the postmortem brain genome to characterize risk alleles within specific cell types will help determine which biological processes are most impacted by stress. These findings provide a global picture of the cell type-specific molecular regulatory mechanisms that govern stress effects on the human prefrontal cortex and provides a blueprint for integrating single cell type genomic data to characterize the molecular landscape of other brain regions implicated in traumatic stress.

Abstract: Gene regulation is dynamic and cell type specific. Differences in regulation at various levels (genetic, epigenomic, and transcriptomic) contribute to psychiatric disorders, such as PTSD, by converging on specific biological pathways that have clinical significance. Understanding the neurobiology and molecular mechanisms associated with PTSD will require investigation of gene regulation at multiple levels across multiple brain regions. We generated a multi-omic, postmortem brain dataset comparing PTSD, neurotypical control, and a psychiatric control (major depressive disorder), that includes RNA expression and DNA methylation from the dorsolateral prefrontal cortex, amygdala and the hippocampus. Single nucleus RNA-seq data was generated at cell type-specific resolution with matching bulk-tissue RNA-sequencing for the dorsolateral prefrontal cortex. Targeted methyl-sequencing was performed on the same cohort for the amygdala and hippocampal subregions. We identified differentially enriched pathways in PTSD and MDD that included glucocorticoid signaling, GABA transmission, and inflammation. PTSD risk loci, including *CRHR1*, *ELFN1*, and *MAD1L1*, had differential expression at the RNA and methylation level. PTSD and MDD have unique genomic characteristics and this approach demonstrates how convergent pathways across molecular modalities contribute to stress-associated etiology.

Title: Effect of repetitive transcranial magnetic stimulation on anxiety

Authors: *M. TEFERI[1], M. PATEL[2], A. CASALVERA[1], W. MAKHOUL[1], D. OATHES[1], Y. I. SHELINE[1], N. L. BALDERSTON[3];

Abstract: BACKGROUND: Repetitive transcranial magnetic stimulation (rTMS) treatment protocols have been effective in reducing anxiety symptoms comorbid with depression but have not shown the same efficacy in non-depressed individuals, calling for a novel approach to general anxiety reduction. In this study, intermittent theta burst stimulation (iTBS) will be used to stimulate the right dorsolateral prefrontal cortex (dlPFC) to target regions in the fear/anxiety circuit.
OBJECTIVE: Our aim is to determine the effects of a one-week course of iTBS on anxiety and anxiety-related working memory deficits in comparison to the sham stimulation. METHOD: In this double-blinded, cross-over design, 28 healthy subjects underwent 12 study visits over a 4-week period. They received 4 iTBS sessions, which included ten 60-pulse iTBS trains, over the course of a week with a post-stimulation testing session occurring 24 hours following the final iTBS session. The order of active/sham delivery was counterbalanced across subjects. The effects of the stimulation on anxiety and anxiety-related working memory deficits were assessed using the unpredictable shock-threat paradigm and Sternberg working memory task during threat of shock, respectively. The unpredictable shock-threat task consists of three conditions: neutral or no shock, predictable shock in presence of a cue, or unpredictable shock. In the Sternberg working memory task, letters are shown individually in which subjects have to memorize them in the order presented (maintain) or alphabetically (sort) and respond if a letter and its position in the series is correct or not correct.
RESULTS: Results show that there was a significant main effect in startle responses for both coil and response types. Both fear potentiated startle (FPS) and anxiety potentiated startle (APS) increased after active compared to sham iTBS. Consistent with previous studies, FPS responses were greater than APS responses. For sternberg accuracy and reaction time, there were no main effects of either coils or conditions.
CONCLUSION: Contrary to our hypothesis, these findings suggest that iTBS to the right dorsolateral prefrontal cortex increased anxiety compared to sham stimulation. Future studies can examine the effects of iTBS in anxious patients.

Title: Interleaved TMS/fMRI shows that threat decreases dlPFC-mediated top-down regulation of emotion processing.

Authors: *M. PATEL, M. TEFERI, A. CASALVERA, K. LYNCH, W. MAKHOUL, D. OATHES, Y. SHELINE, N. BALDERSTON;
Univ. of Pennsylvania Dept. of Psychiatry, Philadelphia, PA

Abstract: Background: The right dorsolateral prefrontal cortex (dlPFC) has been indicated to be a key region in the cognitive regulation of emotion by many previous neuromodulation and neuroimaging studies. However, there is little direct causal evidence supporting this top-down regulation hypothesis. Furthermore, it is unclear whether contextual threat impacts this top-down regulation. By combining TMS/fMRI, this study aimed to uncover the impact of unpredictable threat on TMS-evoked BOLD response in dlPFC-regulated emotional networks. Based on the previous findings linking the dlPFC to the down-regulation of emotional network activity, we hypothesized TMS pulses would deactivate activity in anxiety expression regions, and that threat would reduce this top-down regulation.
Methods: 44 healthy controls (no current or history of psychiatric disorders) were recruited to take part in a broader study. Subjects completed the neutral, predictable, and unpredictable (NPU) threat task while receiving TMS pulses to either the right dlPFC or a control region. dlPFC targeting was based on data from a separate targeting session, where subjects completed the Sternberg working memory (WM) task inside the MRI scanner.
Results: When compared to safe conditions, subjects reported significantly higher levels of anxiety under threat conditions. Additionally, TMS-evoked responses in the left insula (LI), right sensory/motor cortex (RSM), and a region encompassing the bilateral SMA regions (BSMA) differed significantly between safe and threat conditions. There was a significant TMS-evoked deactivation in safe periods that was significantly attenuated in threat periods across all 3 regions.
Conclusions: These findings suggest that threat decreases dlPFC-regulated emotional processing by attenuating the top-down control of emotion, like the left insula. Critically, these findings provide support for the use of right dlPFC stimulation as a potential intervention in anxiety disorders.

Title: Threat of shock increases distractor susceptibility during the short-term maintenance of visual information.

Authors: *A. M. CASALVERA[1], M. GOODWIN[3], K. LYNCH[2], M. TEFERI[1], M. PATEL[1], C. GRILLON[3], M. ERNST[3], N. L. BALDERSTON[1];

Abstract: BACKGROUND: Work on anxiety related attention control deficits suggests that elevated arousal impacts the ability to filter out distractors. To test this, we designed a task to look at distractor suppression during periods of threat. We administered trials of a visual short-term memory (VSTM) task, during periods of unpredictable threat, and hypothesized that threat would impair performance during trials where subjects were required to filter out large numbers of distractors.
METHOD: Experiment 1 involved fifteen healthy participants who completed one study visit. They performed four runs of a VSTM task comprising 32 trials each. Participants were presented with an arrow indicating left or right, followed by an array of squares. They were instructed to remember the target side and disregard the distractors on the off-target side. A subsequent target square was shown, and participants indicated whether it matched one of the previously presented target squares. The trial conditions included 50% matches and 50% mismatches, with an equal distribution of left and right targets. The number of target and distractor squares varied systematically, with high (4 squares) and low (2 squares) target and distractor conditions. Trials alternated between periods of safety and threat, with startle responses recorded using electromyography (EMG) following white noise presentations. Experiment 2 involved twenty-seven healthy participants who completed the same VSTM task inside an MRI scanner during a single study visit. The procedure mirrored that of Experiment 1, except for the absence of white noise presentations.
RESULTS: For Experiment 1, subjects showed significantly larger startle responses during threat compared to safe period, supporting the validity of the threat manipulation. However, results suggested that the white noise probes interfered with performance. For Experiment 2, we found that both accuracy was affected by threat, such that distractor load negatively impacted accuracy only in the threat condition.
CONCLUSION: Overall, these findings suggest that threat affects distractor susceptibility during the short-term maintenance of visual information. The presence of threat makes it more difficult to filter out distracting information. We believe that this is related to hyperarousal of parietal cortex, which has been observed during unpredictable threat.

Title: Sex dependent effects of delayed exercise in transgenic rat model of Alzheimer's Disease (TgF344-AD) following adolescent binge-like ethanol consumption

Authors: N. REITZ[1], ***P. NUNES**[2], L. M. SAVAGE[3];
[1]SUNY Binghamton, Binghamton, NY; [2]Binghamton Univ., Binghamton, NY; [3]Psychology-Behavioral Neurosci., SUNY - Binghamton Univ. Behavioral Neurosci., Binghamton, NY

Abstract: There is growing evidence that alcohol-related brain damage (ARBD) during a critical developmental timepoint, such as adolescence, interacts with AD-related pathologies to accelerate disease progression later in life. Furthermore, female humans and rodents, show more rapid cognitive decline and accelerated progression of brain atrophy. The current study investigates whether delayed voluntary exercise in mid-adulthood can recover memory deficits caused by the interactions between ethanol exposure in adolescence and AD-transgenes. To study this, the current project utilized a transgenic rat model of AD (TgF344-AD) and an adolescent intermittent ethanol (AIE) exposure model of binge drinking. Male and female TgF344-AD and wildtype F344 rats (WT) were exposed to an intragastric gavage of water (control) or 5g/kg of 20% ethanol (AIE) for a 2 day on/off schedule throughout adolescence (PD27-57). At 6 months old, rats either remained in their home cage (control) or were placed in a voluntary wheel running apparatus for 4 weeks. At 7 months old, all rats were tested on spatial working memory and pattern separation. Voluntary wheel running recovers spatial working memory deficits assessed by spontaneous alternation selectively in female rats with TgF344-AD exposed to AIE. Voluntary exercise also recovers the pattern separation impairment in control TgF344-AD female rats, but provided only a trend towards improvement for AIE-exposed TgF344-AD female rats. This delayed exercise had no effect on behavior in male rats. There were also sex-dependent effects on brain pathology: Exercise improves the integration of recently born neurons in AIE-exposed TgF344-AD female rats. In contrast, in only male AIE-exposed TgF344-AD, exercise decreases amyloid burden in both the hippocampus and entorhinal cortex. The number of neurons expressing the cholinergic phenotype was not affected by AD transgenes in either sex. AIE, selectively in females, reduced cell counts of the cholinergic phenotype. Unexpectedly, exercise suppressed cholinergic cell counts in both male and female rats. Our data provide support that even after symptom onset, AIE and AD-related cognitive decline, along with the corresponding neuropathologies, can be rescued with exercise in unique sex-specific ways.

Title: Voluntary wheel running exercise rescues cortical acetylcholine efflux during spontaneous alternation in female rats and novel object in place behavior in male rats following adolescent intermittent ethanol exposure

Authors: *M. J. FECIK, P. T. NUNES, L. M. SAVAGE;
Psychology - Behavioral Neurosci. Area, Binghamton Univ., Binghamton, NY

Abstract: Adolescent intermittent ethanol (AIE) exposure has been shown to cause significant reductions in cholinergic phenotype throughout the basal forebrain, which persists into adulthood. Cortical acetylcholine (ACh) efflux from projections originating in basal forebrain structures have been shown to be blunted by AIE, both in the medial prefrontal cortex (mPFC) and orbitofrontal cortex during spontaneous alternation maze exploration. While this is likely due to a reduction in markers of cholinergic phenotype throughout the basal forebrain, it is unlikely that cholinergic cells are dying off, as it has been shown that voluntary wheel running exercise (VEx), can prevent AIE-induced loss of choline acetyltransferase if used during treatment and reverse the loss if used after treatment. Therefore, the goal of the current study was to investigate whether VEx following AIE treatment could rescue ACh efflux in the mPFC during spontaneous alternation. 62 Long Evans rats of both sexes were given either AIE treatment via intragastric gavage of 20% ethanol (5mg/kg) or tap water on a two-day-on two-day-off schedule from postnatal day 25 to 54. Following AIE, all rats were given surgery to implant a guide cannula into the mPFC. Afterwards, AIE and control rats were assigned to either a cage with a running wheel attached from P75 to 105 (VEx), or to remain in their home cage during that time (Stat). Rats had free access to the wheels and running data was recorded via an infrared beam breaker. Following VEx, rats were run on a four-arm spontaneous alternation maze, during which a probe was inserted into the guide cannula to collect extracellular ACh efflux. We found that mPFC ACh efflux was blunted following AIE exclusively in females, a consequence that was rescued by VEx. In males, AIE did not blunt ACh efflux, but there was a trend toward an increase in efflux in VEx rats regardless of AIE treatment. Following this experiment, we investigated a cholinergic dependent behavior, the Novel object in place (NOP) task. 32 Sprague Dawley rats of both sexes were put through the same AIE and VEx paradigm as described above. Following this, subjects were run on NOP, in which they spent two days habituating to the objects, one of which was relocated on the third day. The time spent investigating the moved object and the unmoved object was recorded. We found that male AIE rats showed a preference for the unmoved object, which was rescued via VEx. There were no effects of AIE or VEx in female rats. Overall, these results show that there may be sex difference in cholinergic dependent behaviors and neurochemistry following AIE, which may be rescued with voluntary wheel running exercise.

Title: Modulating the p75NTR during adolescent intermittent ethanol exposure preserves basal forebrain cholinergic phenotype, prefrontal cortical acetylcholine signaling, and sustained attention performance

Authors: *B. T. KIPP, L. M. SAVAGE;
Binghamton Univ., Binghamton, NY

Abstract: Adolescent intermittent ethanol exposure (AIE) recapitulates the binge withdrawal ethanol consummatory patterns of adolescents and facilitates long-lasting changes in neurobehavioral functioning across the lifespan. Basal forebrain cholinergic neurons are particularly susceptible to the toxic effects of AIE, leading to loss of the expression of the cholinergic phenotype, reductions in prefrontal cortical ACh release, and impairments across several cognitive domains. While the presence of dysregulated target-derived pro and mature neurotrophins during AIE suggests a potential causative role in AIE-associated cholinergic degeneration, this mechanism has mostly been unexplored. There is a dichotomous relationship between mature neurotrophins (NGF and BDNF), which are crucial for the development and maintenance of cholinergic neurons through binding and retrograde transport through TrkA and TrkB receptors, and proneurotrophins (proNGF and proBDNF), which can exert degeneration through p75NTR. This system has recently been explored as a therapeutic target in multiple neuropathologies- including alcohol use disorder. We sought to further understand the mechanism of cholinergic degeneration in AIE by manipulating the p75NTR during AIE with the use of LM11A-31, a p75NTR modulator, and examined the cholinergic profile and associated cholinergic and cognitive function in adulthood. Male and female Sprague Dawley rats were administered 5g/kg of 20% ethanol via intragastric gavage from PND 25-57 following a two-day-on-two-day off schedule. A subset of rats was also administered 50mg/kg LM11A-31 twice a day, 30 minutes before and 8 hours following each ethanol gavage. In adulthood, rats were tested on a sustained attention task, revealing attention deficits in AIE-treated animals, but not animals co-treated with LM11A-31 or controls. Additionally, reductions in prefrontal cortical ACh activity were detected in AIE rats on this task during cue presentation and reward through fiber photometry with the GRAB ACh 3.0 biosensor. Moreover, AIE-treated rats were also found to have significant reductions in the cortical projection Nucleus Basalis Magnocellularis cholinergic cell population alongside reductions in TrkA receptor co-expression. LM11A-31 treatment during adolescence was found to have protective effects on cholinergic cell populations and TrkA receptor co-expression in AIE-treated animals, but not animals that did not

receive AIE. Taken together these findings highlight a causative role of pro neurotrophin-p75NTR dysregulation in cholinergic degeneration in AIE.

Title: Social Dominance and Social Behavior: Sex-Specific Impact of Adolescent Intermittent Ethanol Exposure

Authors: *D. T. APPLEGATE[1], E. I. VARLINSKAYA[1], D. F. WERNER[2];
[1]Psychology, [2]Psychology and Behavioral Neurosci., Binghamton Univ., Binghamton, NY

Abstract: Adolescent alcohol use is a significant public health concern, with binge drinking during adolescence associated with adverse health outcomes, including an increased risk of developing alcohol use disorder as well as affective disorders. Preclinical models of adolescent binge drinking, particularly adolescent intermittent ethanol (AIE) exposure models have been used for assessment of long-lasting behavioral alterations associated with adolescent alcohol use. While previous research from our lab has shown that males are particularly sensitive to AIE effects on social behavior, exhibiting increased social anxiety-like behavior in adulthood, it is not known whether AIE can affect social dominance in a sex-dependent manner. This study was designed to (a) investigate the impact of AIE exposure on social status and (b) determine whether dominant or subordinate-like adolescent or adult social status predict social behavior in adulthood. Male and female cFos-LacZ transgenic Sprague-Dawley rats were initially assessed at postnatal day (P)27 for social rank (dominant or subordinate) using the social dominance tube test (SDTT). Animals were exposed to either water (controls) or ethanol (4 g/kg, 25% solution, v/v) given intragastrically on a 2-day on, 2-day off schedule during adolescence (P28 - P53). Following a 17-day period of forced, protracted abstinence, experimental subjects were retested on the SDTT at P70. On P75, social behavior of experimental subjects was assessed in the modified social interaction test, followed by rapid brain extractions and further tissue processing. 70% of water-exposed control males changed their adolescent social status in adulthood, while only 45% of AIE-exposed males displayed changes in dominant and subordinate-like phenotypes. In females, 37.5% of water-exposed controls changed their adolescent social status in adulthood, while 45% of AIE-exposed females displayed changes in dominant and subordinate-like phenotypes. Similar to previous findings in our lab, only AIE-exposed males displayed decreased social investigation relative to water-exposed counterparts. Social status in adolescence or in adulthood did not predict (a) AIE-associated changes in social investigation in

males and females or (b) social investigation of water-exposed subjects. Future studies will assess potential changes in stress and steroid hormones (corticosterone, progesterone, testosterone) which may contribute to social status in males or females and/or social deficits observed in males following AIE.

Title: Adolescent intermittent ethanol-induced effects on activity, anxiety, memory & biological markers: sex-specificity and prevention by dietary choline

Authors: *K. HEALEY[1], A. BELL[1], S. MARSHALL[2], H. SWARTZWELDER[1];
[1]Duke Univ. Sch. of Med., Durham, NC; [2]Biol. and Biomed. Sci., North Carolina Central Univ., Durham, NC

Abstract: Alcohol exposure during adolescence causes CNS and behavioral changes that persist into adulthood, particularly in the domains of memory and anxiety-related behaviors. Adolescent intermittent ethanol (AIE) exposure alters neurochemical signaling and molecular mechanisms in the brain, including disruption of the cholinergic system, which may underlie known AIE-induced behavioral deficits in adulthood. Choline is an essential nutrient and a precursor to acetylcholine, which is known to regulate attention, learning, motivation, and memory. Choline supplementation has been shown to ameliorate neurobehavioral deficits associated with prenatal ethanol exposure, and therefore may ameliorate or prevent some of the persistent behavioral effects of AIE. Adolescent male and female Sprague-Dawley (PD 29) rats were exposed to 14 doses of ethanol (5 g/kg; *intragastric gavage;* AIE) or isovolumetric water over 23 days. Daily choline (100 mg/kg, fed in 6% sweetened condensed milk) or vehicle (6% sweetened condensed milk) began on PD 24 and continued daily until PD 56. In adulthood (PD 70), animals were tested on measures of activity (figure-8 maze, open field test: OFT), anxiety (elevated-plus maze: EPM), and memory (novel object recognition: NOR). A subset of animals was sacrificed at PND 70, in the absence of behavioral testing, for tissue harvesting.AIE reduced activity (figure-8 maze, distance moved in EPM) in male but not female animals. The AIE-induced reduction in activity was prevented by choline supplementation only in the figure-8 maze. Additionally, in the OFT, males exposed to AIE spent less time in the center, suggesting elevated anxiety and/or reduced risk-taking, and this was prevented by choline supplementation. In females, we have previously found that AIE increased risk-taking behaviors (increased open arm time on the EPM), an effect that was both replicated in the present study and prevented by choline

supplementation. Finally, in both sexes, AIE significantly reduced the discrimination index in the NOR, indicating that AIE exposure impairs memory functioning. At sacrifice, dietary choline, AIE and their interaction were found to sex-dependently affect organ weight, fat content, and the liver enzyme alanine transferase. Investigations of cholinergic function in the medial prefrontal cortex, dorsal hippocampus and basal forebrain are ongoing. The prevention of AIE effects by choline supplementation is consistent with AIE-induced changes to the cholinergic system and suggests a potential agent to prevent AIE effects.

Abstract: When adolescents drink alcohol, they often binge drink, which can lead to long-lasting changes in brain and behavior. One consequence of adolescent binge alcohol in humans and rodents is reduced cognitive flexibility, or the ability to adapt one's strategy in response to changing circumstances. Using a rat model, we found that adolescent intermittent ethanol (AIE) exposure impaired reversal learning in an attentional set shift task and reduced functional connectivity among cortico-striatal-thalamic circuits measure by resting-state fMRI. Parvalbumin-expressing (PV+) GABAergic interneurons are critical for cortical excitatory-inhibitory balance and gamma oscillations that are thought to contribute to neural coupling between brain regions, with the anterior insula as one such region that acts as a hub switch among functional connectivity networks. Thus, we used immunohistochemistry to evaluate PV+ neurons in the anterior insula in rats that underwent reversal learning. We also evaluated

perineuronal nets (PNNs), which surround PV+ and other neurons and are dynamic extracellular structures that help maintain synapses and regulate extracellular ion concentrations. Based on ours and others' previous studies, we predicted that AIE exposure would promote increases in size and/or counts of PV+ neurons and PNNs, and this neurochemical change would be associated with behavioral deficits in reversal learning. To test this, male and female Sprague Dawley rats underwent AIE (5 g/kg via gavage) or volume-matched water control (CON) from postnatal day 25-54 on a 2-day-ON/2-day-OFF regimen (n = 8-10 per group). Rats underwent behavioral training in adulthood, including reversal learning on an attentional set shift task. Immunofluorescence (IF) was performed in the aIC to visualize PV+ interneurons and binding of WFA, a marker of PNNs. We found that AIE significantly increased the number of PV cells in the aIC of female and male rats. Additionally, PNN numbers were significantly increased in the AIE groups, as well as the proportion of PV cells surrounded by PNNs. Finally, we ran a principle component (PC) analysis on the IF parameters to reduce the dimensionality of the data into three PCs. The third PC accounted for 14% of the variance in IF parameters and was heavily weighted by the number of PNNs (0.856) and the proportion of PV+ neurons surrounded by PNNs (0.864), and this PC significantly mediated the effect of AIE exposure on behavioral flexibility measurements, specifically reversal 2 total trials. These results suggest that AIE may alter excitatory/inhibitory balance in the aIC via changes in PV interneuron number and their regulation by PNNs.

Title: Investigating differences in reversal learning and set shifting in adolescent intermittent ethanol-exposed and control-exposed Parvalbumin-Cre rats

Authors: *S. GARRISON[1,2], E. D. SULLIVAN[2], A. S. KUMAR[2], S. GIANG[2], C. A. BOETTIGER[2], D. L. ROBINSON[2];
[1]Pharmacol., Univ. of North Carolina Chapel Hill, Chapel Hill, NC; [2]Bowles Ctr. for Alcohol Studies, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Adolescent binge alcohol consumption is a widespread issue with 8.3% of youth between the ages of 12 to 20 reporting at least one binge (defined as 4 drinks for girls and 5 drinks for boys) over the past month in 2021. Of these youth, 19% reported heavy alcohol use, meaning five or more binge incidences in the last month. Binge drinking in adolescence is a major concern due to the vulnerability of the brain during development, subsequent long-term cognitive effects that can emerge in adulthood, and an increased chance of developing dependence or addiction. These deficits can lead to various negative consequences in adulthood, including an increase in risk-taking behaviors, impaired judgment, and cognitive impairments. Cognitive flexibility, or the ability to adapt to change and switch from one task to another, is one aspect impacted by adolescent alcohol use. Using an animal model, we investigated adolescent intermittent ethanol (AIE) impact on cognitive flexibility measured via an attentional set-shifting task (ASST), a behavioral assay used to assess behavioral flexibility. Rats underwent a nine-day experimental protocol where they were trained to learn a set of rules applied to cues. Rats needed to differentiate between relevant cues (odors) and irrelevant cues (digging media) with a number of intra-dimensional and extra-dimensional set shifts where the rules were changed. In this study, we used PV-Cre rats to explore how AIE exposure across adolescence (P25-54) can lead to deficits in adulthood (P81-P114). Additionally, we compared results to those from previous Robinson lab ASST experiments to see if increasing the criterion of correct trials from 6 to 8 would reveal more robust differences between AIE and control subjects. Our preliminary data show untreated rats can learn the task despite the more challenging criterion, and the initial reversal of the ASST led to more errors (7±2) than a second reversal (4±1) or an extradimensional set shift (2±1). Ongoing studies are adding data from AIE-exposed male and female rats, where we expect AIE rats to learn rule associations like controls but have deficits in reversal learning. Future directions include the manipulation of parvalbumin-expressing (PV+) interneurons using Cre-dependent excitatory and inhibitory DREADDs to interrogate the role of prefrontal PV+ interneurons in behavioral flexibility as these neurons regulate synaptic plasticity and neural synchrony.

Title: Investigating the Role of Drosophila Dorsal Paired Medial (DPM) Neurons in Alcohol-Associated Memories

Authors: *E. CORTEZ[1], K. M. SCAPLEN[1,2];
[1]Psychology, Bryant Univ., Smithfield RI, RI; [2]Neurosci., Brown Univ., Providence, RI

Abstract: Alcohol use disorder (AUD) is a chronic relapsing disorder that manifests as problematic patterns of alcohol use. At the core of AUD's behavioral manifestations is alcohol's profound effect on the brain. Alcohol engages and ultimately subordinates memory circuits resulting in enduring preferences, habitual behaviors, and persistent cravings. Insight to the circuit mechanisms that underlie how alcohol-associated memories are encoded, maintained, and expressed is critical to understanding why these memories are remarkably resistant to change. However, understanding the circuit basis of reward-related learning and addiction has been challenging. Efforts are often hindered by the neuronal heterogeneity that exists within dopamine (DA) sub-regions, as well as the lack of spatial and temporal resolution to distinguish neuronal subpopulations or isolate individual neurons. Drosophila melanogaster is a powerful model organism to address these challenges because they offer a rich genetic toolkit that permits dissection of heterogenous circuits with precise temporal and spatial resolution. Importantly, Drosophila form persistent alcohol reward memories, which impel them to overcome aversive stimuli in pursuit of alcohol-associated cues. Previous work identified discrete circuits that underlie alcohol reward memories and their temporal requirements. In Drosophila alcohol reward memory requires the mushroom body (MB), a region essential for learning and memory as well DA modulation of the MB which shifts from an entire population during acquisition to two discrete DA subsets known to process memories with opposing valences. However, it remains unclear the mechanisms by which these memories are consolidated. The Dorsal Paired Medial neurons (DPM), which innervate the MB have an established role in sleep regulation and memory consolidation. Using neurogenetic tools available in Drosophila we investigated the role of DPM neurons in alcohol reward memories and other alcohol associated behaviors. We utilized a transcriptional reporter of intracellular calcium (TRIC) to measure DPM neuronal activity and report postsynaptic targets using trans-Tango. Preliminary data suggest that DPM is required for the consolidation of alcohol reward memories, but not acquisition or retrieval. These findings provide insight to the circuit mechanisms underlying alcohol associated memories and why they are so resistant to change.

Abstract: Dopamine has an established role in a variety of processes including motivation, reward, and regulation of goal-directed and motor-related behavior across species. Furthermore, dysregulation of dopamine is thought to underlie the effect of alcohol and other drugs of abuse resulting in modified reward circuits. Given the heterogeneous role of dopamine, it is essential to gain a better mechanistic understanding of dopamine regulation and how its regulation is disrupted in maladaptive states, like those associated with alcohol. *Drosophila melanogaster* is a powerful model organism to investigate the neural dynamic changes that create persistent drug-related memories for alcohol intoxication and underlie alcohol-associated behaviors because of the excellent genetic tools that provide unprecedented spatial and temporal resolution. Previous work in *Drosophila* identified distinct dopamine circuits that underlie alcohol-associated memories and defined their temporal requirements (Scaplen et al., 2020). More recent evidence suggests that subsets of dopamine neurons (DANs) also mediate alcohol-induced locomotor activity. Here we use a multipronged approach that combines behavior, thermogenetic, and high-content behavioral analysis and take advantage of the precise circuitry of the mushroom body to investigate whether distinct DANs implicated for alcohol reward are also important for modulating locomotor responsiveness to alcohol. Preliminary data demonstrated that different subsets of DANs innervating the Mushroom Body play dynamic roles in modulating alcohol induced locomotor activity. Inactivation of DANs has the most substantial effects in late stages of alcohol exposure at high doses. We hypothesize more DANs are recruited during later stages of alcohol intoxication to counteract the sedating effects of alcohol. High-content behavioral analysis using Flytracker and Ctrax, post-processing computer vision software, suggests that distinct subsets of DANs modulate alcohol associated behavioral features characterized by fly activity, coordination, interaction, and social clustering. Interestingly, DAN subsets that are required for retrieval of alcohol reward memories do not appear to be required for alcohol-induced locomotor activity. We also describe the influence of DANs on locomotor activity in the absence of alcohol. Overall, this study clarifies the dose-dependent manner DANs mediate locomotor activity in *Drosophila* and is a starting point for further investigation of the mechanism in which drugs of abuse coops natural reward pathways and contribute to addiction.

Title: Nucleus accumbens BDNF-TrkB mediated encoding of ethanol reward

Authors: *A. N. SICLAIR[1], P. N. MCKEON[2], M. H. PATTON[2], E. B. ABEL[2], E. A. DOUGLASS[2], S. H. SHEATS[2], B. N. MATHUR[2];

Abstract: The nucleus accumbens (NAc) integrates many inputs to enable cue-reward associations. Our lab previously identified a form of inhibitory long-term depression in the NAc (NAc-iLTD) that requires brain derived neurotrophic factor (BDNF) signaling via the tyrosine kinase B (TrkB) receptor. This form of plasticity is enhanced by ethanol in a TrkB-dependent manner. This positions ethanol to disinhibit the NAc and, thereby, enhance reward encoding. Testing this idea, we found that dopaminergic terminals in the NAc serve as a sufficient and necessary source of BDNF to drive NAc-iLTD. In vivo, we show that light activation of the dopaminergic terminals in the NAc - in a manner that induces NAc-iLTD ex vivo - drives a conditioned place preference in a TrkB receptor-dependent manner. Coupling a subthreshold light activation of dopaminergic terminals and a subthreshold rewarding dose of ethanol also elicits a TrkB receptor-dependent conditioned place preference. These data suggest that ethanol interacts with BDNF-TrkB signaling in the NAc to mediate ethanol reward.

Title: Chronic Intermittent Ethanol disturbs claustrum neuronal activity

Authors: *A. B. WULFF[1], S. H. SHEATS[1], E. A. DOUGLASS[2], B. N. MATHUR[1];
[1]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Alcohol Use Disorder (AUD) is a prevalent disorder affecting more than 10% of adults in America and comprising more than 5% of the global burden of disease and injury. Prior

research strongly points to a bidirectional relationship between impaired cognitive control and heavy alcohol use, suggesting a mechanism for the development and exacerbation of AUD. While recent studies point to the claustrum as a locus for orchestrating synchronized cortical activity required in cognitive control, it is yet unknown how claustrum activity is affected by alcohol exposure.To determine whether claustrum neuronal activity is affected by chronic alcohol exposure we performed whole-cell patch clamp recordings in claustrum-containing brain slices from mice subjected to either chronic intermittent vaporized ethanol or chronic intermittent air (water vapor). We found that claustrum neurons from ethanol-exposed mice exhibited perturbed intrinsic excitability and action potential properties that may lead to over-excitable claustrum neurons. We further found subtle changes in passive membrane properties suggestive of dendritic reorganization.
These findings suggest that chronic ethanol exposure may lead to profound and widespread changes in claustrum neuronal activity that may mediate alcohol-induced impairments to cognitive control.

Title: The Bed Nucleus of the Stria Terminalis 5HT2c receptor system sex-dependently suppresses compulsive alcohol seeking

Authors: *M. FLANIGAN[1], M. CASTLE[2], C. A. GIANESSI[1], W. DORLEAN[2], V. SIDES[1], T. KASH[3];
[1]Bowles Ctr. for Alcohol Studies, [2]UNC Chapel Hill, Chapel Hill, NC; [3]UNC- Chapel Hill, Chapel Hill, NC

Abstract: The serotonin $5HT_{2c}$ receptor has been widely implicated in the pathophysiology of Alcohol Use Disorder (AUD), particularly alcohol seeking and the affective consequences of chronic alcohol consumption. However, very little is known about the specific brain sites in which $5HT_{2c}$ exerts its effects on specific alcohol-related behaviors, especially in female subjects. Here, we investigated the effects of site-specific knockdown of the $5HT_{2c}$ receptor in the BNST on operant alcohol self-administration behaviors in adult mice of both sexes, including alcohol seeking (fixed-ratio responding), motivation for alcohol (progressive ratio), and quinine-adulterated alcohol seeking (compulsive alcohol seeking). To dissociate the effects of $5HT_{2c}$

knockdown from the effects of reducing the activity of $5HT_{2c}$-containing neurons, we carried out the same operant alcohol self-administration behavioral sequence while performing chemogenetic inhibition of BNST $5HT_{2c}$-containing neurons. We report that BNST knockdown of $5HT_{2c}$ did not affect alcohol seeking or progressive ratio responding for alcohol in either sex. While BNST $5HT_{2c}$ knockdown drove perseverant operant responding for 1000 μM quinine alcohol selectively in females, this manipulation did not promote increased consumption of quinine alcohol. Chemogenetic inhibition of BNST $5HT_{2c}$-containing neurons ($BNST^{5HT2c}$) increased fixed-ratio responding for alcohol and alcohol consumption in early self-administration sessions, particularly in males. It also increased operant responding for 1000 μM quinine alcohol in males. However, similar to results of $5HT_{2c}$ deletion in females, chemogenetic inhibition of $BNST^{5HT2c}$ did not alter the actual amount of quinine alcohol consumed in males. Importantly, chemogenetic inhibition of $BNST^{5HT2c}$ did not alter sucrose seeking, motivation for sucrose, or compulsive sucrose seeking in either sex. Immunohistochemistry combined with chemogenetics revealed that $BNST^{5HT2c}$ project to similar regions in males and females, but that inhibition of $BNST^{5HT2c}$ reduces vlPAG activity selectively in males. Given the role of the vlPAG in generating aversive behavioral responses, we therefore describe a potential new role for $BNST^{5HT2c}$ in generating increased aversion to alcohol-related stimuli via activation of the vlPAG in males. Together, these results demonstrate that the BNST $5HT_{2c}$ receptor system is engaged in sex-specific ways to selectively modulate compulsive alcohol seeking and vlPAG activity while only weakly influencing alcohol consumption itself.

Title: Septohypothalamic nociceptin/orphanin-fq receptors modulate binge-like alcohol consumption.

Authors: *H. HAUN[1], L. YAN[1], R. HERNANDEZ[2], T. L. KASH[3];
[1]Univ. of North Carolina Chapel Hill, Chapel Hill, NC; [2]Morgan Community Col., Fort Morgan, CO; [3]Bowles Ctr. for Alcohol Studies, UNC-Chapel Hill, Chapel Hill, NC

Abstract: Excessive alcohol consumption is a hallmark of Alcohol Use Disorder (AUD) and presents as a major public health concern. To curb excessive drinking behavior, antagonists

targeting the opioid-like nociceptin receptor (NOP) have shown promise in reducing heaving drinking in patients with an AUD, and reduce alcohol intake in preclinical models. We have previously identified the lateral septum (LS) to be enriched in neurons expressing the endogenous ligand to NOP, nociceptin/orphanin-fq (N/OFQ), and found that these neurons ($LS^{N/OFQ}$) bidirectionally regulate alcohol consumption in male and female mice. The present studies were designed to functionally map $LS^{N/OFQ}$ projections, and determine the contribution of NOP therein to excessive alcohol consumption. Pnoc-cre mice were used to direct expression of AAV8-DIO-Synaptophysin-mCherry to $LS^{N/OFQ}$, and terminal fields were observed locally within the LS, and downstream in the lateral hypothalamus (LH) and supramammillary nucleus of the hypothalamus (SuM). Channelrhodopsin-assisted circuit mapping was then conducted to determine functional connectivity of $LS^{N/OFQ}$ in these projection fields. Briefly, slices containing the LS, LH, or SuM were collected and incubated in aCSF and inhibitory post synaptic currents (IPSCs) were isolated, given that $LS^{N/OFQ}$ is a GABAergic population. Recordings were collected from each structure during blue light stimulation and picrotoxin-sensitive optically evoked IPSCs were observed from synaptic targets of $LS^{N/OFQ}$ in the LS, LH, and SuM, indicating functional GABAergic synapses. We then used the Drinking-in-the-Dark (DID) paradigm to model binge-like alcohol consumption, and used a genetic deletion strategy to determine a functional role for NOP in the LS, LH, and SuM in binge drinking. Male and female NOP*fl/fl* mice received bilateral infusion of AAV8-hSyn-cre (or GFP) into the LS, LH or SuM, and mice were given access to alcohol (20%; v/v, 2hr) for 3 weeks. Male mice lacking the NOP receptor in the LS displayed decreased binge-like alcohol intake compared to controls (-23%; P=0.016), while drinking in females remained unaffected. Genetic deletion of NOP from the LH reduced alcohol intake in females (-19%; P=0.011), without affecting drinking in males. Preliminary findings (N=3-5/sex/AAV) indicated that NOP deletion from the SuM reduced alcohol intake in female mice (-16%; P=0.03), with no effect in males. In summary, these findings demonstrate novel functional $LS^{N/OFQ}$ projections to the LS, LH, and SuM, and highlight important sex differences in the ability of NOP to regulate binge drinking behavior.

Title: Effects of acute and chronic alcohol consumption on extended amygdalar calcium dynamics

Authors: *A. ROLAND[1], T. KASH[2];
[1]Univ. of North Carolina, Chapel Hill, NC; [2]UNC- Chapel Hill, Chapel Hill, NC

Abstract: The central amygdala (CeA) and bed nucleus of the stria terminalis (BNST) are reciprocally connected nodes of the extended amygdala that are differentially engaged during initial alcohol consumption and following withdrawal from chronic drinking. Studies of immediate-early genes indicate that BNST and CeA are acutely activated following alcohol drinking and may promote alcohol reward in nondependent drinkers, while increased stress signaling in the extended amygdala following chronic alcohol exposure promotes relapse drinking via negative reinforcement. However, the dynamics of neural activation in BNST and CeA during drinking behavior are unknown. In this study, we used fiber photometry and the genetically encoded calcium sensor GCaMP to assess acute changes in neural activity during alcohol consumption in BNST and CeA before and after a chronic drinking paradigm. Activity was examined in the pan-neuronal population and separately in genetically defined dynorphinergic neurons. BNST and CeA showed strongly synchronized pan-neuronal activity and coordinated increases in activity during acute consumption of alcohol as well as other fluid tastants of both positive and negative valence, as well as highly palatable chow. Calcium increases were greatest during the initial consummatory bout and decreased in amplitude with repeated consumption of the same tastant, indicating modulation of the response by the novelty of the stimulus. Dynorphin neurons showed similar consumption-associated calcium increases in both brain regions. Following a three-week continuous access (CA) alcohol drinking paradigm, both pan-neuronal and dynorphinergic calcium increases during drinking were maintained, but the initial response to alcohol in the CeA was reduced compared to the pre-CA baseline. These results indicate that the extended amygdala, and dynorphin neurons specifically, are engaged during consummatory behavior and suggest that stimulus novelty may influence the activity of these regions.

Title: A role for the retrosplenial cortex in heightened adult fear expression following binge-like alcohol exposure during adolescence

Authors: L. TAXIER[1], L. COLEMAN[2], ***T. KASH**[3];
[1]Univ. of North Carolina-Chapel Hill, Chapel Hill, NC; [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]UNC- Chapel Hill, Chapel Hill, NC

Abstract: Adolescent binge drinking increases risk for developing an Alcohol Use Disorder (AUD) and other comorbid conditions in adulthood, including anxiety and post-traumatic stress disorders (PTSD). Yet, how adolescent binge drinking engenders such negative health outcomes remains largely unknown. Here, we tested the hypothesis that binge-like alcohol exposure during adolescence (AIE) promotes aberrant fear expression in adulthood, and that AIE-heightened fear is linked to altered function of the retrosplenial cortex (RSC), a region critical for retrieval of episodic-like fear memory. Male and female C57Bl/6 mice underwent a regimen of water or AIE via gavage during adolescence (P25-P55), followed by trace fear conditioning in adulthood (P90). All mice acquired fear to a similar extent, suggesting that AIE did not alter fear acquisition. However, during fear retrieval, AIE-exposed mice of both sexes froze more than water controls, suggesting that AIE promotes heightened retrieval of a trace fear memory. In a separate cohort of male C57Bl/6 mice that underwent water or AIE, slices containing the RSC were prepared to assess intrinsic excitability using whole-cell patch clamp electrophysiology. AIE-treated males exhibited a higher rheobase, or minimum current required for an action potential to fire, relative to water controls. Combined, these data suggest the possibility that reduced intrinsic excitability in the RSC may be a contributing mechanism to altered fear expression following AIE.

Title: Adolescent-onset voluntary ethanol consumption and subsequent negative affective behavior and whole brain cFos expression during forced abstinence in mice

Authors: *C. M. EDWARDS[1,2], R. B. SIMERLY[1,2], D. G. WINDER[1,2];
[1]Mol. Physiol. & Biophysics, [2]Vanderbilt Ctr. for Addiction Res., Vanderbilt Univ., Nashville, TN

Abstract: Negative affect experienced during abstinence from alcohol can significantly contribute to relapse and the development of alcohol dependence. In particular, chronic alcohol use during adolescence poses a substantial risk for the later development of alcohol use disorder. This study aimed to investigate the voluntary consumption of ethanol and its impact on negative

affective behavior, as well as associated neural changes, in mice that initiated ethanol consumption during early adolescence (~PND30). Male and female adolescent C57BL/6 mice went through the Chronic Drinking Forced Abstinence (CDFA) paradigm in which half of the mice ("Ethanol" group) were given two-bottle choice between ethanol and water whereas the control mice ("Water" group) were given two bottles containing water. In Experiment 1, ethanol bottle weights were manually recorded to measure ethanol intake (g/kg/day) and ethanol preference over a six-week period. Subsequently, the bottles were removed, and two weeks later, the animals underwent several behavioral tests to evaluate negative affect, including the light/dark box, elevated plus maze, forced swim test, and novelty suppressed feeding test. While female C57BL/6 mice prefer and consume more ethanol than males as adults, we found that male and female mice that began drinking during early adolescence consume similar levels of ethanol and display similar preference for ethanol over water. We also observe negative affective behaviors in mice during forced abstinence. In Experiment 2, ethanol intake was assessed using the Lick Instance Quantifier (LIQ) system, enabling a more precise measurement of ethanol consumption behavior, including lick number and lick duration. Additionally, brains were collected at 24 hours and 2 weeks into forced abstinence and analyzed for regionally specific changes in whole brain cFos expression. Adolescent onset of CDFA provides a translationally relevant model of negative affect following chronic alcohol consumption and could provide interesting insight into neural circuitry underlying the development of alcohol use disorder.

Title: Neural adaptations in the insular cortex following abstinence from chronic ethanol exposure

Authors: P. YOUNG[1], A. TAYLOR[2,1], D. ADANK[2,1], ***D. WINDER**[2,1];
[1]Vanderbilt Ctr. for Addiction Res., [2]Mol. Physiol. and Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: The insular cortex (IC) is a brain region that integrates sensory and interoceptive cues to inform downstream circuitry executing adaptive behavioral responses. The IC communicates with areas involved canonically in stress and motivation, and lesion analyses heavily implicate the region in addiction. Studies from a number of groups implicate the IC in alcohol use disorder (AUD), particularly during periods of withdrawal and forced abstinence. Using a mouse model of AUD known as chronic drinking forced abstinence (CDFA), we examined molecular changes

in the IC following acute and protracted abstinence from chronic alcohol exposure. Following a 6-week voluntary drinking period, we collected tissue containing the IC and performed *in situ* hybridization analyses to test the hypothesis that potassium channels previously demonstrated as ethanol sensitive were altered in their expression. We assessed potassium channel mRNA expression 24 hours and 2 weeks into forced abstinence. Informed by previously collected data indicating changes in neuronal excitability at these timepoints, we looked at three potassium channels in this region: BK, SK, and A-Type channels. After determining that BK mRNA was the most abundant in the IC, we assessed whether its expression changed following CDFA. Analysis revealed significant differences in BK mRNA expression during acute abstinence compared to control and protracted abstinence. Additionally, we identified the cell types in the IC that exhibit the highest enrichment of BK by quantifying BK mRNA expression colocalized with mRNA expression of vGlut1, somatostatin, and parvalbumin. We counted significantly fewer BK puncta in all cell types in the 24hrs FA group. Using whole cell patch clamp electrophysiology and BK channel pharmacology in control mice, we found that the antagonist paxilline mimicked elevated firing patterns in seen in the IC of 24hrs FA subjects. These results may inform identification of new therapeutic targets as well as potential timing for recovery treatments.

Title: Aversion resistant ethanol intake and seeking: A step towards understanding vulnerable subpopulations in Alcohol Use Disorder using a C57BL/6J mouse model

Authors: *M. DOYLE, A. S. PARK, M. E. ALTEMUS, M. E. TROUTMAN, D. N. ADANK, L. LANTIER, C. A. SICILIANO, D. G. WINDER;
Vanderbilt Univ., Nashville, TN

Abstract: In the Alcohol Use Disorder (AUD) treatment seeking population, periods of abstinence define a highly vulnerable portion of the AUD cycle, as during this time individuals report heightened craving and experience increased negative affect. Given the heterogeneity of alcohol use and behaviors observed in the clinical population, animal models highlighting individual differences may provide novel insight to the development of targeted therapeutic

interventions. Here, we used an operant conditioning task known as Structured Tracking of Alcohol Reinforcement (STAR) to assess changes in ethanol intake and aversion resistance following a forced abstinence period. Male and female C57BL/6J mice were trained to self-administer a 20% ethanol solution via a retractable sipper. Following a training period, mice self-administered ethanol in daily 1-hour sessions for 14 days before starting a forced abstinence period (28 days). Mice then underwent the STAR procedure. Here, mice were returned to ethanol self-administration for 3 days before increasing concentrations of quinine (0.25, 0.5, 0.75, and 1.0 mM) were added to the ethanol to assess aversion-resistant (compulsive) intake behaviors. Under this assay, mice reliably segregate into high, low, or compulsive drinking phenotypes. Critically, our data suggest that compulsive drinkers may represent a particularly vulnerable subpopulation, exhibiting greater ethanol seeking in protracted abstinence compared to high and low drinking mice. Additionally, we found that females largely grouped into high drinkers while males primarily categorized as compulsive drinkers, revealing an intriguing sex difference in compulsive ethanol intake. Because the bed nucleus of the stria terminalis (BNST) is known to undergo plastic changes during forced abstinence following ethanol exposure, we next used in vivo fiber photometry to record BNST GCaMP transients as a method of assessing changes in BNST activity across operant sessions. Preliminary data suggest increased BNST activity across all STAR drinking phenotypes during the initial ethanol intake sessions; however, only compulsive drinking mice showed persistent BNST activation during ethanol seeking, highlighting an intriguing maladaptive involvement of the BNST in this vulnerable phenotype. These recordings may yield insights into sex differences in BNST adaptations, and future directions seek to identify BNST specialized neuronal subtype(s) that drives these effects.

Title: Motor cortex control of the insular cortex as a target for exercise-alcohol interactions

Authors: *D. N. ADANK[1,2], A. TAYLOR[1,2], N. PETERSEN[1,2], Y. QUAN[2], J. R. LUCHSINGER[1,2], D. G. WINDER[1,2];

Abstract: Alcohol use disorder (AUD) is a chronic relapsing condition often driven by negative affective states. We and others have demonstrated in mice that voluntary wheel running can ameliorate negative affective states during alcohol abstinence. The insular cortex (IC) has emerged as an essential driver of negative affect through interconnections with the bed nucleus of the stria terminalis (BNST). We have previously shown the IC as a critical player in negative affective behaviors that arise during alcohol-forced abstinence and in active coping bouts during restraint stress in mice. Intriguingly, we found that IC activity decreases during voluntary wheel running in mice. Our previous mapping studies established somatomotor cortical areas as major afferents to IC neurons that project to the BNST. Active coping events during stress are associated with the activation of insular projection neurons. These bouts were also associated with transient reductions in extracellular GABA levels. IC GABA is a regulator of chronic stress adaptation, suggesting the possibility that somatomotor afferents impinge on interneuron populations in IC. We utilized anterograde and retrograde tracing approaches to test the hypothesis that primary motor cortex (MOp) afferents also innervate interneuron populations in the IC. Our convergent data suggest that MOp projections synapse onto GABAergic somatostatin (SST) cells in the IC. We then used channelrhodopsin-assisted mapping to demonstrate functional excitatory transmission between MOp-IC^{SST}. While acute ethanol does not greatly influence the basal excitability of IC^{SST} cells, it reduces excitatory transmission from MOp afferents onto these cells. These findings suggest the MOp-IC^{SST} as a novel circuit to explore in exercise modulation of alcohol-related behaviors.

Title: Exposure to Chronic Intermittent Ethanol Vapor in Adolescence Differentially Affects Consummatory and Appetitive Behavior in Response to a Non-Drug Reward in Adulthood

Authors: *C. MAJORS, C. M. MARKS, D. C. PATEL, P. I. INSCORE, G. A. DEEHAN, Jr.; East Tennessee State Univ., Johnson City, TN

Abstract: Alcohol-use disorders affect 15 million people nationwide, 4% of which are adolescents (12-17). Clinical data indicate that adolescents who binge drink greatly increase their likelihood of developing an alcohol-use disorder later in life. Moreover, research indicates that binge-drinking during adolescence produces long-lasting alterations in brain circuitry that underlie the processing of rewarding stimuli. The current study sought to determine the effect of adolescent exposure to chronic intermittent ethanol (CIE) on the consumption of, and motivation to obtain, sucrose solution in adulthood. Alcohol naïve, male Wistar rats arrived at the laboratory

on post-natal day (PND) 25 and were randomly divided into two exposure groups (CIE and Air). Animals were provided 3 days to allow for acclimation to the animal colony, prior to the start or experimental procedure (PND 28). The CIE procedure involves inducing alcohol dependence by placing rats, in their home cage, into an alcohol vapor chamber for 14 consecutive days, with each exposure day consisting of 12 hrs of exposure in the chambers (8 am to 8 pm) and 12 hrs out of the chambers. The control rats (Air) are treated the same as CIE rats but without exposure to ethanol vapors. Following the CIE paradigm, all rats remained in their home-cage until adulthood (>PND 70) at which time they started operant training/testing in standard operant chambers equipped with two sipper tubes connected via tubing to liquid delivery solenoids. When the response requirement (# of licks) was met, animals received a delivery of 0.1 ml of 5% sucrose solution. All animals were instrumented to the operant procedure on a fixed-ratio (FR) 2 schedule which increased to an FR4 then FR8. Finally, all rats underwent a progressive ratio test in which response requirement increased exponentially for each liquid delivery. On lower schedules (FR2 and FR4) animals did not exhibit a significant difference in licks or reinforcers earned. However, for higher schedules (FR8 and PR) animals in the Air group exhibited a significantly higher level of behavior (licks) and received a significantly greater number of reinforcers than the CIE group. Overall, the data suggest that exposure to CIE, which approximates binge-like EtOH intake and dependence, differentially affects consummatory and appetitive behavior in response to a non-drug reward in adulthood.

Title: Effects of ethanol consumption and noise exposure during adolescence on hippocampal-related behaviors

Authors: L. C. ARAUJO AÑON[1], G. CORSI[1], S. MARCOS[1], F. J. MICHALINA[1], G. E. BUJÁN[2], L. D'ALESSIO[3,2], L. R. GUELMAN[1,2], *S. J. MOLINA[4];

Abstract: Adolescents frequently consume alcoholic beverages in entertainment venues such as discos and bars, where they are often exposed to high levels of noise. Animal studies have demonstrated that both ethanol (EtOH) and noise can cause damage to the hippocampus (HC), a brain region associated with memory and anxiety-related behaviors. However, there is limited information regarding the effects of noise on female rats. Thus, the aim of this work was to examine the effects of EtOH and noise exposure on HC-related behaviors in adolescent female rats. Female Wistar rats (28-days-old) were subjected to a two-bottle choice intermittent EtOH intake paradigm for a duration of 4 weeks. Additionally, during the 6th and 9th drinking sessions, a subgroup of rats were exposed to noise (95-97 dB, 2h). Finally, Open Field, Elevated Plus Maze and Object Location tasks were performed. The results revealed that noise exposure alone led to an increase in anxiety-like behaviors, while EtOH intake alone or in combination with noise decreased head dipping (a risk assessment behavior). Moreover, both stimuli separately or together resulted in a decrease in exploratory behavior. However, no significant differences were observed in spatial and habituation memories. These findings suggest that both exposure to noise and EtOH during adolescence are capable of causing changes in HC-related behaviors of female rats. On the one hand, the fact that EtOH intake promotes lower exploration and risk assessment behaviors could be dangerous since it implies less caution and greater exposure to potential dangers. On the other hand, increased anxious behavior and decreased exploration of the environment, as observed in noise-exposed rats, could result maladaptive in different situations. Finally, the combination of both stimuli does not generate greater behavioral changes than those observed in rats that only consumed EtOH. These findings are clinically relevant since they reproduce part of the behavioral alterations in human adolescents, resulting in an appropriate animal model to investigate in the future the mechanisms involved in hippocampal alterations.

Title: Sex differences in anxiety-like behavior, adolescent intermittent ethanol-induced drinking, and c-Fos in limbic brain structures in male and female C57BL/6J mice

Authors: T. DEAN[1], J. DENNIS[1], I. C. THOMAS[2], J. A. BAKER[2], K. A. SIMONTON[2], A. KUMARI[1], M. J. SHOBANDE[3], C. E. EMEHEL[1], R. CANNADY[1], ***A. M. MALDONADO-DEVINCCI**[2];

Abstract: Adolescence is a period associated with increased binge drinking and long-term changes in brain and behavioral outcomes. Adolescent males and females are also motivated to drink alcohol by different factors including stress and coping for females and sociability for males. Indeed, in recent years binge drinking rates in adolescent females have surpassed that of adolescent males. In this experiment, we tested baseline sex differences in anxiety-like behavior during early adolescence and later tested adolescent intermittent ethanol-induced changes in voluntary alcohol drinking and subsequent withdrawal-induced changes in c-Fos, a marker for neuronal activation. During early adolescence (postnatal day (PND) 24) we observed an increased anxiety-like phenotype in females compared to males. When mice were exposed to adolescent intermittent ethanol (AIE; PND 28-44) and tested for subsequent recurrent ethanol drinking, we found that males and females showed increased ethanol drinking after AIE (PND 45-49) and after re-exposure (PND 52-73). This pattern was sustained over repeated cycles of ethanol re-exposure in males and dissipated in females over time. Brains were collected and AIE withdrawal-induced changes in c-Fos were observed across different limbic structures. Together, these data indicate that adolescent ethanol exposure increased subsequent ethanol drinking and neuronal activation in limbic structures is altered during withdrawal from ethanol re-exposure. Future work will incorporate cell-type specific markers to determine which types of cells are implicated in these lasting sex-specific effects.

Title: Effect of DPI-125 on opioid withdrawal behaviors in rats: a comparison study with methadone and buprenorphine

Authors: B. GAMALLO LANA[1], B. JULIAN[2], E. VERSI[2], ***A. C. MAR**[3];
[1]NYU Langone Hlth. - Neurosci. Inst., New York, NY; [2]DMK Pharmaceuticals, Somerville, NJ;
[3]New York Univ. Sch. of Med., New York, NY

Abstract: Opioid withdrawal syndrome, which comprises symptoms such as increased pain sensitivity and sickness-like behavior, is a major impediment in the treatment of opioid use disorder. While medication for opioid use disorder (MOUD) can reduce opioid use, a major hurdle for patients is the experience of withdrawal when transitioning to stable MOUD dose regimens, reducing the desire to initiate treatment. Prior evidence suggests that DPI-125, a small molecule triple (mu, delta and kappa) opioid receptor agonist, has safety and efficacy advantages over currently available MOUD agents in terms of reduced respiratory depression (delta agonism) and reduced likability (kappa agonism). In this study we examine the timing and effectiveness of DPI-125 in reducing symptoms of opioid withdrawal relative to traditional MOUD ligands, methadone and buprenorphine. Induction of analgesia was used to establish a comparative dose-response and time course for each test agent. Twenty male Sprague Dawley rats (250-325g, Envigo) were tested on the tail flick analgesia meter (IITC) at -1, 30, 60, 120, 180 mins after subcutaneous injection with vehicle, DPI-125 (0.25, 0.5 or 1.0mg/kg), buprenorphine (0.05 mg/kg) or methadone (2.5 mg/kg). Results indicated a dose-dependent analgesic effect of DPI-125, where 0.5mg/kg DPI-125 shows a similar peak and time course of analgesia as 2.5mg/kg methadone. To assess the comparative effects of DPI-125 on withdrawal-like symptoms, 48 rats were implanted subcutaneously with 2 x 75mg morphine pellets to induce opioid dependence with pellets then removed 8 days later. Control animals were treated identically but implanted with vehicle pellets. Body weight and tail flick assessment 24 hours after pellet implantation confirmed the acute hyperphagic and hypoalgesia effects of morphine treatment. 48 hours following pellet removal, rats were subcutaneously injected according to treatment group (veh-veh, morph-veh, morph-DPI-125[0.25,0.5,1.0mg/kg], morph-bup[0.05mg/kg], morph-meth[2.5mg/kg]) and were video recorded in an observation cylinder for 3 hours. Somatic signs of withdrawal (SSW) were assessed by two, blinded independent observers across three 15-min time periods. Body key points were also labelled and machine learning algorithms used to detect behavioral differences between treatment groups. Both 0.25mg/kg and 0.5mg/kg DPI-125 reduced the global number of SSW relative to morph-veh treated rats with the magnitude and time course again indistinguishable from reductions observed with 2.5mg/kg methadone treatment. These data suggest that DPI-125 might be a potentially useful MOUD to help improve outcomes in opioid use disorder.

Title: Gabaergic mediation of abstinence induced anxiety following repeated binge pattern toluene exposure in a murine model

Authors: D. SVENSON[1], T. BENDER[2], S. POINTE[2], ***S. BOWEN**[2];
[1]Psychology, [2]Wayne State Univ., Detroit, MI

Abstract: Inhalant abuse continues to be a serious world-wide problem and can inflict numerous pathological and neurobehavioral outcomes. The aromatic hydrocarbon toluene is one of the most widely abused inhalants and its inhalation produces neurobehavioral effects similar to CNS depressants. Abuse of toluene has also been shown to cause serious withdrawal effects. Previous work from our lab has shown that toluene can induce anxiety-like effects after prolonged exposure to high concentrations. The present study aimed to further explore the involvement of GABA and the amygdala in mediating the anxiogenic effects of toluene-abstinence. Adolescent male and female Swiss-Webster mice (N = 96) were exposed to either air (0 ppm) or toluene (4000 ppm) for 30 min/2x daily for 4 days. Twenty-four hours following the final toluene

exposure, all mice received i.p. injections of either saline, muscimol (0.5 mg/kg), or bicuculline (1 mg/kg) followed by a sham air exposure and tested immediately for changes in locomotor activity (LMA), followed by testing on the elevated plus maze (EPM) and marble burying test (MBT). Subsequently, animals were euthanized for assessment of c-Fos within the amygdala. Results showed that the first toluene exposure significantly increased LMA, which significantly tapered over the next 3 days until reaching control levels, suggesting a tolerance effect. Toluene-abstinence increased closed-arm time on the EPM in male mice only. This effect was rescued by muscimol. No significant differences were observed in the MBT. Further analyses with immunofluorescence showed that toluene produced decreases in c-Fos expression within the BLA of air/saline mice (male only) and an increase within the CeA of toluene-abstinent/muscimol mice (male only). Results from this study show an underlying GABAergic mechanism mediating the anxiety-inducing effects of toluene-abstinence following repeated binge-pattern exposure. These findings may further inform clinical practice and suggest a useful therapeutic target (i.e., GABA) in treating withdrawal-induced anxiety following toluene abuse.

Title: Reinforcing and hedonic effects of the e-cigarette solvents propylene glycol and vegetable glycerin in male rats

Authors: *T. NELSON, N. A. ADDY, D. BAGDAS;
Yale Univ., New Haven, CT

Abstract: Propylene Glycol (PG) and Vegetable Glycerin (VG) are common solvents used as vehicles in e-cigarettes. PG and VG are also used as humectants, which are substances used to keep things moist, in combustible cigarettes and smokeless tobacco products such as oral nicotine pouches. Although tobacco product characteristics can affect nicotine use behaviors, the addictive potential of PG and VG are unknown. Therefore, we evaluated the potential reinforcing and orosensory properties of PG/VG in operant behavior and oral sensory paradigms. Male Sprague Dawley rats and PG/VG at 50/50 ratio were used throughout the study. Rats were exposed to PG/VG vapor in a combined passive and self-administration procedure in an e-cigarette vapor delivery system. During the passive administration phase, rats received a 3-second vapor puff every 8 minutes for a total of 15 vapes in one session. This phase continued for 5 days. Then, rats were allowed to self-administer PG/VG vapor (3-second puff with a 30-second timeout period) 1 hour daily. Rats completed 6 days of fixed ratio (FR)1, 5 days of FR3,

and 7 days of FR5 schedule, respectively. The vapor paired nose poke was identified as active response. Next, we used the intraoral self-administration paradigm in intraoral catheter-implanted rats. The rats were placed into the chambers where the PG/VG or water was connected to their intraoral catheters and the active lever press was connected to the test solution for a 1-hour session daily. Rats completed 5 days of FR1, 3 days of FR2, 7 days of FR5, and 1 day of progressive ratio schedule. Lastly, we investigated hedonic and aversive orosensory properties of PG/VG in the taste reactivity test. The animals received 20 random 4-s infusions of the PG/VG via their intraoral catheters over a 45-minute session. The face reactions of rats were recorded, and the videos were analyzed for their hedonic and aversive responses to the PG/VG and water control. Rats discriminated vapor/oral solution-paired active and non-paired inactive nose holes/levers. The active nose pokes were significantly higher than inactive nose pokes during vapor self-administration. Rats also showed significantly higher active lever presses compared to inactive lever presses and water control in the intraoral self-administration. Rats also had significantly higher hedonic taste responses to PG/VG compared to water control. Additionally, there were no differences in aversive taste responses between PG/VG and water. In summary, PG/VG has reinforcing potential, possibly due to its hedonic properties. Our future studies will clarify PG/VG's reinforcing potential in female rats and its effects on nicotine use behaviors.

Title: Examining the consequences of adolescent benzodiazepine exposure

Authors: *D. PAPASERGIA[1], S. BATES[2];
[2]Psychology, [1]CSU Chico, Chico, CA

Abstract: *Background:* Benzodiazepines are commonly used to treat anxiety disorders. However, in the past decade the intentional abuse and misuse of benzodiazepines has increased in adolescent age groups with adolescent females reporting more misuse than males. Additionally, users often engage in polydrug use, involving opioids. Despite the prevalence of benzodiazepine use in adolescence, few preclinical studies have examined its ramifications on this age group. *Question:* Will diazepam (DZP) exposure during adolescence have a rewarding effect and will withdrawal potentiate anxiety-like behaviors? Additionally, will DZP exposure increase the behavioral response to morphine? Will these effects be sexually dimorphic? *Methods:* Adolescent male and female mice were group housed in one of three conditions,

diazepam (1, 2 mg/kg) and saline. Anxiety levels were measured using the elevated plus maze (EPM) before and after drug or vehicle exposure. A 14-day conditioned place preference (CPP) paradigm was used to examine the rewarding effects of DZP. To examine the effects of polydrug use with opioids, all mice were injected with 10 mg/kg morphine and locomotor behavior was recorded in an open field. All data were analyzed using two-way analysis of variance (ANOVA) with sex and dose as factors. *Results:* Our results suggest that DZP at both doses (1 & 2 mg/kg) produce a significant place preference in males, but not in females. However, withdrawal from DZP increased anxiety-like behaviors in both sexes. Furthermore, DZP exposure potentiates the response to morphine as shown in changes to locomotor behavior in both males and females. *Conclusion:* DZP induced withdrawal and potentiated the locomotor response to morphine in adolescent male and female mice. However, the rewarding properties of DZP are only seen in males. Little is known about benzodiazepine misuse in adolescence, with this study helping shed light on its potential consequences. These findings should be of interest to clinicians who prescribe benzodiazepines, as well as the broader scientific community.

Title: The Lethal Toxicity of 3,4-Methylenedioxymethamphetamine (MDMA) and Methylone in Combination with Alcohol or Nicotine

Authors: *S. DRESSEL;
Dept. of Pharmacol. and Exptl. Therapeut., Univ. of Toledo, TOLEDO, OH

Abstract: The Lethal Toxicity of 3,4-Methylenedioxymethamphetamine (MDMA) and Methylone in Combination with Alcohol or Nicotine Abdulrahman Ba Gunaid[1], Sydnee P. Dressel[1], Faith E Digby[2], Corey J. Widman[2], Alexander S. Wisner[2,3],Frederick E. Williams[1], Isaac T. Schiefer[2,3], F. Scott Hall[11]Department of Pharmacology and Experimental Therapeutics, [2]Department of Medicinal and Biological Chemistry, [3] Center for Drug Design and Development, College of Pharmacy and Pharmaceutical Sciences, The University of Toledo, Toledo, OH, USABackground: 3,4-methylenedioxy-methamphetamine (MDMA) and 3,4-methylenedioxy-N-methcathinone (methylone) are drugs that are commonly abused. These drugs are known for their psychoactive effects that result from increased synaptic levels of the monoamine neurotransmittersdopamine (DA), serotonin (5-hydroxytryptamine; 5-HT), and norepinephrine

(NE). MDMA and methylone are often taken with other substances like alcohol or nicotine in social scenes. These combinations may result in an increased toxicity and lethality. Methods: The lethal and toxic effects of MDMA and methylone were examined in combination with alcohol and nicotine as a model of drug overdose in 5-day post fertilization (dpf) larval zebrafish (*Danio rerio*). In each assay 6 zebrafish larvae were exposed to a drug or drug combination at multiple concentrations for 5 hours. Conclusion/Results:Lethal concentrations (LC50) for all drugs were determined. Combinations of MDMA and alcohol produced greater lethality than either alone, e.g., addition of the maximal non-lethal concentration(MNLC) of alcohol reduced the LC50 for MDMA, and addition of the MNLC of MDMA reduced the LC50 for alcohol. The addition of the MNLC of MDMA to nicotine also produced a small reduction in the LC50 value. However, when the MNLC of nicotine was added to MDMA, the LC50 value was *increased* (i.e., it was protective). The same pattern of effects was observed for methylone. Based on these results, when MDMA and methylone are combined with alcohol, greater lethality and toxicity occur than with either drug alone. However, the combination of MDMA and methylone with the MNLC of nicotine showed a promising reversal in lethality and toxicity. This may provide a rationale for developing a treatment for MDMA/methylone overdose, for which there are no current treatments aside from symptomatic relief.Supported by grants from the National Institute on Drug Abuse (USA): R03DA045350 (FSH),R03DA045833 (ITS), U01DA054330 (ITS)

Title: Morphine self-administration alters brain structure and neuronal/glial density in male Wistar rats

Authors: *C. J. CARRANZA-AGUILAR, A. ELIZARRARAS-HERRERA, M. SERRANO-RAMIREZ, D. MEDINA-SÁNCHEZ, J. RASGADO-TOLEDO, D. ANGELES-VALDEZ, L. TRUJILLO-VILLARREAL, E. A. GARZA-VILLARREAL;
Inst. de Neurobiología, UNAM, Juriquilla, Mexico

Abstract: Introduction: Opioid use disorder involves compulsive use of opioids despite negative consequences. Studies have demonstrated that morphine produces changes in brain volume and glial activation, although the underlying mechanisms remain unclear. This study aimed to investigate the effect of morphine on drug-seeking behavior, brain volume, and neuronal/glial density in rats. Our hypothesis was that chronic morphine exposure would result in region-

specific alterations in brain structures characterized by distinct changes in cellular density. Methods: Male Wistar rats on Postnatal (P) day 35 underwent handling and habituation to operant chambers. Subsequently, a catheter connected to a non-magnetic access button was implanted in the Jugular vein. After a recovery period, two protocols involving active or inactive lever pressing for self-administration of morphine or saline (0.9%) infusions were conducted: 1) Morphine self-administration (0.01 mg/kg/infusion) under a Fixed Ratio 1 (FR1) schedule for 20 days, and 2) Morphine self-administration (0.1 mg/kg/infusion) using the same FR1 schedule, followed by a Progressive Ratio 9-4 (PR) schedule for 20 days. To assess structural changes in the brain, in vivo 3D magnetic resonance imaging (MRI) scans (sequence: TR = 30.76 ms, TE = 5 ms, rotation angle = 10°, slice thickness = 25.6 mm, FOV = 28.2 x 19 x 25.6 mm, and isometric voxel size = 160 µm) were performed before treatment and during FR1 and PR schedules. Immunofluorescence staining of microglia (anti-Iba1) and neurons (anti-NeuN) was conducted after each protocol. Results: We observed a gradual increase in morphine infusions during the FR1 schedule that stabilized during the PR schedule. Furthermore, the morphine group exhibited a progressive increase in active lever pressing, while inactive lever pressing remained stable and similar to the control group. MRI scans showed that morphine led to decreased volume in six brain regions, including the insular cortex ($p = 0.043$), while 14 regions, including the brainstem ($p = 0.045$), exhibited increased volume. In comparison to the control group, morphine self-administration increased the population of microglial cells in the brainstem, while the number of neurons remained unchanged. Similarly, in the insular cortex, there was an increase in microglial cell count, but a decrease in neuronal cell count. Conclusion: The changes in brain volume induced by morphine are related to alterations in neuronal populations and influenced by neuroinflammation, indicating a potential association between cellular changes and macrostructural modifications.

Title: Adolescent Social Isolation Increases Vulnerability to Voluntary Opioid Consumption in Adulthood in Rats

Authors: *P. LEMEN, H. CHEN, J. HUANG;
Integrated Biomed. Sci. - Genetics, Genomics, Informatics, Univ. of Tennessee, Memphis, TN

Abstract: Social stress during adolescence can cause behavioral changes lasting into adulthood and is a risk-factor for substance use disorder, but the effect varies between individuals. This

study characterizes how social isolation in adolescence affects opioid use and anxiety-like behavior in adulthood using the inbred strains WKY and DSS rats. We compare adulthood oxycodone intake in self-administration and behavior in an elevated plus maze (EPM) between rats either group housed (GH) or isolated for 6 weeks during adolescence. We also develop a method (PeerPub) for operant oral intake of two rats in the same chamber to better model human social condition. Our data shows rats isolated during adolescence (n = 12/group) have higher vulnerability to oxycodone consumption in adulthood (WKY females P=0.006, WKY males P=0.01, DSS females P=0.02, DSS males P=0.05). We also found differences in anxiety-like behavior between experimental phases (baseline, post-drug, and withdrawal). Overall, our data indicates that rats isolated during adolescence have less anxiety-like behavior before oxycodone exposure, a decreased sensitivity to the negative effects of oxycodone, however, they consume more drug. These data demonstrate a need for better understanding in the role social environments play in vulnerability to drug use. We plan to examine underlying molecular mechanisms associated with these phenotypes in future studies.

Title: Flualprazolam, a designer benzodiazepine, induces psychological and physical dependence in rodents

Authors: *D. KIM, Y. LEE, W.-A. KOOK, A. DONIO, H.-W. MIN, S.-B. HWANG, S.-Y. LEE, C.-G. JANG;
Sungkwunkwan Univ., Gyeonggi-do/Suwon, Korea, Republic of

Abstract: Flualprazolam is a designer drug to clandestinely circumvent government regulations. It can be purchased via internet easily. Thus, it is generally abused for its sedative/hypnotic effects by young adults for recreation. Flualprazolam is structurally related to the triazolobenzodiazepine, producing central nervous system (CNS) depression. Although flualprazolam is structurally similar to alprazolam, a single fluorine atom of it increases pharmacokinetic parameters including half-life and volume of distribution leading to a potential for greater toxicity and drug addiction than alprazolam. For strict vigilance and to make regulations for this drug, we must know the effect of flualprazolam including psychological and physical dependence. So, we planned to estimate the drug effect using C57BL/6J mice(7~8weeks) at locomotor activity test and withdrawal (WD) test to confirm effect on baseline locomotor activity and physical dependence. Sprague Dawley (SD) rats (4weeks) were

used for intravenous self-administration (IVSA) to investigate flualprazolam induced psychological dependence. In locomotor activity test, five dose of flualprazolam, 0.03, 0.1, 0.3, 1 and 3 mg/kg significantly reduced spontaneous locomotor activity in C57BL/6J mice (n=9). Continually, we injected flualprazolam intraperitoneally during 7days. 24 hours after the last flualprazolam injection, we observed the withdrawal symptoms. We confirmed that treatment with flualprazolam at 0.6mg/kg dose induced physical dependence, especially high forepaw tremor (n=9). In IVSA, two dose of flualprazolam, 0.01 and 0.03mg/kg per infusion significantly increased the number of infusions and active lever pressing compared to vehicle (n=6). All data were analyzed using ANOVA with Fisher's LSD post hoc test. The findings of this study demonstrate that flualprazolam has reinforcing effect and dependence in rodent models.

Title: Chronic toluene exposure and diabetes increases vascular adrenergic effects in rats

Authors: L. TAPIA-HERNANDEZ[1], D. GODINEZ-HERNANDEZ[2], L. F. ORTEGA-VARELA[3], *M. Y. GAUTHEREAU-TORRES[1];
[1]Facultad de Ciencias Medicas y Biologicas "Dr. Ignacio Chavez", [2]Inst. de Investigaciones Quimico Biologicas, [3]Facultad de Salud Publica y Enfermeria, Univ. Michoacana De San Nicolas De Hidalgo, Morelia, Mexico

Abstract: Recreational use of inhalants, like toluene, is a serious drug abuse problem all over the world, mainly affecting children and teenagers. Toluene shares pharmacological properties with central nervous system depressants, and it is commonly inhaled to achieve intoxicating states. It can be found in products like thinner, spray paint and glue. Toluene can cause cardiovascular damage, arrhythmias and sudden sniffing death probably due to adrenergic sensitization of the heart. On the other hand, diabetes is one of the main chronic diseases with a high incidence and death. It is known that diabetes can generate serious health problems such as cardiovascular damage, lowering quality of life. Adrenergic receptors are present in different amounts in tissues, including brain, heart and blood vessels. The main functions of these receptors include modulation of neurotransmission, regulation of metabolism, inotropy, chronotropy, and

vasoconstriction. The purpose of this study was to investigate if chronic toluene exposure modifies alpha-1 adrenergic responses in aorta of diabetic rats. 4 groups of Male Wistar rats (8-9 weeks) were placed in static exposure chambers during 30 minutes, twice a day, during 4 weeks. Group 1 was a control group exposed to air; group 2 was induced to diabetes (50 mg/dl of streptozotocin) and exposed to air; group 3 was exposed to 6000 ppm of toluene and group 4 was induced to diabetes and exposed to 6000 ppm of toluene. After this period, rats were euthanized with sodium pentobarbital (65 mg/kg) and aorta was isolated, it was cut into rings and the endothelium was removed from half of them. Arterial rings were bathed in a 10 ml chamber, filled with Krebs-Henseleit solution, and attached to the bottom of the chamber and to an isometric force displacement transducer. Aortic rings were subjected to an initial optimal tension of 3 g and were stimulated with a submaximal concentration of phenylephrine ($1x10^{-7}$ M). Concentration-response curves to phenylephrine (alpha-1 adrenergic agonist: $1x10^{-9}$ - $1x10^{-5}$ M) were made. Our results showed that phenylephrine produced a contraction in a concentration-dependent manner in all groups, and that chronic toluene exposure in aortic rings with endothelium from diabetic rats produced a higher response to phenylephrine compared with the other groups. In addition, in endothelium-denuded rings, chronic toluene exposure generated a greater response to phenylephrine compared with control, diabetes and toluene-diabetes groups. In conclusion, our findings suggest that chronic toluene exposure in diabetic and non-diabetic rats increases alpha adrenergic responses probably due to an endothelium-dependent mechanism.

Title: Evaluation of the effects on the dopaminergic reward system and the blood-brain barrier permeability of diphenidine derivatives using rat brain microdialysis

Authors: *Y. TAKAHASHI[1,2], K. OKUDA[1], M. ASARI[1], K. MORI[1], R. NAMBA[1], W. OCHIAI[2], K. SHIMIZU[1];
[1]Asahikawa Med. Univ., Asahikawa City / Hokkaido, Japan; [2]Hoshi University, Grad. Sch. of Pharmaceut. Sci., Shinagawa-Ku / Tokyo, Japan

Abstract: Background: Diphenidine (DPD) - a new psychoactive substance - has a chemical structure similar to phencyclidine and ketamine. DPD and some of its derivatives are designated as controlled drugs in Japan and many other countries. Recently, we have reported that brain dopamine contents are increased after intraperitoneal (i.p.) administration of DPD and its

derivatives (4-methoxy-DPD and 4-hydroxy-DPD): brain concentrations tend to peak at 30 to 45 min after administration, and then gradually decrease in a time-dependent manner. These results demonstrated that the DPD derivatives could penetrate the blood-brain barrier (BBB). In this study we evaluated the neurochemical effects on the dopaminergic reward system and the BBB permeability of i.p. injected 4-methoxy-DPD and 4-hydroxy-DPD using rat brain microdialysis.
Methods: Male Slc:Wistar/ST rats were anesthetized and stereotaxically implanted with a microdialysis probe in the right nucleus accumbens (NAc, A: +2.0 mm; L: +1.5 mm from the Bregma; V: -6.0 mm from the skull). Perfusion was performed the following day. An inhibitor of various transporters expressed in the BBB was injected subcutaneously 1 hr before i.p. injection of 4-methoxy-DPD or 4-hydroxy-DPD at 20 mg/kg. Dialysates were collected and then analyzed by HPLC-ECD for the dopamine content and by LC-MS/MS for determination of DPD derivatives.
Results and Discussion: The 4-methoxy-DPD and dopamine contents in the rat-brain dialysate were significantly increased with pretreatment of P-glycoprotein inhibitors, verapamil, and quinidine compared to vehicle control. Conversely, the 4-hydroxy-DPD and dopamine contents in the dialysate were significantly decreased with pretreatment of an organic cation transporter inhibitor, diphenhydramine. The peak concentration of 4-hydroxy-DPD in the dialysate was higher than that of 4-methoxy-DPD. This effect of 4-hydroxy-DPD on the dopaminergic reward system was consistently observed: i.e. levels were always higher compared to DPD and 4-methoxy-DPD. These findings suggest that the efflux transporter P-glycoprotein limits the BBB permeability of 4-methoxy-DPD, and the influx transporter organic cation transporter is involved in the potent BBB permeability of 4-hydroxy-DPD. We conclude that it was important to consider the pharmacokinetics, such as the BBB permeability and behavior of the metabolites, when evaluating the effects of novel psychoactive substances.

Title: High ambient temperatures potentiate the lethality of MDMA and MDMA-like synthetic psychoactive cathinones in larval zebrafish

Authors: *L. KOUNTZ;
Univ. of Toledo, Toledo, OH

Abstract: High ambient temperatures potentiate the lethality of MDMA and MDMA-like synthetic psychoactive cathinones in larval zebrafish

Logan E. Kountz[1], Sasha Heeren[1], Corey J. Widman[2], Faith E. Digby[2], Alexander S. Wisner[2,3], Frederick E. Williams[1,3], Isaac T. Schiefer[2,3], and F. Scott Hall[1]

In recent years, there has been an increase in the number, potency and availability of novel psychoactive drugs that duplicate the effects of many well-established illicit drugs. Between 2005 and 2011, the European Monitoring Centre for Drugs and Addiction (EMCDDA) Early Warning System identified 164 new psychoactive substances in the EU (Bretteville-Jensen, 2013). Many of these are derivatives of cathinone, the naturally occurring β-ketone analogue of amphetamine found in *Khat (Catha edulis)* that produce amphetamine-like sympathomimetic effects (Valente, 2014). These effects include tachycardia and hypertension, as well as some psychoactive effects such as euphoria and increased alertness. There have been some synthetic psychoactive cathinones (SPCs) derived that mimic methylenedioxymethamphetamine (MDMA) and cocaine as well, and have come into wide illicit use. Many individuals take these drugs unknowingly, thinking they are other drugs, as shown in a study of individuals that thought they were consuming MDMA (Palamar, 2016). The majority of these individuals have consumed SPCs, including methylone, dimethylone, α-pyrrolidinovalerophenone, and others. SPCs are often taken at parties or clubs. The lethal and toxic effects of MDMA and methamphetamine are exacerbated by elevated ambient temperatures (Cappon, 1997), and this has been shown in mice (Chen, 2021). As a higher throughput approach to evaluating SPC toxicity, the Hall laboratory has been using larval zebrafish. It is not known whether higher ambient temperatures exacerbate lethal toxicity in larval zebrafish. This question was addressed in experiments examining MDMA, and a series of structurally similar MDMA-like SPCs. Firstly, these studies showed that high ambient temperatures exacerbate MDMA toxicity in larval zebrafish. Moreover, the same was observed for all SPCs. There was some variability in the magnitude of this effect which may be used to identify structure activity relationships as a wider range of analogues are studied.

Title: Characterization of spontaneous withdrawal following continuous fentanyl administration in female and male rats

Authors: *M. M. MORGAN, K. ATARAS;
Psychology, Washington State Univ., Vancouver, WA

Abstract: Fentanyl, a high potency synthetic opioid, is the leading cause of drug overdose in the United States. The widespread use of fentanyl suggests that dependence develops rapidly and withdrawal symptoms are severe. This hypothesis was tested by examining withdrawal symptoms in female and male Sprague-Dawley rats receiving continuous fentanyl administration for 3 days. Given that opioid administration to treat pain can be a gateway to opioid dependence, rats were injected with CFA into the right hindpaw to induce persistent inflammatory pain. The side effects of fentanyl (1 mg/kg/day) administration almost completely depressed home cage wheel running during the first day of administration. Running in male rats recovered to CFA levels on Days 2 and 3, whereas running in female rats remained depressed for all 3 days. Abrupt termination of fentanyl administration induced withdrawal as measured by depression of wheel running, a decrease in body weight, and an increase in wet dog shakes. Both male and female rats lost approximately 10% of their body weight in the 24 hrs following termination of fentanyl administration. An equally quick decrease in wheel running and increase in wet dog shakes occurred in female rats undergoing withdrawal. Depression of wheel running and increased wet dog shakes was delayed until the second day of fentanyl withdrawal in male rats. Withdrawal symptoms persisted for at least 4 days in female and male rats. These data demonstrate that fentanyl dependence develops rapidly with continuous administration and withdrawal symptoms are more severe in female compared to male rats.

Title: A functional network for evidence accumulation during perceptual decision-making revealed with model-based fMRI

Authors: *J. WONGTRAKUN, S.-H. ZHOU, M. A. BELLGROVE, T. T. J. CHONG, J. P. COXON;
Turner Inst. for Brain and Mental Hlth., Monash Univ., Melbourne, Australia

Abstract: Accumulating sensory information to inform a decision is a noisy process that occurs in close temporal proximity to attentional selection and motor planning and execution. Consequently, elucidating which networks encode the different stages of a perceptual decision with fMRI has proven challenging. Here, we employed a custom random dot-motion paradigm, alongside a conjunction analysis, in a sample of 50 healthy adults (27 females; age mean ± standard deviation, 25 ± 5.98 years) with the aim of reducing the impact of attention and motor-related processes on evidence accumulation, i.e., the act of gathering sensory information towards a decision, during perceptual decision-making. We show that BOLD activity increases during perceptual decisions concerning changes in visual motion across a bilateral frontoparietal network consisting of the intraparietal sulci, anterior insula, and premotor and pre-supplementary motor areas. Additionally, activations in the caudate and putamen suggest the basal ganglia plays an active role when gathering sensory evidence. We applied drift diffusion modelling to the behavioural data and parametrically modulated BOLD activation within this network by the modelled parameters of drift rate, decision threshold, and non-decision time. We observed that slower drift rates (prolonged evidence accumulation) and greater non-decision time values corresponded with increased BOLD activity within this network. In contrast, BOLD activity was not parametrically modulated by the decision threshold parameter. Overall, through novel experimental design and analysis procedures, these findings clarify brain regions thought to be involved in the evidence accumulation, but not attentional selection or motor execution, stage of perceptual decision-making in humans.

Title: Unveiling the Mechanism of Temporal Scaling in Neural Representations in a multiple-timescale model

Authors: *T. KURIKAWA;
Future Univ. Hakodate, Hakodate, Japan

Abstract: Unveiling the Mechanism of Temporal Scaling in Neural Representations in a multiple-timescale model

Understanding how temporal information is encoded in the neural system is pivotal for comprehending various cognitive functions, including working memory tasks. Recent experimental studies have demonstrated that neural states exhibit varying speeds depending on contextual factors, while maintaining highly similar trajectories—an intriguing phenomenon known as temporal scaling. Theoretical investigations have utilized reverse engineering methods to analyze this temporal scaling of neural representations. However, the underlying mechanism remains elusive, with the process often described as a black box.
In our previous study (Kurikawa and Kaneko, 2021, Frontiers in Computational Neuroscience), we developed a multiple-timescale neural network capable of generating robust sequential patterns for performing working memory tasks (Kurikawa, the proceedings of ICANN 2021). This network model is constructed using a simple learning rule that adheres to the principle of locality, requiring only pre- and post-synaptic information. As a result, the structure of the neural dynamical systems following learning becomes transparent. In the present study, we employed this model to elucidate the mechanism underlying temporal scaling in neural representations across different contexts.
By training the network to generate sequences under specific contexts, represented by distinct input strengths of the external input and varying gain parameters of the activation function in the neurons, we observed the emergence of temporal scaling. We discovered that neural trajectories are composed of pseudo fixed-point attractors, and the stability of these attractors is simultaneously modulated by the strength of the external input and/or the gain parameter. The regulated stability of these attractors leads to transitions of neural states from one attractor to another at different speeds, contingent upon the input strength and/or the gain parameter. Additionally, we identified a network structure that enables global regulation of attractor stability. Collectively, our findings propose a novel mechanism underlying temporal scaling in the neural system.

Title: Feature-level uncertainty, estimated via temporal difference reward prediction errors, may describe a mechanism underlying paradoxical learning phenomenon.

Authors: *A. R. SHIPP, K. KISHIDA;
Wake Forest Univ. Sch. of Med., Kernersville, NC

Abstract: Computational reinforcement learning theory has a well-established role in investigating value-based decision-making and learning in computational and biological agents. It has been used to consider other decisions, like implicit choices expressed as 'selective attention' (Dayan, et al., 2000). In contrast to considering selective attention as a resource constraint problem, Dayan and colleagues proposed a novel approach that viewed attention as an optimal learning problem. Their approach requires prior knowledge of the statistical variance of various features' reward predictability. This can work extremely well for computer agents where such knowledge may be provided; however, biological agents require a way to estimate this variance in a constantly evolving environment. We hypothesize that phasic dopamine levels, generated in response to temporal-difference reward prediction errors (TD-RPEs), can provide not only a learning signal for reward-value updating, but also direct estimates of associated uncertainty (i.e., information levels).
Our approach largely follows Dayan and colleagues' framework, but instead of requiring prior knowledge of statistical variance, we hypothesize that the standard deviation may be directly conveyed by TD-RPEs (and thereby phasic dopamine levels in mammals, including humans). From this signal, we show how uncertainty may modulate estimates of feature precision, reliability, and learning rates. Specifically, TD-RPE's can provide the quantitative signal required to adjust learning rates and differentially weight the expected values of predictive features. Our model provides a hypothetical mechanism for selective attention through precision-weighting of features and value-based choice. It also provides a hypothetical mechanism for how mammalian brains may estimate feature-level uncertainty. We explored whether our model may explain other learning phenomenon that appear paradoxical within traditional reinforcement learning. We ran simulations of various tasks and found that our model may explain Kamin blocking, latent inhibition, extinction and renewal, one-shot learning, and saliency of novel stimuli. Future work will compare our model to human behavioral data and sub-second dopamine fluctuations to test the hypothesis that dopamine levels augment behavior in a manner consistent with signaling of feature-level uncertainty via TD-RPEs.

Title: Statistical framework for identification of individual and social aspects of animal learning in Intellicages

Authors: B. JURA[1], M. LENARCZYK[1], Z. HARDA[2], L. SZUMIEC[2], M. ZIEMIAńSKA[2], J. RODRIGUEZ PARKITNA[2], ***D. K. WOJCIK**[3,1];
[1]Fac. of Mgmt. and Social Communication, Jagiellonian Univ., Kraków, Poland; [2]Dept. of Mol. Neuropharm., Maj Inst. of Pharmacol. of the Polish Acad. of Sci., Kraków, Poland; [3]Lab. of Neuroinformatics, Nencki Inst. of Exptl. Biol. of the Polish Acad. of Sci., Warszawa, Poland

Abstract: Several recent cage designs support studies of multiple animals housed for weeks with minimal human intervention in a single or multiple compartments where they can interact with cage elements and with each other, and their behavior can be tracked in various ways. Here we focus on Intellicage system where up to 14 female mice housed together can be identified with an RFID transponder interacting with intelligent corners providing reward, and the behavior is described in terms of discrete events. We present a general conceptual, analytical and computational framework for stochastic description, analysis and modeling of data from such cages. This framework combines the theory of point processes (as used in spike train analysis) with reinforcement learning models. We demonstrate how individual and social aspects of learning can be identified within the data, and show different specific approaches which facilitate study of effects of the whole group on an animal or formation of a hierarchy of social effects in group learning. The results of the analysis are validated with equivalent simulated data.
To illustrate this conceptual framework and our analytical approach we designed an experimental paradigm where rewards are offered depending on an arbitrary assignment of an animal to one of two groups, “majority” or “minority”. The two groups were assigned different locations with reward availability, changing in consecutive phases of the experiment. We show that the data support importance of the social effects in animal learning of the reward and may also be used to identify a social structure within the group. Corresponding generative models can be used for validation of various analytical methods and for prediction of mice behavior.

Title: Striatal dopamine teaching signals reflect an agent's perceived locus of control

Authors: *T. BERNKLAU, B. RIGHETTI, L. S. MEHRKE, S. N. JACOB;
Klinikum rechts der Isar, Tech. Univ. of Munich, Munich, Germany

Abstract: Striatal dopamine drives associative learning by acting as a teaching signal. Much work has focused on simple learning paradigms, in which dopaminergic signals passively track the statistics of externally controlled outcomes. However, higher cognition requires an agent to generate internal concepts of its environment, in which sensory stimuli, actions, and outcomes become associated. To address the role of dopamine in this learning process, we performed direct dopamine measurements across the striatum and computational modeling in mice learning cue-instructed actions following implicit task rules. We found that cue-triggered and outcome-triggered dopamine signals were not consistently coupled through an inverse relationship as in Pavlovian learning, but depended on the adopted behavioral response strategy. When animals applied simple behavioral strategies that did not incorporate mechanistic links between cues, actions, and outcomes, passive reward predictions were reflected in distinct cue dopamine signals for trials in which animals expected higher or lower returns. As the animals rediscovered the impact of their own actions, dopaminergic reward predictions for the different trial events were recoupled, indicating a crystalizing understanding of the current task. Temporal-difference reinforcement learning models reproduced the main behavioral and dopaminergic signatures. We incorporated mechanistic hypotheses derived from our experimental findings into the models' architectures and found that reward prediction errors (RPEs) in the form of state-action value prediction errors approximated the observed dopamine signals well. Modeling suggested an adjustment in the animals' learned cue-action-outcome associations after rule switches. The experimental data showed that outcome dopamine signals re-emerged upon introduction of a new task rule and did so equally across different conditions despite strong differences in behavioral performance, which should have triggered different RPEs. This disruption after rule switches could be modeled by a reset of state-action values that was only partial and discarded outcome-predictive information but retained choice-guiding information, indicating that the learned cue-action-outcome association had been cut. Off-policy and on-policy learning predicted qualitatively different RPE signatures after rule switch. Our dopamine data clearly favored the on-policy variant, matching the deterministic nature of our task that did not encourage exploration. Together, our experimental and modeling results suggest that dopaminergic RPEs reflect an agent's perceived locus of control.

Title: Disentangling self- and object-motion in a target interception task: normative strategies and neural circuits

Authors: *J. VASTOLA[1], V. VENCATO[2], J.-P. NOEL[2], G. C. DEANGELIS[3], D. E. ANGELAKI[2], J. DRUGOWITSCH[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]New York Univ., New York City, NY; [3]Univ. of Rochester, Rochester, NY

Abstract: Whether motion across the retina is due to object motion, self-motion, or a mix of both is often ambiguous. Resolving this ambiguity is important, since animals may have to react differently depending on whether, e.g., a predator is moving towards them or not. We study the required disentangling of self- and object-motion, a form of dynamic causal inference, in the context of a novel navigation task for both humans and macaque monkeys. In each trial, subjects in a virtual reality environment first briefly observe a target that may or may not be moving, and they may also experience self-motion. After that, the target becomes invisible and subjects must attempt to intercept it by using a joystick to steer through the virtual environment. We find that the behavior of humans (N = 5 naïve, 2 non-naïve) and a monkey (N = 1) is consistent with the predictions of a normative model which couples (i) a Bayesian strategy for target trajectory inference with (ii) near-optimal navigation that minimizes a certain set of costs (including movement costs and proximity-to-target costs). In particular, major qualitative features of the behavioral data (like a biased assessment of target motion given self-motion) are consistent with the model, and quantitative features like subjects' trajectories can be fit reasonably well. Given that the model appears to describe behavioral data well, we also construct a biologically plausible neural circuit model that suggests how our proposed strategy might be implemented by the brain. The circuit model, which couples several probabilistic population codes, is consistent with ideas about how causal inference may be reflected in the cortical hierarchy: primary sensory cortices reflect estimates according to each possible causal structure, which are then combined in intermediate areas (e.g., posterior parietal cortex), and used to drive decisions in downstream areas.

Title: Impulsive decision-making and indicators of psychoemotional and cardiovascular health in a cohort of Medical Students

Authors: *S. GUARDO[1,3], A. F. SARMIENTO[3], M. GAVIRIA[3], E. LADINO[3], G. TOVAR[3], G. D. BRICEÑO[4], J. A. CESPEDES[3,5], S. LOPEZ-GUZMAN[2];
[2]NIMH, [1]Natl. Inst. of Mental Hlth. (NIMH), Bethesda, MD; [3]Escuela de Medicina y Ciencias de la Salud, Univ. del Rosario, Bogota, Colombia; [4]Uniminuto, Bogota, Colombia; [5]Fundacion Cardioinfantil, Bogota, Colombia

Abstract: Depression and anxiety in medical students are known to be linked to psycho-emotional and social factors. High academic demands and stress can lead to unhealthy choices in lifestyle that range from lack of exercise, poor nutrition, all the way to alcohol and drug use. These unhealthy behaviors can have lasting consequences on mental and cardiovascular health that could persist into their professional work life and potentially impact patient care. The link between stress and unhealthy habits is not fully understood and has been understudied in this population, but other studies have pointed to maladaptive decision-making as candidate mechanism. This type of decision-making, also known as choice impulsivity, refers to the tendency to prefer immediate rewards over better long-term rewards, and is known to be increased in individuals with substance use disorders, and in people with obesity. In college students, choice impulsivity is associated with lower academic performance, greater alcohol use, and a lower age for starting smoking and risk of obesity. In this study we explore the relationship between stress, impulsive decision-making, and poor health in a cohort of medical students in Colombia.**Materials and Methods:** Cross-sectional observational study (n = 176 students) of first-year medical students at a university in Bogota, Colombia (ages 17-19). We obtained baseline measures of cardiovascular health (CVH), nutrition, body mass index (BMI), perceived stress, self-reported empathy, self-reported emotional intelligence, and choice impulsivity in the first months after starting the program. Choice impulsivity was assessed through a computerized delay discounting task, where students had to choose between immediate and delayed monetary rewards. A computational model was applied to each individual dataset to derive subject-specific parameters, the discount rate (DR) that indexes the level of choice impulsivity.**Results:** Preliminary results did not indicate a significant correlation between DR and CVH. However, a specific relationship was found between BMI and DR. Regarding the relationship with psycho-emotional factors, DR was proportionally related to the level of perceived stress, and it was inversely proportional to the level of empathy.**Conclusions:** Data collection and analyses are still ongoing, but these preliminary results indicate that choice impulsivity may be an indicator of poor lifestyle in medical students and it may reflect high levels of stress. Psycho-emotional compensatory mechanisms such as empathy and emotional intelligence may be important coping tools for minimizing the impact of stress on decision-making and lifestyle.

Title: Cognitive model discovery via disentangled RNNs

Authors: *K. MILLER, M. ECKSTEIN, M. BOTVINICK, Z. KURTH-NELSON;
Google DeepMind, London, United Kingdom

Abstract: Computational cognitive models are a fundamental tool in behavioral neuroscience. They instantiate in software precise hypotheses about the cognitive mechanisms underlying a particular behavior. Constructing these models is typically a difficult iterative process that requires both inspiration from the literature and the creativity of an individual researcher. Here, we adopt an alternative approach to learn parsimonious cognitive models directly from data. We fit behavior data using a recurrent neural network that is penalized for carrying information forward in time, leading to sparse, interpretable representations and dynamics. When fitting synthetic behavioral data from known cognitive models, our method recovers the underlying form of those models. When fit to laboratory data from rats performing a reward learning task, our method recovers simple and interpretable models that make testable predictions about neural mechanisms.

Title: Marmosets accumulate dynamic sensory evidence for decision-making

Authors: *X. XIA, N.-L. XU;
Ctr. for Excellence in Brain Sci. and Intelligence Technology, Chinese Acad. of Sci., Shanghai, China

Abstract: Dynamic evidence accumulation is an important cognitive process, in which the brain accumulates the dynamically unfolding sensory evidence for discriminating the complex stimulus. The dynamic evidence accumulation task recently has been used in rodents to research

the neural mechanisms of perceptual decision-making, while only a few studies in non-human primates. Marmoset is a promising non-human primate model in cognitive neuroscience, however, the cognitive task training in marmoset still is a main technical bottleneck, which has limited its application in cognitive neuroscience. In here, we established a head-fixed marmoset behavior training protocol, and we trained the marmoset to learn an auditory-based dynamic evidence accumulation task. During the task training, there are three nozzles in front of the head-fixed marmoset. For each trial, the marmoset initiates the task by licking the central nozzle, after which the auditory stimulus is delivered, and the marmoset reports its decision by licking the left or right nozzle to get the reward. With this training paradigm, we established an evidence accumulation task in marmosets. In this task, the auditory stimulus is a pure tone sequence which consists of low frequency (5.4KHz) and high frequency(11.8KHz). There are 5 tones in each stimulus and the tone duration and tone interval both are 125ms. The marmoset needs to adjudicate whether there are more high-frequency or low-frequency tones. If the low-frequency tones are more, the marmoset should lick left nozzle and vice versa. During the auditory stimulus playing, the marmoset is not allowed to response until a go cue to inform marmoset to response. We found that the marmoset can learn this task with about 80% accuracy. For this task, another possible task strategy is random selection strategy, in which the animals randomly select one tone to make decision, this strategy does not require evidence accumulation. we built a behavior model based on random selection strategy and compared the behavior performance between the marmoset and model. We found that the difficult trial accuracy of marmoset is higher than the model. This result suggests that the marmoset indeed accumulates the evidence to make decision. Given the marmosets are easier to increase training throughput and use various circuit analysis tools comparing with rhesus monkey, our work paves the way for uncovering the neural circuit mechanisms of auditory evidence accumulation in non-human primates.

Title: Humans are excessively indecisive under time constraints

Authors: *S. R. SULLIVAN[1], R. LOKESH[1], J. A. CALALO[1], A. ROTH[1], C. S. PETERS[1], J. H. BUGGELN[1], T. T. NGO[1], M. J. CARTER[2], J. CASHABACK[1];

Abstract: Failing to decide on a movement when acting under time constraints can be detrimental, such as a driver who fails to decide where to steer a car and causes a crash. Research

in decision-making has explored how humans select motor plans to maximize reward given the inherent sensorimotor delays and uncertainties. Yet studies imposing time constraints have not examined indecisive behaviour, where humans fail to decide before a deadline. Here we test the idea that optimal motor planning that accounts for sensorimotor delays and uncertainties will result in indecisions.To investigate, participants grasped the handle of a robotic manipulandum. A screen displayed a start position and two potential targets. The right and left targets were 20 cm forward of the start position. The participant hand position and a computer agent were displayed with separate cursors. Participants received one point if they reached the same target as the agent, zero points if they reached the opposite target, or zero points if they were indecisive and failed to reach a target by 1500 ms. The participant and agent began each trial in the start position. The agent cursor moved directly from the start position to either the right or left target. Movement onset of the agent was drawn from a normal distribution, with the mean and standard deviation fixed within a condition. Between conditions we manipulated the mean and standard deviation of the movement onset of the agent using a 3 (mean: 1000, 1100, 1200 ms) x 2 (standard deviation: 50, 150 ms) repeated measures design. We developed a model that finds the optimal time to either react to the agent or guess a target to maximize expected reward. Inputs to the model include the delays and uncertainties associated with reaction time, movement time, coincidence timing, and the agent movement onset. Based on the optimal timing for each experimental condition, the model can also predict the percentage of trials that should result in indecisions. The model predicts more indecisions in the 1100 ms conditions than the 1000 ms conditions, and less indecisions in the 1200 ms conditions than the 1000 ms conditions. Aligning with the model, we found that participants made more indecisions in the 1100 ms compared to the 1000 ms conditions ($p < 0.001$). However, participants made more indecisions in the 1200 ms condition than the 1000 ms condition ($p = 0.004$), which was the opposite trend predicted by the model. Critically, on average the participants made 19% more indecisions in the 1200 ms condition relative to the model. Taken together, our results suggest that humans suboptimally account for sensorimotor and temporal uncertainties, leading to an excessive number of indecisions.

Title: Is metacognitive ability conserved across perceptual and value-based decision-making?

Authors: *D. GOVIL[1], R. PIZARRO[1], A. RENFRO[1], C. R. PLATE[1], Z. BOUNDY-SINGER[3], C. M. ZIEMBA[4,1], S. LOPEZ-GUZMAN[2];

[2]NIMH, [1]NIH, Natl. Inst. of Mental Hlth. (NIMH), Bethesda, MD; [3]1510 W North Loop Blvd., Univ. of Texas at Austin, Austin, TX; [4]UT Austin, UT Austin, Austin, TX

Abstract: Objective: Metacognition is the process of reflecting on one's own thoughts and decisions. Metacognitive ability refers to the accuracy with which confidence reports capture decision quality. Typically, metacognitive ability is measured through modeling the relationship between confidence reports and behavior in decision-making tasks where each trial has an objectively correct answer. As a result, studies of the generalization of metacognitive ability across different cognitive domains have mostly been limited to tasks where decision accuracy can be assessed, such as perceptual decision-making and memory. A relatively unexplored domain is value-based decision-making, where tasks probe preference rather than performance based. However, computational models of value-based choice allow for an analysis of preference behavior akin to that of perceptual decision-making, rooted on the assumption of a probabilistic choice process that is a function of signal strength, in this case, subjective value superiority. Here, we leveraged this computational approach and addressed the question of domain generality by comparing metacognitive ability across three different decision-making tasks spanning perception and value. Methods: Online participants enrolled through CloudResearch completed three computerized decision-making tasks (an orientation discrimination task, a delay discounting task, and a risk/ambiguity preference task) with trial-by-trial confidence reports. The orientation discrimination task was composed of two high-complexity blocks (oriented gratings presented at 5-6 different levels of contrast) and two low-complexity blocks (1-2 levels of contrast). Confidence reports from all three tasks were fit with the CASANDRE model which interprets confidence as an estimate of decision reliability (not of the probability of a decision being correct) and captures metacognitive ability with a single parameter, "meta-uncertainty", expressing the precision of uncertainty representation (Boundy-Singer, et al., 2023). Results: Preliminary results confirm a strong correlation of metacognitive ability within the perceptual domain, when comparing meta-uncertainty derived from the high-complexity versus low-complexity blocks. Similarly, our results show meta-uncertainty correlated across the two value-based decision tasks. Interestingly, we found that meta-uncertainty from the perceptual task was also related to meta-uncertainty from the value-based task, suggesting that metacognitive ability may be domain-general across confidence in both performance and preference.

Title: A Hierarchical Model of Decision-making Fit to Simulated Behavioural and Neural Decision Signal Data using a Single trial Joint Likelihood

Authors: *J. EGAN, S. KELLY, E. CORBETT;
Univ. Col. Dublin, Dublin, Ireland

Abstract: Recent research has demonstrated benefits in using human EEG signatures of decision formation alongside behavioral data to construct and fit models of perceptual decision-making that reflect the brain's decision algorithms. However, while neurally-informed models have been fit using grand-average neural data, or to neural data from specific individuals separately, neurally-informed models have yet to be fit using a hierarchical design that combines group and individual data. Here, using simulated 'ground-truth' data, we demonstrate a neurally-informed hierarchical modelling approach that uses simulation and Approximate Bayesian methods to combine RT and EEG data in a joint-likelihood. This approach respects the relative reliability of each information source, and can furnish reliable individual parameter estimates in the face of sometimes unreliable individual data. To examine the performance of the approach, we compare its performance in recovering known (ground-truth) parameter values to another approach based on individual-specific maximum-likelihood estimation.
We chose a neurally-informed model of decision-making during a cued 2-alternative motion-discrimination task as an example model to demonstrate the approach. The decision process was modelled as a race between two thresholded motor signals: RTs were modelled as the time taken for the first racing motor-signal to hit a threshold, plus motor-execution time, while beta-activity was modelled as the trajectory of the motor-signal plus EEG noise. Ten sets of model parameter values were generated by adding independent noise to each previously obtained best-fitting parameter, and these parameter sets were used to simulate single-trial RT and Beta-activity data for ten individuals. Parameter Likelihood was determined by applying Multivariate Kernel Density Estimation to simulated single-trial data, and an adaptive-MCMC algorithm (Haario, 2001) was used to sample from the Posterior distribution. For comparison, we also used a Particle-Swarm search to determine the Maximum-Likelihood (ML) parameter estimates for each individual separately.
The 95% Highest Posterior Density regions contained the ground-truth values for all parameters. It is particularly noteworthy that parameter recovery was successful even in the case of a parameter set with an EEG signal strength set to 0. Posterior expected parameter values obtained through our hierarchical modelling approach were significantly better than ML estimates obtained for each individual separately. We plan to use this highly versatile procedure to investigate decision-making differences between real individuals.

Title: Investigating a Neurocomputational Basis of Effort-Based Decision Making in Substance Use

Authors: *K. P. SPRY[1], K. T. KISHIDA[2], M. A. ADDICOTT[2];
[1]Neurosci. Grad. Program, Wake Forest Univ. Sch. Of Med., Winston Salem, NC; [2]Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Effort-based decision making evaluates the magnitude and probability of receiving a reward in relation to the effort required to obtain it. If effort expenditure is perceived as increasingly costly, the choice becomes devalued. Dopamine modulates effort-based decision making, as shown in human and animal studies, indicating that increasing or decreasing dopamine transmission enhances or diminishes (respectively) the willingness to expend effort for rewards. Dopamine has also been shown to be affected by chronic substance use, such that over time production, transmission, absorption, and sensitivity to dopamine is altered. However, it remains unclear whether effort-based decision making is affected by the chronic use of substances that affect dopamine. To address this knowledge gap, we investigated the neurocomputational basis of effort-based decision making and its alteration among groups characterized by tobacco use history. Compared to traditional analytic approaches, computational models account for complex relationships and patterns, trial-by-trial changes, feature extraction, and exploratory analysis. In this study, cigarette Smokers (n = 24), Ex-smokers (n = 17), and Never-smokers (n = 23) completed an effort-based decision making task that manipulated reward magnitude and probability for high and low effort options. Computational models were used to assess the subjective value of the high and low effort options based on reward magnitude, reward probability, and effort expenditure, which influences the decision between the high and low effort options. Group differences were revealed in the use of reward magnitude, reward probability, and effort expenditure to modify the subjective value of the choices. Never-smokers modified their subjective value more using effort expenditure (p-value<0.001), whereas Ex-smokers and Smokers modified their subjective value more using reward probability (p-value<0.001). Further, reward probability and reward magnitude were found to have a significant interaction for Never-smokers (p-value<0.001) and Ex-smokers (p-value = 0.004), indicating that the effect of reward probability on subjective value depends on the reward magnitude, whereas this interaction was not present for Smokers. Together, these results suggest that chronic tobacco use affects effort-based decision making. Understanding a neurocomputational basis of effort-based decision making in chronic substance use may enhance our comprehension of both typical and atypical effort-based decision making. These contributions hold the potential for translational utility in the diagnosis and treatment of substance use.

Title: Elucidating the circuit mechanism underlying task-dependent representational geometry of perceptual decisions

Authors: *Y. ZHANG[1], X. SHEN[2], G. OKAZAWA[3], B. MIN[4];
[1]Fudan Univ., Shanghai, China; [2]Peking Univ., Beijing, China; [3]Ctr. for Neural Sci., Inst. of Neurosci., Shanghai, China; [4]Shanghai Ctr. for Brain Sci. and Brain-Inspired Technol., Shanghai, China

Abstract: Understanding how neural population dynamics represent perceptual decisions is a central question in cognitive neuroscience. Previous studies have shown that the average firing rate of neurons in the lateral intraparietal (LIP) area increases with supporting evidence during motion discrimination tasks. However, recent findings from a novel face discrimination task have challenged this classical view, revealing that LIP firing rates actually decrease with supporting evidence (Okazawa et al., 2021 Cell). These contrasting results arise because LIP population encodes decision formation on a curved manifold in state space. The observations call for a revision of circuit models for perceptual decisions. In this study, we present a revised circuit model using an innovative recurrent neural network training technique. First, we recapitulate a Wong-Wang-like circuit model (Wong & Wang, 2006 J Neurosci), which successfully explains the representational geometry of perceptual decisions in motion discrimination tasks, including the curved manifold phenomenon. Building upon this foundation, we develop a new model inspired by the observed single neural dynamics in the data, specifically addressing the initial dip during stimulus onset. Importantly, our modeling work demonstrates that the firing rate reversal phenomenon can be explained by the addition of a single neural population to the existing Wong-Wang-like model. This simple circuit mechanism offers insights into the task-dependent representational geometry of perceptual decisions. Our findings challenge and refine existing models, paving the way for future investigations into the intricate processes shaping cognitive phenomena.

Title: A dynamic log-odds computation drives time-based decisions

Authors: *M. GRABENHORST[1], N. HEIN[2], L. T. MALONEY[3], G. MICHALAREAS[4], D. POEPPEL[1,3];
[1]Ernst Struengmann Inst. for Neurosci. in Collaboration with Max Planck Society, Frankfurt Am Main, Germany; [2]Max Planck Inst. for Biol. Intelligence, Seewiesen, Germany; [3]New York Univ., New York, NY; [4]Max Planck Inst. for Empirical Aesthetics, Frankfurt am Main, Germany

Abstract: Many decisions under uncertainty are shaped by environmental temporal dynamics. The underlying computations are commonly investigated in the context of evidence accumulation over time. However, decisions are often based on estimates of time itself and do not require accumulation of sensory evidence. Under such conditions, the computational primitives of time estimation in decision making are not well understood. Here we conceptualize decision making as a dynamic process based on estimation of elapsed time and probability, leading to choice between options. Building on our previous work on temporal anticipation, we test three hypotheses: 1) Humans infer the 'best-choice' probability over time based on the outcome of their decisions and adapt their choice behavior accordingly. 2) In such dynamic decision making, the uncertainty in time estimation is affected by 'best-choice' probability over time (e.g. large probability, small uncertainty). 3) The uncertainty in elapsed time estimation is affected by time itself, i.e. the scalar property (e.g. large time span, large uncertainty). We used a visual 'set' - 'go' task in which the 'go' cue probability was uniform across time and thus did not provide decision information. Participants were asked to respond as fast as possible to the 'go' cue by pressing one of two buttons which was followed by a feedback signal (correct/incorrect choice). Over trials, the feedback signal encoded the dynamic 'best-choice' probability, i.e. the probability which of the two options is likely correct as a function of time. Analysis of behavior indicates that participants used the feedback signal to infer the dynamic 'best-choice' probabilities. We report three main results: 1) A model based on the log-odds of the 'best-choice' probabilities (ln(P/1-P)) captured choices over time. 2) 'Best-choice' probability is negatively related to the uncertainty in elapsed time estimation, resulting in precise temporal estimates when probability is large. 3) The canonical model of elapsed time estimation (scalar property) only accounts for a minor part of the behavioral variance, highlighting the strong effect of probability on time estimation. In sum, our results demonstrate that a simple computation based on the log-odds drives decision dynamics in the absence of evidence accumulation.

Abstract: In order to make accurate decisions in noisy or otherwise uncertain environments, agents need to integrate relevant information over time. In static environments, the optimal strategy for decision-making involves perfect integration of all available evidence. However, many real-life environments can change unpredictably. Recent normative modelling has shown that in such contexts, optimal decision-making requires agents to weigh evidence differently over time, and to pay special attention to signals indicating that a change may have occurred. In this study, we investigate how two prominent decision-related EEG signals, the centroparietal positivity (CPP) and motor beta lateralisation, may reflect such normative belief updating in volatile contexts.

Human participants (N = 20) monitored a set of checkerboard patches ('samples') appearing anywhere along a semi-circular arc in the lower visual hemifield. Sample locations were drawn from one of two overlapping Gaussian distributions. Participants viewed a maximum of 10 samples per trial, and the distribution from which sample locations were drawn could change during the trial with a fixed probability (hazard rate) of 0.1. Their task was to report what they inferred to be the 'active' distribution at the end of each trial.

Participants weighted later evidence more heavily in their choices, and upweighted surprising evidence. We fit several evidence accumulation models to participants' choices, and replicated previous findings showing that behaviour in this task is best captured by the normative model. In the neural domain, we found that both centroparietal signals and motor preparation responses evoked by each sample scaled with how much evidence it provided (i.e. its log-likelihood ratio, *LLR*), and were also modulated by how surprising the sample was, as expected from normative computations. Motor signals, but not centroparietal ones, additionally reflected prior beliefs.

Our results suggest that centroparietal signals encode the effective magnitude of sample-by-sample belief updates (i.e. *LLR* modulated by decision-relevant contextual variables, like surprise in our context) rather than tracking the decision variable across samples. By contrast, motor beta lateralisation reflects the current state of the decision variable, encoding both prior belief at the time a sample is presented and the belief update evoked by the new information. Our results provide new insight into the long-standing question about which aspects of a decision drive signals like the CPP and beta lateralisation, and pave the way for future work assessing the interplay between them.

Title: Dynamic cognitive control states exhibit widespread distributed encoding in multiple brain regions

Authors: *D. B. DORMAN[1], A. L. SAMPSON[2], P. SACRÉ[3], J. A. GONZÁLEZ-MARTÍNEZ[4], V. STUPHORN[2], E. NIEBUR[2], S. V. SARMA[1];

Abstract: Cognitive control is critical for making goal-directed decisions and inhibiting biased behavior, and its deficits are associated with many neuropsychiatric disorders. Thus, predicting internal cognitive control states from neural data would have broad therapeutic impact. However, quantifying internal cognitive states from behavior to identify neural correlates remains challenging—for instance, cognitive control may fluctuate over time, requiring a method to identify dynamic cognitive control from behavior. Here, we use a state space modeling approach to model dynamic internal cognitive control during a gambling task and identify its neural correlates from intracranial EEG data. Intracranial (stereotactic) EEG was recorded from patients undergoing surgical monitoring for epilepsy while performing a simple card game in which participants drew from a uniform deck and then bet either $5 or $20 that their card would be higher than the computer card. A dynamical model with time-varying weights was fit to participant bets to estimate cognitive control. The model used a logistic choice function to predict bets based on both rational choice variables (expected return and expected risk given current card value) and history-dependent bias variables (recent reward prediction error and card history), and the weights of the bias variables varied over time. The cognitive control signal was then quantified as the ratio of the rational choice weights to bias weights. This allowed us to decouple bias from cognitive control, as participants may experience a high bias but still inhibit that bias on a given trial if their control state is high. Neural correlates of the cognitive control signal were computed by first computing wavelet spectrograms and then computing correlations using a nonparametric cluster statistic on the spectrotemporal data to find regions in time-frequency space for each brain region that were correlated with cognitive control signals. We found that dynamic cognitive control states accurately predicted choices and found that these states exhibited significant correlations with neural time-frequency data across multiple brain regions, including occipital, parietal, and frontal areas. Our results indicate widespread distributed encoding of cognitive control, suggesting that higher level visual areas may experience top-down modulation by cognitive control to attend to critical visual information informing decision making. Together, by decoding cognitive control from behavior and identifying its neural correlates, this work has implications for improving neuromodulatory therapeutic treatments for disorders of cognitive control.

Title: Biases in motion direction estimation are consistent across response effectors

Authors: *E. A. CORBETT[1,2,3], S. M. MORAN[2], P. L. SMITH[4], S. P. KELLY[1,2], R. G. O'CONNELL[2,3];
[1]Sch. of Electrical and Electronic Engin., Univ. Col. Dublin, Dublin, Ireland; [2]Trinity Col. Inst. of Neursocience, [3]Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland; [4]Univ. of Melbourne, Univ. of Melbourne, Melbourne, Australia

Abstract: When people perform perceptual decisions with outcomes on a continuum, they frequently exhibit consistent, but idiosyncratic, biases in response choices and response times. However, it is unclear whether the observed biases might actually be tied to motor responses, as opposed to the perceptual decision process (Topfer et al 2022). To test this, we conducted a study in which six participants reported the perceived direction of motion (spanning 360º) from a random dot kinematogram stimulus at two interleaved coherence levels, in alternating blocks using joystick and eye movement response modes. Responses were made on a circle that surrounded the stimulus. Response times were taken as soon as the response movement was initiated, at which time the stimulus disappeared. Participants were provided feedback on the response movement they made. In the joystick task, a cursor appeared on the screen once the movement was initiated and participants were encouraged to make a ballistic movement to the chosen position on the response circle. With the eye movement, the registered gaze position was displayed to the participant once the response movement was complete. Each participant completed more than 2400 trials in total over four sessions.
We jointly fit individuals' response angles and response times with the circular diffusion model, accounting for encoding failures in the low coherence trials through a mixture component with uniformly distributed drift rates. We fit the directional variation through stimulus biases using the similarity-choice method of Smith et al (2020, 2022), in which the drift rate is the vector sum of the encoded metric (true stimulus direction) and categorical (participant-favoured directions) representations of the stimulus. We jointly fit the data from all conditions, allowing the decision criterion and non-decision time parameters to vary across response modes. We found that the

biases were highly consistent; models with categorical bias parameters shared across the eye and joystick movement data performed better for all participants than those in which the bias parameters were free to vary across response modes, with an average difference in Akaike Information Criterion (AIC) of 12. This result suggests that in this task context in which participants were provided with feedback of their response movement, the behavioural biases largely reflect perceptual decision processing rather than the movements themselves.

Title: A neural circuit mechanism for context-dependent selection via population dynamics

Authors: *P. TOLMACHEV[1], C. LANGDON[2], T. A. ENGEL[2];
[2]Princeton Neurosci. Inst., [1]Princeton Neurosci. Inst., Princeton, NJ

Abstract: The ability to flexibly select relevant stimuli for guiding behavior in different contexts depends on the prefrontal cortex, but the underlying mechanisms are unknown. Traditional hand-crafted neural circuit models hypothesize a suppression mechanism in which the persistent activity of neurons representing context inhibits responses to irrelevant stimuli. On the other hand, reverse-engineering recurrent neural networks (RNNs) trained on context-dependent tasks revealed an emergent mechanism for the flexible selection of relevant stimuli via population dynamics. In RNNs, within a given context, only the inputs aligned with a "selection vector" drive the activity along the line attractor, a continuum of fixed points aligned with the output dimension. In contrast to the inhibitory mechanism, this selection-vector mechanism does not seem to require the suppression of irrelevant stimuli. Yet, it is unclear what circuit structure gives rise to the selection vectors and whether the suppression and selection-vector mechanisms are fundamentally different.
We show that the selection of relevant stimuli via population dynamics can arise from the suppression of irrelevant stimuli. First, we construct a minimal neural circuit model based on the suppression mechanism and show that the circuit dynamics implement the selection-vector mechanism. In reverse, we establish a correspondence between the suppression and selection-

vector mechanisms in RNNs trained on a context-dependent task via backpropagation. We fit RNN responses with a latent circuit model to obtain a low-dimensional mechanistic model of task-related dynamics in the RNN.The latent circuit model revealed the suppression of irrelevant stimulus representations in the RNN, which led to fading of the effective connectivity leading to context-dependent changes in the selection vector.This work links the dynamical-systems description of cognitive computations to the underlying circuit structure, opening new possibilities for causal manipulations of the neural networks to validate these mechanisms in experiments.

Title: Mapping sequential sampling models onto the activity of populations of neurons via the Laplace transform

Authors: *R. KIRKPATRICK[1], M. W. HOWARD[2], P. B. SEDERBERG[3];
[1]Natl. Inst. of Hlth., Bethesda, MD; [2]Ctr. for Memory and Brain, Dept. of Psychological and Brain Sci., Boston Univ., Boston, MA; [3]Dept. of Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: Over the last fifty years, mathematical psychology has developed a class of sequential sampling models to describe evidence accumulation in simple decisions. These models including the diffusion decision model, race models, leaky accumulator models, and leaky competing accumulator models, have been extensively studied behaviorally. Different behavioral experiments have found evidence favoring different models, which can all be understood as distinct parameterizations of a more general cognitive model (Bogacz et al., 2006). The mapping between these cognitive models and populations of neurons in the brain has been a subject of intense interest over recent years, with many authors proposing recurrent neural networks as evidence accumulation circuits. However, the mapping between recurrent neural networks and the different sequential sampling models is unclear. Here we present a theoretical framework that maps these sequential sampling models onto populations of neurons via the Laplace transform and the inverse Laplace transform circuits. These circuits are a special case of recurrent neural networks that have found strong support in the neuroscience of representations of time in memory. Different cognitive models are implemented precisely as different parameterizations of a canonical neural circuit. Neurons in the Laplace representations show monotonic ramping as a function of evidence; neurons in the inverse Laplace representations show circumscribed receptive fields. By studying the covariance matrices of the Laplace and inverse spaces, we find that populations obeying these equations can give rise to sensible low-dimensional dynamics as well as rotational dynamics under appropriate circumstances. Finally, formulating the evidence accumulator in Laplace space leads naturally to a neural representation of evidence as a function of time, which could be used to construct neurocognitive models of decision-making under time pressure and resource rational planning.

Title: Neural circuit underlying economic decisions: insights from a computational model

Authors: *A. BATTISTA[1], C. PADOA-SCHIOPPA[2], X.-J. WANG[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Neurosci., Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Understanding the neural underpinnings of economic choices is fundamental in neuroscience. We present a computational model that sheds light on the neural circuitry instantiating the decision process. Our study utilizes excitatory-inhibitory recurrent neural networks trained with state-of-the-art reinforcement learning algorithms to simulate decision processes in which individuals assign values to available goods and make choices based on their subjective preferences. Analysis of trained networks reveals three types of neurons reminiscent of those observed in the primate orbitofrontal cortex (OFC). These neurons encode the value of individual goods, the value of the chosen good, and the choice outcome. Notably, their activity is independent of spatial contingencies, supporting a good-based model of economic decisions. Furthermore, the dynamics of the networks are low-dimensional, with the relevant dimensions - which explain most of the variance - associated with decision quantities. We extend the model to more complex choice paradigms, including tasks involving multiple features (e.g., quantity and probability), ternary, sequential, and bundled offers. Our network can generalize to new situations akin to real-world decision scenarios.This model challenges previous theoretical assumptions by revealing an heterogeneous activity among the three types of neurons. Unlike prior models, our network does not impose constraints on the functional role of excitatory and inhibitory cells. In particular, it allows for either excitatory or inhibitory neurons encoding the chosen value. This divergence aligns with observations of decision-related neurons in OFC and highlights the importance of considering more diverse neural responses in economic choice contexts.Importantly, we uncover a categorical representation of decision variables, contrasting with a category-free representation found in other prefrontal areas. A recurrent connectivity matrix analysis reveals a highly structured, low-rank pattern indicating low-dimensional population dynamics within the network. We further develop a reduced circuit model based on our trained networks, illustrating winner-take-all dynamics between pools of offer value cells as a mechanism for decision solving.Our study offers novel insights into the neural circuits and dynamics underlying economic decisions. The findings provide a foundation for future investigations, offering testable predictions that could be examined in future experimental studies.

Title: Spectral dynamics in slow brain wave oscillons

Authors: *M. ZOBAER[1], L. PEROTTI[2], D. JI[3], Y. A. DABAGHIAN[1];
[1]The Univ. of Texas Hlth. Sci. Ctr. at Houston (UTHealth), Houston, TX; [2]Physics, Texas Southern Univ., Houston, TX; [3]Dept. of Neurocience & Dept. of Mol. and Cell. Biol., Baylor Col. of Med., Houston, TX

Abstract: Discrete Padé Transform (DPT) is a recently developed computational method that allowscarrying nuanced analyses of the brain waves' structure. In particular, it reveals a novel,detailed picture of the brain wave dynamics1. By applying DPT technique to analyzing thelocal field potential (LFP) recorded in the CA1 area of rat's hippocampus, we found a newlevel of structure—a set of discrete waves with time-modulated frequencies, which we calloscillons. The frequency domains occupied by the individual oscillons roughly correspond tothe frequency bands attributed to the traditional, Fourier-defined brain waves. In particular,the spectrum of the lowest-frequency oscillon occupies the θ-band (about 4-12 Hz) and thenext oscillon changes at the slow-γ; rate (20-45 Hz). By analyzing the LFP data recordedduring active movements, we found that the mean frequencies and the amplitudes of the θand slow-γ; oscillons are coupled to the animal's speed, which parallels the behavior of theFourier-defined θ and slow-γ; waves. We then studied the dynamics of the embeddedfrequencies in the oscillons' dynamic spectra—the spectral waves, using Welch spectraldecomposition. We demonstrate that embedded frequencies in both oscillons exhibit complexbehaviors at several timescales2. In particular, we observe slow frequency alterations thatmay be attributed to endogenous CA1 network dynamics, and some rapid changes that mayreflect abrupt external inputs from the CA3 area or from the medial entorhinal cortex. Theseresults qualitatively expand the scope of the hippocampal oscillons' properties and shed newlight on the structure and functionality of synchronized neuronal activity in hippocampocortical circuits.Reference: (1) Perotti L, DeVito J, Bessis D, Dabaghian Y. Title: Decomposing the neurocomputational mechanisms of reward and aversive motivation on mental effort allocation

Authors: *D. YEE, M. PRATER FAHEY, X. LENG, M. TARLOW, J. KIM, K. MUNDY, S. NEVINS, A. SHENHAV;
Brown Univ., Providence, RI

Abstract: Humans demonstrate a remarkable ability to determine when and how much effort to allocate based on the expected positive or negative outcomes (e.g., bonus earned or job termination). Here, we aim to identify the neural and computational mechanisms underlying the dissociable influence of reward and punishment in shaping mental effort allocation. We combine computational modeling and fMRI to test a key prediction of the Expected Value of Control (EVC) theory, which organizes a neural circuit around temporally distinct sub-processes that underlie the 1) evaluation of positive vs. negative incentives, 2) integration of those incentives to decide how to allocate control, and 3) exertion of the chosen control. 100 college-student participants (58F, 18-23 years) performed a multi-incentive control task, where they could earn monetary bonuses for correct responses and were penalized with monetary losses for errors. We characterized task performance with a drift-diffusion model (DDM) and found that reward promotes attentional control via increasing the rate of evidence accumulation (drift rate v; p=.003), whereas punishment promotes caution via increasing response threshold (threshold a; p<.001). Our fMRI results revealed a network of regions that encoded higher potential rewards (e.g., striatum [Str]: p=.009; dorsal anterior cingulate cortex [dACC]: p=.002). A distinct network encoded higher potential penalties (e.g., anterior insula [AI]: p=.003; Lateral Prefrontal Cortex [LPFC]: p<.001; Inferior Frontal Gyrus [IFG]: p=.004). Model-based fMRI analyses revealed that components of these networks were associated with distinct forms of control allocation. Several of these regions were further associated with variability in control allocation on the upcoming trials, with IFG activity for instance predicting increases in threshold (p<0.001). Preliminary analyses of separate dACC networks delineated by membership in distinct functional networks (salience attention [dACC-sal] vs. frontoparietal control [dACC-ctrl]) revealed a dissociation whereby dACC-sal was more closely associated with changes in drift rate (p<.001) whereas dACC-ctrl was more closely associated with changes in threshold (p=.007). These regions further modulated the influence of specific incentives on control adjustments (e.g., dACC-sal interaction reward is associated with threshold (p<.001), and dACC-ctrl interaction with reward is associated with drift rate (p=.04)). These data provide novel evidence for the neurocomputational circuitry underlying the integration of positive and negative incentives into the Expected Value of Control.

Abstract: Abstract reasoning is a hallmark of human intelligence and remains a challenging feat for state-of-the-art artificial intelligence systems. Designing a framework that captures fundamental aspects of abstract reasoning would not only push the limit of artificial systems, but also broaden our current understanding of human thinking and reasoning abilities. To this end, we have focused our efforts on modeling potential mechanisms using the Abstraction and Reasoning Corpus (ARC). In a trial within the ARC task, given a small set of puzzle-and-solution pairs, a solver must identify and apply a rule to a novel puzzle to construct a solution. The task provides a useful benchmark for testing human-like reasoning ability given limited observations, as initial work across multiple groups, including our own, has demonstrated that humans are adept solvers while AI systems fall short. We built a modeling framework where abstraction is the equivalent of constructing different graph representations given visuospatial inputs. Reasoning is modeled by transforming an input graph into an output graph via a multilayered perceptron (MLP) network. Attaining the right level of abstraction for the reasoning demands is the equivalent of choosing the graph representations such that the MLP can be trained using a few examples within a handful of iterations. We demonstrated the applicability of our framework to the ARC and showed that the trained MLP - driven by suitable graph representations - can exhibit few-shot learning and is capable of discovering specific rules. This framework also generates predictions for human problem-solving. In particular, the model suggests that problem-solving could be subdivided into distinct processes: identifying an appropriate level of abstraction and optimizing the input-to-output transformation.

Title: Choice biases during learning reflect strategic exploration

Authors: *Z. ZHU[1], K. KUCHIBHOTLA[2];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Humans, even as infants, use purposeful cognitive strategies such as exploration and hypothesis testing to learn about causal interactions in the environment. In animal learning studies, however, it has been challenging to disentangle potential purposeful strategies from errors arising from imperfect knowledge or inherent biases. Here, we trained head-fixed mice on a wheel-based auditory two-choice task and exploited the intra- and inter-animal variability to understand the drivers of errors during learning. Early in learning, rather than choosing randomly or based on immediate trial history, mice displayed a strong bias towards a given choice (left or right). This choice bias was dynamic - continuing for tens to hundreds of trials, before switching abruptly to an unbiased state or to the other side, ruling out inherent motor biases. Moreover, biased states coincided with rapid motor kinematics, reflecting less deliberation and more directed choice exploration. Finally, throughout learning we introduced 'catch' trials (correct choices that are not reinforced) followed by a block of ten non-reinforced trials. During these blocks, animals performed significantly better with less bias, abruptly changing strategies to exploit their acquired cue-response learning to test for potential changes in outcome contingencies. These findings argue that rodents actively probe their environment in a directed manner, potentially engaging in a rudimentary form of hypothesis testing to refine their decision-making and maintain long-term flexibility.

Title: Confidence bias implies the underlying decision-making mechanism

Authors: *F. SUN[1], Y. NI[2], W. LU[1], J. SU[1], S. WANG[1], N. LIU[3], X. WAN[1];
[1]Beijing Normal Univ., Beijing, China; [2]Peking Univ., Beijing, China; [3]Inst. of Biophysics, Chinese Acad. of Sci., Beijing, China

Abstract: When dissecting the decision-making process, we often pay close attention to the characteristics of choices and response time. However, several computational models could produce the similar statistics of choice and response time while reflecting different neuro-computational mechanisms. Therefore, only used choices and response time may not be sufficient to measure human decision-making behavior. Confidence report about the decision is correct is another important feature of decision-making that could provide additional insight into the neuro-computational mechanism of decision-making. To investigate this, we recruited male and female participants to perform a perceptual (n=28) or a value-based (n=27) decision-making task and report their confidence inside the magnetic resonance imaging (MRI) scanner. We found that the participants' confidence ratings were systematically biased towards the chosen option across both tasks, regardless of whether the choices were correct or not. By contrast, their choices were equally accounted for by the evidence of both options, and the objective accuracy also remained unbiased. We also found that confidence bias was not only present in behavior but also in neural activity. The dorsal anterior cingulate cortex (dACC) activities, which represented confidence commonly across both tasks, was also biased to the chosen option. Furthermore, the representation of the confidence related bias in the brain was not separate from the decision variable. To capture this confidence bias, we used variants of drift diffusion models to fit with the participants' behavioral data. The best-fitting model was the one equipped with both mutual inhibition and an urgency signal and only this model could replicate the confidence bias which is confirmed by simulation. We also found a relationship between bias strength and model parameters, especially the mutual inhibition strength. Further analysis on the decision-making dynamics pointed out that winner-take-all states caused by mutual inhibition were crucial for the confidence bias. These findings suggest that mutual inhibition and an urgency signal are indispensable components of neurocomputational models accounting for the decision-making process.

Title: Communicating with surprise - a novel computational model for Tacit Communication Game

Authors: *T. BUIDZE[1], Y. YAO[2], J. P. GLAESCHER[3];
[1]Inst. for Systems Neuroscience,, Universitaetsklinikum Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. for Systems Neuroscience,, [3]Inst. for Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Traditionally, expectation violations signal the need for improvement of predictions through learning, but during communication, surprise can be used intentionally to direct the attention of the Receiver of a message toward relevant information. In language-based communication, this is accomplished by creating salient events within a message through verbal and prosodic cues (e.g., raising the voice). However, in unfamiliar settings without a shared language, the mechanism of effective communication remains poorly understood. Here we propose that the intentional use of unexpected events, or surprise, can effectively communicate goal-relevant information by defying expectations. We test this mechanism in the context of Tacit Communication Game (TCG), a non-verbal communication game played on a square grid board, where the Sender must convey the Receiver’s goal location through her movement patterns (‘messages’). By observing the message, the Receiver infers his goal location. We developed a novel computational model for the Sender’s message design that is based on the idea of communicating through surprise: it uses intuitive priors based on principles of movement kinetics and goal orientation and constructs messages step by step by maximizing information-theoretic surprise at the Receiver’s goal state. We compared our model against an existing Theory of Mind belief-updating model, which selects messages through exhaustive search and updates beliefs based on the Receiver's success, but lacks step-by-step predictions. We fit both models to the behavioral and eye-tracking data obtained from two data sets consisting of 29 and 31 pairs of participants playing the roles of Sender and Receiver in the TCG. The participant's behavioral data (message type, message profile, i.e., the number of moves in either direction) was better described by the surprise model than by the belief updating model. The Pupillary Dilation Response was also positively associated with the model-derived surprise signal across all participants, consistent with its role in detecting unexpected events. Our results indicate that in a novel environment, surprising events can be intentionally deployed to guide the Receiver’s attention and goal orientation, and therefore convey the communicative intention of the message more effectively.

Title: A generalized computational model of learning structures in time

Authors: *N. RAZMI[1,2], M. R. NASSAR[2];
[1]Brown Univ., providence, RI; [2]Neurosci., Brown Univ., Providence, RI

Abstract: Intelligent behavior in biological systems requires storage and retrieval of knowledge in a dynamic world where sensory experiences are informed by context and memory. Yet theoretical, and computational accounts of learning in humans and animals normally consider learning in isolated contexts or stationery environments. We begin to address this problem with a normative approach of inferring latent contexts in a predictive inference task previously used to study adaptive learning. Outcomes in the task are generated from "contexts" that change in a structured but discontinuous manner, i.e., context can persist, change abruptly, or return to a previously seen one. This dynamic is formalized in the standard Markov process language with a "matrix of transition probabilities". To learn this task, we use a normative approach, specifically using a nonparametric Bayesian model, endowed with hyperparameters that control the probabilities of creating a new cluster or expressing a previously seen cluster in addition to a cluster persistence factor. Inverting this generative model with Bayes rule can facilitate exact or approximate inference on the hidden context for a given set of hyperparameters. Here we implement this Bayesian inference model and extend it to simultaneously do inference over hyperparameters, thereby allowing it to "learn" the structure of the environment. We then compare the qualitative behavior of this generalized model, specifically the trends in accuracy and learning rate changes throughout the course of learning the task, to previously observed results in human participants doing similar tasks. More specifically, human participants have been reported to be sensitive to big changes in the environment (i.e., big prediction errors) by increasing their learning rate when changes are thought to come from a persisting cause whereas insensitive to big changes when they are indicative of oddball trials. They are also able to learn to predict outcomes generated from a repetitive sequence of contexts (reversal learning or sequence learning tasks). We believe that most computational models have not yet considered the problem of learning the whole range of different temporal structures that exists in neural and behavioral experiment data from scratch and still lack predictions for what might be the neural substrates of learning structures in a temporally dynamic world.

Title: Theory of Mind during cooperative and competitive interactions in a social foraging task

Authors: *S. KHONEIVEH[1], J. GLÄSCHER[2];
[1]Universitaetsklinikum Hamburg-Eppendorf, Hamburg, Germany; [2]Univ. Hosp. Hambrug-Eppendorf, Hamburg, Germany

Abstract: Theory of mind (ToM) involves cognitive abilities, to construct mental models of others to predict their behavior. Such mental models are commonly referred to as 1st level ToM ("I think you will choose X."). When the mental models include the other person's model of oneself, ToM becomes recursive, referred to as 2nd level ToM ("I think you think I will choose Y."). Some studies argue that ToM sophistication varies across interactional contexts: in competitive situations humans reason at a higher ToM level because they have to anticipated and compensate the strategic choices of their opponents. However, during cooperation involving action coordination a sophisticated mental model that predicts the partner's action based her mental model about me is also beneficial. Here, we investigate whether transitioning between these interactional contexts leads to changes in ToM levels or whether the ToM sophistication is maintained. To address this issue, we designed a novel Social Foraging Task (SFT), in which participants first have to make foraging decision by selecting between different patches with cooperative (Stag Hunt game), competitive (Hide and See game), or independent decision-making tasks in each trial. We administrated the SFT to 74 pairs of participants in an online experiment. Model-free analyses of the reaction times(RTs) after removing the commonly observed unspecific acceleration of RTs through exponential curve fitting, revealed significantly prolonged RTs during competitive play suggesting and increase mental effort possibly due to higher ToM sophistication. We then developed a computational ToM model that estimates beliefs about the co-player at each levels of the ToM hierarchy. Unlike existing ToM models, our approach also dynamically updated the choice strategy at the lowest level (L0) on which higher ToM levels are built. The preferred ToM level is estimated based on prediction accuracy at each level. We investigated whether different interactional contexts elicited changes ToM levels or whether they remained constant during context switches. Comparing these model variants using the Bayesian Information Criterion (BIC), we found support for a change in ToM levels in the SFT suggesting that humans can efficiently recruit sophisticated recursive reasoning strategies of different complexity if it is beneficial in the respective interactional contexts.

Title: Computational modelling of the dorsal and the ventral streams

Authors: *T. B. REZA[1], S. LUO[2], R. JAIN[2], J. CAI[3], M. NIEMEIER[1];
[1]Psychology, [2]Computer Sci. and Mathematics, [3]Engin. Sci., Univ. of Toronto, Toronto, ON, Canada

Abstract: The brain divides the processing of visual information into two separate neural streams: the ventral stream, responsible for perception, and the dorsal stream, responsible for action. The dorsal stream translates visual characteristics into motor commands (i.e., grasping), typically modelled as a regression task in artificial neural networks (ANNs). Grasp representation in ANN involves taking visual data of an object and configuring suitable grasp points on an object. In contrast, the ventral stream converts retinal images into abstract representations for object recognition, which is modelled as a classification task in ANNs. It has been hypothesized that differences between the two streams are due to differences in how the two streams are optimized. Consistent with this, neural networks trained for object classification or to steer robotic grasp movements yield different response properties. However, these networks differ in architecture and training. To gauge the influence of task-specific training differences, we designed a novel map-based ANN and a task-agnostic double-log loss function suitable for classification and visual grasp analysis. Our method penalizes boundary predictions for both tasks, allowing a direct comparison between classification and grasping networks with identical optimization rules. To understand the emerging difference between the two pathways we used representational similarity analysis revealed that our classification model, despite having similar optimization principles, exhibits activation patterns more like state-of-the-art classification models like AlexNet, while our grasp network shows greater similarity to models such as GR-ConvNet.Furthermore, Guided Backpropagation showed that the classification network emphasizes local information of object parts and surface features, while the grasp network focuses on global features. The emergence of dorsal and ventral stream-like properties suggests that our approach provides a fair and task-agnostic method to compare optimization trends across action-based and perception-based learning agents. Our approach contributes to a quantitative approach of modeling the visual cortex.

Title: Joint Structure-Function Network Modeling of General Intelligence

Authors: *R. R. WILCOX[1], B. HEMMATIAN[1], E. D. ANDERSON[3], P. ROBLES-GRANDA[1], C. ZWILLING[1], A. NAYAK[2], L. R. VARSHNEY[2], A. K. BARBEY[1]; [1]Psychology, [2]Electrical and Computer Engin., Univ. of Illinois, Urbana, IL; [3]711th HPW, Air Force Res. Lab., Dayton, OH

Abstract: Network Neuroscience represents the brain as a complex information processing system made of discrete, interconnected regions that form locally- and globally-organized networks (Bassett & Sporns, 2017). The topology of the brain's structural and functional networks displays small-world properties, such that locally integrated sets of regions are connected via long-range projections (Bassett & Bullmore, 2017). Specialized 'connector-hub' nodes in small-world networks represent regions with high nodal degree and diverse connectivity across networks. They facilitate inter-network integration, considered a key biological mechanism underlying higher cognition (Barbey, 2021). To date, the relationship between connector hubs and cognition has been separately studied in the functional (Bertolero et al., 2018) and structural (Gu et al., 2015) domains. The findings motivate the use of joint-domain modeling to examine the role connector hubs play in cognition, as network topology reflects a balance between competing processing demands and structural constraints (Bassett & Sporns, 2017). We predict human intelligence using joint structure-function modeling of hub connectivity, derived from multimodal connectomes based on tractography and functional independent component analysis (Chu et al., 2018). By considering biological constraints on brain function, this approach produces assessments of connectivity that better reflect the underlying neurobiology of brain networks, while also accounting for common methodological issues in the estimation of structural pathways. We apply this method in a representative dataset of multimodal imaging and cognitive performance. Using a predictive cross-validation framework, our joint structure-function modeling approach predicts general intelligence ($R = 0.31$) more accurately than structure- ($R = 0.12$) or function-specific ($R = 0.03$) connectomes. Network participation coefficients further demonstrate that connector hubs mediate general intelligence. Incorporating the hubs' topological properties into models explains significantly more variance ($R^2 = 0.70$) than the joint structure-function model alone (Chu et al., 2018). Our results highlight the benefits of jointly modeling brain networks' structure and function to find the neurobiological properties that underlie individual differences in cognition.

Inst., Weill Cornell Med., New York, NY; [5]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [6]Weill Cornell Med. Col., NEW YORK, NY

Abstract: The application of closed-loop approaches in systems neuroscience and the use of deep brain stimulation (DBS) and brain-computer interfaces (BCI) in neurology hold great promise for advancing our understanding of the brain and developing novel systems to restore lost function. Treatment-resistant brain disorders are increasingly viewed as dysfunctions in neuronal activity across widely distributed brain 'networks', and invasive neuromodulation strategies, like DBS and BCI, are emerging as promising therapeutic options. However, current systems have been optimized to treat Parkinson's Disease and Epilepsy, which significantly limits their application in emerging indications, where large-scale surface or depth recording and/or stimulation capabilities will be essential for an effective therapy. One emerging indication is the treatment of arousal dysregulation, which is hypothesized to contribute to cognitive dysfunctions in various neurological disorders, most prominently following a moderate to severe traumatic brain injury (msTBI) in humans. In a recently completed study (NCT02881151), we explored the use of daytime central thalamic deep brain stimulation (CT-DBS) to treat chronic dysregulation of arousal in five msTBI patients, and here CT-DBS was linked to improved executive attention and reduced mental fatigue. However, the mechanisms of this promising therapy are not well understood, and the development of novel bidirectional neuromodulation systems will need to be validated in large animal models before their exploratory use in humans. In this study, we explored the use of closed-loop CT-DBS to dynamically regulate the arousal 'state' of two healthy non-human primates (NHP) to restore behavioral performance. We used pupillometry, behavioral performance measures, and real-time analysis of ECoG signals to episodically initiate closed-loop CT-DBS by using a clinical-grade bidirectional neuromodulation research platform, the DyNeuMo-X, and we were able to restore behavioral performance in both animals. The internal DyNeuMo system is being used in three clinical trials in the UK across different conditions (NCT05437393, NCT05197816, NCT03837314), and the approach developed here demonstrates the safety and feasibly of rapidly testing adaptive CT-DBS protocols in large animal models. These proof-of-concept results support our long-term goal of developing bidirectional neuromodulation systems to monitor and influence the dynamics of arousal regulation, ultimately to treat cognitive dysfunctions in patients with structural brain injuries and other etiologies.

Title: Altered mid-frontal theta dynamics indicate failure to engage cognitive control for working memory in Parkinson's disease

Authors: *B. E. YEAGER[1], A. SINGH[2], A. I. ESPINOZA[1], R. C. COLE[1], N. S. NARAYANAN[1];
[1]Neurol., Univ. of Iowa, Iowa City, IA; [2]Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Patients with Parkinson's disease (PD) commonly have impairments of cognitive control. The neurophysiological origins of these impairments in PD are unclear. It has been proposed that mid-frontal theta activity (~4-7 Hz) signals the need for cognitive control mechanisms needed to successfully resolve task demands in a goal-directed manner. Our prior work has shown that patients with PD have impaired cue-evoked mid-frontal theta activity. Here, we probed whether alterations in mid-frontal theta power extend to working memory tasks, as cognitive control is needed to simultaneously ignore task-irrelevant information and maintain information within working memory. We hypothesized that patients with PD have attenuated cue-evoked mid-frontal theta power compared to healthy adults in a working memory task. Scalp electroencephalography (EEG) was collected from 23 participants (9 PD, 14 healthy adults) while they completed a modified Sternberg memory test. Time-frequency analysis revealed lower mid-frontal theta power at the beginning of the encoding period for patients with PD

compared to healthy adults. These results suggest a similar neurophysiological signature between cue-triggered responding (Simon task) and working memory (Sternberg memory test) potentially representing the recruitment of cognitive control. In addition to mid-frontal theta power, we investigated changes in midline theta phase synchrony during the Simon and Sternberg tasks to further define electrophysiological alterations in PD. We hypothesized that patients with PD have reduced theta phase synchrony between mid-frontal and mid-parietal sources during both tasks compared to healthy adults. For the Simon task, data were analyzed from a previously collected dataset of 102 participants (64 PD, 38 healthy adults). Focusing again on cue-evoked theta activity, the weighted phase lag index (wPLI) was calculated between Cz and Pz sources which likely overlie major nodes of the salience and default mode networks involved in cognitive control. Strikingly, we found reduced midline theta phase synchrony in patients with PD compared to healthy adults during the Simon and the Sternberg tasks. These results indicate that both mid-frontal theta power and network connectivity are altered in PD. Overall, altered mid-frontal theta dynamics in patients with PD may indicate failure or difficulty to engage cognitive control, which may be a biomarker of disease-related cognitive changes.

Title: Effects of carotid revascularization on cognitive function and brain functional connectivity in carotid stenosis patients with cognitive impairment

Authors: *M. KOHTA[1], Y. OSHIRO[2], Y. YAMAGUCHI[1], Y. IKEUCHI[1], A. FUJITA[1], K. HOSODA[1], K. TANAKA[1], S. MIZOBUCHI[2], E. KOHMURA[1], T. SASAYAMA[1]; [1]Neurosurg., [2]Anesthesiol., Kobe Univ. Grad. Sch. of Med., Kobe, Japan

Abstract: Background: Carotid stenosis can lead to both cognitive impairment (CI) and ischemic stroke. Although carotid revascularization surgery, such as carotid endarterectomy (CEA) and carotid artery stenting (CAS), can prevent future strokes, its impact on cognitive function is controversial. In this study, the authors examined resting-state functional connectivity (FC) in carotid stenosis patients with CI undergoing revascularization surgery, with a particular focus on the default mode network (DMN).Methods: Twenty-seven patients with carotid stenosis who were scheduled to undergo CEA or CAS between April 2016 and December 2020 were prospectively enrolled. A cognitive assessment, including the Mini-Mental State Examination (MMSE), Frontal Assessment Battery (FAB), and Japanese version of the Montreal Cognitive Assessment (MoCA), as well as resting-state functional MRI, was performed 1 week preoperatively and 3 months postoperatively. In the analysis of FC, a seed-based analysis was

performed, where the seed was placed in the region associated with the DMN. The patients were divided into two groups according to the preoperative MoCA score: a normal cognition (NC) group (MoCA score ≥ 26) and a CI group (MoCA score < 26). The difference in cognitive function and FC between the NC and CI groups was investigated first, and then the change in cognitive function and FC after carotid revascularization was investigated in the CI group.Results: There were 11 and 16 patients in the NC and CI groups, respectively. The FC of the medial prefrontal cortex with the precuneus and that of the left lateral parietal cortex (LLP) with the right cerebellum were significantly lower in the CI group than in the NC group. In the CI group, significant improvements were found in MMSE (25.3 vs 26.8, p = 0.02), FAB (14.4 vs 15.6, p = 0.01), and MoCA scores (20.1 vs 23.9, p = 0.0001) after revascularization surgery. Significantly increased FC of the LLP with the right intracalcarine cortex, right lingual gyrus, and precuneus was observed after carotid revascularization. In addition, there was a significant positive correlation between the increased FC of the LLP with the precuneus and improvement in the MoCA score after carotid revascularization.Conclusions: These findings indicate that carotid revascularization, including CEA and CAS, might have positive impact on cognitive function by influencing brain FC in the DMN in carotid stenosis patients with CI.

Title: Frontoparietal network stability predicts attentional control and cognitive flexibility

Authors: *S. LYONS, Z. IRVIN, B. DEPUE;
Psychological and Brain Sci., Univ. of Louisville, Louisville, KY

Abstract: The frontoparietal network (FPN), comprised of the lateral prefrontal cortex (LPFC) and posterior parietal cortex (PPC), is highly involved in the recruitment of lower-level brain regions in the service of cognitive and behavioral task execution. Using dynamic resting state functional connectivity (rsFC) to understand how the FPN functions has emerged as a promising avenue to research the neural substrates of cognition and may be more sensitive at identifying its underpinnings. We investigated the intranetwork stability of the FPN and their contributions to cognition. We hypothesized that, generally, less stability of the FPN at rest would predict performance on both attention and cognitive flexibility. A total of 116 participants (62.9% female; Age = 33.8) from the NIMH Healthy Volunteer dataset were included. Participants completed a rsfMRI session and behavioral testing using the NIH Toolbox. Resting data were segmented into 20 windows of 60 seconds each with a 30 second overlap between windows.

Standard deviations between each ROI pair (6 pairs) were calculated for each window and were entered into two multiple linear regressions. The pooled variability of the overall model significantly predicted performance in the flanker task, $F(109, 116) = 2.7$, $p = .018$, $R^2 = .13$. Two specific ROI pairings indicated increased variability negatively predicted flanker performance [(right LPFC and left PPC); $\beta = -2.11$, $p = .004$], and positively predicted performance [(bilateral PPC); $\beta = 1.13$, $p = .048$]. Pooled variability of the overall model further predicted performance on the dimensional change card sort test, $F(109, 116) = 2.47$, $p = .028$, $R^2 = .12$. Again, the two specific ROI pairings significant in the flanker task indicated the same directionality of increased variability and performance in the dimensional change card sort test [(right LPFC and left PPC); $\beta = -2.21$, $p = .031$], [(bilateral PPC); $\beta = 1.86$, $p = .049$]. Our results add to existing literature connecting dynamic rsFC with both attention and cognitive flexibility. Variability of resting functional coupling within the FPN predicts the ability to deploy attention, as well as updating fluid task rules. Interestingly, paired variance among specific regions appears to influence cognitive functioning more than others, particularly between the right LPFC and left PPC and within the PPC, bilaterally. Functional instability between the right LPFC and left PPC potentially interferes with global attention to task relevant goals. However, increased variability was not always detrimental as greater functional instability between the bilateral PPC may subserve local attention to relevant task contexts.

Title: How Task Representations Integrate Information from Multiple Sources

Authors: *S. C. LEACH, H. MORROW, J. JIANG, K. HWANG;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The human brain is composed of distributed subunits that encode diverse sources of information. As such, the ability to integrate multiple streams of information to guide behavior is integral to cognitive flexibility. It is long thought that the frontoparietal system in the human brain is involved in integrative functions, however, how cognitive representations encoded in these regions support integration is not well understood. We propose a framework where integration is achieved by creating a joint distribution that encodes multiple task-relevant features to guide goal-directed behavior. In this framework, the degree of integration can be quantified by the statistical properties of this joint distribution. To test this framework, we

collected functional MRI data from 26 participants that performed a paradigm requiring them to integrate perceptual (color) information with non-observable state information to select the right task for the current trial. Each trial started with an array of red and yellow dots, in which the dominant color informs the task (face or scene judgement) subjects should perform, and the mapping between color and task randomly switched between two non-observable cognitive states. We used a Bayesian generative model to investigate integrative processes for this task. This model estimates, on a trial-by-trial basis, the subject's probabilistic belief on the cognitive state and perception of color. Critically, the model integrates these two probabilistic distributions of information into a joint distribution to encode the correct task they should perform. Using model-based fMRI analysis, we identified regions that encode the entropy of the joint distribution, as well as regions that encode cognitive state, color, and task representations. We also tested other key model-derived metrics, including the prediction error (PE) of state and task. When uncertainty in state and/or color was higher (i.e., greater entropy), dorsomedial prefrontal cortex (dmPFC), rostro-lateral PFC, and intraparietal cortex showed a greater BOLD magnitude. Moreover, decoding analyses successfully decoded task representation from these regions. Finally, in line with previous work, we found a greater BOLD magnitude in dmPFC and parietal cortex in response to a greater state PE. Our results support a framework where the integration of observable and non-observable information is achieved by creating a joint distribution that encodes multiple task-relevant features.

Title: Distributed context representations in the mouse brain during sensory task-switching

Authors: C. BENNETT, S. D. GALE, E. G. MCBRIDE, J. KUYAT, B. HARDCASTLE, H. CABASCO, A. SRIDHAR, C. MOCHIZUKI, R. GILLIS, H. BELSKI, H. LOEFFLER, S. DURAND, ***S. OLSEN**;
Allen Inst., Seattle, WA

Abstract: Humans and animals can flexibly control their behavioral responses to sensory stimuli based on goals and context. The mechanisms of signal routing in the brain supporting flexible sensory-action mapping are not well understood. We developed a task switching paradigm in mice that requires selective responding to either visual or auditory stimuli in blocks of trials. After block switches, mice rapidly shift the modality to which they respond. Standard reinforcement learning (*Q*-learning) does not capture fast switching dynamics, but adding a

context belief state to the RL model leads to better correspondence with mouse behavior. To characterize cortical and subcortical activity during task switching, we made multi-regional Neuropixels recordings. Within and across brain areas we observe diverse activity dynamics and coding by single neurons. At the population level, task context (visual-rewarded versus auditory-rewarded blocks) can be decoded from many brain regions including cortex, striatum, and midbrain. Moreover, behavioral errors are predicted by the trial-wise fidelity of this context representation. Average stimulus-evoked activity in early sensory areas does not differ between contexts, suggesting stimulus routing in this task is not mediated by simple gain modulation in these regions.

Title: Propofol induced burst suppression evokes neuronal firing and local field potential traveling waves in the human brain

Authors: *V. ZARR[1], M. ALLEE[1], T. DAVIS[1], B. GREGOR[2], P. A. HOUSE[3], E. SMITH[1]; [1]Dept. of Neurosurg., Univ. of Utah, Salt Lake City, UT; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Pheonix, AZ; [3]Intermountain Neurosci. Inst., Salt Lake City, UT

Abstract: 230 million people each year undergo general anesthesia. Despite substantial work, the spatiotemporal neural dynamics underlying medically induced loss of consciousness (mLOC) remain a mystery. Neural traveling waves are electrical perturbations that propagate across the brain with systematic phase delays. Recent work has characterized traveling wave propagation mechanisms in non-human primates (NHP) during mLOC and showed that they change directions. Prior work has shown the presence of burst suppression firing during mLOC. However, ours is the first study to characterize the spatiotemporal dynamics of traveling waves in human action potential and local field potential (LFP) activity during mLOC. We hypothesized that burst suppression evokes brain oscillations that propagate as traveling waves. We examined direct brain recordings during propofol induced loss of consciousness, from Utah-style microelectrode arrays from two adult patients with intractable epilepsy who were undergoing monitoring for surgical treatment for medically resistant seizures. Upon identification of burst suppression, we then regressed the timing of LFP and neuronal firing against the two spatial dimensions of the microelectrode array. We operationally defined traveling waves as regression models with slopes that significantly differed from zero, assessed via an F-test against a permutation distribution of N spatially shuffled LFP or firing times. We fit

these models with both L1 and L2 regularization for both signals, and controlled for false positives with permutation testing. We recorded a total of 96 LFPs and 71 single unit recordings for patient one. Out of 93 total bursts in patient one, traveling waves were identified from 30% of LFPs and from 54% of single unit recordings, using the L1 regularization regression model, respectively. Using the L2 regularization regression model, traveling waves were identified from 52% of LFPs and from 29% of single unit recordings, respectively. We recorded a total of 71 local LFPs and 96 single unit recordings for patient two. Of the channels recorded, traveling waves were identified from 14% of LFPs and from 27% of single unit recordings, using the L1 regularization regression model, respectively. Using the L2 regularization regression model, traveling waves were identified from 25% of LFPs and from 33% of single unit recordings. We therefore showed that neural activity during burst suppression propagated as traveling waves, suggesting that subsequent research into anesthesia burst suppression evoked traveling waves may identify spatiotemporal signatures of traveling waves that can differentiate among consciousness states.

Abstract: A central goal of neuroscience is to develop a parsimonious understanding of how cognition, perception, and action arise from the interactions between the brain, body, and environment. This goal is complicated by the system's tangle of interdependencies across many functional and structural scales which frustrates the traditional reductionist approach. Here we apply methods from statistical physics and dynamical systems to create a unified theory of internal and external processes. We treat the joint system as a macroscopic state with a given order parameter then model the dynamics of that abstracted value. We then use neural recordings from multiple brain regions in rats during self grooming as an experimental lens into these complex, self referential neuro-behavioral feedback loops. We then show how such loops can be

integrated into a control paradigm to actively maintain a state of criticality. By providing a unified framework for understanding how complex cognitive constructions can emerge from the same low-level neural processes that support behavior, this research has the potential to inform a range of science from future machine learning algorithm development to clinical treatments for issues involving mental health and mental distortions.

Title: Altered Brain Connectivity during Resting State as Electrophysiological Signatures in Cognitively Healthy Individuals with Pathological CSF Amyloid/tau

Authors: *A. MOHAMMED[1], C. MOLLOY[1], D. BUENNAGEL[1], A. N. FONTEH[1], R. BUTLER[1], M. KLEINMAN[4], R. J. ARECHAVALA[4], R. A. KLONER[2,3], X. ARAKAKI[1]; [1]Neurosci., [2]Neurosci. and 2Cardiovascular Res., [3]Cardiovasc. Res., Huntington Med. Res. Inst., Pasadena, CA; [4]Dept. of Envrn. and Occup. Hlth., Univ. of California, Irvine, Irvine, CA

Abstract: Alzheimer's disease (AD) pathology, including amyloid beta, the hyperphosphorylation of tau proteins, and inter-neuronal transmission, appears several years before AD symptoms. However, the effect of amyloid and tau (AT) pathology on resting-state (RS) electroencephalogram (EEG) connectivity in cognitively healthy (CH) Individuals remains unclear. A dataset of RS 21-channel EEG recordings with eyes closed was used from a total of 46 CH individuals according to their cerebrospinal fluid (CSF) amyloid/total-tau status, pathological (CH-PAT, n = 27) versus normal (CH-NAT or controls, n = 19). Brain volumetrics (e.g., MRI) and Heart rate variability (HRV) were assessed with NeuroQuant, and electrocardiogram (ECG), respectively. We analyzed and compared between CH-NATs and CH-PATs: 1) Effective connectivity (EC) between different brain regions (Frontal, Temporal, Parietal, Central, and Occipital); 2) relationships between EC and volumetrics; 3) relationships between EC and HRV. A Two-sided t-test and spearman's correlation were used for statistics and $p<0.05$ was considered significant. Connectivity analysis in the alpha frequency band (8-12 Hz) shows: 1) CH-PATS presented significantly greater EC in the occipital region than in CH-NATs ($p=0.008$) (Figure 1 (A, C)). 2) CH-PATS presented a significant positive correlation between frontal EC and left middle temporal intracranial volume (Icv) ($r = 0.465$, $p = 0.015$), temporal EC and frontal lobe total (Icv) ($r = 0.449$, $p = 0.019$), and temporal EC and Fusiform Total Volume ($r = 0.426$, $p = 0.027$), meaning higher EC related to greater volumes. Conversely, CH-NATS showed significant negative correlations between frontal EC and amygdala (Icv) (r =

- 0.465, p = 0.045), frontal EC with hippocampus (Icv) (r = - 0.623, p = 0.004). 3) In addition, the CH-PATS demonstrated a positive correlation between frontal EC and RMSSD (r = 0.446, p = 0.042), supporting higher EC related to greater HRV, which was not seen in CH-NATs. Our results demonstrate that the A/T pathology was accompanied by enhanced RS-EC in the occipital cortex in CH stage; In CH-PATs, higher frontal or temporal EC was related to higher volumes of temporal or frontal lobe, and higher HRV, supporting a potential compensation mechanism. The results highlight the RS-EC signatures as potential biomarkers for the detection of early AD pathology in CH stage.

Title: Supra-modal beta rhythms track contextually relevant information

Authors: *E. EL RASSI[1], C. GRET[1], A. AUMEISTERE[1], S. HAEGENS[1,2,3];
[1]Donders Ctr. for Cognitive Neuroimaging, Nijmegen, Netherlands; [2]Dept. of Psychiatry, Columbia Univ., New York, NY; [3]Div. of Systems Neuroscience, New York State Psychiatric Inst., New York, NY

Abstract: Despite their involvement in many cognitive functions, beta oscillations are among the least understood brain rhythms. Reports on whether the functional role of beta is primarily inhibitory or excitatory have been contradictory. Our framework attempts to reconcile these findings and proposes that several beta rhythms co-exist at different frequencies. It is so far underappreciated that beta could influence behavior by shifting in frequency. In this magnetoencephalography experiment, 32 human participants performed a perceptual discrimination task where they reported which of two sequential auditory or tactile stimuli vibrated faster. We found that changes in beta power and frequency in auditory cortex and motor cortex could predict behavioral outcomes. Our results imply that the analysis of beta oscillations requires caution as beta dynamics are multifaceted phenomena, and that several dynamics must be taken into account to reconcile mixed findings in the literature.

Title: Effects of Working Memory Training on Task-related Functional Connectivity of Cognitive and Somatosensory Networks

Authors: *P. SKOLASINSKA, E. T. SMITH, C. BASAK;
The Univ. of Texas at Dallas, Richardson, TX

Abstract: Large-scale brain networks of older adults are flexible, showing changes in both resting-state (rsFC) and task-related functional connectivity (taskFC) following cognitive training (Lampit et al., 2015; Iordan et al., 2020). Increased taskFC between cognitive networks is shown to support performance of demanding cognitive control tasks (Finc et al., 2020). This study presents secondary analyses of the Phase I randomized clinical trial (NCT03988829) aimed at comparing the effects of an adaptive working memory training requiring higher cognitive control / unpredictable switching (HighC) and similar training requiring lower cognitive control / predictable switching (LowC). In the current study, we investigated the effects of LowC or HighC training on taskFC. We used the whole brain seed-to-voxel approach to identify the brain regions whose taskFC increased or decreased in relation to hub regions of large-scale networks. TaskFC was assessed during performance of the random n-back task with trained (bird) and untrained (digits) stimuli in healthy older adults. The random n-back fMRI task consisted of three 5 min runs of six 40 s task blocks interleaved with seven fixation blocks of 6 s. The blocks had a memory load increasing from 0-back to 2-back to 3-back. The presented stimuli were either pictures of birds (trained) or digits (untrained). Each block consisted of twenty 1.5 s trials. fMRI images were acquired using a slice accelerated multiband EPI sequence with TR/TE = 500/30 ms. Complete pre-training and post-training neuroimaging fMRI data of 28 adults (LowC: N=13, HighC: N=15) were available. We found changes in taskFC between the hubs of the salience network, that is left and right fronto-insular cortex (FIC), and regions of the cognitive and somatosensory networks. There was increased integration between the right FIC and left frontal pole, as well as between left FIC and the right temporal occipital fusiform cortex. Increased segregation was found between right FIC and the right postcentral gyrus and occipital pole as well as between left FIC and the left and right somatomotor regions. No changes in taskFC were identified for FPN and DMN hubs. The results suggest greater increases in taskFC between the cognitive networks, and more segregation between cognitive and somatosensory networks following HighC compared to LowC, and for the trained task rather than the untrained task. Cognitive-somatosensory segregation after HighC training might indicate efficient motor and visual processing on the trained task while increased cognitive network integration might support cognitive control.

Title: Causal evidence for hierarchical predictive coding among cingulo-opercular and frontoparietal networks supporting cognitive control

Authors: *J. WOOD, A. MEYER, D. E. NEE;
Florida State Univ., Tallahassee, FL

Abstract: Cognitive control is the ability to align behaviors with goals when habit will not suffice. Control engages the frontoparietal (FPN) and cingulo-opercular (CON) networks in humans. Within both networks, distinct sub-systems can be organized along a present/external to future/internal axis from sensorimotor-proximal to sensorimotor-distal areas (Nee, 2021; Wood & Nee, 2023). We have hypothesized this organization allows for temporally organized cognitive control. However, how these networks and sub-systems interact to support this organization remains unclear. One class of models posits CON areas motivate FPN areas to engage control (Botvinick et al., 2001; Menon & Uddin, 2010; Shenhav et al., 2013). Yet other models focus on the reciprocal interactions among the CON and FPN for hierarchical computing of predictions that guide control (Alexander & Brown, 2018). Here, we sought to adjudicate amongst these models by causally perturbing the FPN and examining the impact on the FPN and CON. 34 young, healthy adults performed a task designed to contrast present/externally oriented and future/internally oriented control (Nee & D'Esposito, 2016) during functional MRI (fMRI). Continuous theta burst stimulation (cTBS) was administered to individualized functional, and anatomically defined targets followed by task-based fMRI in a counter-balanced, cross-over design. cTBS was used as a causal probe of effective connectivity with the reasoning that cTBS would primarily impact efferent, but not afferent connections (Bergmann & Hartwigsen, 2021). If the CON acts primarily as a motivator to the FPN, we predicted FPN-cTBS would impact the FPN, but not the CON. By contrast, if reciprocal FPN-CON interactions support prediction computation, disruption of the FPN would cause prediction errors and increased CON activations. Moreover, if FPN and CON areas are arranged hierarchically, prediction errors would propagate throughout the FPN and CON. cTBS was administered to two areas involved in future oriented control: the lateral frontal pole (FPl) and mid-dorsolateral prefrontal cortex (mid-DLPFC), as well as a control site (S1). We found during the future oriented task, mid-DLPFC-cTBS produced increased activations throughout both the CON and FPN. Interestingly, these increases were least pronounced in the targeted future oriented FPN sub-system but were significant in all other network/sub-system pairs. These data demonstrate disruption of a sub-

system leads to prediction errors which propagate across networks and sub-systems. These results suggest temporally organized cognitive control can be understood from a framework of hierarchical predictive coding.

Title: Connectome Fingerprinting Predicts Prefrontal Cognitive Control Activation During Abstract Reasoning

Authors: *K. ISENBURG[1], Y. LIU[2], T. M. MORIN[3], C. E. STERN[1];
[2]Psychology, [1]Boston Univ., Boston, MA; [3]MGH Martinos & Brandeis Univ. Psychology, Boston, MA

Abstract: Recently, machine-learning approaches have been implemented to reliably predict an individual's task-based activity patterns from their resting state functional connectivity, a technique known as "connectome fingerprinting" (CF) (Passingham & Wise 2012, Mars et al. 2018, Tobyne et al 2018, Osher et al. 2019, Finn et al. 2015). These methods could be particularly useful in examining individual differences during higher-order cognitive tasks, such as abstract reasoning. Previously, our group developed a simplified version of the Raven's Progressive Matrices task for use during functional Magnetic Resonance Imaging (fMRI). During the task frontoparietal brain regions in the cognitive control network (CCN) showed increased activity associated with symbolic reasoning (Morin et al. 2023). In the current study, we hypothesized that when compared to the group average map of task activation, an individual's CF would better predict individual brain activation patterns in the lateral prefrontal cortex (lPFC) of the CCN during a symbolic reasoning task. We chose this region based on its task activation during our previous study and its involvement in both working memory and abstract rule encoding processes (Funahashi et al. 1989, Wallis et al. 2021). We used the Schaefer 400 parcellation of the Yeo 7 network atlas (Yeo et al. 2011, Schaefer et al. 2018) to define the lPFC and CF ROIs. We implemented a nested leave-one-out, penalized-based ridge regression method based on the implementation by Tobyne et al. 2018, to predict brain activity associated with symbolic reasoning based on subjects' CF. We show that CFs are a better at predictor of subject-specific task activation in the lPFC (left hemisphere: r= 0.51, right

hemisphere: r= 0.52) compared to the standard general linear model group-average (left hemisphere: r=0.31, right hemisphere: r=0.39). This difference was statistically significant for both hemispheres (left: p=0.00004, right: p=0.0009). This result suggests that the CF may provide a more accurate model in predicting individual-level task activation during fMRI. Further, we show that CF methods can be used in tasks that measure higher order cognitive processes such as abstract reasoning.

Title: Individual Variation in Task Signals from a Precision fMRI Dataset

Authors: *N. LABORA[1,2], M. DORN[3], D. M. SMITH[3], A. DWORETSKY[1,2], C. GRATTON[1,2]; [1]Program in Neurosci., [2]Dept. of Psychology, Florida State Univ., Tallahassee, FL; [3]Northwestern Univ., Evanston, IL

Abstract: When completing goal-oriented tasks, humans flexibly configure information processing to meet task demands through control signals related to task initiation, maintenance, and error processing. Past studies have found that these control signals are identified in cingulo-opercular and fronto-parietal brain networks across multiple tasks. However, to date, a relatively unexamined question is whether (and to what extent) task control signals differ across people. In this study, we used a 'precision' fMRI approach which utilizes extended data collection from each individual to examine the characteristics of task signals in individuals. The dataset includes data from N = 34 participants (24 F, ages = 18-35), each with ~9 hours of MRI data, including resting-state fMRI and 40 min. per 3 mixed block event-related designs: a visual rhyming word task, an auditory abstract/concrete word judgement task, and a visual mental rotation task. Using a general linear model with finite-impulse-response coding of events, we obtained estimates for correct and error signals and their contrast in each task, for each participant across sessions. These signals were compared across participants, tasks, and split-half sessions using spatial correlation. In all cases, activation map similarities were largest for within-subject/within-task comparisons, followed by within-subject/across-task, across-subject/within-task, and finally across-subject/across task. The consistency across tasks was amplified when limited to the cingulo-opercular and fronto-parietal control networks, but strong differences across individuals remained. These results were consistent across nearly all participants and indicate a large effect of individual variation on correct and error trial activity, as well as within their differences. This large individual variation effect has strong implications for the study of task control signals, and

contributes to the growing body of evidence for the value of examining subject data at the individual level.

Title: Investigating individual differences in aging networks: a Precision fMRI dataset in older adults

Authors: *D. C. PEREZ RIVERA[1], G. WULFEKUHLE[2], J. J. HERNANDEZ[1], G. TRAN[1], E. M. GORDON[4], C. GRATTON[3];
[1]Psychology, Northwestern Univ., Evanston, IL; [2]Florida State Univ., Henderson, NV; [3]Florida State Univ., TALLAHASSEE, FL; [4]Ctr. of Excellence for Res. on War Veterans, Waco, TX

Abstract: Understanding the changes in brain networks associated with aging is crucial in neuroscience. Aging is associated with cognitive decline, but with substantial variability in cognitive performance and brain measurements across individuals. In this study, we present a dataset of extended fMRI measurements in a small cohort of older adults (N = 8, ages = 65-75). Our objective is to provide a benchmark for the reliability and stability of precision fMRI in older adults, and to explore individual differences in brain networks in the context of aging. The dataset includes 96-231 minutes of low-motion resting-state functional connectivity (rs-FC) data per cognitively healthy individual. Preliminary results indicate that precision measurements of rs-FC in older adults achieve high reliability ($r > .85$) with an average of 50 minutes of data. While younger adults reach this level of reliability with significantly less data ($p < 0.02$), with sufficient data, older and younger adults do not differ significantly in their peak reliability. Measurements of older adults are stable across sessions, though older adults are moderately less stable than younger adults ($p < 0.04$). Interestingly, older adults exhibit increased inter-individual variability compared to young adults ($p < 0.001$), primarily driven by association networks. This finding underscores the importance of studying brain network variation in aging. We propose three potential applications of precision data for the study of brain aging. First, our analyses suggest that more data (~40 minutes) is needed to produce reliable and unbiased measurements of network properties like segregation. Second, we show that precision data can be used to create individualized parcellations of the cortical surface, revealing substantial variability in brain

network organization across individuals. Third, we demonstrate that precision data can be used to find localized regions where individuals differ substantially from the group average rs-FC patterns. These analyses highlight the importance of leveraging modern methods to study brain network variation in aging, improving our understanding of cognitive heterogeneity. Precision fMRI in older adults provides a comprehensive platform to investigate individual differences in brain networks during aging, enhancing our knowledge of individual trajectories of brain health and facilitating the development of precision medicine for age-related cognitive disorders.

Title: A characterization of connector hub brain regions across individuals

Authors: *G. WULFEKUHLE[1], D. C. PEREZ RIVERA[3], Z. LADWIG[4], A. DWORETSKY[1], E. M. GORDON[5], C. GRATTON[1,2];
[1]Psychology, [2]Neurosci. Program, Florida State Univ., Tallahassee, FL; [3]Psychology, [4]Interdepartmental Neurosci., Northwestern Univ., CHICAGO, IL; [5]Washington Univ. in St. Louis, St. Louis, MO

Abstract: The brain is organized into discrete systems, or networks, which exhibit correlated activity during fMRI, a technique termed functional connectivity (FC). Interactions between networks are aided by “connector hubs” or regions of the brain that have links to multiple networks. Studies have emphasized the importance of hubs in facilitating cognitive processes and maintaining network organization. Hubs can be identified using the participation coefficient (PC) metric which quantifies the distribution of a node's connections across different networks. Most prior work has calculated PC based on group-average fMRI data. However, given recent reports of large individual differences in brain networks, this approach may hide idiosyncratic hubs. Here, we used data from the Midnight Scan Club dataset (N = 9, F = 4, ages = 24-34) to locate individual and group hubs and characterize their properties. We identified hub regions by computing PC for individualized parcellations of the cortex. Parcels with a PC value in the top 20 percent were marked as hubs. PC was calculated using individual and group-average fMRI data. Additionally, all the individual PC maps were averaged to create an “overlay” map. When compared, the group PC map had an average r = .2 (range = .16-.23) to each individual’s PC map, while the overlay PC map an average r = .53 (range = .49-.57) to each individual’s PC map.

We also found a large proportion of hubs in regions of each individual's PC map that did not show hub representations in the group or overlay maps; while some regions were adjacent to group and overlay hubs and had similar connectivity patterns, others were more unique. Future directions include examining how group and individual hubs in young adults compare to older adults. The current data suggests that some connector hubs are shared across individuals, but that there is a large proportion of individual-specific hub regions. The prevalence of idiosyncratic hubs demonstrates the importance of looking at individualized data.

Abstract: The organization of the human brain into large-scale functional networks has been well-validated at the group level. However, recent work using resting-state functional MRI (fMRI) has revealed locations of idiosyncratic, individual-specific differences in functional network organization. Focal regions with the strongest individual variation, termed "network variants," have been shown to be common, stable across task states, and related to behavior.

Here, we further investigate the properties of network variants by classifying them into two forms: (1) "border shift" variants which represent proximal, spatially contiguous extensions of an individual's network boundary relative to a group-average, and (2) "ectopic intrusions," which appear as distal, spatially unconnected functional network changes in an individual relative to the group. Using data from highly sampled individuals in the Midnight Scan Club (N=9) and Human Connectome Project (N=823) datasets, we demonstrate that border and ectopic variants differ in their spatial distributions across the cortex and in their relative frequency of association with functional networks. Additionally, in both datasets, we show that border and ectopic variants exhibit shifted task responses: in a large set of task contrasts, we demonstrate that border and ectopic variants show shifted activations relative to the group-average networks, with border variants' activations more closely approximating their attributed functional network than ectopic variants. Further, we investigated the relationship between genetics and network variant location: while both forms of variants show evidence of heritability, border variants are more similar than ectopic variants among pairs of identical twins. We find that both forms of variants can be used to cluster individuals into groups based on their functional network affiliations, but border and ectopic variants produce categorically different sub-groups. Finally, exploratory analyses show that border and ectopic variants predict different behavioral phenotypes to a small degree. Together, these findings provide evidence for two separable forms of network variants, with different network properties and links to genetics and behavior, bolstering the need for further discussion on how to properly account for various types of individual differences in studies of cortical system organization.

Abstract: Many animals, including humans, are thought to share conserved neural mechanisms for processing semantic information, which serve as a common foundation by which to navigate their respective environments. While prior comparative studies have shed important light on neuroanatomical similarities across animal species, understanding whether and to what degree semantic information may be similarly represented by neurons has remained a significant challenge. Here, we aimed to begin addressing these questions by performing single-neuronal recordings in both monkeys and humans in a homologous prefrontal area previously shown to be involved in semantic processing and categorization. To further allow for comparison, we presented similar sets of images that varied broadly in semantic content, valence and theme and which could be commonly compared across species. We also included normative ratings of the images using a Mechanical Turk, cross-modal testing across distinct stimuli and behavioral validation to confirm their salience and generalizability. By creating vectorial representations of each stimulus and by employing a combination of single-neuronal and population analyses, we find that many of the neurons in both monkeys and humans responded selectivity to specific semantic domains and that their population activities could be used to decode categorical information about the image being presented. We find, however, a wide range in how semantic information is represented within neuronal ensemble across species and how the stimuli mapped across the population's response patterns - with striking similarities in the relationships between certain semantic domains and their hierarchical organization. Together, these findings reveal a detailed cellular representation of semantic information in the prefrontal cortex of monkeys and humans and begin to identify the core semantic manifolds that may be shared across animal species.

Title: Rational use of limited resources for compositionality in sequence working memory in macaque prefrontal cortex

Authors: *S. LI[1], J. CHEN[1], Y. XIE[2], L. WANG[1];
[1]Inst. of Neuroscience, CAS Ctr. for Excellence in Brain Sci. and Intelligence Technology, Chinese Acad. of Sci., Shanghai, China; [2]Lingang Lab., Shanghai, China

Abstract: Our brain is remarkably limited in how many items it can hold simultaneously, but it can also represent unbounded novel items through compositional generalization. However, at the neural level, how the brain represents and optimally uses the limited resources in working memory (WM) remains unknown. Here, we investigated the neural mechanisms of sequence working memory (SWM) resources using two-photon calcium imaging and high-throughput electrophysiological recordings to record thousands of neurons in the prefrontal cortex (PFC) of macaque monkeys performing a delayed-sequence-reproduction task. We found the geometry of SWM in PFC neural states exhibiting a compositional code with generalizable and separate low-dimensional rank subspaces. SWM capacity is not fixed by the number of items but rather is a limited resource characterized by neural population activity shared rationally between ranks. Crucially, this rational use of resources is determined by the compositionality of SWM, such that the responses of each neuron allocated among items depend on the geometry of associated rank subspaces. The neural encoding strength in each rank subspace, resulting from the proportion of resources allocated, faithfully predicted the precision of remembered items and their capacities in monkeys' behavior. Thus, the geometry of compositionality underlies the rational use of limited resources in SWM.

Title: Relationships between frontal lobe hemodynamics and working memory task performance.

Authors: *J. E. KOCH, H. A. JACQUEZ;
Psychology, Univ. of WI Oshkosh, Oshkosh, WI

Abstract: Links between frontal cortex activity and cognitive task performance can be revealed by numerous available imaging techniques, one of which is functional near infrared spectroscopy (fNIRS) that detects levels of oxygenated (HbO) and deoxygenated hemoglobin in cortical (PFC) areas. In this exploratory study, college-aged participants (N = 27) completed six computer-based working memory tasks of varying difficulty (three n-backs, detection, 1-card learning, and maze completion) while fNIRS HbO data were collected. Performance accuracy decreased

systematically and significantly across tasks as difficulty increased, but task-related differences in HbO levels were less consistent and were found only at fNIRS optode 15. In addition, the maze task produced a wide array of performance results with little effect on changes in optode 15 HbO levels from baseline. Regression analyses of individual task performance and their respective optode 15 HbO levels revealed inverse relationships in four of the six tasks, the strongest being found during the 2-back task and the weakest during tasks for which performance ceiling effects existed. These results complement similar research demonstrating relationships between cognitive task difficulty and changes in frontal lobe hemodynamics and contribute to the growing body of research on fNIRS and frontal lobe-based performance capabilities involving working memory, including the potential for using fNIRS data to predict performance on these and similar tasks.

Title: Mesoscale modules for the control of working memory in primate frontoparietal cortex

Authors: *X. WANG[1,2], D. HÄHNKE[3], S. N. JACOB[3];
[1]Dept. of Neurosurgery, Technische Univ. München, Munich, Germany; [2]Grad. Sch. of Systemic Neurosciences, Ludwig-Maximilians-Universität München, Munich, Germany; [3]Klinikum rechts der Isar, Tech. Univ. of Munich, Munich, Germany

Abstract: Working memory tasks often reveal sustained neural activity that represents the memorized information. However, recent discoveries suggest an alternative biophysical model with temporally sparse, short-lived oscillatory activity arranged in bursts. How these oscillatory bursts relate to the functional organization of local and long-range circuits in the working memory network and the storage and processing of working memory content remains unclear. To address these questions, we recorded spiking activity and local field potentials (LFP) in the lateral prefrontal cortex (PFC) and ventral intraparietal area (VIP) of two rhesus monkeys performing a delayed-match-to-sample task with visually presented target numerosities (sets of dots) and interfering distractor numerosities. We analyzed the spatiotemporal patterns of LFP bursts across recording sites and their relationship to neuronal spiking activity. We found that the burst probability was monotonically modulated by numerosity, while individual neurons typically showed peaked tuning to number. In both brain regions, bursts of different frequencies exhibited unique patterns during different task epochs. In PFC, where precise reconstruction of the spatial layout of recording sites was possible, sensory signals triggered by sample presentation arrived at separate anterior sites, associated with either gamma (60-90Hz) or beta (15-35Hz) band oscillations. Sample memory maintenance was accompanied by gamma bursts at

a more posterior site. Remarkably, following distraction, sample information was recovered in the same posterior sites, albeit with beta bursts dominating. Local and inter-regional functional connectivity differed across these prefrontal clusters, further supporting their distinct roles in working memory processing. These mesoscale modules remained spatially stable across recording days. Our findings indicate that LFP bursts in the frontoparietal cortex are not direct representations of working memory content. Instead, frequency-specific oscillatory neural activity contributes to contextual processing and dynamic organization within a distributed cortical network. Spatially separable modules in the prefrontal cortical sheet are tasked with sensory and memory coding. Our study sheds light on the complexity of working memory mechanisms and circuit organization in frontoparietal cortex, emphasizing the importance of considering mesoscale spatiotemporal dynamics in future research.

Title: Context dependent changes in neural representation of working memory

Authors: *M. UCHIMURA[1], M. PANICHELLO[3], T. BUSCHMAN[2];
[2]Princeton, [1]Princeton Univ., Princeton, NJ; [3]Stanford Univ., Palo Alto, CA

Abstract: Working memory is central to cognition, allowing one to hold items ‘in mind’. However, despite its importance, working memory is faulty - stimuli are imperfectly encoded in memory and memories can degrade over time. Previous psychophysical studies suggest the accuracy of memories depends on the context. Memories are inaccurate when there is a large range of stimuli that could be remembered on any given trial. However, when the range of stimuli is smaller, memories are more accurate. This suggests working memory representations are adaptable, changing to efficiently store information in working memory for the current context. To understand the neural mechanisms that support this adaptability, we trained two monkeys to perform a working memory task that required them to remember two colored squares and, then, after a memory delay, report the color of the ‘selected’ memory. Initially, the color of each stimulus was randomly selected from the full color wheel (i.e., the entire rainbow). However, after a few hundred trials, the stimuli colors were drawn from one half color space (arbitrarily chosen). Consistent with previous work, the monkeys were more accurate when colors were drawn from a smaller range of possible values (the half color space). In addition, we found the monkey’s response was attracted towards the center of restricted range, reducing the accrual of errors over time. To understand the neural basis of these improvements, we

simultaneously recorded from prefrontal and parietal cortex as the monkeys performed the task. The distance in neural space of the representation of nearby colors was greater when the color range was restricted. Furthermore, the geometry of the color representation changed from semi circular to triangular, allowing nearby colors to be more finely discriminated and, thus, improving working memory accuracy. Our results provide insight into how neural representations adapt to the context in order to improve working memory accuracy.

Title: Flexible control of sequence working memory in macaque frontal cortex

Authors: *J. CHEN[1], C. ZHANG[1], P. HU[1], Y. XIE[2], B. MIN[3], L. WANG[1];
[1]CAS Ctr. for Excellence in Brain Sci. and Intelligence Technology, Chinese Acad. of Sci., Shanghai, China; [2]Lingang Lab., Shanghai, China; [3]Shanghai Ctr. for Brain Sci. and Brain-Inspired Technol., Shanghai, China

Abstract: To memorize a sequence, one must serially bind each item to its order. In this process, how the brain flexibly controls a given input to its associated order in sequence working memory (SWM) remains unknown. Here, we trained two macaque monkeys to perform a delayed sequence-sorting task. Monkeys had to memorize and reproduce spatial sequences of random length (length 1, 2, or 3) using different sorting algorithms, either in the presented order (forward task) or in the reverse order (backward task). We investigated the neural representations of the SWM control process by conducting high-throughput electrophysiological recordings, capturing activity from thousands of neurons in the frontal cortex. We employed a task subspace decomposition framework to break down the high-dimensional neural state space into smaller, task-relevant subspaces while adaptively determining when the representation of task-related variables appears in each subspace. We found separate representations of sensory and SWM at the population level within the same frontal circuitry, reflecting the control process through their organized neural dynamics. Item at each rank was sequentially entered into a common entry subspace and, depending on the sorting algorithm, flexibly and timely controlled into their associated rank-selective SWM subspaces. Crucially, neural activities in these subspaces can faithfully predict monkeys' behavior in single trials. Thus, well-orchestrated neural dynamics in the frontal cortex underlie the flexible control of SWM.

Title: Optogenetic Manipulation of V4 to FEF Projections during Working Memory

Authors: *P. COMEAUX[1], L. NURMINEN[2], F. FEDERER[1], A. ANGELUCCI[1], B. NOUDOOST[1];
[1]Univ. of Utah, Salt Lake City, UT; [2]Optometry, Univ. of Houston, Houston, TX

Abstract: Working memory (WM) is the cognitive ability that allows an organism to maintain recent information in order to guide behavior. Communication between the sensory areas that process visual information and prefrontal areas that prepare plans of action is pivotal to the information flow during WM tasks, and the efficacy of this communication has been shown to depend on the content of WM. Moreover, coherence between prefrontal and posterior visual areas has been shown to correlate with success in WM tasks. We tested whether local oscillations within prefrontal cortex and coherent oscillations between this area and visual areas determine the efficacy of inputs arriving in prefrontal cortex. We injected an anterograde viral vector expressing channelrhodopsin-2 into rhesus macaque V4. After allowing viral expression in V4 axon terminals, we performed photostimulation within the Frontal Eye Field (FEF) to stimulate V4 axon terminals. Photostimulation was performed during a classic memory guided saccade (MGS) task and during a modified MGS task with a visual distractor. We recorded local field potentials and spiking activity within both regions. We found that the efficacy of V4 inputs to drive FEF spiking activity depends on oscillation phase within FEF. Moreover, we found evidence that the excitation of V4 axon terminals within the FEF can bias WM-guided behavior. We present the analysis regarding the role of oscillatory phase within FEF, as well as the relationship between FEF and V4 oscillations, in gating the efficacy of V4 inputs to FEF. This approach for causal manipulation of projection-specific pathways between FEF and V4 during WM will enable us to characterize the factors affecting the dynamic gating of information transmission and how this flexible gating can serve as a basis for privileged processing of behavioral targets.

Title: Nicotinic a7 receptor interacting with muscarinic M1 receptor enhances working memory related activity in primate dorsolateral prefrontal cortex

Authors: *M. WANG[1], S. YANG[2], V. C. GALVIN[3], A. F. ARNSTEN[4];
[1]Yale Univ. Sch. of Med., New Haven, CT; [2]Yale Univ., Yale Univ., New Haven, CT; [3]Duke Univ., Duke Univ., Durham, NC; [4]Yale Med. Sch., Yale Med. Sch., New Haven, CT

Abstract: Acetylcholine (Ach) plays an important role in the cognitive function of the prefrontal cortex (PFC) through both ionotropic nicotinic and metabotropic muscarinic receptors. Our previous studies have revealed both α7 nicotinic acetylcholine receptors (α7-nAChR) and muscarinic M1 acetylcholine receptors (M1R) are localized in dorsolateral PFC (dlPFC) glutamatergic-like synapses. The stimulation of α7-nAChR or M1R enhances working memory related activity of Delay cells in primate dlPFC, and is permissive for NMDAR actions, rescuing neuronal firing from NMDAR blockade. However, over-stimulation of α7-nAChR may cause receptor desensitization and over-stimulation of M1R may hyperpolarize the membrane through PKC-cAMP-PKA signaling. Indeed, physiological studies found that over-stimulation of either α7-nAChR or M1R reduced working memory related activity and impaired working memory function, potentially limiting clinical utility. We hypothesize that the Delay cells may respond to both of M1R and α7-nAChR stimulations, thus, combined low-dose stimulation of M1R and α7-nAChR will synergize to greatly enhance Delay cell firing. In this study, we iontophoretically applied low doses of the α7-nAChR agonist PHA 543613 (PHA) and the M1R positive allosteric modulator VU 0357017 (VU) to Delay cells in primate dlPFC as monkeys performed an oculomotor delayed response task. Our data show that the same dlPFC neuron can respond to both of M1R and α7-nAChR stimulations. Co-application of low dose of VU and PHA showed synergistic enhancing effects on delay firing. These data suggest that low-dose stimulation of multiple cholinergic receptors could be a potential treatment strategy to boost PFC cognition under conditions of reduced cholinergic signaling.

Title: Optogenetic investigation of medial prefrontal cortical contributions to delayed response working memory performance in young and aged rats

Authors: *L. CAO[1], M. FARAJI[1], C. HERNANDEZ[4], K. GONZALEZ[2], C. C. LABISTE[2], A.-R. WHEELER[2], N. G. WRIGHT[2], S. M. BETZHOLD[2], C. FRAZIER[3], B. SETLOW[1], J. L. BIZON[2];
[1]Psychiatry, [2]Neurosci., [3]Pharmacodynamics, Univ. of Florida, Gainesville, FL; [4]Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Changes within the medial prefrontal cortex (mPFC) are associated with age-related cognitive impairments including deficits in working memory. Working memory, the ability to retain information over a relatively brief delay, is known to involve the mPFC as shown by lesions and pharmacological manipulations. Such studies do not demonstrate how the mPFC specifically contributes to temporally-discrete phases of working memory (acquisition, maintenance, and retrieval), however, nor is it known whether mPFC contributions to these distinct phases changes across the lifespan. To address these questions, we optogenetically activated or inactivated pyramidal neurons within the mPFC of male young adult and aged rats to dissect the role of the mPFC during distinct phases of working memory. Young adult (6 mo.) and aged (24 mo.) male Fischer 344 x Brown Norway F1 hybrid rats were surgically implanted with bilateral guide cannulae targeting the mPFC, through which AAVs encoding halorhodopsin, channelrhodopsin, or a control construct were delivered and optic fibers were implanted. Rats were subsequently trained in operant chambers in a three-stage delayed response working memory task. On each trial in this task, rats were presented with a sample lever (either left or right), a press on which initiated a delay phase ranging from 0-24 s. After the delay expired, both levers were extended, and rats had to choose the same lever pressed during the sample phase in order to earn a food reward. Rats were trained until reaching stable baseline performance, at which point they received laser light of the appropriate wavelength delivered to the mPFC. Aged rats showed impaired task accuracy relative to young under baseline conditions. Inactivation of mPFC during the sample phase impaired accuracy in both age groups, particularly at longer delays. In contrast, mPFC inactivation during the choice phase enhanced accuracy at the longest delay, particularly in aged rats. Surprisingly, neither inactivation nor activation affected accuracy in either age group. The results suggest that the mPFC plays temporally distinct roles in working memory, but that its contributions may differ across the lifespan.

Title: Flexible neuromodulation of synaptic strengths via electrical shunting in dorsolateral prefrontal cortical dendritic spines

Authors: *H. CHO[1], J. D. MURRAY[1], A. F. ARNSTEN[2];
[1]Yale Univ., New Haven, CT; [2]Sect Neurobiol, Yale Univ. Sch. Med., New Haven, CT

Abstract: Prefrontal cortical circuits rely on strong recurrent excitations to sustain representations for working memory and other cognitive functions. Control of effective recurrent strength can endow these circuits with flexibility in their computational and dynamical regimes, and immunoelectron microscopy data, coupled with physiology, of the primate dorsolateral prefrontal cortex (dlPFC) suggests this may involve key molecular actions on dendritic spines which receive excitatory connections. The specific functions of spines has been debated for decades as either being purely biochemical, where calcium gradients support synaptic plasticity, or electrical, where spines function as electrical compartments that modify synaptic potentials. Recent experiments have established that spines are indeed electrically isolated from parent dendrites and capable of activating independently in subthreshold potentials. Spines in layer III of dlPFC have also been shown to contain complex molecular machinery where neuromodulators (e.g. acetylcholine, noradrenaline, dopamine) via feedforward cAMP-calcium signaling can alter the open state of potassium channels on spines, dynamically altering network connection strength (Dynamic Network Connectivity). Here, we examined through multiscale computational modeling how experimentally-constrained electric compartmentalization can be a mechanism for such neuromodulatory effects to control the regime of a cortical circuit's effective recurrence. First we simulate a spatial neuron model with a single spine on a dendrite and a minimal set of channels to study how voltage-dependent calcium feedback loops and calcium-dependent potassium channels in spines can modify somatic synaptic potentials, via electrical shunting at high-resistance spine necks. Phenomenological fitting to capture synaptic strength dependence on neuromodulation can then be embedded in spiking network models of attractor dynamics supporting working memory. Spine-based control of recurrent strength can shift a network's operating regime, from robust working memory that resists distractors, to distractible working memory, to putting the circuit "off-line" for externally-driven behavior. These multiscale modeling results establish the feasibility of rapid reconfiguration of recurrence in prefrontal circuits by neuromodulation, identify computational functions of dendritic spines, provide testable predictions for future experiments, and inform future neural circuit models of cognitive function.

Title: Parallel representation of visual, saccadic, and abstract working memory signals in FEF and LIP

Authors: *M. ROSEN[1], S. DAVID[1], D. J. FREEDMAN[2];
[1]Univ. of Chicago, Chicago, IL; [2]Neurobio., Univ. of Chicago, CHICAGO, IL

Abstract: In primates, neuronal activity in cortical oculomotor networks encodes a diverse array of variables relevant for visually-guided behavior — among others, the location and features of visual stimuli, information in working memory (WM), abstract decision variables, and the targets of intended or ongoing eye movements. To study how these visual, WM, and saccadic signals interact, we designed a task that requires animals to make eye movements to visual targets that are alternately informed by or independent of abstract category information in WM. One monkey (*Macaca mulatta,* 10kg) was trained to classify a motion stimulus (100% coherence; 1 of 6 directions) into one of two categories, indicated by an eye movement to an associated color target after a 1s delay. On some trials, the animal was also instructed during the delay to make a category-independent eye movement to a salient peripheral target (1 of 4 locations, chosen at random). This design requires the animal to remember information about the abstract category of the sample stimulus while also planning and executing saccades. We used multiple linear electrode arrays to record from neuronal populations in the frontal eye fields (FEF; 7 sessions, mean=58 units/session), lateral intraparietal area (LIP; 11 sessions; mean=80 units/session), and lateral prefrontal cortex (LPFC; 8 sessions; mean=111 units/session) during task performance (82.5 ± 10.6% correct, mean ± s.d. across sessions). Spiking activity of units in both regions was significantly modulated by visual target presentation, saccade preparation/execution, and stimulus category (target location: 295/411 units (FEF), 463/880 units (LIP); stimulus category: 185/411 units (FEF), 471/880 units (LIP); for each variable, Kruskal-Wallis test, significance at $P < 0.05$). State-space and decoding analyses of neural population activity in FEF on single trials show that saccade targets and WM content are represented simultaneously. During instructed category-independent eye movements made in the delay, FEF activity separately encoded both the currently-relevant target's location and the remembered, but currently-irrelevant, category (logistic regression from single trials' activity, averaged through time; category: 82.0 ± 6.8% cross-validated accuracy, chance=50.4 ± 0.3%; saccade target location: 63.5 ± 14.8% cross-validated accuracy, chance=25.5 ± 0.4%; mean ± s.d. across sessions). Ongoing data analyses aim to clarify further how neural populations in brain regions associated with sensorimotor processing and executive functions integrate and multiplex representations of the distinct variables important for ongoing behavior.

Title: Impact of subcortical inputs on frontal cortex via MD thalamus

Authors: *A. KAMALOVA[1], E. JANG[2], M. HUANG[2], A. G. CARTER[2];
[1]Ctr. for Neural Sci., New York Univ., NEW YORK, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The frontal cortex orchestrates complex, high-level behaviors, including action selection, decision-making, and short-term memory. Neural activity in the prefrontal cortex (PFC) is driven by long-range excitatory projections from the mediodorsal thalamus (MD). Communication between the PFC and MD is particularly important for cognition and becomes disrupted in various mental health disorders. While PFC can support activity in MD, the ability of subcortical inputs to impact activity in these thalamocortical loops is unknown. Here, we use retrograde and transcellular viral tracing, electrophysiology, and optogenetics to determine how multiple subcortical inputs engage specific nuclei in MD to influence PFC in the mouse brain. We find that PFC-projecting thalamocortical cells in MD receive distinct inputs from subcortical inputs, including superior colliculus (SC) and ventral pallidum (VP). We show that inputs from SC and VP are anatomically segregated in PFC-projecting MD subdivisions. Lastly, we find that by differentially engaging subdivisions of MD, subcortical inputs influence distinct subregions within the PFC. Together, our findings illustrate how MD route different subcortical signals to influence neural activity in the PFC.

Title: Spatial scales of coding for working memory in primate lateral prefrontal cortex

Authors: *J. MILLER[1], Y. XIE[2], A. F. ARNSTEN[3], L. WANG[2], J. D. MURRAY[4];
[1]Yale Univ., New Haven, CT; [2]Inst. of Neurosci., Chinese Acad. of Sci., Shanghai, China;
[3]Neurosci., [4]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: The prefrontal cortex (PFC) is consistently active during working memory (WM). While non-human primate (NHP) electrophysiology finds that PFC maintains WM representations, these item-related PFC signals are harder to detect with human neuroimaging. This discrepancy may result from spatial intermixing of neurons in PFC with different functional tuning. However, uncovering the functional microcircuitry for WM is difficult without detailed spatial organization about neuronal populations. Here, we leveraged a novel, two-photon calcium imaging dataset in NHPs (Xie et al., Science, 2022) to investigate the functional organization of WM circuits. In a multi-item delayed saccade WM task, 2 or 3 spatial locations were sequentially presented and subjects (N=2) had to reproduce the target locations, in order, after a delay period. During task sessions, calcium traces were recorded from 33 fields-of-view (~500x500μm) in area 9/46 of lateral PFC (~5,300 total cells). We then analyzed the relationship between WM coding and microscale organization. First, neurons closer together in cortical space were more likely to share functional tuning properties for WM locations. However, this pattern of spatial autocorrelation among neurons is much shallower and flatter than the exponential drop-off of spatial autocorrelation among neurons in visual areas, indicating a greater functional mixing of nearby cells in PFC. Second, neurons with the strongest conjunctive/abstract coding - whose spatial tuning changed based on the sequence position in WM - were clustered tightly together at a 100μm scale. Finally, this single-neuron organization also influenced population decoding measures: neural activity spatially averaged at finer scales (25μm) showed stronger WM item representations at position 1 in sequences, but this spatial scale degraded at positions 2 and 3 with increased WM load. The degradation of fine spatial scales of neuronal coding with WM order and load may help reveal a circuit-level bottleneck for fundamental capacity constraints on the WM system. Overall, there is a fine microscale organization of abstract WM coding in PFC likely inaccessible to voxel-level sampling, helping to reconcile discrepancies between human neuroimaging and NHP electrophysiology perspectives of WM coding in PFC.

Title: A cholinergic mechanism enabling task-specific computation across the cortex

Authors: *J. LUO[1], P. S. SALVINO[1], A. RAPP[1], S. IBARRA[1], J. CANTON-JOSH[1], R. LU[1], L. PINTO[1,2];
[1]Neurosci., [2]Neurobio., Northwestern Univ., Chicago, IL

Abstract: Global activity patterns in the dorsal cortex are reorganized when mice perform perceptual decision-making tasks involving different underlying computations with varying complexity. However, the circuit mechanisms responsible for these large-scale activity changes remain unknown. An interesting possibility is that they involve neuromodulatory input to the cortex. In particular, cholinergic neurons in the basal forebrain project widely across cortical areas while exhibiting topographical and functional heterogeneity. They are therefore well equipped to serve as an orchestrator of task-dependent large-scale cortical activity. To test this hypothesis, we transgenically expressed Cre-dependent GCAMP6s in cholinergic (choline-acetyltransferase-expressing) neurons in mice and imaged cholinergic axonal activity using mesoscale widefield calcium imaging across the entire dorsal cortex. During imaging, the mice performed a cued task-switching paradigm while navigating in virtual reality, with dozens of unpredictable switches within a session. Specifically, they rapidly switched between a complex task that requires evidence accumulation over time and a simple task where the correct choice on each trial is indicated by a salient visual cue. We observed clear task differences in cholinergic activity, which appeared heterogeneous across cortical areas and task epochs. To investigate whether cholinergic input is required for behavioral performance in a task-specific manner, we injected the pan-muscarinic cholinergic antagonist scopolamine or saline prior to behavioral sessions. Strikingly, blocking cholinergic input specifically impaired performance in the complex task while leaving performance in the simple task intact. In addition, muscarinic acetylcholine receptor blockade diminished task differences in cortical excitatory activity and reduced decorrelation across areas in the complex task. These findings suggest that cholinergic input is recruited during perceptual decision-making in a task-dependent manner to shape cognitive computation across the cortex.

Title: Large-scale cortical dynamics during decision making are shaped by computation timescale

Authors: *R. M. COSTA, *R. COSTA, P. S. SALVINO, J. K. LUO, S. M. IBARRA, L. PINTO;
Dept. of Neurosci., Northwestern Univ., Chicago, IL

Abstract: Behaviors requiring different computations recruit distributed yet distinct cortical dynamics. However, the principles organizing these distributed dynamics are unknown. In particular, the role of computation timescales in the recruitment of cortical dynamics remains untested. To address this gap, we have developed a novel task for mice navigating in virtual reality (VR), termed delayed match-to-evidence (DMTE). This is a variant of delayed match-to-sample, in which the sample is variably noisy and gradually revealed to the mouse, such that it requires evidence accumulation. Thus, the task dissociates in time the computations of evidence accumulation, short-term memory, and choice. Crucially, we also use VR movement gain manipulations to independently and systematically vary the duration of accumulation and memory. Task performance improved with decreased sample noise and increased duration of evidence accumulation, but suffered with increased short-term memory durations. A behavioral logistic regression model showed that sample noise made the largest contribution to performance, closely followed by computation timescales. Importantly, evidence duration and memory duration impacted performance by similar magnitudes but in opposite directions, showing that the DMTE task dissociates computation timescale and computation difficulty. To ask whether computation timescales are a principle guiding the organization of large-scale cortical activity, we are performing mesoscale widefield Ca^{2+} imaging from layer 2/3 excitatory neurons across the dorsal cortex, as mice perform the task. Our preliminary findings show that cortical activity patterns vary according to task epochs, consistent with distinct large-scale networks supporting different cognitive computations. Moreover, comparing activity levels between trials of long or short duration revealed that areas of the frontal cortex are preferentially engaged during longer-lasting computations, regardless of their identity, while the pattern of posterior recruitment is computation specific. Strikingly, the pattern of cortical recruitment during short-term memory could be largely explained by a hierarchy of spontaneous timescales, measured separately from the task. Taken together, our findings suggest that the identity and duration of a cognitive computation interact to determine large-scale cortical activity patterns during decision making.

Title: Timescale-specific functional connectivity between layer 2/3 cortical neurons.

Authors: *J. CANTON-JOSH[1], R. COSTA[1], P. S. SALVINO[1], L. PINTO[2];
[2]Northwestern Univ., [1]Northwestern Univ., Chicago, IL

Abstract: The cortex is organized into a macroscopic hierarchy of spontaneous timescales, which are shorter in sensory cortices than association areas. These timescales are likely fundamental to the computations performed by cortical regions, but the microcircuit mechanisms generating them are poorly understood. Specifically, they are likely influenced both by intrinsic neuronal properties, such as ion channel composition, and circuit properties like connectivity patterns. Here, we set out to understand how circuit properties give rise to distinct area-level timescales across cortical layer 2/3.

We first confirmed that the mouse dorsal cortex is organized into a timescale hierarchy. We performed mesoscale widefield Ca2+ imaging from head-fixed mice expressing GCaMP6s in excitatory layer 2/3 neurons (Cux2-Cre x Ai96 cross), while they ran in the dark. Mirroring previous findings in humans and macaques, we found a timescale gradient increasing from posterior sensory areas to frontal and medial association areas. To understand how circuit properties generate timescales, we performed cellular-resolution 2-photon Ca2+ imaging from mouse layer 2/3 pyramidal cells co-expressing the calcium sensor GCaMP6s (Thy1 promoter) and the red-shifted excitatory opsin ChRmine (CamKII promoter). We imaged from either the visual cortex (V1) or the premotor cortex (M2) during spontaneous running. We found broad distributions of neuronal timescales in both areas, but that V1 neurons have shorter timescales than those in M2. Additionally, neurons in M2 were spatially clustered according to their spontaneous timescales. To understand how connectivity patterns in different cortical areas give rise to their macroscopic timescales, we have been performing all-optical functional connectivity measurements, optogenetically stimulating single neurons while measuring network responses with two-photon microscopy. In M2, we found that stimulation of long-timescale neurons is more likely to evoke activity in the network. Neurons display timescale-specific functional connectivity: ensembles of short- or long-timescale neurons are preferentially connected with themselves. We are currently performing similar experiments in V1 to understand how cortical areas differ in their functional connectivity properties.

This work begins to elucidate how distinct cortical networks can create unique profiles of activity timescales, contributing to our mechanistic understanding of cortical computation. Our future work will focus on timescales in the context of behavior, to examine how these properties could underlie cognitive processes such as working memory and task selection.

Abstract: We simultaneously recorded local field potential activity in the cerebellar nuclei (CN) of control mice (CT) and *Atoh1*-conditional knockout mice (KO) with loss of the homeobox transcription factor genes Engrailed1/2 (*En1/2*) in embryonic excitatory cerebellar neurons, including all excitatory cerebellar nuclear neurons (eCN). Conditional loss of En1/2 in Atoh1-derived neurons results in preferential loss of eCN in the posterior domains of the medial and intermediate CN. These mutants allow us to investigate the role of these genes in eCN function and contribution of these neurons to various brain functions. Time resolved analysis of the power of neuronal oscillations in the CN shows spontaneous fluctuations in power that independently occur in different frequency bands. There is increasing evidence supporting a cerebellar role in coordinating communication between cerebral cortical areas through modulating the coherence of neuronal oscillations. Here we asked whether the occurrence of oscillation power peaks in the CN is associated with changes in the coherence of neuronal oscillations in the medial prefrontal cortex (mPFC) and dorsal hippocampal CA1 region (dCA1). We detected power peaks that exceeded 2 standard deviations of the baseline power fluctuations and marked the times of power peak onsets and ends as temporal aligns for further analysis. We marked power peaks in this way in each of the traditional frequency bands used for neuronal oscillations. Electrophysiological signals were captured with an eCube Server (White Matter LLC) and analyzed offline in Matlab (MathWorks, Inc.). Recordings were performed in 6 CT and 6 KO mice. We performed time resolved analysis of coherence between the mPFC and dCA1 aligned on the onset of power

peaks in the CN. In both CT and KO mice CN power peaks occurring in the high-gamma band (80-100 Hz) were found to be associated with significant increases in mPFC-dCA1 coherence across a broad frequency range (60-200 Hz). For both groups coherence values reached their maximum after power peak onset. In KO mice the mPFC-dCA1 coherence increase aligned on CN power peak onset reached significantly higher values than in CT mice, suggesting changes in cerebrocerebellar communication in the KO mice possibly due to the partial loss of eCN. These findings support the idea of a cerebellar involvement in the modulation of coherence between cerebral cortical areas and that coherence between the mPFC and dCA1 may specifically require an intact population of eCN in either the posterior medial or interposed nucleus or both.

Title: Neuronal timescales are dynamic and not intrinsic during human working memory

Authors: *D. CELLIER[1], Q. VAN ENGEN[1], R. GAO[2], B. VOYTEK[1];
[1]UCSD, La Jolla, CA; [2]Univ. of Tuebingen, Tuebingen, Germany

Abstract: Cognition operates at timescales spanning several orders of magnitude: from millisecond auditory perception to lifelong goal planning. While a great deal remains unknown about how the brain represents these timescales, recent research suggests that neural populations have intrinsic timescales that are hierarchically organized across the cortex. In this view, neurons in lower sensorimotor regions have shorter timescales, encoding information briefly before activity returns to a relatively uncorrelated state. In contrast, neural timescales are longer in association cortices, where activity can be maintained for seconds or more. However, the scope of this research in empirical data in humans is often limited to resting-state contexts, which may result in neural timescales being interpreted as intrinsic, and not dynamic. There is a gap in the research linking neural timescales with cognitive tasks that require the manipulation of information over varying timespans.
Here, we investigate the possibility that neuronal timescales are not strictly intrinsic, but rather are dynamic and task-related modulated as a function of task demands. To analyze this, we leveraged an open-access dataset (taken from Johnson et al. (2018)) that includes intracranial electroencephalography (iEEG) recordings from patients performing a visual working memory

task. The task entailed experimental control of temporal processing of stimuli: whereas short-timespan conditions require simple stimulus feature-response mappings, longer-timespan conditions require responses contingent upon the temporal relationships of stimuli. We predicted that timescales will be longer for conditions requiring longer timespans of integration.
We first replicate previous findings that showed that, collapsing across all timespan conditions, neural timescales lengthen during a working memory delay period (as compared to a pre-trial baseline). We additionally find trending effects of condition-specific modulation of neural timescales, whereby task conditions demanding integration across longer timespans exhibit modestly longer neural timescales.
Given that the majority of neural timescales research is focused on "intrinsic" resting-state derived timescales, this work is a critical first step in establishing their functional relevance in human cognition.

Title: Distinct neural codes of mnemonic and sensory representations in early visual cortex

Authors: *S. KIM[1], J. LEE[1], H. GU[2], M. CHOE[1], H. LEE[1], J. LIM[1], H.-J. LEE[1], D.-G. YOO[1], S.-H. LEE[1];
[1]Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Stanford Univ., Stanford, CA

Abstract: Many studies have shown that working memory (WM) representations can be found in the early visual cortex (EVC) (Harrison and Tong, 2009; Serences et al., 2009; Ester et al., 2013). The sensory recruitment hypothesis postulates that EVC uses the same code to represent WM as it does for sensory representations ('sensory code'), which allows WM to benefit from the high fidelity of the sensory code (Adam et al., 2022; D'Esposito and Postle, 2015). However, a recent study challenges this view, reporting that EVC's population activity pattern during sensory encoding does not match that during WM maintenance (Kwak and Curtis, 2022). Here, to examine whether EVC uses the same code to represent sensory and mnemonic information, we developed a paradigm where sensory and mnemonic representations are sufficiently separated in time and compared them using several measures of neural codes.

In an MRI scanner, human observers (N=50) briefly viewed an oriented grating and reproduced its orientation after a long delay period (16.5 s), which is long enough for the blood-oxygen-level-dependent (BOLD) responses to the grating to dissipate. The sensory representations were defined from the BOLD responses during the period when the univariate BOLD activity peaked. On the other hand, the mnemonic representations were defined from those during the last moment of the delay period.
The sensory and mnemonic representations differed in the following aspects. First, when projected onto a low-dimensional state space, the sensory and mnemonic orientations were formed in the two separated planes orthogonal to each other. Second, when the inverted encoding model (Brouwer and Heeger, 2009) was trained to decode stimulus orientation, the mnemonic orientation information could not be decoded using the voxel weight trained to the sensory representations, whereas the sensory orientation information could not be decoded using the voxel weight trained to the mnemonic representations. Third, when inspected for behavioral relevance, the errors in the reproduction task were better predicted by the orientations decoded in the mnemonic representation than those decoded in the sensory representation. Lastly, when examined for retinotopic properties, the voxels' orientation preferences in the sensory representation were tightly correlated with their radial positions in retinotopic space, whereas their preferences in the mnemonic representation did not display such a correlation.
Our findings suggest that EVC uses distinct codes to represent sensory and mnemonic orientations. This would allow the brain to carry out tasks that involve comparing both types of representations without interference.

Title: Brain-wide neuronal activity underlying memory-to-decision transformation

Authors: *Y. WANG[1], C. T. LI[2];
[1]Inst. of Neuroscience, CAS, shanghai, China; [2]Inst. of Neurosci., Shanghai Inst. of Biol. Sciences, Chinese Acad. of Sci., Shanghai, China

Abstract: Brain-wide neuronal activity underlying memory-to-decision transformation**Abstract:** Cognitive processes are intertwined to mediate behavior. How neural substrates underlying these processes are globally organized to guide behavioral performance is unclear. Here we developed

a new behavioral paradigm consisting with two delay periods. In this task head-fixed mice need to maintain odor-memory information during the first delay period, comparing it with the test-odor information during the test-delivery period, and maintain the left or right-choice information during the second delay period. Successful performance of the task requires mice to use the working-memory information during the test-odor delivery period. Thus, population neural activity will be transformed from maintaining sensory information into maintaining choice information. We then used Neuropixels probes to simultaneously record brain-wide single-unit activity in mice performing the task. Optogenetic suppression was also performed in designed brain regions, including prefrontal cortex, mediodorsal thalamus, and anterior piriform cortex, which showed differential activity patterns as revealed by Neuropixels recordings. Our results shed important insights on brain-wide neural mechanisms underlying cognition, specifically in memory-to-decision transformation.

Title: Interhemispheric Sensory Flow: Unraveling Sensory information and Working Memory transfer in Mouse Cortical Posterior Areas

Authors: *E. AVIDAN, S. D. SHERER, S. YADLIN, A. GILAD;
Med. Neurobio., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The interhemispheric transfer of information in the cortex plays a significant role in the way we perceive the world. The cortex does not only integrate sensory information but is also required to retain information in memory for several seconds. This function is defined as working memory (WM) and is thought to be encoded across many brain areas. Whereas the process of sensory information and WM in one hemisphere has been broadly investigated in previous studies, interhemispheric transfer of sensory information and WM is poorly understood. We trained mice expressing calcium indicators across layer 2/3 of the cortex, to match between two textures (smooth or rough sandpapaers) from both sides of their whiskers in a go/no-go task. Matching textures required mice to lick for a reward (Hit), and non-matching textures required withholding licking (correct rejection; CR). Once the mouse has reached expert level, we introduced a delay period in-between textures presentation. Thus, the WM of the first stimulus needs to be retained and transferred to the other hemisphere. Using dual-hemisphere wide-field calcium imaging, we compared cortex-wide neuronal activity to study interhemispheric transfer of sensory information and WM. We found involvement of the Barrel cortex (BC) in processing

choice-information, where ‘Hit’ displayed higher activity compared to ‘CR’. Furthermore, BC did not encode the type of texture, as there was no discernible difference in BC activity between ‘Hit’-smooth and ‘Hit’-rough during the sensation epoch. By introducing a delay period (1-3 sec) between texture presentations, we observed sequential activity across hemispheres in posterior areas. Specifically, the left posterior area (P) initially held the sensory and type-information at the beginning of the delay period and subsequently transferred it to the homotopic P area even before the arrival of the second texture. Moreover, we found additional posterior areas such as the posterior-medial (VISpm) and the retrosplenial-dorsal (RD) involved in the transfer of WM. To further investigate the areas involved in choice and/or texture information during the WM transition, we used a support vector machine (SVM) to classify choice or texture type based on neuronal signals across the entire cortex. This analysis enabled us to outline which areas contribute to the mouse's decision based on the sensory input. Consequently, our dual hemisphere behavioral task and imaging approach provide valuable insights into the processing and availability of sensory information for daily activities.

Title: Dynamic changes in neural representations during selective long-term memory retrieval in the prefrontal and parietal cortex

Authors: *J. PARK[1,2], S.-H. LEE[2];
[1]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of; [2]Dept. of Psychology, Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Goal-dependent retrieval of selective information from long-term memory (LTM) is pivotal for guiding our behaviors. State-based models of working memory propose that the contents of working memory are representations from either perception or LTM that are in an activated state, controlled by attentional processes. However, the specific neural mechanisms underlying goal-dependent information processing during selective retrieval from LTM remain poorly understood. To address this gap, we conducted an event-related functional magnetic imaging (fMRI) experiment comprising distinct learning and retrieval sessions. During the learning session, participants memorized scenes in which multiple objects are naturally placed.

On the following day, the participants were asked to selectively retrieve a cued object from the memorized scenes while being scanned in the MRI, followed by separate scans of object and scene perception. By employing multi-voxel pattern analysis, we found representational dynamics over time in the dorsolateral prefrontal cortex (dlPFC) and angular gyrus (AG) during selective retrieval of long-term memory. The direct comparison of neural response patterns during selective retrieval with those elicited by perception revealed distinct patterns of representation in the AG and dlPFC. Specifically, during the early phase of retrieval, both the AG and dlPFC represented the retrieved scene information. However, the AG primarily represented the targeted object, while the dlPFC showed prominent representation of non-targeted objects. In the later phase of retrieval, shared representation between retrieval and perception was not observed in either area. Instead, there was a persistent retrieval cue-specific representation in both the dlPFC and AG throughout the later phase. Further analysis of pattern similarity between adjacent time points during retrieval confirmed a distinction in neural representations between the early and later phases of retrieval. These results suggest that selective long-term memory retrieval involves not only distinct information processes in the prefrontal and parietal cortex but also dynamic changes in information processing over time in these cortical areas.

Title: Connectome-constrained multi-area recurrent neural networks performing working memory tasks

Authors: *W. SOO[1], X.-J. WANG[2];
[1]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom; [2]Ctr. for Neural Sci., New York University, NY

Abstract: Over the past decade, recurrent neural networks (RNNs) have been widely adopted as mechanistic models of the brain. Fundamentally, they provide insights on how a group of interconnected neurons can function together as a single network to perform specific brain functions or cognitive laboratory tasks. However, due to memory constraints, RNNs trained in the past are small (ranging from 2 to 100 neurons). For the same reason, such networks typically model specific brain areas such as the prefrontal cortex, while oversimplifying the functionalities of other areas. In recent years, computational constraints have been greatly reduced due to

improved computing hardware. Yet, RNN models in neuroscience continue to adopt the same simplifying assumptions which undermines the expressivity of such models.
Here, we address these issues by training RNNs comprising of 15 distinct brain areas, including 2 early visual areas, 3 ventral visual areas, 4 dorsal visual areas, 2 areas corresponding to frontal eye fields and 4 prefrontal areas. The interareal synaptic weights between any two brain areas are constrained by experimentally-measured connectomic data. Visual stimulus is presented only to a single area, V1, resulting in a change in neural activity within V1 which then propagates to higher-order areas. The functionality of each brain area (such as identification of stimulus position by the dorsal visual areas) is incorporated by supervised learning. At the same time, the networks are trained to perform 1 of 9 visual working memory tasks. The responses of the networks are read out from the frontal eye fields, representing a saccadic response similar to subjects in laboratory settings. We find that our trained networks achieve their training objectives using well-understood attractor dynamics, where sensory areas employ stable population codes while prefrontal areas exhibit dynamic coding properties. We formulate a principled mathematical framework to quantify information transfer between areas. This allows us to understand how information is transferred between areas, as well as how information is held in working memory. With these results, we compute an information hierarchy across brain areas, which we find to closely match an experimentally-derived hierarchy. When the training is repeated without connectomic constraints, we find that the trained networks employ biologically-implausible degenerate solutions. Our results represents an improvement in the expressivity of trained RNNs in neuroscience, and our proposed framework of information flow represents a unique approach to understanding the mechanisms underlying these complex and intractable models.

Title: Neurophysiological responses during the binding process in working memory

Authors: *J. MARCUÉ-ARANA, S. CANSINO;
Lab. of NeuroCognition, Univ. Nac Autónoma de México, Mexico City, Mexico., Mexico City, Mexico

Abstract: Working memory is a limited-capacity system responsible for handling and temporarily maintaining information. The multicomponent model of working memory includes

the episodic buffer, which encodes, retains, and integrates multimodal information from the visuospatial sketchpad and the phonological loop. Although the model is highly accepted, little research has been conducted to examine the binding process in working memory. This research aims to examine the neurophysiological similarities and differences of three different kinds of binding according to their modality: visual-visual, verbal-verbal, and visual-verbal. Event-related potentials were recorded in 30 participants while two pairs of stimuli from the different binding modalities were presented, followed by a single pair. Participants indicated whether the single pair was equal to one of the previous two pairs even if the stimulus position was changed, or was not equal to any of them. Subsequent correct unimodal binding, compared to that for multimodal binding, elicited during codification a greater P300 and sustained positive wave (SPW). The P300 was observed in frontal sites and central middle derivations, and the SPW was observed in frontal and central sites. During retrieval, a similar pattern was observed for these same components. However, for the P300, the effect was detected in the frontal, central, and occipital left sites. Different neurophysiological patterns characterize the binding of modalities compared to those associated with the binding of information from the same modality.

Title: Differential information processing in the parietal cortex during tactile-visual cross-modal transfer

Authors: *D. PARK[1], Y. RYOO[1], K. LEE[2], S. HWANG[2], H. F. KIM[2], S.-H. LEE[3];

Abstract: Perceiving the spatial characteristics of objects, such as shape, occurs through both visual and tactile modalities in our daily lives. Moreover, object information obtained through visual perception can be transferred or predicted to the tactile modality, and vice versa. Previous research has suggested the involvement of the posterior parietal cortex in the integration and cross-modal transfer of tactile and visual information. However, the neural mechanism underlying the transfer of information for the same object between visual and tactile modalities remains unclear. To directly investigate the neural processing associated with visual-tactile

cross-modal transfer, we conducted neural response measurements using functional magnetic resonance imaging while participants performed delayed match-to-sample tasks. During these tasks, participants were instructed to retain a tactile or visual braille stimulus and determine whether the maintained information matched the test stimulus presented in the same or different sensory modality. The participants successfully retained tactile or visual information during the delay period in both within-modal tests (visual-to-visual or tactile-to-tactile) and cross-modal tests (tactile-to-visual or visual-to-tactile). Our findings reveal that superior parietal cortical regions, including superior parietal lobule and intraparietal sulcus, retain stimulus identity information during the delay period in both within-modal and cross-modal tests. Furthermore, cross decoding of individual stimuli between different within-modal tests, as well as the cross decoding between the cross-modal tests, was possible in the superior parietal cortex. However, such cross decoding was observed only during the cross-modal tests, not during the within-modal tests in the inferior parietal regions including the angular gyrus. These results suggest the existence of differential information processing in the superior and inferior parietal regions during the process of cross-modal transfer.

Title: Effects of the Persistence of Theta Oscillations during Working Memory Retention on the Information Flow between Hippocampus and Medial Prefrontal Cortex

Authors: *Y. LI[1], L. TONG[1], F. FAROUQ[1], W. LI[1], J. LEUTGEB[1,2], S. LEUTGEB[1,2];

Abstract: The hippocampus (HPC) and medial prefrontal cortex (mPFC) are essential for working memory (WM) maintenance, with both regions required for the dynamic process of holding information in memory for future decisions. Anatomical and functional connections between HPC and mPFC enable efficient communication between brain regions during WM tasks. Specifically, ventral HPC is directly connected to mPFC, which facilitates the transmission of neuronal firing patterns in one area to the other. Furthermore, there is evidence of oscillatory

coupling, with dorsal HPC leading theta-related prefrontal activity and ventral HPC leading gamma-related prefrontal activity. Despite these findings, it remains unclear how the direction of information flow between HPC and mPFC is controlled by oscillatory activity during different behavior phases, and in particular, during WM retention in the delay interval. To address this gap, large-scale neural recordings along the entire septotemporal axis of HPC and along dorsal to ventral regions of mPFC were performed with two chronically implanted Neuropixels probes in rats in a delayed spatial alternation task. The task included delay intervals of 10-s or 30-s and blocks of trials when rats were either forced to run on a treadmill or allowed to rest. The latter manipulation allowed for the examination of neuronal firing patterns during different brain states - with and without ongoing theta oscillations. As expected, theta power was significantly lower when rats were resting compared to running during the delay. Despite the differences in oscillation patterns, reliable time cells were limited to the first few seconds in both conditions and in 10-s as well as in 30-s delay intervals at recording locations along the entire septotemporal axis of HPC. In 30-s delay intervals, a second population of late-firing cells was observed, which was silent during the first few seconds, but then constitutively active across the remainder of the delay period. With WM lasting 30 s in our experiment and time cell sequences in all hippocampal regions only occurring during the initial few seconds of the delay, WM maintenance likely requires mechanisms other than the sequential activity of hippocampal time cells. We are therefore now testing to what extent mPFC neuronal activity patterns might support WM in delay intervals when different oscillation patterns predominant. By elucidating the directionality of information flow between these regions during different brain states during the retention interval, we anticipate that our findings will contribute to a more complete understanding of the functional dynamics between HPC and mPFC that support WM.

Title: Theta-associated high-frequency oscillations in the CA3-DG network predict future choices in a dentate-dependent working memory task

Authors: *M. WANG[1], Y. ZHANG[1], T. SASAKI[3,4], S. LEUTGEB[1,2], J. LEUTGEB[1,2];

Abstract: Different brain states associated with behavior are characterized by a wide range of oscillatory frequencies that reflect distinct underlying network mechanisms to support different phases of memory. Yet, memory-guided behavior requires the uninterrupted retention and updating of task-relevant information across numerous transitions between brain states. One of the remaining key outstanding questions is thus how information is not only retained but also organized to become task-relevant throughout these transitions. To study this question, we will focus on the hippocampal dentate-CA3 network where we have recently shown that the dentate gyrus (DG) is critical for the generation of prospective coding of future correct choices by CA3 cells during sharp-wave ripples (Sasaki et al., *Nat Neurosci,* 2018) in a dentate-dependent working memory (WM) task. While our previous work determined that prospective coding occurred during SWRs at reward locations for possible correct choices, here we analyze activity during theta oscillations within intervening periods. Dorsal DG-CA3 ensembles were assessed while male Long-Evans rats performed a spatial memory task on the eight-arm radial maze. In this task, reward consumption at each of the eight locations requires updating of memory about the remaining goal locations. We identified prominent high frequency (150-250 Hz) local field potential (hf-LFP) events in CA3 during active exploration between reward sites. The CA3 hf-LFP events were associated with increased CA3 population activity at the trough of theta, and correlated with increased DG neural activity, but not with high-frequency LFP in CA1. Bayesian decoding of CA3 neural activity during CA3 hf-LFP events reliably predicted the next upcoming choice of animals at choice points. The same correlation was not observed during periods when WM was not needed, suggesting a role of hf-LFP in WM-guided decision-making. Compared with sharp-wave ripples at reward, the CA3 hf-LFP events during movement displayed lower neural firing synchrony but were associated with higher DG neural activity. Taken together, in an effort to explore how network mechanisms across different brain states support WM, we observed neural activity that supports the hypothesis that the neuronal representations of all available choices are played out during SWRs, while a selection of the next choice can be predicted during the subsequent theta state.

Title: Visual working memories are abstractions of percepts

Authors: *Z. DUAN, C. E. CURTIS;
New York Univ., New York City, NY

Abstract: Following pioneering studies demonstrating that patterns of multivoxel activity in early visual cortex can be used to decode the contents of visual WM (Harrison and Tong, 2009; Serences et al., 2009), decoding from visual cortex has been a workhorse for neuroimaging studies testing aspects of the sensory recruitment hypothesis of WM. This hypothesis posits that visual WM storage utilizes the encoding machinery in visual cortex, often assuming that memory and perception rely on similar mechanisms. Although a vast majority of this work has used oriented gratings as memoranda, the interpretation of a number of fMRI decoding studies involving the perception of oriented gratings has been challenged. Rather than simply a reflection of orientation tuning, orientation decoding depends on complex interactions between the orientation of the grating, the aperture edges, and the topographic structure of the visual map (Carlson, 2014; Roth et al., 2018). Here, our goal is to both 1) test how these aperture biases described during perception may affect WM decoding, and 2) leverage carefully manipulated visual stimulus properties of gratings to disambiguate sensory-like WM codes from recoded abstractions of sensory features. We used as memoranda gratings multiplied by radial and angular modulators to generate orthogonal aperture biases despite having the same orientation. Therefore, if WM representations are simply maintained sensory representations, they would be predicted to have similar aperture biases. If they are abstractions of sensory features, they would not be biased and the modulator would have no effect on orientation decoding. Results indicate that patterns of delay period activity while maintaining the orientation of a grating with one modulator (eg, radial) are interchangeable with patterns while maintaining a grating with the other modulator (eg, angular). We find significant cross-classification in early visual and parietal cortex suggesting that WM representations are insensitive to aperture biases during perception. During a perceptual control task without memory, we demonstrate the aperture bias and find a lack of cross modulator decoding in these areas. Finally, we visualize memory abstractions of stimuli using a population receptive field model of the visual field maps (Kwak & Curtis, 2022). Regardless of the modulator and sinusoidal nature of the carrier grating, the WM representation takes on the appearance of a single oriented line. These results provide strong evidence that visual WM representations are abstractions of percepts, immune to perceptual aperture biases, that form efficient codes proximal to behavioral demands.

Title: Frontal persistent activity impacts the quality of working memory representations in early visual cortex

Authors: S. LI[1,3], ***S. L. MASTER**[2], K. K. SREENIVASAN[4], C. E. CURTIS[2];
[2]Psychology, [1]New York Univ., New York, NY; [3]Psychology, [4]Div. of Sci. and Mathematics, New York Univ. Abu Dhabi, Abu Dhabi, United Arab Emirates

Abstract: One key prediction of the sensory recruitment hypothesis of working memory (WM) is that WM involves a coordination between visual cortex, where sensory features are stored, and frontal cortex, where top-down feedback signals to sensory cortex originate. Previous fMRI studies generally report robust persistent activity during memory delays in frontal, but not visual cortex, and precise decoding of WM content in visual, but not frontal cortex. Here, we test the hypothesis that persistent activity in frontal cortex may be the source of top-down signals that improve the quality of WM representations in visual cortex. To do so, we measured fMRI responses while human participants maintained a target location in WM over a long delay period, and then judged whether a probe was clockwise or counter-clockwise to the memoranda. Trials began with a cue as to whether the trial would be hard (probe very close to target) or easy (probe far from target) as a means to vary the effort, and presumably top-down input, needed. Delay activity in frontal cortex persisted above baseline and was greater for hard compared to easy trials. The accuracy and uncertainty of WM representations encoded in the population activity within early visual cortex, as measured using a Bayesian decoder, were also affected by task difficulty. Critically, in support of our hypothesis, we found that trial-by-trial variations in the amplitude of delay period activity in frontal cortex predicted the decoded accuracy and uncertainty in early visual cortex. Correlations were more robust when top-down signals related to effort were employed in the hard compared to easy trials. These results suggest that persistent activity in frontal cortex may in part reflect feedback signals targeting WM representations in visual cortex. We hypothesize that these feedback signals may sculpt population activity in visual cortex, improving mnemonic fidelity and reducing mnemonic uncertainty.

Title: Do perturbations to primary visual cortex impact visual working memory?

Authors: *M. DAKE[1], C. CURTIS[1,2];
[1]Dept. of Psychology, [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Despite 50 years of focus on the role of the prefrontal cortex in WM, neuroimaging studies in the past decade have repeatedly demonstrated that early visual cortex plays an important role in WM. For instance, precise information about the contents of WM can be decoded from V1. Such evidence led to the development of a sensory recruitment hypothesis of WM, which posits that visual WM storage utilizes the encoding machinery and mechanisms of visual cortex. However, a critical test of this hypothesis involves the degree to which early visual processing is necessary for accurate WM representations. To test this hypothesis, we used transcranial magnetic stimulation (TMS) to perturb neural activity in V1 in humans performing carefully controlled visual WM experiments. Participants maintained in WM stimuli that were either in or away from a portion of the visual field within which TMS to V1 evoked phosphenes. After a delay, they made memory-guided saccades towards a target (prosaccade) or to a mirrored location away from a target (antisaccade). This allowed us to test hypotheses about the potential role of V1 in simply maintaining a previous visual target, as well as potential roles in maintaining WM representations that were never retinally stimulated. Our preliminary results suggest that TMS to V1 produces no impact on visual WM in any of these conditions, despite that previous studies demonstrated that memory-guided saccade accuracy is highly sensitive to even very small perturbations, and despite that slightly stronger TMS evoked robust and spatially specific phosphenes. To mitigate interpretational issues with null effects, we simultaneously recorded electroencephalography (EEG) to assess the impact of TMS to V1 on a well established marker of WM maintenance. On control trials without TMS, we noted robust and sustained alpha (8-12 Hz) power lateralization with respect to the WM targets. TMS to V1 abolished the alpha lateralization confirming the effectiveness of our TMS procedures. However, after a few hundred milliseconds the typical alpha power lateralization reformed prior to the end of the delay period. Together, these preliminary results suggest that V1 activity may not be necessary for accurate visual WM under these specific conditions. On one hand, perhaps other types of stimuli, oriented gratings or dot motion, may depend more on V1 than simple target locations. On the other hand, a strong interpretation of these results might suggest that top-down signals from higher order cortex may re-write over errors or loss of information encoded in V1 during memory. In either case, our results indicate the sensory recruitment hypothesis of WM may need revision.

Abstract: Recent evidence suggests that searching for valuable objects can become quite efficient (diminished dependance of search time on display size) given sufficient object-reward association. Both ventrolateral prefrontal cortex (vlPFC) and basal ganglia output, substantia nigra reticulata (SNr) are known to control gaze by projections to superior colliculus (SC) and encode object value memories. Here we report and compare single-unit activity in vlPFC and SNr in two macaque monkeys while they engaged in value-based search for a high-value object among low-value objects in target-present (TP) or target-absent (TA) trials. Both regions showed a stronger differentiation of TP and TA trials (value signal) in efficient search based on population average firing rate and on high gamma power (100-200 Hz) local field potential (LFP). The strength of firing and LFP value signal was correlated with search efficiency in both regions ($p<0.001$). Notably while the the onset of firing rate value signal in vlPFC and SNr was not significantly different ($p>0.05$) the onset of gamma value signal in vlPFC was significantly faster than SNr ($p<0.001$). Furthermore, vlPFC firing had a saccadic component that differentiated TP and TA trials in efficient search. SNr firing had a lower spatial selectivity for the location of target compared to vlPFC. Together these results suggest that while SNr firing rate suppression in TP trials disinhibits SC, it is vlPFC that provides the spatial information and the saccadic command to direct gaze toward valuable objects in search.**Keywords:** value memory, visual search, search efficiency, single-unit recording, prefrontal cortex, basal ganglia, substantia nigra reticulata, macaque monkey, LFP, spiking variability.

Title: Mechanisms for Learning Task State Representations in the Frontal Cortex

Authors: *P. NILCHIAN[1,2], M. EL-GABY[1], D. DUPRET[1], T. BEHRENS[1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Weill Cornell Med., New York, NY

Abstract: The tasks we encounter often share common structures. Therefore, forming generalized task structure representations may allow animals to re-use knowledge across tasks, thus solving new problems more quickly. However, how individual neurons represent task structures remains an open question. We previously developed an ABCD-structured task in which mice collected four water rewards (a-d) in a repeating sequence of four locations. As such, the animals continuously transitioned between four task states (A-D). We identified "state cells" in the medial frontal cortex (mFC). These neurons were tuned to particular task states. In this study, we investigated how state cells form during early learning. We used electrophysiological recordings from the mouse mFC, taken during tasks one and two; the first time animals experienced a task change. To identify newly formed state cells, we extracted neurons' putative preferred states and evaluated if the extent of state tuning changed between the tasks. We demonstrated that newly formed state cells display elevated tuning to spatial locations (i). However, we did not find evidence to suggest that state cells show increased tuning to auditory cues (ii) or water rewards (iii). Furthermore, we observed that neurons' state preferences changed between tasks. We demonstrated that such changes are random in task space. Our findings were consistent with a model in which newly formed state cells initially tune to spatial positions (i). Our study is one of the first to investigate how individual neurons represent task structures. This opens a window into understanding the computational principles underlying the formation of task structure representations at the cellular level.

Title: Individual differences in ventrolateral prefrontal cortex thickness and memory performance in adolescents and adults

Authors: *M. CASTRILLON, M. WOODBURY, S. VIJAYARAJAH, M. L. SCHLICHTING; Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Previous work has demonstrated a relationship between individual differences in brain structure and memory performance. One particular region that has been implicated in memory-related cognitive operations is the ventrolateral prefrontal cortex (vlPFC), which is involved in selecting between related memories. As adolescents still show differences from adults in retrieval success at this age, especially when tasks are challenging, these faculties of the vlPFC are likely still developing. Furthermore, past evidence suggests that the vlPFC is late to mature, and undergoes significant development throughout adolescence. However, the specific association between vlPFC structure and the ability to select among competing memories remains poorly understood. This study aimed to investigate how individual differences in vlPFC structure relate to memory performance. Adolescents (12-13 years old) and young adults (25-35 years old) first learned pairs of items with overlapping elements, which created memory competition. After, participants completed a retrieval task that assessed their ability to select the correct memory from among related ones. We used structural magnetic resonance imaging (MRI) processed with Freesurfer to quantify cortical thickness in regions of the vlPFC for each participant, and then examined the relationship between these measurements and performance on the retrieval task. Behaviourally, adults performed better on the retrieval task than adolescents, consistent with the notion that adolescents are still refining their ability to retrieve overlapping memories. Consistent with prior work, we also found that adults had a significantly thinner vlPFC than adolescents. Among adults, thinner vlPFC was associated with better memory performance, particularly in terms of response times. This relationship does not seem to be a general relationship between overall cortical maturity and memory performance, as we did not see the same associations when we considered the postcentral gyrus as a control region. Additionally, the association was not observed broadly across all cognitive tasks, as vlPFC thickness was unrelated to performance on a separate attentional control task. Further analyses will investigate whether individual differences in vlPFC structure are related to age, self-reported pubertal maturity, and anxiety/depression scores. These findings offer novel insights into the neurobiological underpinnings of memory selection during adolescence, emphasizing the role of individual differences. Variations in the structural maturity of this region may contribute to individual differences in memory abilities.

Title: Defining the cellular and circuit contributions of medial prefrontal cortex interneurons in associative recognition memory

Authors: *G. YVON-DUROCHER, P. J. BANKS, G. R. I. BARKER, C. BOOTH, E. C. WARBURTON, Z. I. BASHIR;
Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Associative recognition memory, such as recognising your misplaced house key or finding your car in a carpark, requires the quick integration of familiarity, spatial location and temporal information that is vital for everyday learning and episodic experience. The medial prefrontal cortex (mPFC) is a key integration hub within the associative recognition memory circuit as it receives long range excitatory inputs from the nucleus reuniens (NRe) and intermediate hippocampus (iCA1), both pathways being critical for learning. It is well known that inhibitory interneurons play essential roles in spatial and working memory function by gating signal flow and sculpting microcircuit dynamics. However, there is little understanding of the role mPFC interneurons have in associative recognition memory and its networks. Combining intersectional transsynaptic viral tracing, slice electrophysiology and *in vivo* wireless optogenetics, this project investigates; 1) if parvalbumin (PV), somatostatin (SST) and neuron derived neurotrophic factor (NDNF) interneurons in mPFC are involved in different phases of associative recognition memory, 2) the anatomical distribution and possible convergence of afferent excitatory projections from the iCA1 and NRe onto mPFC interneurons and 3) if these projections differentially engage interneuron subtypes, to bring about discrete modulation of mPFC network activity.
Using PV, NDNF or SST^{Cre} female and male mice (>8 weeks old), we show that iCA1 and NRe projections have distinct laminar distribution within the prelimbic cortex, NRe predominately targets layer 1 (L1) whereas iCA1 inputs are more uniformly distributed across prelimbic layers. Interneuron expression patterns showed spatial segregation, SST within layers 2-5, PV in 5/6 and NDNF interneurons predominately within L1. However, we also found NDNF positive cells within the dorsal tenia tecta that were GAD65/67 negative. Optogenetically activating iCA1 and NRe inputs differentially recruited PV interneurons compared to pyramidal neurons and had opposing short term plasticity at L1 NDNF interneurons. Wireless, in vivo optogenetic inhibition of NDNF and PV interneurons during an object in place associative recognition task is currently being undertaken and results analysed, with preliminary results showing high specificity of the inhibitory opsin. This work reveals that mPFC interneurons not only receive iCA1 and NRe inputs, but also differentially integrate these signals into mPFC microcircuits that could ultimately modulate distinct phases of associative recognition memory.

Title: Distinct neuronal populations differentially contribute to prefrontal encoding of threat-related information

Authors: *A. MENEGOLLA[1], G. LOPEZ-FERNANDEZ[2], C. HERRY[2], M. MARTIN-FERNANDEZ[2];
[1]INSERM U1215, BORDEAUX CEDEX, France; [2]INSERM U1215, Bordeaux, France

Abstract: In face of a threat, animals must choose one among a range of defensive behaviors, and the selection of a response suitable to each situation is essential for their survival. This response selection relies on the characteristics of the threat itself and its multimodal integration with environmental features that constrain the repertoire of strategies used to cope with the threatening encounter. With a novel paradigm that allows the execution of different defensive behaviors in response to distinct threatening situations, we recently demonstrated that neuronal populations in the dorsomedial prefrontal cortex (dmPFC) encode both a general danger state and specific threats. However, how these general and specific threat representations arise from the coordinated activity of different neuronal populations and guide the selection of the most adaptive defensive response in each threatening condition remains to be elucidated. To investigate this, calcium imaging on pyramidal ($CaMKII^+$), parvalbumin- (PV^+) and somatostatin-expressing (SST^+) neurons of the dmFPC was performed while mice executed the novel behavioral paradigm. Although the presence of a threat could be predicted from the patterns of population activity of all neuronal types, we observed a higher SST^+ unspecific activation compared to other neurons. Indeed, threat-related information was found to be more robustly encoded by the SST^+ population than by the PV^+ and $CaMKII^+$ ones. Furthermore, SST^+ neurons were the only neurons generating a sustained representation of safety during the discrimination of neutral from threatening stimuli. With this work, we started to identify how threat-related information is encoded in distinct prefrontal neuronal populations and how their coordinated activity gives rise to population representations of threats and contributes to the selection of defensive behaviors.

Title: A subpopulation of locus coeruleus noradrenergic neurons projecting to prefrontal cortex regulate flexible memory processes during contingency reversal

Authors: *S. AMEMIYA, T. J. MCHUGH;
RIKEN Ctr. for Brain Sci., Saitama, Japan

Abstract: In changing environments, adaptive decision making requires memory processes that allow flexible reference and updating memory. Locus coeruleus noradrenergic neurons (LC-NA) are involved in controlling memory processes in accordance with current task demands, however the underlying neural circuit mechanisms are still unclear. Previous studies have reported that the prefrontal cortex (mPFC) and hippocampus, both of which receive LC-NA innervation, are involved in flexibility and learning, suggesting these connections may be key. Here, we examined LC-NA circuits involved in reversal learning which requires flexible memory processes. First, we examined the anatomical organization of LC-NA projections to the mPFC and the hippocampal CA1 region by using retrograde tracing with adeno-associated virus vectors (retroAAV). We injected retroAAVs carrying constructs that encode different fluorescent proteins (EYFP and mCherry) into the mPFC and the CA1 and found that a small number of LC-NA overlapped, with distinct populations of LC-NA projecting to the mPFC and the CA1 respectively. Next, we examined the involvement of mPFC-projecting LC-NA in reversal learning in a T-maze with chemogenetic inhibition of activity of mPFC-projecting LC-NA. Inhibitory Gi DREADD (designer receptor exclusively activated by designer drug) receptors were expressed in mPFC-projecting LC-NA. Subject mice were trained on the T-maze with one arm baited with a pellet and the other having no rewarded for three consecutive days, then the reward contingency was reversed and mice ran the reversal condition for four consecutive days. During the contingency reversal mPFC-projecting LC-NA were inhibited by injection of the DREADD ligand deschloroclozapine (DCZ), resulting in impaired reversal learning and suppressed head orienting behavior (“vicarious trial-and-error” (VTE)), which reflect memory-based deliberation after contingency reversal, at the choice point Our data suggest that the subpopulation of LC-NA projecting mPFC plays a role in flexible memory processes and adaptive decision making.

Title: Circuit mechanisms of dopamine teaching signals in mouse frontal cortex

Authors: *B. RIGHETTI, T. BERNKLAU, S. N. JACOB;
Klinikum rechts der Isar, Tech. Univ. of Munich, Munich, Germany

Abstract: As a neurotransmitter with extensive neuromodulatory properties, dopamine plays an important role in a wide range of distinct brain functions. A large body of experimental and theoretical evidence has shown that midbrain dopamine neurons are required for high-level cognitive processes generated by the medial prefrontal cortex (mPFC). Phasic dopamine transients encode a reward prediction error (RPE), which represents the difference between predicted and actual reinforcing outcomes. The RPE is a canonical learning signal, and converging evidence suggests that the mPFC functions as a crucial recipient for dopamine neuromodulatory signals to guide learning. However, the prefrontal neuronal mechanisms that govern this process are not known. We examined the role of dopaminergic transients in mPFC during abstract associative learning. Specifically, we investigated whether and how dopaminergic signatures evolve as task competency increases. We developed an auditory decision-making task with implicit (uncued) rules switches that was designed to capitalize on the hypothesized role of mPFC dopaminergic neuromodulation in cognitive processing and decision-making. Head-fixed mice learned to associate auditory cues with directed motor outputs (licks) to obtain liquid rewards. Auditory stimuli varied along the dimensions of location (left or right) and frequency (high or low). Only one feature dimension was relevant at a given time, depending on the currently applied task rule, which was changed after the animals reached expert performance levels. Dopamine concentrations in cortical areas are orders of magnitude lower than in the typically studied striatum, posing considerable experimental challenges for the investigation of prefrontal dopaminergic neurotransmission. To this end, we virally expressed the newly developed high-sensitivity fluorescent dopamine sensor GRAB DA3h in mPFC. Dopaminergic transients were measured with fiber photometry over the course of several months while the animals learned and re-learned the required tasks. Our efforts have resulted in successful dopamine recordings in the mouse mPFC with high levels of specificity and sub-second temporal resolution. Preliminary results show that the measured dopamine signals were event-locked and followed the task structure. Phasic dopamine transients evoked by the auditory cue and the obtained rewards were also modulated by the animals' performance levels and thus reflected their mechanistic understanding of the task. Together, our results will contribute detailed insights into the role of prefrontal dopaminergic neuromodulation in abstract associative learning.

Title: Assessing Differences in Effective Network Connectivity during Reward-Based Learning in Children with Prenatal Drug Exposure

Authors: *S. PERI[1], K. FERSTER[1], F. ADAMS[1], A. RAMAKRISHNAN[2], T. BEL-BAHAR[3], M. A. PARVAZ[4];
[1]Icahn Sch. of Med. At Mount Sinai Grad. Training Program In Neurosci., New York, NY; [2]Rutgers Univ., Larchmont, NY; [3]Icahn Sch. of Med. at Mount Sinai, New york, NY; [4]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Prenatal drug exposure is prevalent worldwide, with 10% of pregnant persons using alcohol and up to 30% using tobacco. Prenatal alcohol and tobacco exposure in youth have been associated with higher impulsivity and worse reward-based learning, with previous literature demonstrating changes in microstructural neurodevelopment. There is little understanding of connectivity differences between these groups during reward-based learning. This study will leverage the Monetary Incentive Delay (MID) fMRI data from the Adolescent Cognitive Brain Development (ABCD) Study. The ABCD baseline cohort was stratified into four groups: prenatal alcohol exposure only (n = 895), prenatal tobacco exposure only (n = 225), prenatal alcohol and tobacco exposure (n = 174), and no exposure (n = 3049Based on prior meta-analyses, we chose six regions of interest that have been implicated in reward anticipation and reward outcome. Our stimuli of interest for hypothesizing effective connectivity models were reward anticipation and reward delivery. Results from a representative subject from each group show that anticipation of reward most suppresses the self-connection in the right frontal operculum in participants exposed to tobacco prenatally. For non-exposed individuals, anticipation of reward most suppresses the influence of the right frontal operculum on the right insular cortex. The goal is to understand the initial effective connectivity reward-learning state in 9-10-year-old youth and will be a step to further longitudinal analyses to track neurodevelopment of these connectivity patterns. In addition, with deficits in reward-based learning implicated as risk factors for substance abuse, we are interested in effective connectivity neurobiological risk factors for substance abuse and other psychopathologies associated with prenatal alcohol/tobacco exposure.

Title: Sequence generalization via modular curriculum learning

Authors: *D. SCOTT, K. E. CONEN, T. M. DESROCHERS, M. R. NASSAR;
Brown Univ. Dept. of Neurosci., Providence, RI

Abstract: Many organisms use old skills and knowledge in new situations, as doing so strongly supports adaptive behavior. How humans and other primates accomplish this has been difficult to determine, but building general computations out of more basic capacities - i.e., compositional generalization - appears especially important. Simple sequence-based tasks often naturally require the latter, and we present work examining how recurrent neural networks solve them. To investigate this, we decomposed a sequence-learning task involving two forms of generalization into various plausible sub-tasks, and trained neural networks on combinations of these. Using restrictions on network training parameters and structure, we also enforced modularity, such that different sub-networks learned about different sub-tasks in some of our models. We hypothesize that networks differing in modularity and training curricula should show characteristic differences in learning speed, generalization, and error distributions, mediated by competence in relevant task primitives. These measures characterize the behavioral, performance characteristics of our networks, but we further expect that, mechanistically, unstructured networks should be less likely to learn the same sorts of representations as their modular, curriculum-trained counterparts as task complexity increases. Moreover, we expect that the extent to which unstructured networks generalized properly should correlate with their discovery of mechanisms similar to those employed by the modular, curricular networks. The specific sub-tasks we have trained networks on require tracking sequence-position, storing items in working memory, enumerating seen items, and predicting upcoming inputs based on observed associations. Preliminarily, we have observed that by training individual working memory networks, then training networks with multiple such sub-networks, our training success rate on the tasks for the larger networks are somewhat higher, as would be expected. We expect similar results to hold as we engage more curricula, and we plan to compare the mechanisms our models use to solve these tasks as outlined above. In addition to testing our mechanistic and behavioral hypotheses, our modeling experiments will be of broader relevance to psychiatric and aging neuroscientists. By exploring how compound behaviors and functional competence on task components are related, they will provide mechanistic hypotheses about the capacities of different cognitive systems to compensate for one another when important component functions, such as working memory, are impaired.

Abstract: The medial prefrontal cortex (mPFC) plays a critical role in cognitive tasks; however, understanding the modulation of specific neuronal subtypes during these tasks remains an ongoing investigation. In this study, we employed fiberphotometry (FIP) to record the activation patterns of mPFC GABAergic and glutamatergic neurons in mice while they performed the BarnesMaze (BM) cognitive task over a 4-day behavioral trial. To enable simultaneous FIP and BM, we implemented a modified structural and procedural protocol for the BM, which was successfully validated. Our preliminary results demonstrate significant changes in the activation intensity and event frequency of both glutamatergic and GABAergic neurons in specific task contexts across the trial days. Moreover, when analyzed in relation to BM performance parameters such as task completion latency and adopted strategy, both glutamatergic and GABAergic neurons exhibited a significant decline in activation patterns and event frequency throughout the trial. These findings suggest that glutamatergic and GABAergic mPFC neurons play important roles in learning, memory, and decision-making, and that the activation patterns of these neuronal groups may serve as markers for cognitive progression and/or dysfunction.

Title: Effects of chronic vagus nerve stimulation on cognitive performance in aging

Authors: *J. SEEDANSINGH[1,2,3], A. BUMANGLAG[1], D. BAKHTIAR[1], S. ZEQUEIRA[1,2,3], J. FRANKLIN[1], K. LUCAS[1], S. BURKE[1,3], E. DALE[1,4,3], B. SETLOW[5,4], J. BIZON[1,3]; [1]Neurosci., [2]Grad. Program in Biomed. Sciences, Neurosci. Concentration, [3]Evelyn F. & William L. McKnight Brain Inst., [4]Dept. of Physiol. & Functional Genomics, [5]Dept. of Psychiatry, Univ. of Florida, Gainesville, FL

Abstract: Disruptions in both excitatory and inhibitory signaling within the prefrontal cortex (PFC) contribute to age-related impairments in executive functions. Moreover, these disturbances in neuronal excitability associated with age-related cognitive decline may interact with or worsen due to elevated inflammatory signaling, which is itself associated with cognitive impairments in aging. Electrical vagus nerve stimulation (VNS) is an approved treatment for intractable epilepsy and certain neuropsychiatric disorders, and some individuals receiving VNS therapy have reported improvements in cognitive function as a side effect. This current study has two aims: 1) to investigate the effects of chronic VNS on working memory in aging and 2) to investigate the effects of chronic VNS on inflammatory markers that are elevated with age and linked to cognitive dysfunction. Male and female FBN rats (24 mo.) were surgically implanted with a cuff electrode around the left vagus nerve. For aim 1, the rats underwent daily testing on a delayed response working memory task in operant chambers, in which they had to learn and remember the left/right position of a response lever over short delays. Rats were tested on the task in the mornings and received sessions of VNS in the afternoons using parameters shown previously to enhance cortical plasticity and other forms of PFC-dependent learning (100 stimulus trains/session at 30Hz, 700 µA, 120 µs biphasic pulse width, 0.8 s train duration). For aim 2, rats underwent the same VNS parameters for 30 days, and blood and brain samples were collected at the endpoint and analyzed using ELISA. Control groups for both aims consisted of rats implanted with sham cuffs that underwent identical procedures in the absence of VNS. Data to date show that after 25 sessions, rats that received VNS exhibited improved working memory compared to controls. In addition, after 30 days of VNS there was a significant reduction in circulating levels of galectin-3 (a lectin that can regulate and amplify inflammatory cell behavior, and that is elevated in aged compared to young adult rats) in comparison to controls. These findings suggest that chronic VNS has the potential to remediate age-related impairments in working memory, possibly via reductions in elevated inflammatory signaling that occurs in aging.

Abstract: Prefrontal cortex simultaneously encodes interactive adaptive processes with slow and fast dynamics in value learning
Seyed Reza Hashemirad[2], Mojtaba Abbaszadeh[2], Ali Ghazizadeh[1,2*1] Bio-intelligence Research Unit, Sharif Brain Center, Electrical Engineering Department, Sharif University of Technology, Tehran, Iran[2] School of Cognitive Sciences, Institute for Research in Fundamental Sciences (IPM), Tehran, Iran* Corresponding: alieghazizadeh@gmail.com
Abstract: Valuable objects such as food items, mates and currencies tend to keep their worth over time but every so often values of certain objects can change requiring flexible learning and memory. Previous work suggested a segregated network for stable and flexible value processes in the caudate nucleus tail and head, respectively; however, the neural circuitry underlying the interaction of these two processes remains unknown. Given the role of primate ventrolateral prefrontal cortex (vlPFC) in value learning and its broad connectivity with caudate nucleus, we recorded single-unit activity in two macaque monkeys (Monkey_H n=60, Monkey_P n=65) who performed a paradigm in which stable object values underwent an abrupt reversal using an object reward learning task. Free-viewing and passive-viewing tasks were used to probe changes in gaze bias and neural firing, respectively, before, immediately after, 15 minutes after and a day after the reversal training. The free-viewing results revealed a gaze bias switch immediately after reversal training. Notably, this switch faded after >15 minutes testing and reverted back toward the initial stable bias a day after the reversal training. We show that this snap-back phenomenon cannot not be produced by a single learning and forgetting rate but implies a value learning system with two processes one with fast learning and forgetting and the other with slow learning and forgetting. Interestingly, vlPFC neurons firing encoded both the slow and fast processes multiplexed in early and late component of their firing rates after object onset, respectively. The early part of firing consistently signaled the old object values and remained relatively unchanged following value reversal. On the other hand, the late component showed a change immediately after reversal which faded in the later testings. Taken together, these results suggest two interactive processes with slow and fast dynamics underlying value learning and memory and implicate vlPFC as the plexus for interaction of these two processes that possibly originate from caudate head and tail.

Title: Reorganization of Prefrontal Cortical Neuronal Network during Conditional Fear Memory Consolidation

Authors: ***Y. JEON**[1], Y. YEO[2], J. KWAG[2], S.-P. KIM[1];
[1]Dept. of Biomed. Engineering, UNIST, Ulsan, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The prefrontal cortex (PFC) plays a crucial role in the consolidation of long-term memory (LTM) by interacting with the hippocampus and amygdala. While previous studies have explored the inter-regional connectivity between the PFC and these regions during fear conditioning, little is known about the changes in intra-regional networks within the PFC during memory consolidation. In this study, we investigated the network organization of the PFC neurons in rodents using the contextual fear conditioning paradigm. Mice were habituated to the experimental context and subjected to a conditioning phase with multiple shocks delivered at regular intervals of 120 s. Fear memory retrieval was assessed on days 1, 7, and 14 following conditioning. Calcium imaging was used to analyze neuronal activity in the PFC from which we divided PFC neurons into three disjoint groups as follows: Group 1 (G1) included neurons that exhibited immediate responses to shocks (i.e., shock cells). Group 2 (G2) included neurons that displayed strong connectivity with G1 during conditioning (correlation coefficient > 0.5). Group 3 (G3) included the remaining neurons. Then, we constructed a network combining all these groups together and evaluated the network properties of degree of connectivity and centrality for each neuron, which could indicate the importance of single neurons to transfer information through the network. During the habituation phase, G1 and G2 exhibited high centrality, whereas G3 exhibited low one. Among the groups, G2 showed the highest degree of connectivity. Then, this pattern was altered such that the centrality and degree of connectivity of G1 and G2 decreased whereas those of G3 increased over days during memory retrieval assessment. Furthermore, the overall degree of connectivity peaked on day 1, then decreased on the following days. These changes in network properties of each group may suggest a reorganization of

networking among PFC neurons, presumably related to changes in inter-regional connectivity of PFC and other brain regions. Further studies on underlying mechanisms of the network reorganization of PFC neurons in fear memory consolidation should follow to help us understand the implications of intra-regional networks of PFC in memory formation.

Title: Decoding of remote fear memory from ensemble activity in prefrontal cortex

Authors: *Y. YEO[1], J. KWAG[2];
[1]Korea Univ., Seoul, Korea, Republic of; [2]Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The prefrontal cortex (PFC) has been proposed to play a role in both the consolidation and retrieval of long-term memory. However, how memory consolidation and retrieval are represented in ensembles of PFC neurons is poorly understood. In order to investigate this question, we performed *in vivo* Ca^{2+} imaging in ensembles of excitatory neurons in PFC under the contextual fear conditioning (CFC) paradigm, and memory retrieval was tested on day (D)1, D7, and D14 after CFC to test recent (D1) and remote (D7, D14) memory retrieval in C57BL/6J mice. During conditioning, we observed that excitatory neurons in the prefrontal cortex (PFC) could be divided into two subpopulations of shock-responsive (SR) and non-responsive (SNR) cells. Although there were no significant differences in the calcium activity of the two subsets of neurons on D1 and D7, there was an increase in the calcium event frequency of shock-responsive (SR) cells on D14. Furthermore, training a support vector machine (SVM) using SR cells and predicting the behavior state (Freezing/Unfreezing) resulted in a progressive increase in decoding performance after conditioning, enabling successful prediction of mice behavior by remote recall, while the decoder trained using SNR cells consistently performed below the null model. Together, these results indicate that the PFC SR cells are an important substrate for the retrieval of remote contextual fear memory.

Title: Neocortical synaptic engrams for remote contextual memories

Authors: *J.-H. CHO, J.-H. LEE;
Univ. of California, Riverside, Riverside, CA

Abstract: While initial encoding of contextual memories involves the strengthening of hippocampal circuits, these memories progressively mature to stabilized forms in neocortex and become less hippocampus dependent. Although it has been proposed that long-term storage of contextual memories may involve enduring synaptic changes in neocortical circuits, synaptic substrates of remote contextual memories have been elusive. Here we demonstrate that the consolidation of remote contextual fear memories in mice correlated with progressive strengthening of excitatory connections between prefrontal cortical (PFC) engram neurons active during learning and reactivated during remote memory recall, whereas the extinction of remote memories weakened those synapses. This synapse-specific plasticity was CREB-dependent and required sustained hippocampal signals, which the retrosplenial cortex could convey to PFC. Moreover, PFC engram neurons were strongly connected to other PFC neurons recruited during remote memory recall. Our study suggests that progressive and synapse-specific strengthening of PFC circuits can contribute to long-term storage of contextual memories.

Title: Learning of the Latent Structure of Object Relationship in Rhesus Monkeys

Authors: *X. WEN[1], S. DHUNGANA[2], A. NEUMANN[2], M. WATSON[2], T. WOMELSDORF[2];
[1]Vanderbilt Brain Inst., Nashville, TN; [2]Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Learning the latent structure of information is a key process to enhance flexible and intelligent cognition. The benefits of learning latent structure become evident in the spatial domain when subjects flexibly navigate learned spatial maps despite new obstacles or when subsections within the map change. Similar benefits of latent-structure learning are likely evident in the object domain, but it has remained unclear how subjects benefit from learning the latent relationships of objects. Here, we hypothesized that learning the latent temporal relationship of objects facilitates flexible adjustment to changing object relationships, reduces interference from distracting objects, and enhances long-term retention of relevant objects.
To test these hypotheses, we trained nonhuman primates (NHP's) to learn object sequences and then (i) introduced distracting objects to quantify how learned structure reduces interference, (ii) swapped the order of objects to quantify how fast subjects adjust to changes of learned latent structures, and (iii) repeated learned sequences to test whether long-term retention is enhanced when abstract object relationships have been learned. NHP's performed the object-sequence task at touchscreen Kiosk stations with multidimensional objects. Each sequence consisted of five sequence-relevant objects and one sequence-irrelevant distractor that was similar to only one of the sequence-relevant objects. After incorrect choices the display was reset with new, random object positions to ensure an object-based and prevent a spatial-based learning strategy. Each object sequence was repeated once with swapped object order, and it was repeated once more later in the session to test long-term retention.
We found that NHPs rapidly learn sequences of five objects with above-chance performance. Learning speed improved for object-sequences that contained objects with swapped position, indicating that the abstract temporal ordering of objects was learned. The distractor object caused less interference in sequences that contained swapped objects and that were repeated later in the session. Finally, NHP's showed a long-term memory advantage evident in faster learning of sequences that repeated after twelve or more intervening sequences.
Taken together, these results suggest that NHPs rapidly learn abstract sequential relationship of objects and leverage the learned latent structure to reduce interference, enhance flexible adjusting to changing structures, and for improving long-term retention.

Title: Multi-agent evidence accumulation in the anterior cingulate cortex of monkeys

Authors: *R. CHEN[1,2,3], N. VALLURU[1,2,3], S. M. YOO[1,2,3], S. RADKANI[1,2,3], M. JAZAYERI[1,2,3];
[2]McGovern Inst. for Brain Res., [3]Dept. of Brain and Cognitive Sci., [1]MIT, Cambridge, MA

Abstract: When making decisions under uncertainty, humans and animals combine evidence from their own experience with that of others. For example, when choosing which restaurant to dine in, we may combine information from our last visit with testimonials from others. However, animal experiments where precise neural measurements are feasible have largely focused on evidence accumulation from self-experience only. Therefore, the neural basis for multi-agent evidence accumulation is not known. The anterior cingulate cortex (ACC) has been implicated in a variety of cognitive and social processes, including hierarchical decision making, conflict monitoring, and reward-monitoring for self and other agents. Here, we investigated the role of ACC in multi-agent evidence accumulation. We recorded simultaneously from ACC of two monkeys, sitting next to each other, while they played a virtual hunting game. The game was designed such that animals could benefit from integrating evidence across experiences of self and other. Each trial consisted of two phases. In phase 1, both animals were presented with two arenas and each made a choice between them. On every trial, only one arena could yield reward, and the correct option changed covertly after 12-25 trials. As such animals had to choose judiciously using evidence from previous trials. In phase 2, one monkey was randomly assigned as the “actor” and had to hunt preys in its chosen arena (i.e., use a joystick to intercept dropping tokens), while the “observer” watched. The actor could receive reward only if it had chosen the correct arena with a probability that increased with the number of captured preys. The observer received no reward but could observe the actor playing and the trial outcome. Behavioral analyses indicated that animals were able to integrate evidence across trials both based on their own experience and the experiences of the other animal. Specifically, animals' arena choices were sensitive to the history of their own choices and outcomes as well as those of the other animal. ACC neurons were strongly modulated by behaviorally relevant task variables for both self and other including choice of arena, inter-agent choice conflict, and reward outcome. In both animals, patterns of activity across the population of neurons (i.e., encoding axis) reflected the cumulative evidence based on the history of outcomes for self and other. Notably the axes of evidence accumulation between self-experience and observed other-experience were aligned and overlapping. These findings suggest that ACC may support decisions that rely on information gathered from experiences of multiple agents.

Title: Optogenetic stimulation of mPFC modulates sleep in Sprague-Dawley rats

Authors: *Y. LEE[1], Y. LEE[2], S. HWANG[3], H. LEE[4], S. JUN[3];
[1]Ewha Womans Univ., Seoul-City, Korea, Republic of; [2]Ewha Womans Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [3]Ewha Womans Univ., Seoul, Korea, Republic of; [4]Ewha Womans Univ. Sch. Med., Seoul, Korea, Republic of

Abstract: Several studies have been conducted to improve the quality of sleep using brain stimulation. It is well known that the quality of sleep is related to the sleep depth, duration, onset latency, and the ratio of non-rapid eye movement (NREM) sleep to rapid eye movement (REM) sleep. In particular, sleep spindle and slow wave in the electroencephalography (EEG) during NREM sleep are regarded as important factors for cognitive functions. Sleep spindles are implicated in long-term potentiation for memory consolidation and slow wave is shown to play an important role in the reinforcement of memory. In order to modulate sleep, accordingly, many studies attempted the stimulation of thalamic reticular nucleus (TRN) which is known to be origin of sleep spindle. However, TRN is located in the deep brain region, making it challenging for clinical use. In this study, medial prefrontal cortex (mPFC) was chosen as a target brain area of optogenetic stimulation because mPFC forms a cortical-thalamic network, a major neural circuit involved in sleep-awake control by oscillating neural signals with TRN and thalamus. Three different frequencies of light stimulation were attempted to Sprague-Dawley rats expressing channelrhodopsin-2 (ChR2) in the mPFC region. First, 2 Hz (50 % duty cycle) was applied to induce slow wave. Second, 10 Hz (50 % duty cycle) was applied for REM sleep control and the effect was previously demonstrated. Third, spindle-like stimulation was used to increase sleep spindle. The protocol for spindle-like stimulation contains light pulses (62 ms duration) at 8 Hz which is the intrinsic frequency of sleep spindles, and the stimuli were repeated at 0.5 s intervals which is the average interval between sleep spindles. EEG and electromyography (EMG) signals were recorded for one hour as a baseline, one hour during the optogenetic stimulation period, and six hours as a post-stimulation period. Power spectrum analyses of EEG and EMG were performed to estimate sleep stages. The delta power of EEG was obtained as a measure of deep sleep and sleep spindles were detected as an indicator of long-term memory consolidation. Additionally, the Y-maze test was conducted to evaluate the cognitive enhancement. As a result, this study verified that optogenetic stimulation of mPFC can effectively modulate sleep patterns, leading to improved sleep quality as well as cognitive function.

Title: Roles of intratelencephalic and pyramidal tract neurons of the prefrontal cortex in probabilistic reversal learning

Authors: *Y. YOON[1,2], J. YI[2], S. JUNG[1,2], M. JUNG[1,2];
[1]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of; [2]Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: The prefrontal cortex (PFC) is known to play a crucial role in flexible control of behavior. To investigate roles of intratelencephalic (IT) and pyramidal tract (PT) neurons of the PFC in flexible control of behavior, we performed optogenetic modulation and calcium imaging of these neurons in deep layers of the medial PFC (mPFC) in adult mice engaged in a probabilistic classical conditioning task with cue-outcome contingency reversal. Our preliminary findings suggest that the effect of optogenetic modulation on behavior and neural activity dynamics during reversal learning differ between IT and PT neurons. Optogenetic inhibition of PT neurons, but not IT neurons, tended to increase the number of trials to reach the reversal criterion. Calcium imaging revealed that many PT neurons maintained cue- and expected outcome-dependent activity, but the majority of IT neurons displayed complex activity dynamics during the progress of behavioral reversal. Also, only the PT neuronal population showed an abrupt change in punishment-related responses following reversal onset. Although further studies are needed to determine specific functional roles of these cell types in probabilistic reversal learning, our findings so far suggest a more direct involvement of PT than IT neurons.

Title: Differences In Prefrontal Cortex During Recall Due To Sample-Match Discordance

Authors: *B. M. ROEDER[1], M. R. RILEY[2], R. E. HAMPSON[2];
[1]Physiol. Pharmacol., Wake Forest Sch. of Med., WALKERTOWN, NC; [2]Physiol. Pharmacol., Wake Forest Univ. Sch. of Med., Winston Salem, NC

Abstract: The Prefrontal Cortex (PFC) region of the brain is involved in the recall of images and where computations of relevant task-related information (i.e. “Matched” compared to “Not Matched”). Other brain areas of the Papez memory circuit exert a modulatory control on hippocampal-prefrontal communication via hippocampal connections, leading to gating of information and a way to compare expected vs. actual information processed by the memory circuit, however there still remains a question as to whether a similar influence is exerted on the PFC. Our study aimed to determine if such an effect is present.

To test this influence, we used a delayed-match-to-sample (DMS) task. In the sample phase of the DMS task, a sample image is presented to the subject on a touch screen, where the subject responds by touching the image. Upon response, the sample image disappears and a delay of 9 to 11 seconds occurs before the match phase begins. The match phase consists of 1 matching image and 3 non-matching images. The subject successfully completes the trial by touching the correct matching image. Half of the trials used normal match and non-match images, while the remaining trials used distorted match and non-match images. Each unique sample image was used twice, once in a trial with normal match and non-match images and once in a trial with distorted match and non-match images. The trials were arranged so that half of the sample images had their trial with normal images precede the trial with distorted images, and the remainder sample images had the trial with distorted images precede the trial with normal images. This allowed for investigation into how differences between sample and match images can influence recall, but also to determine if later trials were influenced by previous trials with the same sample image.

Early results showed both an increase and decrease in activity within session, which suggests that there is a difference in recall when there is a mismatch between the sample and match image. As such, our data suggest that the PFC may be influenced by other brain areas of the circuit during recall similar to the hippocampus.

This better understanding of how mismatches lead to *differential* encoding and recall will lead to a better understanding of how that information is remembered. In addition, additional work on how prior memories influence later ones will assist in the development of treatments and devices to assist not only storage and recall for Alzheimer’s Disease and brain injury, but also how to “filter” human memory to reduce the impact of abnormal or intrusive memories such as those involved in PTSD, drug abuse relapse, and psychological health disorders.

Title: Characterization of neural processes involved in flexible discrimination learning in a value-based decision making task using functional magnetic resonance imaging in mice

Authors: *D. LICHTMAN[1,2], E. BERGMANN[1,2], D. RINBERG[3], I. KAHN[1];
[1]Dept. of Neuroscience, Mortimer B. Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY; [2]Dept. of Neuroscience, Rappaport Fac. of Med., Technion – Israel Inst. of Technol., Haifa, Israel; [3]NYU Langone Hlth., NYU Neurosci. Inst., New York, NY

Abstract: One of the fundamental aspects of the process of memory is the ability to learn from experience and hence guide value-based decisions. While these cognitive processes are studied extensively in humans using fMRI, characterization of brain-wide networks in the behaving rodent remains a major challenge. We evaluated the neural processes implicated in learning from the naïve state to task proficiency in the mouse by combining fMRI, precise odor delivery system and high-resolution behavioral monitoring of sniff and lick behaviors. In a task that combined a Go/No-go odor discrimination learning phase and subsequent to it a reversal of odor association with responses, we sought to identify the brain structures that contribute to the formation and reformation of lick responses to a target odorant. We found that whole-brain responses to correct behavioral responses in Go trials (Hits) showed an opposite neural response between the striatal and hippocampal memory systems, along with motor control and reward-processing responses in cortical (infralimbic and orbitofrontal cortices) and subcortical regions (nucleus accumbens and amygdala). Furthermore, mice displayed rapid reversal learning of the association between odor stimuli and reward, showing brain-wide neural responses. Current analyses aim to identify brain targets that are potentially necessary for this process, which in future experiments will be tested for causality using chemogenetic and optogenetic control. Further, using models of decision-making, we will test the extent to which neural responses in specific structures follow predicted learning patterns. Collectively, this approach will serve to enable whole-brain monitoring of learning processes which will enable the study of the nature of neural responses underlying complex behavior.

Title: Interactions between visual short- and long-term memory in the primate brain

Authors: *A. PICCATO, M. JAZAYERI;
Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Primates exhibit a rich repertoire of behaviors dependent on visual memory, or memory of objects and their locations. Visual memory spans multiple timescales - visual short-term memory (vSTM) stores information on the order of seconds, and is critical for perceptual decision-making. Visual long-term memory (vLTM) stores information over much longer timescales, and is the basis of our knowledge of the visual world. Functional and anatomical distinctions between these two types of memory have inspired cognitive models of memory in which vLTM and vSTM are considered dependent on distinct retrieval and storage mechanisms. However, the presence of two memory systems does not imply that they do not interact during visual memory-guided behavior. For example, short-term retention of a name is likely easier if it is the same as that of a close friend. Recent behavioral and imaging experiments in humans suggest that there may be interactions between the mechanisms underlying memory at these two timescales. We have designed a novel behavioral paradigm suitable for rhesus macaques to examine the impact of vLTM on vSTM and its neural basis. An animal has to make a memory-guided saccade to a peripheral location associated with a centrally-cued object. Critically, information about the peripheral location must be retrieved from either vSTM or vLTM. Congruent vSTM trials, requiring retrieval of an object-location association previously encoded in vLTM, are randomly interleaved with incongruent vSTM trials. This task thus allows us to rigorously test for interactions between memory systems by controlling the congruence of information between these two systems on a trial-by-trial basis. We have trained one monkey on the task, and verified that the animal is able to rapidly acquire multiple sets of visuospatial object-location associations within a single session and accurately retrieve from either vLTM and vSTM. Notably, retrieval was more accurate for congruent trials compared to incongruent trials. Previous work has implicated the dorsolateral prefrontal cortex (dlPFC) and hippocampus (HC) in storage of information over short- and long-term timescales, respectively. We have begun recording the activity of neurons in dLPFC while an animal performs the task. Preliminary data suggests that, when controlling for stimulus identity and target location, activity in dlPFC is modulated by type of memory retrieval (vSTM or vLTM). Activity on vSTM trials is also dependent on whether this information was previously encoded in vLTM (congruence). We plan to continue recording from HC and dlPFC to characterize interactions between long- and short-term memory in these regions.

Title: Early growth response protein 2 signaling modulates stress resistance function in the medial prefrontal cortex

Authors: *Y.-J. JEON, N.-H. KIM, Y.-S. JANG, J.-S. HAN;
Konkuk Univ., Seoul, Korea, Republic of

Abstract: Early growth response protein 2 (EGR2) is an immediate early gene and transcription regulatory factor that contains three zinc fingers. EGR2 mRNA and protein are observed in various brain regions, including the neocortex, hippocampus, amygdala, olfactory bulb, striatum, cerebellum, and brainstem. Decreased levels of EGR2 have been reported in the dorsolateral prefrontal cortex (dPFC) of patients with post-traumatic stress disorder (PTSD). Rats with lesions in the medial prefrontal cortex (mPFC) exhibited decreased resistance to stress. Therefore, we investigated the impact of down-regulating EGR2 in the mPFC on resistance to stress-induced cognitive impairment. Rats with viral-mediated knockdown of EGR2 in the mPFC were subjected to either a brief 20-min restraint plus 20 intermittent tail shocks (20-min stress), which did not induce memory impairments, or a prolonged 60-min restraint plus 60 intermittent tail shocks (60-min stress), resulting in memory impairment. The cognitive status of these stressed rats was assessed using a novel object recognition task. Control rats showed intact recognition memory following 20-min stress and impaired memory following 60-min stress. However, rats with EGR2 knockdown in the mPFC displayed impaired recognition memory after experiencing 20-min and 60-min stress. Subsequently, we investigated the effect of EGR2 overexpression in the mPFC on stress resistance. When EGR2-overexpressing rats underwent 20-minute stress, recognition memory was similar to the control (empty vector) group. However, the control group that received 60-min stress displayed cognitive impairment, while the overexpression group showed no memory impairments. Our findings suggest that EGR2 signaling in the mPFC is crucial in modulating stress resistance. Dysregulation of EGR2 signaling may contribute to the development of stress-related psychiatric disorders, but overexpression of EGR2 could represent a novel therapeutic approach for the recovery of cognitive function.

Title: Phasic cholinergic modulation of medial prefrontal cortex during learning under uncertainty

Authors: *G. TU[1,2,3], P. WEN[3], K. TAKEHARA-NISHIUCHI[3,4,2];
[2]Collaborative program in neuroscience, [3]Psychology, [4]Cell and system biology, [1]Univ. of Toronto, Toronto, ON, Canada

Abstract: Anticipating future uncertain threats and making adaptive decisions are crucial for surviving in an ever-changing world for animals. Theory posits that neuromodulators play essential roles in uncertainty estimate and posits their influences on learning and decision-making. In particular, acetylcholine modulates sensitivity to the known unreliability of predictive relationships among cues, actions, and outcomes (expected uncertainty) (Yu and Dayan, 2005). In the mammalian brain, basal forebrain (BF) cholinergic neurons provide the major acetylcholine input to the entire cortex and show transient activation upon threats within milliseconds (Hangya et al., 2015). It led us to hypothesize that threat-evoked phasic cholinergic signaling might provide uncertainty-related information to cortical regions for processing future uncertain threats. To address this, we manipulated BF cholinergic terminals activity in one of the efferent targets, medial prefrontal cortex (mPFC), a region critical for adaptive threat anticipation, in a probabilistic spatial learning task. In this task, mice received probabilistic delivery of air puffs midway when traversing one of two paths in a square maze. Male ChAT-IRES-Cre mice (C57B6J) were injected with adeno-associated viral vectors carrying channelrhodopsin (ChR2 or its red-shifted version, ChrimsonR), or yellow fluorescent protein (control) in a Cre-recombinase-dependent manner. When air puffs were delivered 25% of the time in one path and 75% in the other, control mice preferentially chose the path associated with lower puff probability. However, optogenetically enhancing cholinergic terminals activity during air puffs abolished choice preferences in ChR2 and ChrimsonR mice. In contrast, the same manipulation did not affect adaptive path selection when air puffs were delivered in one path but not in the other path, highlighting an exclusive involvement of phasic cholinergic signaling in learning under uncertainty. Furthermore, we monitored mPFC pyramidal neuronal activity with genetically encoded calcium indicator GCaM6f and applied simultaneous optogenetic stimulation to the cholinergic terminals (inscopix nVoke2 system). Imaging data showed that mPFC neurons activity changed upon air puffs delivery and were sensitive to air puffs probability in each path. However, cholinergic terminal stimulation disrupted such activation in the mPFC network. Together, these data suggest that threat-evoked phasic cholinergic signaling enables mPFC to incorporate uncertainty into threat coding, thereby supporting the development of adaptive threat anticipation sensitive to threat probability.

Title: Distributed representations of time-linked memory in rat medial prefrontal and lateral entorhinal cortex

Authors: *M. PILKIW[1,2], M. D. MORRISSEY[1,3], K. TAKEHARA-NISHIUCHI[1,3,2,4]; [2]Cell and Systems Biol. Dept., [3]Psychology Dept., [4]Neurosci. Program, [1]Univ. of Toronto, Toronto, ON, Canada

Abstract: Many cognitive functions, such as episodic memory and decision-making, rely on the ability to associate an environmental stimulus with a salient outcome over a temporal gap. An established paradigm to study this time-linking process is trace eyeblink conditioning. In this paradigm, subjects are presented with pairings of a neutral conditioned stimulus (CS) and an aversive electric stimulation to the eyelid (US), separated by a stimulus-free period called trace interval. The acquisition and expression of the CS-US association depend on the integrity of the medial prefrontal cortex (mPFC, Takehara-Nishiuchi et al., 2005) and the lateral entorhinal cortex (LEC, Tanninen et al., 2015). Parallel investigations on spiking activity found selective firing patterns for the CS-US association in both regions (Morrissey et al., 2017; Pilkiw et al., 2017). To uncover the specific roles these regions play in representing the CS-US associations, the present study directly compared the information represented in firing patterns during the trace interval in the mPFC and LEC. A support vector machine classifier was trained to differentiate population firing rates (pFR) during four task phases, before the CS, during the CS, trace interval, and after the US. With pFRs from both regions, the classifier successfully discriminated pFRs during the trace interval from those during the other phases. However, the decoding accuracy was higher with mPFC pFRs than with LEC pFRs. With LEC pFRs, most errors originated from confusion between the trace interval and the CS. In contrast, with mPFC pFRs, errors were due to misclassifications of the trace interval as the US. In addition, when a classifier was trained with pFRs during trials with one CS and tested on those during trials with a different CS, decoding accuracy was dramatically decreased in the LEC but was not affected in the mPFC. These findings suggest that the LEC maintains accurate representations of stimuli after they have terminated, whereas the mPFC converts the stimulus information into expectation signals for the imminent outcome.

Abstract: Humans have the remarkable ability to take a sequence of verbal instructions and rapidly "program themselves" to execute this new task at a high degree of accuracy. How is this remarkable flexibility implemented in the brain? To explore this question, we asked patients in the Epilepsy Monitoring Unit (EMU) to perform a spatial sequence memory task for the first time while we recorded single-neuron activity in multiple prefrontal and mediotemporal brain regions. Patients had to find and remember the spatial locations of four hidden goals on a 2D grid displayed on a computer monitor, and then visit these goals repeatedly in sequence. After several sequence repetitions, the locations of the goals change, and patients had to find and cycle through the new locations. This was repeated 24 times with 6 unique goal layouts. We have recorded data from 11 patients in 14 behavioral sessions so far.
We find encoding of progress towards a goal in single neurons in the pregenual anterior cingulate ($n = 5/9$ neurons, $p < 0.0001$) and entorhinal cortex ($n = 7/56$ neurons, $p = 0.021$). These representations appear to remap as the goals change location, where a cell's peak in activity indicated the same level of progress, albeit towards a different goal, with different goal layouts. These representations look very similar to those found in the analog to the pregenual anterior cingulate in the mouse (unpublished data from Timothy Behrens' lab). This similarity is despite the fact that mice take weeks to train on this task, while human patients perform it within a few minutes of reading the instructions and at a higher degree of accuracy.
We also find encoding of the currently-sought goal in the entorhinal cortex ($n = 10/56$ neurons, $p = 0.00042$). This variable is significantly decodable from the entorhinal population, independent of the spatial locations of the goals (6-fold cross validation, $p < 0.0001$). Future work will elucidate how the role of these two representations in rapidly learning and performing the task.

Title: Behavioral and neural correlates of superstitious learning during transitive inference learning in nonhuman primates

Authors: *Y. JIN[1], F. A. MUNOZ SILVA[1], G. G. JENSEN[3], J. GOTTLIEB[1], V. P. FERRERA[2];
[2]Neurosci., [1]Columbia Univ., New York, NY; [3]Psychology, Reed Col., Portland, OR

Abstract: Complex environments offer multiple learning opportunities thus posing a "strategic planning" dilemma - the need to choose how to allocate cognitive resources to a given aspect of the environment at any given time point. The normative solution to this problem is based on learnability, with the prior belief that an informative structure exists and can be successfully learned. However, it is unknown whether or how animals estimate learnability in novel and complex environments. Here, we show that nonhuman primates (NHP) infer fictitious structure in objectively random events. We used a transitive inference task in which NHP repeatedly visually interacted with two sets of pictorial stimuli: a "learnable" set in which pictures were assigned cardinal orders and monkeys were rewarded for saccading to the higher-rank stimulus, and an "unlearnable" set in which stimuli were unordered and feedback was either random or actively discouraged consistent choices. The NHP learned the implicit order of the learnable set, but also behaved as though some ordering existed in the unlearnable set under both reward schedules. The behavior was not explained by model-free Q-learning algorithms, suggesting that fictitious ordering reflected an internal representation of stimulus order. Neurons in the dorsal anterior cingulate cortex (dACC, 24c, N=50) presented responses predominantly during choice selection or after feedback delivery and encoded learnability, reward value, and their interaction. Particularly during the second half of the session when behavior was more stabilized, many neurons (47.1%) encoded both the objective rank and prediction error in the learnable context and the fictitious rank and subjective prediction error in the unlearnable context. These results suggest that dACC may support diverse learning strategies when facing environments with mixed learnabilities.

Abstract: Shared representation of conceptual knowledge among students duringclassroom teachingAuthorsXiaodan Feng, Xinran Xu, Yangchunxiao Wang, Chunming Lu*; State Key Laboratoryof Cognitive Neuroscience and Learning and IDG/McGovern Institute for BrainResearch, Beijing Normal University, No.19 Xinjiekouwai Street, Beijing 100875, PRChina;**DisclosuresXiaodan Feng:** None. **Xinran Xu:** None. **Yangchunxiao Wang:** None. **ChunmingLu:** None.**Acknowledgements:** This work was supported by the National Natural ScienceFoundation of China (62293550, 62293551, 61977008).**Abstract**Previous extensive studies have been conducted on the cognitive and neuralrepresentation of conceptual knowledge at the individual level. However, little isknown about how conceptual knowledge is represented among individuals duringteaching in the classroom, and how learning tyles modulate the cognitive and neuralrepresentations. To address this issue, an integrated functional near-infraredspectroscopy hyperscanning system with 21 nodes was employed to measurechanges of hemoglobin concentrations from 21 students while an active or a passivelearning occurred during classroom teaching. By vectoring the takeaways using theLatent Dirichlet Allocation model and transforming semantic representations intonetworks of takeaways, we found the stronger the semantic connections a takeawayhas with other takeaways, it is better to be remembered. Next, to understand theneural representation, a representational similarity analysis was conducted betweenbrain activity pattern and takeaways annotations. The results indicated that, whileshared neural representation was found in the angular gyrus during passive learning,no consistent pattern was found among students during active learning, suggesting adeep processing of knowledge through subjective construction during activelearning. Additionally, we found that after a passive learning that immediatelyfollowed the active learning, a significant shared neural representation appeared inthe middle frontal cortex. We also asked the students to perform an active learningimmediately after a passive learning. Again, a significant shared neuralrepresentation was found in the MFC. Together, these results suggested that theshared representation of conceptual knowledge was associated with the knowledgehierarchy. While passive learning was associated with the shared representation ofshallow semantics, active learning was associated with the deep semanticsaccessed through subjective construction probably based on individual's priorknowledge.**Keywords**

Title: Functional brain network predictors of surprise in controlled task and naturalistic viewing contexts

Authors: *Z. ZHANG[1], M. D. ROSENBERG[2];
[1]The Univ. of Chicago, Chicago, IL; [2]Dept. of Psychology, Univ. of Chicago, Chicago, IL

Abstract: Functional brain network predictors of surprise in controlled task and naturalistic viewing contexts
Our environment is always changing. To navigate the world around us, we generate predictions, form beliefs, and learn from surprising changes that violate our beliefs, such as when objects move abruptly or people behave unpredictably. What are the brain networks that predict this experience of surprise in a complex environment? To address this question, we reanalyzed openly available fMRI data collected as participants performed a task in which they learned to predict the location of an upcoming object (N=32; McGuire et al., 2012; Kao et al., 2020). McGuire et al. (2012) developed a normative model tracking *surprise* (changes in the mean of an occluded generative distribution of the object's location) and *uncertainty* (about the generative mean) in this task. To identify functional brain networks whose strength predicted these measures, we calculated the co-fluctuation time course (Faskowitz et al., 2020, Zamani Esfahlani, 2020) of all pairs of 268 brain regions in a functionally defined atlas as the product of their *z*-scored BOLD-signal time series. Using leave-one-subject-out cross-validation, we identified region pairs ("edges") whose co-fluctuation varied across trials with normative surprise and uncertainty. These edges predicted surprise and uncertainty in held-out individuals: edges *positively* correlated with surprise were stronger on trials with more unexpected outcomes (mean within-subject rho=0.09; $t(62)$=7.65, p<0.001) whereas edges *negatively* correlated with surprise showed the opposite pattern (mean rho=-0.09; $t(62)$=-7.15, p<0.001). We next asked whether the same edges predicted surprise in a naturalistic context. We measured dynamic changes in these edges in openly available fMRI data collected as novel participants watched NCAA basketball games (N=20; Antony et al., 2021). Edge strength tracked a validated measure of surprise (change in a team's win probability) from basketball analytics. These results suggest that brain dynamics in a common functional network predict surprise in very different contexts.

Title: Representational drift of contextual fear engrams across the brain

Authors: *T. WANG[1], T. ZHANG[2], B. DUNGATE[2], J. SNYDER[2];
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The physical manifestation of memory is an "engram", the population of neurons that is activated during a learning experience and, when reactivated, contributes to the process of memory retrieval and subsequent behaviour (Josselyn & Tonegawa, 2020). Traditionally, it has been believed that neural representations must remain stable to maintain memories (Guzowski et al., 1999; Reijmers et al., 2007). However, memories are dynamic and recent investigations have revealed that neural representations are more fluid than formerly thought. In the hippocampus, a critical structure for daily event memory, neurons previously recruited during an experience show variation through time, a process called representational drift (Sweis et al., 2021). This phenomenon has been overlooked due to limitations in traditional electrophysiological approaches that often only record from identified neurons on a timescale of minutes to hours (Leutgeb et al., 2005). However, modern mouse models (or Ca2+ imaging), which permanently label activated neurons, suggest varying reactivation rates in the hippocampus over days (Ramirez et al., 2015; Redondo et al., 2014). Understanding how representations drift over longer intervals is crucial to comprehending how short-term and long-term memories guide future behaviour. Since perception and memory rely on a myriad of brain regions, and drift has been identified in areas outside of the hippocampus (Rule et al., 2019), it is essential to adopt a broad network-level approach to truly understand the stability of neural representations. Recent research stresses this idea by demonstrating that activity in individual regions fail to correlate with fear memory retrieval (Santos et al., 2021). Here, to characterize representational drift across sensory and associational regions of the brain, FosTRAP2 mice and activity-dependent tagging are used to indelibly label activated neuronal populations during two identical contextual fear conditioning events, at recent and remote timepoints. This work will help to identify the extent to which representations drift in individual brain regions and brain-wide networks that are involved in perception and memory.

Title: Hippocampal CA2 E/I imbalance in the circuit of cognition and social memory

Authors: *A. FRANZ[1,2], S. JAEGER[2], M. FUNK[2], D. KÄTZEL[1], B. HENGERER[2];
[1]Inst. of Applied Physiol., Ulm Univ., Ulm, Germany; [2]CNS Dis. Res., Boehringer Ingelheim Pharma GmbH & Co. KG, Biberach, Germany

Abstract: Disturbances in the neuronal activity of the hippocampal CA2 subregion have been shown to result in impaired social memory in rodents. However, the current assessment of behavioural role of CA2 within the circuit of cognition relies on classical tests, presenting only a snapshot of the behaviour of subjects. As both clinical and preclinical data have revealed a relevance for CA2 in psychiatric disorders such as schizophrenia, it is crucial to uncover the effects of CA2 E/I imbalance in more natural social environments over longer periods of time. Furthermore, gaining a deeper understanding of molecular alterations within the underlying circuit of cognition is essential for the development of future therapeutic treatments. To further characterise downstream effects of an E/I imbalance in murine CA2, CA2 pyramidal neurons were chronically silenced using viral-mediated Designer Receptors Exclusively Activated by Designer Drugs (DREADD) expression. During early adulthood, we performed automated behaviour analysis of individuals in social groups using long-term radio-frequency identification (RFID)-supported video tracking. Subsequently, we utilized high-throughput confocal microscopy combined with automated image analysis to investigate molecular effects of CA2 E/I imbalance on key proteins involved in neuronal activity of target brain regions. Our findings provide a detailed examination of the effects of chronic DREADD-mediated CA2 E/I imbalance on several distinct social behaviours during the light and dark cycle. Additionally, our study contributes to a broader understanding of the molecular consequences associated with this imbalance.

Abstract: Autism spectrum disorders (ASD) are a group of neurodevelopmental disorders characterized by persistent deficits in social communication and social interaction. Altered synaptogenesis and aberrant connectivity responsible for social behavior and communication have been reported in autism pathogenesis. Autism has a strong genetic and heritable component; however, environmental factors including toxins, pesticides, infection and *in utero* exposure to drugs such as VPA have also been implicated in ASD. Administration of VPA during pregnancy has been used as a rodent model to study pathophysiological mechanisms involved in ASD, and in this study, we used the mouse model of prenatal exposure to VPA to assess the effects on striatal and dorsal hippocampus function in adult mice. Alterations in repetitive behaviors and shift habits were observed in mice prenatally exposed to VPA. In particular, such mice presented a better performance in learned motor skills and cognitive deficits in Y-maze learning frequently associated with striatal and hippocampal function. These behavioral changes were associated with a decreased level of proteins involved in the formation and maintenance of excitatory synapses, such as Nlgn-1 and PSD-95. In conclusion, motor skill abilities, repetitive behaviors, and impaired flexibility to shift habits are associated with reduced striatal excitatory synaptic function in the adult mouse prenatally exposed to VPA.

Title: Enhanced temporal memory and diminished temporal compression after slow and fast theta tACS

Authors: *Y. WANG, P. DE WEERD, V. VAN DE VEN;
Univ. of Maastricht, Maastricht, Netherlands

Abstract: Theta oscillations (3-8 Hz) are believed to play a crucial role in supporting episodic memory formation. Rather than a unitary frequency range, theta oscillations may functionally specialize between slow (3 Hz) for short term memory accuracy and fast theta (8 Hz) for other cognitive functions. Several studies have suggested that theta oscillations play a role in temporal memory formation and sequence learning, but this relation remains to be causally tested. Transcranial alternating current stimulation (tACS) offers a way to modulate theta oscillations of the associative memory network to test its involvement in temporal memory. We aimed to test the contribution of slow vs. fast theta stimulation on temporal memory formation. Participants (N=24) completed three tACS sessions in which stimulation was administered during sequence

encoding. In each session, participants were presented with a series of 72 visual objects, each presented within a frame that changed color every eight items, while simultaneously receiving tACS over area P3 at 8 Hz, 3 Hz, or sham. After encoding, participants indicated the serial position (1-72) at which a picture was presented during encoding on a visual analog scale representing the sequence's timeline. We analysed temporal bias - the rated position minus the actual position, with negative (positive) values indicating temporal compression (temporal dilation) - and temporal accuracy - the absolute magnitude of the rated minus actual position - as a function of tACS conditions.Results showed that slow vs. fast theta tACS affected temporal performance in different ways. During sham stimulation, participants consistently showed a temporal underestimation bias (p<0.001) for items presented further away from a change in frame color, compared to items presented at a color change. This finding is reminiscent of temporal compression that has been observed in event segmentation. Notably, 8 Hz tACS (p=0.009), but not 3 Hz (p=0.071), suppressed this temporal bias. Concurrently, slow theta (p=0.003), but not fast theta stimulation (p=0.31) diminished absolute temporal error (i.e., improve temporal accuracy), compared to sham tACS. Our study represents the first application of brain stimulation to test the contribution of theta stimulation on temporal memory, showing evidence for a functional dissociation of slow and fast theta. We think it is possible that our tACS stimulation affected hippocampal function in temporal memory formation. As such, our study contributes to our understanding of the neural mechanisms underlying episodic memory formation.

Title: Neural basis of interference between memory-driven perception and ongoing experience

Authors: *M. PRAJAPAT, N. DAS, E. LOBO, P. JAISWAL, B. JAYAPRAKASH;
Ctr. for Neurosci., Indian Inst. of Sci., Bengaluru, India

Abstract: Declarative memories are a collection of everyday experiences and facts that can be stated explicitly. Episodic memories, a sub-class of declarative memories, when retrieved, are accompanied by the perception of the particular episode. Such memory-driven percepts also invoke the emotional states that were experienced during the experience of the event, along with factual and sensory information. In this study, we hypothesized that the hippocampal subfield CA1 is the neural locus of memory-driven perception; when activated, it interferes with normal sensory perception. Any conflict between memory and sensory perceptions creates a perception

of mixed reality, suppressing the behaviours associated with the sensory or memory-based information alone. We used the tet-tag system in transgenic mice and optogenetic tools to capture and reactivate the memory ensembles. Our findings reveal that activation of memory of the training context did not have any effect when mice were tested in the same context, i.e., when no conflict existed between present and past experiences. However, when the mice were tested in a neutral context, the hippocampal activation led to a conflict of information in perceptual space. Cortical areas detect such conflict, and behaviour linked with mixed perceptual reality emerges. These results provide valuable insights into the cognitive processes of memory and perception and how these interact to modulate behaviour. The identification of the hippocampus as the seat of memory-driven perception provides crucial insights into the neural basis of this phenomenon. Moreover, the detection of conflicts between memory and sensory perceptions by the cortex highlights the role of this brain region in shaping and modulating behaviour. The observed behavioural changes, triggered by the presence or absence of conflict detection, emphasize the intricate interplay between memory, perception, and behaviour.

Title: Genetic Differences in the Influence of Acute Ethanol on Trace Fear Conditioning in Mice

Authors: S. J. MURRAY, E. HENRY, *S. LOGUE, T. J. GOULD;
Biobehavioral Hlth., Penn State Univ., University Park, PA

Abstract: Ethanol affects both learning and anxiety but effects of alcohol across individuals are not homogenous. Genetic differences and sex are important factors that may contribute to variability in the effects of acute ethanol on learning and anxiety. We were interested in examining genetic differences in fear learning that engages areas sensitive to ethanol. Trace fear conditioning is a type of fear conditioning in which there is a delay between the conditioned stimulus (tone CS) and the unconditioned stimulus (foot shock US). This results in subjects learning a fear association with the context, which involves the hippocampus, and fear association with the tone CS, which because of the delay between CS offset and US onset, engages prefrontal cortex and hippocampus. Both the prefrontal cortex and hippocampus are sensitive to the effects of ethanol. To explore the genetic differences in the effects of acute ethanol on trace fear conditioning, saline, 1.0 g/kg, or 1.5 g.kg ethanol was administered

intraperitonially prior to training in trace fear conditioning in male and female C57BL/6J (B6) and DBA/2J (D2) mice. Fear learning to the context was assessed 24 hr later by measuring the level of freezing when mice were tested for 5 minutes in the training context without other stimuli present. One hour later, fear learning to the tone CS was tested in an altered context for 6 minutes (3 minutes before the tone CS & 3 minutes of tone CS). For context learning, ethanol dose dependently decreased freezing to the context in male and female B6 mice, while both doses of ethanol decreased freezing to the context by the same degree in male and female D2 mice. In the tone CS test, ethanol dose dependently decreased freezing to the tone CS in male and female B6 mice, while both doses of ethanol decreased freezing to the tone CS by the same degree in male and female D2 mice. Sex differences were also detected. These results suggest that acute ethanol has deleterious effects on learning to fear the context and the tone CS in the trace fear conditioning paradigm and genetics and sex may contribute to acute ethanol dose response differences between B6 and D2 mouse strains.

Title: Chronic heroin self-administration impairs hippocampus-dependent short term spatial memory in male and female Long-Evans rats

Authors: *J. G. SEVERINO PEREZ, C. DRESSLER, C. REDDY, M. FUNK, C. TOMAS BALTAZAR, M. JIWANJI, M. E. WIMMER;
Psychology and Neurosci., Temple Univ., Philadelphia, PA

Abstract: There are several comorbidities that arise with substance use disorder, such as sleep disturbances, anxiety, depressed mood, and cognitive deficits. These conditions are not only a consequence of drug use but perpetuate further use as well. There are studies to suggest that cognitive deficits in particular are a direct consequence of drug abuse, and those with poorer cognitive functioning are more likely to drop out of cognitive behavioral therapy focused on relapse prevention. Given the nationwide opioid epidemic that results in about 136 deaths per day, it is imperative that we better understand the cognitive deficits that arise from chronic opioid use. The present study seeks to understand the impact of chronic heroin use on hippocampus dependent memory. Adult male and female Long-Evans rats had daily access to either heroin (0.1 mg/kg/infusion) or sucrose pellets for 15 days on a fixed ratio 1 reinforcement schedule. Following a week of forced abstinence and again at 3 weeks of forced abstinence, all rats underwent an object location memory task. In the object location memory task, subjects

were placed in an arena with a spatial cue on the wall and exposed to two identical objects for three 6-minute training sessions, and after a 30-minute delay, one object was placed in a new location relative to the spatial cue. At 1 week of forced abstinence, sucrose-exposed rats spent significantly more time exploring the displaced object, suggesting that the sucrose-exposed rats had intact object location memory. Heroin-exposed males overall did not spend more time with the displaced object after the 30-minute delay. At 3 weeks of forced abstinence, both heroin and sucrose-exposed males spent significantly more time with the displaced objects after a 30-minute delay. Heroin-exposed females, on the other hand, showed no impairment in short-term spatial memory after 1 week of forced abstinence. Taken together, these data suggest that chronic heroin exposure can result in hippocampus-dependent short term memory deficits in a sex-dependent manner. This model will be the foundation for elucidating circuitry and molecular mechanisms underlying drug-induced cognitive deficits. Because cognitive deficits perpetuate further drug use, this research may serve as a starting point for developing novel therapeutics to ameliorate the deleterious effects of chronic heroin use.

Title: Palmitic acid induce inflammation and changes in cognitive performance and anxiety in female mice

Authors: *K. L. MARTINEZ-GONZALEZ;
Univ. Autónoma Metropolitana, Lerma, Mexico

Abstract: Neuro-inflammation describes an immune-metabolic disorder of the nervous system can be triggered by certain high caloric nutrients such as palmitic acid (PA). Nutrients (such as free fatty acids) may accumulate in the nervous tissues such as microglia due to excessive positive energy balance. The sustained impaired energy balance may invoke glial cells activation and disproportionate production of reactive oxygen species (ROS). Either the excessive generation of ROS or accumulated free fatty acids, such as palmitic acid (PA) might activate the canonical inflammatory pathways or elicit chronic inflammation of the brain (Ngozi et al., 2021). Chronic inflammation may later degenerate into a myriad of neuro-psychopathologies, including cognitive decline, major depressive disorder, and some neurological diseases. PA allowed us to study of changes in cognitive decline PA-induced neuroinflammation (measured by Object Location Memory Task) in female Balb/c mice. After PA challenge, changes associated with

inflammation due to dietary administration of palmitic acid were observed in long-term spatial memory and anxiety in female mice. Administration of palmitic acid could serve as a model to understand what happens at the cognitive level with the consumption of high-fat diets and then propose some treatment that can reverse the cognitive decline associated with consumption of high-fat diets.

Title: Monosynaptic rabies viral tracing unveils hippocampal CA1 GABAergic inputs and extensive neocortical inputs to GABAergic interneuron types in the distal dorsal subiculum

Authors: *P. GAO[1], X. XU[2];
[1]Anat. and Neurobio., Univ. of California Irvine, Irvine, CA; [2]Anat. and Neurobio., Univ. California, Irvine, Irvine, CA

Abstract: The hippocampal formation including the dentate gyrus (DG), hippocampus proper (hippocampus), and subiculum (SUB), plays a crucial role in episodic memory and spatial navigation. While SUB is traditionally considered a relay station between CA1 and downstream regions, emerging evidence indicates that the subiculum possesses unique circuit organizational and functional features distinct from CA1. SUB receives circuit inputs that are not solely dependent on the hippocampus, and it has specific cellular composition and distinct spatial/non-spatial representation. These earlier findings suggest that SUB may have novel cell-type-specific circuit organization that is functionally implicated in learning and memory information processing. However, the subiculum has received considerably less attention compared to the hippocampus, with minimal focus on subicular GABAergic interneurons. Therefore, the objective of this project is to address this research gap by investigating the neural circuit connections of interneurons in the subiculum, specifically focusing on the afferents to the distal part of the dorsal subiculum (dSUB). Using our established monosynaptic rabies virus system, we targeted overall GABAergic cells and three major subtypes: Parvalbumin (PV), Somatostatin (SOM), and Vasoactive intestinal peptide-expressing (VIP) in the dSUB. Our results revealed that GAD2+, SOM+, and PV+ cells in the dSUB receive major inputs from CA1, subiculum, postsubiculum, medial septal diagnal band, thalamus, and entorhinal cortex. All these cell types receive GABAergic long-range inputs from CA1. Notably, GAD2+ cells exhibited significantly more cortical inputs than the other groups, including inputs from the visual cortex, auditory cortex, and parietal cortex. Additionally, we observed that distal dSUB GABAergic cells

received inputs from distal CA1 of the posterior hippocampus, demonstrating a broader connectivity pattern that is different from the canonical topographical connection between CA1 and SUB with proximal CA1 projecting to distal dSUB. Our new circuit mapping findings will help us to better understand the circuit operation basis of specific GABAergic cells in the SUB.

Title: Critical period developmental emergence of oscillatory coupling in the hippocampal-neocortical network

Authors: *L. MA[1], D. KHODAGHOLY[2], J. N. GELINAS[3];
[1]Biomed. Engin., [2]Electrical Engin., Columbia Univ., New York, NY; [3]Neurol., Columbia Univ. Irvine Med. Ctr., New York, NY

Abstract: The mature hippocampal-neocortical system exhibits complex connectivity and is central to multiple cognitive processes, such as learning and memory. Expression and coupling of hippocampal sharp-wave ripples (SWRs) and cortical oscillations facilitate and further differentiate different memory stages. However, precisely coordinated oscillatory activity is not an innate property of nascent neural networks. We hypothesized that hippocampal and cortical oscillations require early developmental interactions to shape large-scale network properties. To test this hypothesis, we performed in vivo electrophysiology on unanesthetized mouse pups during the first three postnatal weeks. We used soft, conformable and implantable interface devices to simultaneously probe the developing hippocampus and neocortex. We found that ripple-band oscillations emerged concurrently in hippocampus and cortex during the second postnatal week. These oscillations robustly recruited local neural firing, and developed temporal coupling patterns. These results suggest the importance of hippocampal-cortical communication in the maturation of neural networks, with implications for memory processes.

Abstract: Role of Parvalbumin interneurons (PV-IN) in memory specificity and Higher order association• Authors: Nirupam Das, Utkarsh pandey, Aditya Chakrabarty, Balaji Jayaprakash*. Center forNeuroscience and The department of Organic Chemistry, Indian Institute of Science (IISc)Bangalore:560012• **Disclosure:** Nirupam Das: none, Balaji Jayaprakash: none, Utkarsh Pandey: none, Adityachakrabarty: none.• **Email:** nirupamdas@iisc.ac.in, jbalaji@iisc.ac.in• **Abstract:**Newly encoded information or experiences are stored in the form of memory. Consolidation andretrieval of such memories rely on coordinated neuronal activity within and between different brainregions. Interneurons play a crucial role in gating the signal flow and shaping the network dynamics. PV-IN is one of the most predominant interneurons known to facilitate the development and consolidationof memory. We modulate the activity of PV-IN,and find that PV interneurons modulate the memoryspecificity rather than the ability to retrive the memory. We also found that the PV-IN has a **role in thehigher-order association (HOA)** ,inhibition of PV-IN **blocks the HOA.**We further investigated the HOAphenomenon in APP/PS1 transgenic animals commonly used to study Alzheimer's disease(AD). It is wellknown that the number of PV-IN drastically decreases in 6-9 months old AD animals , however it is notknown if the memory specificity is affected. We used AD mice models and observed that animals could**retrieve the remote contextual memory but were unable to form HOA** compared to non-transgenicanimals. Our study demonstrated the diverse role of PV-IN in retrieving recent and remote episodicmemories and its role in HOA.• **Acknowledgement:** We thank Prof. Santanu Mukherjee (Dept. of Organic Chemistry,IISc) forhelping us with preparation and characterization.

Title: Investigating the long-term evolution of retrosplenial cortex neuronal activity around hippocampal ripples

Authors: *J. KARIMI ABADCHI, R. SUTHERLAND, M. MOHAJERANI;
CCBN/University of Lethbridge, Lethbridge, AB, Canada

Abstract: The activity of neurons, both at individual cells and populations level, undergoes evolution over time even if its associated external variables stay stable. This evolution has been proposed to mediate memory consolidation by facilitating the incorporation of new information into the corpus of previously stored knowledge in the neocortex. Memory consolidation is thought to involve continual interactions between the hippocampus and neocortex during brain offline states when hippocampal ripples occur. Ripples are transient, high-frequency oscillations in the local field potentials (LFPs) recorded from the CA1 subfield of the hippocampus, during which the hippocampal-neocortical interactions are enhanced. Therefore, it is of significance to the field of learning and memory to investigate the long-term evolution of peri-ripple neuronal activity in the neocortex. Such investigations may provide insight into the mechanisms by which neocortical neural networks contribute to memory consolidation which could have implications for treating dementia and Alzheimer's disease. With this in mind, we addressed the abovementioned question by recording the activity of the same population of pyramidal neurons from layers 2/3 of the agranular retrosplenial cortex (aRSC), an association cortex heavily implicated in memory processing, using two-photon calcium imaging across multiple days. Additionally, simultaneous recording of local field potentials in the hippocampus was conducted to detect ripples, enabling us to study the long-term evolution of peri-ripple neuronal activity in the aRSC.

Title: Impact of Septal Cholinergic Inhibition on CA1 Oscillations, Spatial Memory, & Exploration

Authors: *D. LAYFIELD, S. BICKFORD, K. MOORE, I. CHOI, B. GREGORY, E. L. NEWMAN;
Indiana Univ., Bloomington, IN

Abstract: The medial septum is a critical regulator of the hippocampal network. The majority of cholinergic projections to the hippocampus arise from medial septum. These neurons shift and modulate the hippocampus toward encoding, supporting memory, and learning. These neurons are also theorized to promote exploratory behaviors like rearing. More recent activation studies have found that septal cholinergic neuron activation can support fear learning, enhance theta oscillations, and suppresses sharp wave ripples. However, inactivation studies of septal cholinergic neurons are restricted to permanent lesion studies, leaving it unclear how septal cholinergic disruption may affect hippocampal dynamics and spatial memory. To further elucidate the role of these critical neurons, we selectively optogenetically inactivate the cholinergic neurons of the medial septum while recording oscillations of hippocampal CA1 in awake behaving rats. Septal cholinergic inhibition was timed to different behavioral and task epochs. We find that optogenetic inhibition of septal cholinergic neurons modulates theta and gamma oscillations of CA1 with minimal impact on spatial memory and exploratory rearing behavior. These results are congruent with the theory that medial septal cholinergic neurons are to promote the processing of novel sensory inputs or associations.

Title: Evolution of value representations in medial orbitofrontal cortex with ventral hippocampal inputs for cognitive flexibility in mice

Authors: *K. KUMAR, M. HASANTASH, A. GUNGI, Y. LI, C. ANACKER, K. IIGAYA; Columbia Univ., New York City, NY

Abstract: Acquiring rewards in a complex environment requires identifying relevant features that are predictive of reward within a high-dimensional feature space, and keeping track of changes in this reward contingency across time. However, the neural mechanisms underlying this flexible value computation are not well understood. Here we analyzed neural population dynamics in medial orbitofrontal cortex (mOFC) and ventral hippocampus (vHPC) in mice performing a naturalistic decision making task. The mice must discriminate among multisensory features (e.g., odor, texture, location) and learn the values of these different features which

change over time. For example, animals experienced changes of reward stimulus within the same sensory dimension (e.g., odor A to odor B) and across different sensory dimensions (e.g. odor B to texture A). We developed a novel method, called Representational Evolution Analysis (REA), to examine how the neural representations of feature values evolve across time. Using REA, we found that mOFC dynamically represents the feature value of the environment that the animal decided to act upon, even when the animal made the wrong inference. We also studied how vHPC inputs affect the evolving geometry of feature value representations in mOFC. Our study offers a novel insight into how neural computation underlying flexible value coding supports cognitive flexibility in a complex environment.

Title: Assessing learning and memory dysfunction in rodents following traumatic brain injury using a radial arm maze paradigm

Authors: *M. HABIB[1], C. ADAM[3], E. MIRZAKHALILI[1], J. A. WOLF[2];
[2]Neurosurg., [1]Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Pennsylvania Neurosci. Grad. Group, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) is known to disrupt cognitive processing, especially learning and memory function. We hypothesize that these disruptions arise from disrupted oscillatory communication in the wider hippocampal network following TBI resulting in spatial and working memory dysfunction. In rats, TBI deficits in the Radial Arm Maze (RAM) have been described following a lateral fluid percussion injury (FPI); however, most studies have focused specifically on learning or memory individually. Here we use an adapted version of the RAM that allows us to assess both learning and memory while rats freely run to investigate TBI-associated dysfunction. To this end, Long-Evans rats are food restricted to 85% bodyweight and are acclimated to the RAM where they collect food rewards at the ends of each of the 8 arms. After acclimation the rats are moved to a 3-arm training phase during which rats use spatial cues in the room to navigate to the same 3 baited arms. To successfully perform this task, rats must remember the 3 baited arms and use spatial cues to navigate to them. During a training session, the rats run up to 30 trials, where one trial is complete when all 3 baited arms are visited. While navigating, possible errors include entering an unbaited arm (reference memory) or re-entering a previously retrieved reward arm (working memory). Once the rats complete a session with >40%

error-free trials, they undergo a reversal, which has 2 components: (1) a pre-probe (testing the previous day's arm configuration) and (2) the reversal itself, where one of the 3 arms remains baited while the other two baited arms change locations. Post-probe sessions (assessing the rat's memory of the new configuration) are performed 50 minutes and 24 hours after learning the new set of arms. Rats are then brought back up to weight before undergoing an FPI (2.1 atm) or sham injury. After recovering, rats are returned to 85% bodyweight and reintroduced to the RAM 7 days post-surgery to assess their memory of the pre-surgery 3-arm configuration. They then undergo five additional reversals at the 8-, 9-, 10-, 17-, and 24-day post-surgery timepoints to assess their ability to learn new spatial configurations and retain/consolidate this information. Preliminary results demonstrate no significant difference in the percentage of error-free trials or number of working/reference memory errors per trial between injured (n=1) and sham (n=2) rats. We will continue to power this study to determine if there are TBI-associated learning/memory deficits in our version of this task and will implant high-density, laminar electrodes in the hippocampal CA1 to investigate pathophysiology in behaving rats post-TBI**.**

Title: Activation of cell assemblies associated with rat's skilled reaching task is modulated by hippocampal sharp-wave ripples during sleep

Authors: P. NAZARI ROBATI, M. ECKERT, ***M. TATSUNO**;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Recent research suggests that explicit and implicit memories are represented by groups of anatomically or functionally connected neurons, called cell assemblies (CAs). For CAs associated with explicit memory, it has been reported that the hippocampal and cortical reactivation is coordinated during slow-wave sleep (SWS). However, our current understanding of the relationship between CAs associated with implicit memory and hippocampal activity remains limited. To address this gap, we analyzed neural ensemble activity in the primary motor cortex (M1) during behavioral task and rest periods in four rats that underwent training in a skilled single-pellet reaching task for approximately 15 days (Eckert et al., 2020). Based on the behavioral performance assessed by the success reach rate, four rats were categorized into two fast-learners and two gradual-learners. We applied an unsupervised CA detection method (Russo and Durstewitz, 2017) to the combined task and sleep recording and identified the CAs associated with reaching behavior. The K-means clustering on those reach-associated CAs

revealed that there were four distinct neural dynamics around the reach behavior. Reactivation analysis detected a significant increase of reactivation during post-task SWS than pre-task SWS (paired t-test, p-value< 0.05). Investigation of the hippocampal sharp-wave ripples (SWRs) and the reach-associated CAs revealed the presence of both positive and negative modulation of CAs around SWRs. To further investigate whether the CA modulation around SWRs is influenced by training, we compared the early and late training days. Interestingly, during the early phase of training, fast-learners exhibited more CA suppression around SWRs whereas the gradual learners showed more CA activation around SWRs (Mann-Whitney U test, p-value< 0.05). In conclusion, we found that reach-related CA reactivation in M1 could either be activated or suppressed around SWRs during sleep and that this relationship was different for fast and gradual learners. Our results suggest that cortical reactivation is coordinated with the hippocampus during skill learning and that a potential variation in underlying motor memory consolidation mechanisms leads to faster or slower learning.

Title: Anterior cingulate cortex preferentially drives dorsal CA1 deep neuronal activity during sharp-wave ripples for memory consolidation

Authors: *A. HALL, D. V. WANG;
Drexel Univ. Col. of Med. Neurosci. Program, Philadelphia, PA

Abstract: Memories of events are committed to long-term storage through a process known as system consolidation. Sharp-wave ripples (SPWs), neural oscillations originating from hippocampal dorsal CA1 and occurring predominantly during slow-wave sleep (SWS), play a critical role in system consolidation. SPWs are thought to coordinate the reactivation of hippocampal and cortical ensembles (neural units that encode memories) that were previously active during wakeful memory acquisition. Recently, two subpopulations of hippocampal dorsal CA1 (dCA1) pyramidal neurons that exhibit unique firing properties during SPWs have been identified. Neurons in the superficial pyramidal layer of dCA1 (CA1sup) exhibit more rigid characteristics and show non-significant changes in activity in response to learning, whereas those in the deep pyramidal layer of dCA1 (CA1deep) exhibit more plastic-like characteristics, changing dynamically in response to learning. Although these functional differences have been described, the neural inputs which drive the recruitment of these neurons during SPWs, remains understudied. Evidence we have gathered suggests the anterior cingulate cortex (ACC) is a

possible candidate that drives dCA1 neuron recruitment during SPWs. Using viral labelling and dual site *in vivo* electrophysiology, we have traced a polysynaptic pathway connecting ACC to dCA1 and uncovered preliminary evidence demonstrating functional connectivity between these two regions. Specifically, we found that ACC neuronal population activity immediately preceding SPW onset predicts the firing rates of CA1deep but not CA1sup neurons during subsequent SPWs. Moreover, the predictive strength significantly increases in post-learning compared to pre-learning sleep, suggesting a likely role in memory consolidation. Consistently, optogenetic stimulation of the ACC during SWS selectively activates CA1deep but not CA1sup neurons. Given these findings, we hypothesize that ACC neurons selectively drive CA1deep, but not CA1sup neurons activity during SPWs of SWS, and that this communication is involved in the consolidation of newly acquired memories.

Abstract: Neurological conditions impacting human memory represent a massive hurdle for modern medicine, and the investigation of neuroprosthetic devices that can interact with memory neurocircuitry via electrical stimulation is warranted. Hippocampal sharp-wave ripples (SWR) and hippocampal-neocortical theta oscillations are electrophysiological signatures of memory that coordinate memory storage and retrieval in memory networks. However, few studies have investigated direct causal relationships between theta oscillations and hippocampal SWR. In three patients, closed-loop stimulation was applied in theta frequency (10 pulses per stimulation train) directly to the hippocampus or to white matter tracts in the hippocampal-entorhinal region in- and out-of-phase relative to ongoing hippocampal theta oscillations. The selected stimulation frequency was subject-specific, as stimulation was applied with respect to each patient's resting peak hippocampal theta frequency. SWR characteristics and hippocampal theta power were evaluated both within the stimulation train and proceeding the end of stimulation. Relative to

baseline, in-phase theta stimulation (total 240 stimulation trials) evoked an increase in SWR rate that outlasted the end of stimulation train by 1.5 seconds. Across patients, stimulation-evoked SWR rate was 30% higher than baseline. Further, in trials with increased pre-stimulation hippocampal theta power, post-stimulation SWR rate was also elevated. This study corroborates a relationship between direct electrical stimulation and modulation of human memory neurocircuitry. The application of subject-specific electrical stimulation may evoke enhanced stimulation effect. The implementation of electrical stimulation to augment human memory is a promising frontier, and one that warrants further investigation.

Title: Transition from Rule- to Memory-based Strategy During Task Learning

Authors: *G. YANG, J. JIANG;
Psychological and Brain Sci., Univ. of Iowa, Iowa, IA

Abstract: Different strategies can be utilized when performing tasks. It is usually the best to follow the rules (rule-based strategies) when tackling a task for the first time. However, with extensive practice, more efficient shortcuts (memory-based strategies) can be employed to reduce effort. For example, in the game Minesweeper, remembering how different patterns of numbers correspond to locations of mines can greatly improve performance. However, how practice leads to the switch from rule-based to memory-based strategies remains underexplored. This study aims to investigate the dynamics of applying different strategies in a sequence inference task. We designed a series of tasks, in which participants were initially trained to memorize two distinct task sequences (A and B, each with its unique order). They were then required to recall the task at specific positions of a sequence based on a given cue (e.g., fourth task of sequence A). We hypothesized that participants would start with rule-based strategy initially by mentally replaying the sequence from the beginning to the cued position, but would later switch to a memory retrieval strategy once they had learned the associations between the cues and responses. A total of 34 participants (24.6 ± 6.8 years old; 23 females) took part in the study. The behavioral results revealed that reaction was slower when cued for later positions, but this effect diminished as time progressed. To elucidate their behavioral performance, we developed a computational model that encompassed both the replay of task sequences and the reinforcement learning of associations. Consistent with our hypothesis, the modeling results

suggested that participants employed a replay strategy in the early stage, but transitioned to a memory retrieval strategy later and maintained it until the end. fMRI data during the sequence inference task showed that the replay process was encoded in the frontal-parietal and hippocampus regions. Moreover, the encoding gradually decreased over time, reflecting the shift towards the memory retrieval strategy. In conclusion, our findings demonstrate that sequential task events can be flexibly encoded in our memory, and how they are retrieved depends on the trade-offs between alternative strategies.

Title: Parcellation of the human hippocampus using track weighted dynamic functional connectivity: New insights into structure function relationships.

Authors: *M. A. DALTON, J. LV, A. D'SOUZA, F. CALAMANTE;
Univ. of Sydney, Sydney, Australia

Abstract: Recent technical and methodological advances allow us to conduct increasingly detailed investigations of structural connectivity (SC) and functional connectivity (FC) of the human hippocampus in-vivo using MRI. However, SC and FC are most often analysed independently, thereby limiting our ability to understand structure-function relationships of cortico-hippocampal connectivity in the human brain. To address this gap, we investigated the relationship between SC and FC of the human hippocampus using track-weighted dynamic functional connectivity (TW-dFC) mapping.
In brief, we fused SC and FC data into a quantitative 4D image (i.e., with spatial+temporal information) using TW-dFC. First, ten subjects were selected from the Human Connectome Project (HCP) 100 unrelated subject database. For each subject, we used DWI data to generate SIFT2 weighted streamlines and isolate those connecting the hippocampus with the rest of the brain ('hippocampus tractogram'). We calculated the TW-dFC map for the hippocampus tractogram by assigning each streamline a 'dynamic functional weighting' given by the functional correlation between resting state BOLD fMRI data at its end-points. The TW-dFC data were further analysed using independent component analysis (ICA) to identify clusters within the hippocampus based on the time-series associated with each hippocampal endpoint in the TW-dFC maps. This allowed us to characterise spatially distinct functional clusters within

the hippocampus in a data-driven manner. We then identified the distinct cortical networks associated with each functional cluster in a separate group of 100 participants using HCP data. Using this approach, we identified multiple spatially distinct functional clusters along both the anterior-posterior and medial-lateral axes of the human hippocampus. Group level analysis confirmed that separate functional clusters within the hippocampus were associated with distinct cortical networks, each associated with their own dynamic functional fingerprint. For example, we found strong functional associations between the posterior medial hippocampus and specific medial parietal/occipital areas and, in contrast, between the anterior lateral hippocampus and temporal brain areas.
Our results revealed how circumscribed regions within the human hippocampus display anatomical and dynamic functional connectivity with distinct cortical areas and provide new detailed insights into structure-function relationships within the human hippocampus. These results have implications for theories of human hippocampal function and for understanding hippocampal (dys)function in health and disease.

Title: Distinguishing examples while building concepts in hippocampal and artificial networks

Authors: *L. KANG, T. TOYOIZUMI;
RIKEN Ctr. For Brain Sci., Wako, Japan

Abstract: The hippocampal subfield CA3 is thought to function as an autoassociative network that stores experiences as memories. Information from these experiences arrives via the entorhinal cortex (EC), which projects to CA3 directly as well as indirectly through the dentate gyrus (DG). DG sparsifies and decorrelates the information before also projecting to CA3. The computational purpose for receiving two encodings of the same sensory information has not been firmly established. We model CA3 as a Hopfield-like network that stores both correlated and decorrelated encodings and retrieves them at low and high inhibitory tone, respectively. As more memories are stored, the dense, correlated encodings merge along shared features while the sparse, decorrelated encodings remain distinct. In this way, the model learns to transition

between concept and example representations by controlling inhibitory tone. To experimentally test for the presence of these complementary encodings, we analyze the theta-modulated tuning of place cells in rat CA3. In accordance with our model's prediction, these neurons exhibit more precise spatial tuning and encode more detailed task features during theta phases with sparser activity. Finally, we generalize the model beyond hippocampal architecture and find that feedforward neural networks trained in multitask learning benefit from a novel loss term that promotes hybrid encoding using correlated and decorrelated representations. Thus, the complementary encodings that we have found in CA3 can provide broad computational advantages for solving complex tasks.

Title: Unsupervised hippocampal replay evaluation based on extended Poisson Gaussian-Process Latent Variable Model

Authors: ***D. D. LUO**[1], B. GIRI[2], K. DIBA[3], C. KEMERE[4];
[1]Rice Neuroengineering Initiative, Houston, TX; [2]Univ. of Michigan, Ann Arbor, MI; [3]Dept of Anesthesiol., Univ. of Michigan Neurosci. Grad. Program, Ann Arbor, MI; [4]Electrical and Computer Engin., Rice Univ., Houston, TX

Abstract: It has been shown that the hippocampus plays a major role in memory and its activity is tuned by a wide variety of variables. Hippocampal neural firing patterns during behavior are found to be replayed in a temporally-compressed manner during those population burst events (PBEs) that occur during sharp-wave ripple oscillations, which is thought to be important for

memory consolidation. However, our understanding of those replay events is biased because of the many assumptions imposed in replay detection. To decode and detect replay events in an unsupervised manner, dimension reduction on neural activity paves a way for it by dissociating the measurement of internal neural state repetition from the measurement of external variable tuning.
With assumptions only on the smoothness of latent dynamics and of internal tuning curves, the Poisson Gaussian-process latent variable model (P-GPLVM) (Wu et al., 2017) is a powerful tool to discover the low-dimensional latent structure for high-dimensional spike trains. We extend the P-GPLVM to enable the latent variable inference of new data constrained by the previously learned smoothness and mapping information, thereby allowing the estimation of internal state repetition in new neural activity. We also describe a principled approach for the constrained latent variable inference for temporally-compressed patterns of activity, such as those found in PBEs, as well as metrics for assessing neural state repetition and repetition pattern, which allows replay detection without assuming external variables that drive the neural activity or predetermining replay patterns.
These approaches are applied on hippocampal ensemble neural activity recorded in an experiment where the animal explored two mazes and rested before and after both exploration sessions. A latent space encoding animal position and context is learned merely from neural activity during active maze explorations. Tested by new neural data during active exploration, this extended P-GPLVM can capture the repetition of neural states encoding similar animal experiences. Likewise, neural state repetitions can be evaluated for neural activity during PBEs, allowing the unsupervised identification for replay events of versatile replay patterns and more general experiences.

Title: Hippocampal contributions to dynamic social memory in prairie voles.

Authors: *W. M. SHEERAN[1,4,2], K. E. WINTHER[2], J. A. TEMPLE[3], Z. R. DONALDSON[2,3]; [2]Molecular, Cellular, and Developmental Biol., [3]Psychology and Neurosci., [1]Univ. of Colorado, Boulder, CO; [4]Med. Scientist Training Program, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Substantial work over the past decade has implicated the dorsal CA2 (dCA2)-to-ventral CA1 (vCA1) intrahippocampal circuit in processing social information and related

memories. In mice, activity in both regions is necessary for hours-to-days-long social recognition memory. Both regions also contain neuronal ensembles whose activity discriminates between different conspecific identities. However, several critical questions about this circuit's role in social information processing remain unanswered. For example, how do neuronal dynamics in either region compare as a test animal recognizes conspecifics with fundamentally distinct relationships to itself, such as a peer or a mating partner? Additionally, how stable is coding for a conspecific if the test animal successfully remembers that individual after a long period of separation? Answering these questions requires an animal model that forms multiple distinct attachment relationships and exhibits long-term social memory. Unlike laboratory mice and rats, prairie voles develop same sex affiliative relationships and opposite-sex pair bonds and remember these relationships even after weeks of separation. Using in vivo cellular resolution calcium imaging and manipulative methods in dCA2 and vCA1, our preliminary results indicate that vCA1 is required for prairie voles to form new pair bonds. Additionally, distinct ensembles discriminating a partner from a novel animal exist in dCA2 before and after partner separation. We are continuing to record activity from and are planning to reversibly inhibit both regions throughout the time course of peer relationships and pair bonds.

Title: Bidirectional impact on memory formation by local dendrite-targeting CA1 hippocampal interneurons

Authors: *V. SEKULIC, Y. LIU, D. POLYGALOV, A. HUANG, T. J. MCHUGH;
Lab. for Circuit and Behavioral Physiol., RIKEN Ctr. for Brain Sci., Wako-shi, Japan

Abstract: In mammals, the formation of new memories critically depends on the balance of excitation and inhibition within the circuits of the hippocampus, controlled by a large array of distinct interneuron subtypes. In the CA1 region, somatostatin-expressing (SST) interneurons target pyramidal cell dendrites and *in vitro* these SST+ cells have been shown to simultaneously inhibit distal dendrites but disinhibit proximal dendrites in CA1 pyramidal neurons, suggesting a complex role in modulating principal cell activity during memory encoding. We thus sought to determine the effects of bidirectional SST cell manipulation on hippocampal learning *in vivo* using a combination of chemogenic manipulation (DREADDs) and genetically encoded calcium indicator activity (Soma.GCaMP6f) as readouts in freely behaving mice. We observed that

DREADD-mediated activation of SST+ neurons during training in the trace fear conditioning (TFC) task resulted in enhanced memory 1 week later and an increase in the size of the CA1 engram, while SST+ neuron inhibition decreased both memory and engram size. Calcium imaging analysis found that pyramidal cells exhibited higher firing rates, greater number of place fields, and less spatially selective fields in the SST activation compared to inhibition and mCherry control groups, suggesting a more generalized encoding of memory during TFC. Conversely, the SST inhibition group exhibited more spatially selective, and thus less out-of-field activity than both the activation and control groups. This led us to the prediction that spatial coding may be enhanced in SST inhibition mice compared to SST activation, which was subsequently confirmed in an object location task (OLT) experiment. Our findings suggest a role for SST interneurons *in vivo* that combines both inhibitory and disinhibitory effects depending on whether the memory type is mediated by contextual (proximal) or sensory (distal) information onto CA1 pyramidal dendrites.

Abstract: Memory disorders are associated with Alzheimer's disease, traumatic brain injuries, and aging. Understanding the molecular mechanisms underlying memory formation, storage, and retrieval is cardinal to finding new treatments. Protein synthesis plays a crucial role in memory formation by enabling enduring forms of synaptic plasticity. The mechanistic target of rapamycin complex 1 (mTORC1) contains the regulator-associated protein of mTOR (Raptor) and phosphorylates eukaryotic initiation factor (eIF) 4E-binding proteins (4E-BPs). Phosphorylated 4E-BPs dissociate from the cap-binding protein eIF4E, which then bind to the

mRNA and initiate protein synthesis. We discovered that hippocampal mTORC1 activity sharply declines in the excitatory pyramidal neurons during postnatal development in mice but maintains at a high level in GABAergic neurons. We employed a combination of genetic and chemogenetic methods to study the cell-type-specific role of the mTORC1-4EBPs axis in learning and memory. Our results demonstrate that deleting Raptor or 4E-BP2 (the major brain isoform) in GABA-expressing inhibitory neurons is sufficient to cause hippocampal-dependent memory impairment. Both exaggerating and attenuating mTORC1 activity using DREADDS in hippocampus inhibitory neurons, but not excitatory neurons, blocks long-term memory formation. Taken together, our research highlights the importance of mTORC1-4EBP2 activity in GABAergic inhibitory neurons in learning and memory.

Title: Both interneuronal and pyramidal cell α5-GABA$_a$receptors modulate the threshold of LTP induction

Authors: *S. KOMANDURI[1], M. N. DREGER[1], R. A. PEARCE[2];
[1]Dept. of Anesthesiol., Univ. of Wisconsin - Madison Sch. of Med. and Publ. Hlth., Madison, WI; [2]Dept. of Anesthesiol., Univ. of Wisconsin-Madison Sch. of Med. and Publ. Hlth., Madison, WI

Abstract: GABAA receptors that incorporate α5-subunits (α5-GABA$_A$Rs) are expressed throughout the central nervous system, but they are most highly concentrated within the hippocampus, a structure that plays an essential role in learning and memory. To investigate the mechanisms by which α5-GABA$_A$Rs modulate memory, we selectively eliminated them from pyramidal neurons or interneurons and assessed effects on long-term potentiation (LTP) of Schaffer Collateral (SC) synapses in hippocampal brain slices, a commonly used cellular model of memory formation. Stimulus and recording electrodes were placed in *stratum radiatum*, and LTP was induced by a tetanic stimulus consisting of 600 pulses delivered at a frequency of 20Hz, a paradigm that was reported previously to depend upon α5-GABA$_A$Rs (LJ Martin et al., J. Neurosci. 2010). LTP was quantified as the change in the average fEPSP slope between 50-60 min post-tetanus. Differences were compared using one-way ANOVA and Tukey's HSD test to correct for multiple comparisons, with statistical significance set at p=0.05. We found that LTP was significantly greater in global α5-subunit knockout mice compared to WT (α5-gl-KO 19.6 ±

8.0%, WT -3.90± 15.1%, p=0.007, n=8 each), confirming previous results. In mice lacking α5-GABAARs in either interneurons or pyramidal neurons, LTP was also significantly greater than WT (α5-i-KO 33.14 ± 10.1%, p=0.0042; α5-pyr-KO 26.81 ± 17.9%, p=0.00003, n=8 each). There were no statistically significant differences between the α5-gl-KO, α5-i-KO, and α5-pyr-KO groups. Our results indicate that α5-GABA$_A$Rs on both interneurons and pyramidal cells set the threshold for LTP in this 20Hz tetanus paradigm. Future studies of interneuron subtype-selective a5-GABA$_A$R knockout mice will reveal which interneuron subtypes are involved.

Title: Decreased hippocampal CA1 sharp-wave ripples during consummatory reward licking in head-fixed rats

Authors: *T. SAKAIRI[1], M. KAWABATA[1], A. RÍOS[1], Y. SAKAI[2], Y. ISOMURA[1];
[1]Tokyo Med. and Dent. Univ., Tokyo, Japan; [2]Tamagawa Univ. Brain Inst., Tokyo, Japan

Abstract: In psychology, animals are sometimes considered to behave in a sequence of actions consisting of approaching a desire (preparatory/appetitive behavior) and finally satisfying the desire (consummatory behavior). Preparatory behaviors are exploratory and strategic for accomplishing their desire, whereas consummatory behaviors include drinking, eating, and copulating for consummation (Konorski, 1976). It is known that sharp-wave ripples (SWRs) occur in the hippocampus during consummatory behaviors as well as awake immobility and slow-wave sleep (Buzsaki, 1986). For instance, the SWRs are increased when animals acquire a reward (i.e., consummatory behavior) after they explore space in expectation of reward (preparatory behavior). These SWRs may take a role in memory consolidation on exploratory action and its outcome. However, it remains unclear whether immobility or consummation contributes more to modulating the occurrence of SWRs, since they stand still to get the reward under such freely-moving conditions. To address this issue, we analyzed the SWRs and spike activity in the hippocampal CA1 area during licking a drop of water in constantly immobile rats under a head-fixed condition. We preliminarily observed the SWRs significantly decreased when

naïve (unlearned) rats licked to drink water under the constant immobility. Therefore, we investigated whether this unexpected decrease in SWRs would also be reproduced during licking reward water as a consummatory behavior in an operant learning task. To this end, we trained head-fixed rats to perform a "False-True Consummation" task, in which each pedal release in response to go cue (preparatory action) was unrewarded and rewarded alternately. Thereby, their licking was considered as false and true consummation in unrewarded and rewarded trials, respectively. We found that the SWRs gradually significantly increased towards the pedal release (preparatory action) especially in reward-expectable trials. Intriguingly, the SWRs were rapidly suppressed during true consummatory licking in rewarded trials under the immobility. In addition, a group of hippocampal CA1 neurons displayed a similar decrease in spike activity during the consummatory licking. These results indicate that reward expectation enhances the SWRs occurrence during preparatory behavior and that it was notably suppressed during the consummatory action in constantly immobile situation.

Title: The Effects of Silencing Dorsal and Ventral Hippocampus in a Probabilistic Reversal Learning Task in Rats

Authors: *M. COOKE, T. LIN, B. DUNGATE, P. HOLDER, S.-A. CHOI, L. MALLELA, J. SCHUMACHER, S. FLORESCO, J. SNYDER;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In nature, animals searching for reward, whether food or otherwise, are often not guaranteed success. Animals, and humans, must therefore learn and adapt to these uncertainties and flexibly update their cognitive representations of where and how to procure rewards. This cognitive flexibility is disrupted in psychiatric disorders such as depression, OCD, schizophrenia, and many others. Structurally, these probabilistic outcome associations have been associated mainly with the orbitofrontal cortex, striatum, and amygdala. However, previous work in our lab has shown that the disruption of hippocampal neurogenesis alters reward feedback sensitivity. We therefore hypothesized that the hippocampus, with its projections to cortical regions, amygdala and striatum, may play a critical and understudied role in probabilistic learning. However, the hippocampus is a large and complex structure. Hippocampal function has often been divided into dorsal and ventral aspects; the dorsal hippocampus performing primarily

cognitive functions such as spatial navigation and the ventral encoding emotional valence. Although classically dichotomised, recent research has shown that both the dorsal and ventral hippocampus are involved in many aspects of learning and memory. Our goal with this work is therefore twofold: provide evidence that the hippocampus plays a role in probabilistic learning, and determine which areas of the hippocampus are recruited. In our probabilistic reversal learning task, rats must learn to differentiate between a lever that rewards 80% of the time and one that rewards 20% of the time in an operant chamber. Once the animal has successfully identified and responded on the correct (80%) lever 8 consecutive times, the reward contingencies switch. We have run a successful group of 8 male and 8 female rats through this paradigm and inactivated the dorsal hippocampus using DREADDs. We observed a significant difference in the number of lever reversals between inactivated and control groups, but only in female rats. We are in the process of replicating the dorsal inactivation, as well as inactivating the ventral hippocampus in separate cohorts of rats. Through this work we hope to better understand the physiology of these behaviours, and provide insight into potential therapeutic interventions for various psychiatric disorders.

Title: Modulation of Anxiety and Fear via Distinct Intrahippocampal Projections to Ventral CA1

Authors: *M. KAMBALI[1], M. WANG[1,2], R. NAGARAJAN[1], J. LYU[1,2], H. GRITTON[1], U. RUDOLPH[1];

Abstract: Anxiety and fear are distinct emotional states triggered by different factors. Increased anxiety arises from the anticipation of potential threats, resulting in heightened alertness, while fear is evoked by harmful stimuli, leading to defensive or retreat behaviors. The ventral hippocampus is known to be involved in the modulation of anxiety- and fear-related behaviors. Previously, we showed that inhibiting dentate gyrus and CA3 principal neurons through α2-containing $GABA_A$ receptors (α2-$GABA_A$Rs) is necessary for the reduction of anxiety by diazepam, whereas inhibition of CA1 pyramidal neurons via α2-$GABA_A$Rs is necessary for diazepam-induced suppression of fear responses. In this study, we wanted to test the hypothesis

that while the CA3 to CA1 projection would modulate anxiety-related behavior, the direct projection from EC to CA1 would modulate fear-related behavior. To test this hypothesis, we used optogenetics to modulate ventral intrahippocampal projections bidirectionally. Adult C57BL/6J mice were subjected to bilateral stereotaxic injection of a viral vector expressing channelrhodopsin or halorhodopsion [AAV-CamKIIa-hChR2(H134R)-EYFP or AAV-CamKIIa-eNpHR3.0-EYFP or AAV-CamKIIa-EYFP] into vCA3 or into layers II-III of entorhinal cortex, followed by bilateral implantation of fiberoptic ferrules into vCA1. After three weeks of recovery, mice were assessed for anxiety-like behavior in the open field and the elevated plus maze, followed by the Vogel conflict test, and by contextual and trace fear conditioning for fear assessment. The behavior of the mice was recorded under laser 'ON' and 'OFF' conditions in all experiments. Activation of the vCA3 to vCA1 projection with a blue laser (473 nm, activating channelrhodopsin) decreased anxiety- and increased fear-related behavior, while inhibition of this projection with a yellow laser (593.5 nm, activating halorhodopsin) increased anxiety- and decreased fear-related behavior. Optogenetic activation or inhibition of the EC to vCA1 projection did not affect anxiety-related behavior. In contrast, optogenetic activation of the EC to vCA1 projection increased, and optogenetic inhibition of the EC to vCA1 projection decreased fear-related behavior. These results suggest that vCA3 pyramidal projections to vCA1, but not the EC projections to vCA1, modulate anxiety-like behavior, while both vCA3 to vCA1 projections and entorhinal cortical projections to vCA1 play a role in modulating fear responses. Thus, while fear-related behavior is modulated by both inputs to vCA1, modulation of anxiety-related behavior is input-specific for the vCA3 to vCA1 projection.

Title: Firing rate modulation by sharp wave ripples of dorsal CA1 excitatory neurons is decoupled from environmental novelty in the TgCRND8 mouse model of Alzheimer's disease

Authors: *Y. SUN[1,2], S. CHEKHOV[3], S. MARGARIAN[3], D. ZHAO[3], P. E. FRASER[4,5], K. TAKEHARA-NISHIUCHI[1,2,3];

Abstract: Alzheimer's disease (AD) is a progressive neurological disease associated with the decline in episodic memory. Critical for memory consolidation, sharp wave ripples (SWR) are transient bursts of oscillatory activity (150-250 Hz) in the hippocampus that occur during slow wave sleep and awake rest. Although abnormal SWRs parallel memory deficits in several mouse models of AD, the corresponding deficits of single neuron activity supporting memory and learning remain unknown. We used an array of wire electrodes to record neuronal activity from the dorsal hippocampal CA1 of 3-5 month-old wildtype (WT) and TgCRND8 mice with AD-related amyloidosis and spatial memory deficits. Recordings were performed over two days during rest before (PRE) and after (POST) two types of awake experience: 1) exploration of a familiar environment and 2) exploration of novel objects in a familiar environment. From the recorded signals, the spiking activity of individual neurons was isolated and further classified into putative pyramidal neurons and interneurons based on spike waveforms and temporal patterns. During the PRE sessions, firing rates of putative interneurons within and outside SWR events were significantly lower in TgCRND8 mice than WT mice, while firing rates of putative pyramidal neurons were lower only during SWRs. Both neuron subtypes increased their firing rates during SWRs relative to baseline, however this SWR modulation of firing rates was weakened in TgCRND8 pyramidal neurons. Furthermore, firing rates of WT pyramidal neurons during SWRs were increased in POST compared to PRE sessions after familiar and novel experiences, whereas firing rates outside SWRs were unchanged. As a result, the degree of SWR modulation was strengthened after both experiences. In contrast, pyramidal neurons in TgCRND8 mice showed increased firing rates during SWRs in POST sessions after the familiar but not novel experience. These neurons also increased their firing rates outside SWRs after both experiences. Due to this non-specific firing rate increase, experience-induced strengthening of SWR modulation was absent in TgCRND8 pyramidal neurons. None of these experience-dependent changes in firing rates were detected in putative interneurons in either genotype. Our observations suggest that early-stage amyloidosis differentially affects spiking dynamics of hippocampal pyramidal neurons and interneurons during SWRs, and the lack of proper activity restructuring in response to environmental novelty may be a mechanism underlying associated memory deficits.

Abstract: The hippocampus is an essential hub for episodic memory processing. Despite this, little is known about how neurons in the hippocampus encode and retrieve new episodes. Some argue that each hippocampal neuron codes for an invariant element within an episode. Instead, others have proposed that hippocampal neurons bind together all elements present in a discrete episodic memory. Here, we provide evidence for the latter.
We show that individual neurons, which we term Episode Specific Neurons (ESNs), code discrete episodic memories using either a rate code or a temporal firing code. We find evidence for these neurons exclusively in the hippocampus. Importantly, these ESNs do not reflect the coding of a particular element in the episode (i.e., concept or time). Instead, they code for the conjunction of the different elements that make up the episode.
Next, we will extend these findings to population activity in the local field potential. We report evidence for a reinstatement in high frequency power during successful memory processing that mirrors earlier findings in single neurons. Again, these results cannot be explained by activity induced by a content-code.
Lastly, we embed these findings in the broader literature, identify future experiments, and discuss possible translational applications.

Title: Eeg-tms revealing top-down cortical interactions underlying episodic memory

Authors: *O. DEZACHYO[1,3], C. ZRENNER[4,5], S. HANSLMAYR[6], H. SHARON[2], N. CENSOR[3,1];
[2]Sackler Sch. Of Med. and Sagol Sch. Of Neurosci., [1]Tel Aviv Univ., Tel Aviv, Israel; [3]Sagol Sch. of Neurosci., Tel Aviv, Israel; [4]Univ. Of Toronto, Toronto, ON, Canada; [5]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [6]Inst. of Neurosci. and Psychology, Ctr. For Cognitive Neuroimaging, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Integrating diverse elements into a cohesive memory representation is a hallmark of episodic memory formation and is believed to be guided by top-down executive control. Rhythmic fluctuations in the theta band (4-8 Hz) are thought to reflect such memory control processes, with the phase of prefrontal theta oscillations acting as a gate for recurrent cortical communication. However, the specific mechanisms underlying top-down interactions involved in memory formation remain elusive. We hypothesized that effective connectivity between the dorsomedial prefrontal cortex (DMPFC) and distant cortical regions involved in processing memory-related information is modulated by the frontal theta phase and supports episodic memory encoding. We utilized EEG to assess the propagation of neuronal activity from the DMPFC to downstream regions, resulting from TMS stimulation during an associative memory task. Single-pulses of TMS were delivered at random theta phases, either during task performance or rest periods. This design allowed us to investigate task-dependent and phase-dependent signal propagation dynamics. Importantly, by measuring memory performance, this design also enables the investigation of how signal propagation is associated with successful memory formation. We analyzed TMS-evoked potentials (TEPs) to track the directional propagation of brain activity from the DMPFC. Following TMS, a negative TEP emerged over the stimulated region at 10-50 msec post-TMS. This initial negativity subsequently spread to frontal-central sites at 100-120 msec post-TMS. At 150-190 msec post-TMS, a change in activation pattern occurred, manifested as positive activity at central electrodes. In order to examine the magnitude and spatial distribution of task-induced theta oscillations, EEG was recorded without TMS in a separate group of subjects who performed the same task. Utilizing guided source separation analysis, a distinct medial-prefrontal theta component centred around the Fz frontal electrode was isolated. The observed prefrontal theta oscillations and TEPs demonstrate the dynamic nature of cortical excitability during memory formation. These findings provide a foundation for further investigations into the causal role of top-down neuronal interactions in the process of episodic memory formation.

Title: The Neurobiology of False and True Memory: Examination with EEG Oscillations

Authors: *F. POLAT[1], L. HANOğLU[2], S. AVCı[2];
[1]Psychology, Marmara Univ., Istanbul, Turkey; [2]Neurosci., İstanbul Medipol Univ., İstanbul, Turkey

Abstract: Memory errors, or false memories, are obscure cognitive processes that can result from bias, stereotypes, or expectations that influence our current thinking. These situations, which can be experienced by people of all ages, whether they have a neurological problem or not, cause conflicts in daily life. To make this situation more understandable, scientists have done research and used various paradigms to detect and measure memory errors and examine their conditions. The most well-known and outstanding of these is the DRM paradigm (Deese-Roediger-McDermott). However, various neuroimaging techniques have been used in the literature to learn how memory errors are activated in the brain. In particular, electroencephalography (EEG) is one of the most preferred neuroimaging methods by researchers as it provides a useful environment for the easy application of paradigms. In this study, brain waves will be examined by using EEG while memory errors are created with the DRM paradigm, and it will contribute to the literature by clarifying the neural network and its pattern, which is a marker that distinguishes false memory from true memory. Method: The study will be carried out in the Medipol University, Neuromodulation Laboratory with 30 participants who agreed to participate in the experiment and signed the consent form. Afterwards, a MoCA (Montreal Cognitive Assessment) test will be performed to measure cognitive skills and participants who get enough points will be included in the experiment. After the preparatory procedures for EEG recording, the participants will be taken to the EEG recording room. For the experiment design, 10-15 word lists created with E-prime software and adapted from the DRM paradigm will be projected onto the computer screen and the participants will be asked to try to memorize the words. After the memorization process is over, the previously presented new words, including the lure words, will be reflected on the screen, and the participants will be asked to answer the old or new words by pressing the keys determined on the keyboard, and memory errors will be measured and analyzed. Conclusion : With the analysis of EEG data, neural networks and brain activation patterns of information encoding, retention and correct or incorrect retrieval processes will be established and shed light on the literature on this subject.

Title: Drastic changes in sleep spindle dynamics induced by activation of Cannabinoid-1 receptors

Authors: *I. TOPCHIY, B. KOCSIS;
Harvard Med. Sch., Boston, MA

Abstract: Activation of cannabinoid-1 receptors (CB1-R) was shown to interfere with neuronal oscillations in cortical and hippocampal networks. Sleep spindles are unique among network oscillations, being generated by interplay of thalamic and thalamo-cortical networks. Both in the thalamus and in the cortex, they depend on fast firing parvalbumin interneurons and CB1-Rs were shown to be present at both thalamic and cortical sites. The goal of this study was to investigate sleep spindle dynamics following CB1-R activation in freely behaving rats. The rats were prepared for electrophysiological recordings over the frontal cortex and HPC along with neck muscle activity. Sleep was scored to identify waking and sleep stages, including rapid eye movement sleep (REMs), slow wave sleep (SWS), and intermediate sleep (IS) episodes. This latter is a short episode at the SWS-to-REMs transition when cortical spindles appear on the background of fully established REM sleep-like activity, i.e. theta rhythm in HPC and low-amplitude high-frequency activity in the cortex. Bouts of IS and REM sleep of the entire recording, including pre- and post- saline or CP-55,940 injections, were selected for analysis. Spectral analysis was performed using Fast Fourier Transform and the architecture of each spindle was analyzed using the matching pursuit algorithm. We found that following the injection of the CB1-agonist average length of IS episodes increased from 24.9±1.5 s, starting in the first hour post-injection to reach a maximum of 111.7±20.6 s by the 8th hour, The longest individual IS episodes (>80 s in all rats) were close to or even exceeding (>150 s in three rats) the average length of control REMs (147.1±14). Due to long IS, the rats spent over three times longer in the state of IS than before the injection, even though the frequency of IS episodes remained stable after drug injection. Total spindle-time also increased after CP-55,940 injection, due to progressive increase in the number of spindles generated in each IS episode ($p=0.001$; 7.9±0.7 pre- and 21.3±1.8 post-injection) and an increase in their length ($p=0.023$; 1.8±0.2s and 2.8±0.2s), whereas spindle density remained unchanged ($p=0.076$; 18.43±1.26 to 15.28±0.71). Spindle architecture also drastically changed. Post-injection, the centers of MP-atoms shifted from the normal 8-16 Hz frequency range to lower frequencies distributed in a narrower range below 10 Hz. Spindle activity was shown to play a role in memory consolidation and thus its alteration may be involved in the complex effect of CB1-R on cognition, including cognitive deficits in schizophrenia.

Title: Oscillatory signatures of arithmetic strategies in the left parietal cortex: a transcranial alternating current stimulation study

Authors: *S. FRESNOZA[1,2], P. HÄRTER[1], A. ISCHEBECK[1,2];
[1]Univ. of Graz, Graz, Austria; [2]BioTechMed Graz, Graz, Austria

Abstract: The strategies for solving arithmetic problems are typically inferred from the problem size and operation type. Solutions to simple (e.g., one-digit) and complex problems (e.g., double-digit) are assumed to be retrieved and calculated, respectively. Rote-learned multiplication is also thought to be solely solved by arithmetic fact retrieval, while subtraction is through procedural operations such as online counting. The neural underpinnings of arithmetic operations are embodied in the Triple Code Model (TCM) of number processing; for multiplication, verbal code in the left angular gyrus (AG) is used in the retrieval of arithmetic facts from long-term memory, while for subtraction, the magnitude code in bilateral intraparietal sulcus's horizontal segment (hIPS) is used for manipulating numerical quantities. However, studies using trial-by-trial questionnaires revealed that individuals use different strategies to solve one type of arithmetic operation. Nonetheless, oscillatory activities in the parietal cortex seem to index specific arithmetic strategies: higher left-hemispheric theta (4-7 Hz) event-related synchronization (ERS) is evoked by small problems and fact retrieval, while large problems and procedural strategies evoke alpha (8-12 Hz) event-related desynchronization (ERD). To test the causality of these findings, we applied transcranial alternating current stimulation (tACS) at individual participants' theta and alpha peak frequency to the left AG or hIPS concurrent with multiplication and subtraction tasks performance. The twenty participants answered a trial-by-trial questionnaire to indicate whether they retrieved or calculated the answers. The results showed that theta tACS over the left AG shortened RTs for multiplication and subtraction problems when answers were retrieved from memory. In contrast, left hIPS alpha tACS shortened RTs only for subtraction problems where the answers are calculated. This double-blinded study showed that theta oscillation at the left AG and alpha oscillation at the left IPS could be considered the neural signature of arithmetic fact retrieval and calculation procedure, respectively.

Title: Modulating sleep spindles through auditory stimulation: a physiological perspective

Authors: *H. R. JOURDE[1], E. B. J. COFFEY[2];
[1]Psychology, Concordia Univ., MONTREAL, QC, Canada; [2]Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Sleep spindles and slow oscillations are crucial for memory consolidation and can be enhanced or evoked through closed-loop auditory stimulation (CLAS) of slow oscillation up-states. As slow oscillations and sleep spindles may play different roles in memory consolidation (e.g., Cox et al., 2014, Nishida et al., 2007) and their relative timing may be a key factor in successful memory consolidation (Helfrich et al., 2018), it would be useful to have a means of causally manipulating sleep spindles non-invasively in healthy human subjects. However, CLAS of spindles is technically challenging due to their short duration (less than 3 s) and high frequency (11-16 Hz). Furthermore, previous research has suggested that sleep spindles may act to block sensory information passing through the thalamus, in which case, timing stimulation to coincide with spindles may be ineffective. To address these issues, we have developed a device, called the Portiloop, that detects and stimulates endogenous sleep spindles in real-time (Valenchon et al., 2022). In the present work, we conducted a pair of studies using the Portiloop for CLAS of spindles as well as stimulation that was randomly timed with respect to the phase and evolution of endogenously-generated sleep spindles. We evaluate whether sleep spindles can be manipulated with sound, and if so, how stimulation should be timed. In a first study (N = 40), we used the Portiloop to stimulate sleep spindles in a nap design, and report the physiological differences between stimulated and unstimulated sleep spindles. In a second (overnight) study (N = 20; 5 consecutively-recorded nights totalling 100 nights of EEG), we explored the optimal timing for stimulating spindles in an open-loop design where slow oscillation up-states were detected in real-time and stimulated with a short-duration pink noise (50ms). The results confirm that spindles are susceptible to sound, and explore how the physiological effects can be optimized by considering the spindle phase, and the amplitude envelope over the course of the spindle. Our results motivate the use of CLAS on sleep spindles to study their causal role in memory and learning. This research direction may lead to therapeutic interventions aiming to boost spindle activity, restore slow oscillation - spindle coupling that is degraded in older adulthood (Helfrich et al., 2018), and possibly improve memory outcomes.

Title: Interplay between slow oscillations and spindles as a potential mechanism of odor-mediated memory cueing during sleep

Authors: D. M. BAUM[1,2], *A. SANCHEZ CORZO[3], J. G. KLINZING[5], R. SITARAM[4]; [1]Pontificia Univ. Catolica de Chile, Macul, Chile; [2]Inst. de Ingeniería Biológica y Médica, Macul, Chile; [4]Diagnos. Imaging, [3]St. Jude Children's Res. Hosp., Memphis, TN; [5]Inst. for Med. Psychology and Behavioural Neurobio., Univ. Tübingen, Tuebingen, Germany

Abstract: Memories are actively consolidated during sleep. This process is associated with specific neural activity patterns during Non-Rapid Eye Movement (NREM) sleep, such as Slow Oscillations, Sleep Spindles, and their temporal coordination (phase coupling). Memory consolidation can be enhanced using memory-associated sensory cues. This memory cueing technique is most commonly implemented using sounds but can also be performed with odors. Odor-mediated memory cueing has a variety of advantages but, compared to auditory cueing, its underlying neural mechanisms are yet to be fully described. Using a well-controlled, multi-odor within-subject experimental design, we investigated the neural activity associated with odor cueing of declarative memories during sleep. We recorded high-density electroencephalographic data from 23 participants during two experimental nights. In one night, we performed cueing with an odor that had previously been associated with a declarative memory task. The other night, the odor was associated with a motor task without a declarative learning component. We found that the declarative memory-associated odor triggered widespread increases in spindle rate and frontal spindle duration. Slow oscillation amplitude was increased over central areas. Furthermore, the rate of spindles was increased specifically around the up states of slow oscillations. Our results demonstrate the feasibility of studying memory type-specific brain responses to olfactory cueing. We identify sleep spindles, slow oscillations, and their coupling as the prime candidate mechanism behind memory cueing and thereby memory consolidation in general.

Title: An easy-to-implement system to detect deep sleep and strategic time windows for memory strengthening

Authors: K. VERGARA[1,2], C. VALLE[1,2], A. SANCHEZ CORZO[3], ***D. M. BAUM**[1,2]; [1]Pontificia Univ. Catolica de Chile, Macul, Chile; [2]Inst. de Ingeniería Biológica y Médica, Macul, Chile; [3]Diagnos. Imaging, St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Memories can be modulated by playing memory-associated sounds during sleep, serving as semantic cues that induce strengthening of the memory contents. The efficacy of memory cueing relies on precise timing of the cues. Prior research has shown that optimal targets for auditory memory cueing are Slow Oscillation (SO) up states during Slow Wave Sleep (SWS). While auditory memory cueing has successfully been used in neuroscientific research, real-world applications are missing, partly due to the poor availability of easy-to-use and reliable implementations. Here, we present a closed-loop, cross-platform (PC and mobile) and context-aware system for memory cueing protocols. The system analyzes brain activity in real-time using a single EEG channel, detects SWS, and predicts upcoming SO up states for precise phase-locked cueing. We validated the system in a double-blinded and placebo-controlled experiment. Thirty participants learned the locations of 15 card pairs in a 2D object location task. For each pair, a specific sound was played and thereby associated with the memory of their location. During a subsequent nap, half of the sounds were presented again whenever the algorithm detected optimal time windows (SO up states during SWS). The other half of the card pairs was not cued. To control for unspecific effects of auditory cueing, placebo sounds (not associated with any cards) were presented randomly interleaved with the associated cues. After the nap, subjects showed significantly increased performance in locating cued cards compared to uncued ones. Offline electrophysiological analysis revealed that the system accurately detected SWS compared to sleep scoring performed by sleep experts or published classifiers (overall agreement between 71 ± 7 and 91 ± 3 % and false positive rates between 4 ± 1 % and 11 ± 4, average ± SEM). The system presented sounds during SO up states with a minimal error margin of 45 ± 17 ms (average ± SEM). In summary, we introduce an easy-to-use and portable system with reliable temporal precision for memory cueing protocols. As memory modulation is gaining interest in the therapeutic field, our algorithm may provide an efficient and portable tool for both scientific and clinical contexts.

Title: Occipitotemporal alpha and theta dynamics support memory formation in the developing brain

Authors: *Q. YIN[1], E. JOHNSON[2], K. AUGUSTE[3,4], R. T. KNIGHT[5], E. ASANO[1,6], N. OFEN[1];
[1]Wayne State Univ., Detroit, MI; [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [3]UC San Francisco, San Francisco, CA; [4]UCSF Benioff Children's Hosp., San Francisco, CA; [5]UC Berkeley, Berkeley, CA; [6]Children's Hosp. of Michigan, Detroit, MI

Abstract: The ability to remember past experiences is critical for our daily life. The medial temporal lobe (MTL) is crucial for episodic memory and receives inputs from the occipital cortex to form memories for complex visual stimuli. However, the neurophysiological mechanisms underlying the interaction between these two regions in the developing brain are largely unknown. To understand the oscillatory mechanisms, we analyzed intracranial EEG data from 141 occipital and 71 MTL electrodes in 30 pediatric patients (6.2-20.5 years) who were undergoing direct cortical monitoring for seizure management. Subjects studied pictures of scenes by responding indoor/outdoor during 3-s scene presentation in preparation for a memory recognition test. First, we detected the dominant neural oscillations, i.e., oscillation with the largest peak, for each electrode between 1-15 Hz. Oscillation detection revealed that alpha dominates the occipital cortex (4.50 - 11.87 Hz, 8.43 ± 2.16 Hz), and theta dominates MTL (3.86 - 14.55 Hz, 7.22 ± 2.38 Hz). Critically, the oscillations in the occipital cortex were faster than those in MTL. No age effects were observed in oscillation frequencies for the occipital cortex or MTL. Second, we analyzed phase-amplitude coupling (PAC) between detected oscillations and high-frequency activity (HFA, 70 - 150 Hz), a mechanism posited to support information and mnemonic representation, as a function of subsequent recognition performance, i.e., subsequent hit vs. miss. In the occipital cortex, we observed increased alpha-HFA PAC on subsequent hit compared to miss trials after scene onset and before the indoor/outdoor response. Moreover, the positive PAC effects after scene onset positively correlated with recognition accuracy, and the positive PAC effects before the response increased with age. In MTL, we observed increased theta-HFA PAC on subsequent compared to miss trials before the response, and the positive

PAC effects increased with age. Third, we analyzed oscillation phase synchrony, a mechanism of inter-regional interaction, between the occipital cortex and MTL with the detected occipital alpha and MTL theta oscillations separately. We observed increased alpha and theta phase synchrony on subsequent hit compared to miss trials after scene onset and before the response. Moreover, the positive synchrony effects were higher in theta oscillations than in alpha. These results demonstrate the important role of alpha and theta oscillations in providing the functional infrastructure of memory in the developing brain by facilitating local processing and inter-regional interaction.

Abstract: The medial temporal lobe and prefrontal cortex coordinate their activity in the service of memory. However, the temporal dynamics of activity across these areas is not well understood. Here, we elucidate the relative timing of task-related activity in these regions during both memory encoding and retrieval. To do this, we analyzed intracranial electrophysiological recordings from 24 neurosurgical epilepsy patients (9 females, 15 males; age: 21.1 ± 4.4 years). All patients participated in a visual scene recognition memory task during intracranial

monitoring. Our regions of interest were the dorsolateral prefrontal cortex (dlPFC), anterior cingulate cortex (ACC), parahippocampal and rhinal cortices (PHRC), and the hippocampus (HC). From an initial set of 223 electrodes across these regions, we selected only those with task-related high frequency broadband (HFB) responses - which index neuronal population activity - yielding 109 dlPFC channels, 39 ACC channels, 19 PHRC channels, and 30 HC channels. The peak latencies of HFB responses were submitted to linear mixed effects modeling using region, hit/miss memory performance, and encoding/retrieval task phase as fixed effects. Channel and subject ID were random effects. There was a significant encoding/retrieval by region interaction, which was largely driven by a shift in the timing of PHRC and HC responses. At encoding, PHRC and HC responses were 140ms faster than corresponding dlPFC and ACC responses. At retrieval, HC responses co-occurred with dlPFC and ACC responses, but PHRC responses sped up, leading the other three regions by 160ms. Looked at another way, we considered time between scene onset (t=0) and behavioral response (t=1) on a 0 to 1 scale. At encoding, the PHRC and HC exhibited peak activity at t=.41, compared to t=.50 for dlPFC and ACC. At retrieval, the HC, dlPFC, and ACC exhibited peak activity at t=.47-.49, whereas the PHRC led the other three regions at t=.39. These results suggest that during encoding, the HC functions as an extension of perception, encoding information as it arrives at the end of the visual hierarchy. By contrast, during retrieval, the HC functions as part of a top-down circuit involving the prefrontal cortex.

Michigan, Wayne State Univ., Detroit, MI

Abstract: The medial temporal lobe (MTL) is crucial to episodic memory and is posited to support memory formation in children. However, the neurophysiological mechanisms by which different MTL regions support memory in the developing brain are unknown. We examined theta signatures of memory formation in the hippocampus (HC) as well as parahippocampal and rhinal cortices (PHRC) of individuals aged 5-28 years and related them to HC volumes. We capitalized on a rare opportunity to record intracranial EEG data from 35 neurosurgical patients (14F, 21M; 121 MTL electrodes) while they studied visual scenes, and indicated whether each scene was indoor/outdoor, in preparation for a memory recognition test. We observed positive correlations between HC volume, recognition performance, and age. After separating oscillatory components from aperiodic 1/f activity, we identified distinct slow (~2-4 Hz) and fast theta (~4-8 Hz) oscillations per electrode. We then identified slow and fast theta power and phase resetting signatures of memory formation by comparing subsequently remembered (hit) and forgotten (miss) scenes using linear mixed-effects models. Results showed positive effects (hit > miss) in (1) phase resetting at scene onset across theta frequencies and MTL regions, and (2) power prior to scene onset across theta frequencies and MTL regions. In HC, the latter effect was sustained following scene onset in the slow theta range, and as a function of HC volume in the fast theta range. Results also showed (3) a regional dissociation in power, with negative effects (hit < miss) observed around the indoor/outdoor response in PHRC but not HC. This dissociation is consistent with a growing body of literature in adults and points to a division of labor between adjacent MTL regions in the developing brain. Our results establish slow and fast theta signatures of memory formation within the developing MTL and begin to link MTL neurophysiology and HC structure to the development of episodic memory.

Title: Slow theta cross-frequency mechanisms in human hippocampus and amygdala differentially support working memory

Authors: *S. M. GRAY[1], J. J. LIN[2], I. SAEZ[3], F. GIRGIS[4], O. KIM-MCMANUS[5], S. SATTAR[5], E. F. CHANG[6], K. AUGUSTE[6], A. SHAIKHOUNI[7], R. T. KNIGHT[8], E. JOHNSON[9];

Feinberg Sch. of Med., Chicago, IL

Abstract: Cross-frequency phase-amplitude coupling (PAC) provides a neurophysiological mechanism by which information can be organized and maintained in working memory (WM). Theta-gamma PAC is consistently implicated during human WM maintenance, and PAC in the hippocampus (HC) has been shown to vary with WM load. Less is known about complementary roles of PAC during information encoding and maintenance, and across regions of hippocampal memory networks. Here, we examined stereo-EEG recordings of HC and amygdala (AMY) to delineate the role of PAC in adjacent medial temporal regions. Sixteen neurosurgical patients (6 females, 10 males; M ± SD, age: 29.8 ± 11.6 years) with electrodes sampling HC (n = 43) and/or AMY (n = 41) completed a WM delayed match-to-sample task in which they memorized sequences of three colored shapes (e.g., green triangle, purple square). We first computed event-related power from 1-200 Hz across correct trials, which identified low-frequency activity following presentation of the sample sequence in HC. We then segmented the data into 0.5s baseline, stimulus, and delay epochs and computed comodulograms (1-15 Hz phase, 20-200 Hz amplitude), z-score normalized on permuted data. PAC was identified between fast theta phase and slow gamma amplitude during the presentation and maintenance of the sample and test sequences in both regions (HC: 6.9-10.2 Hz phase, 32.8-53.7 Hz amplitude; AMY: 6.9-12.4 Hz phase, 23.6-45.5 Hz amplitude). In AMY but not HC, PAC between slow theta (2.2-3.9 Hz) phase and fast gamma (45.5-74.6 Hz) amplitude was increased during maintenance of the test compared to sample sequence (cluster-corrected p = 0.034). We last re-segmented the data into 3.25s sample and test epochs and computed oscillatory peaks in the slow and fast theta ranges. In HC but not AMY, slow theta slowed down from study to test (p = 0.014), consistent with longer slow theta cycles organizing additional information represented in gamma activity. These results are consistent with models of HC theta-gamma PAC in WM, highlight differential mechanisms by which HC and AMY may support WM, and raise the intriguing possibility that AMY supports WM for emotionally neutral information.

Abstract: Research in the burgeoning field of network neuroscience yields a picture of how cognitive functions such as working memory (WM) arise from carefully orchestrated interactions among brain regions, particularly the prefrontal and lateral parietal cortices. Our integrative approach combines scalp electroencephalography (EEG) and intracranial EEG (iEEG) to investigate this complex interplay. In the first stage of our research, we used scalp EEG to capture brain activity from 35 healthy adults (18-43 years; 15 males, 20 females) engaged in a sequential WM delayed match-to-sample task. To isolate signatures of cognitive control (CC) with high temporal precision, we compared the sample and test (delayed match) sequences from correct trials using cluster-based permutation tests, keeping other variables including timing and visual demands the same. This analysis yielded two key results. First, CC-related fronto-posterior theta/alpha (4-15 Hz) event-related spectral power correlated with functional brain networks focused in the same channels. Second, CC-related fronto-posterior delta/theta (2-10 Hz) functional connectivity predicted behavioral outcomes, as indexed by both accuracy and response time. Building on these EEG findings, in the second stage we employ iEEG data from 20 epilepsy patients (15-54 years; 15 males, 5 females) with electrodes sampling one or both of prefrontal/anterior cingulate (n = 279) and parietal/posterior cingulate (n = 61) cortices. Our hypothesis, rooted in the observed EEG-based neural activity, postulates that the medial prefrontal and lateral parietal cortices are the sources of observed scalp effects, and their interplay supports successful WM performance. Our iEEG analyses address the inherent limitation of scalp EEG - its low spatial resolution. By examining electrodes in both medial and lateral prefrontal and parietal regions, this research enriches our understanding of the complex brain networks underpinning WM and contributes to the evolving landscape of network neuroscience.

Abstract: The human brain undergoes structural and functional changes during development that parallel changes in cognition. To date, developmental research has primarily used scalp electroencephalography (EEG), which offers low spatial resolution. Further, these studies have traditionally ignored aperiodic ($1/f$) activity, an index of excitation/inhibition (E/I) balance, which is associated with healthy aging compared to age-related cognitive decline and may be a critical marker of brain development. Here, we analyzed intracranial EEG (iEEG) data recorded directly from the brains of neurosurgical epilepsy patients. Using task-based (i.e., attention to-be-remembered visual stimuli) and task-free (resting-state) data from 73 children and adults (5.93 - 30 years, 29 females; *n* channels = 3371), we mapped functional brain development in high definition by quantifying the $1/f$ slope across the cortex. Mixed-effects regressions revealed a

significant non-linear relationship with age across the whole cortex during rest versus visual attention (β; = .58, se = .10, p <.001). From ages 5 - 15 years, for both rest and visual attention, the $1/f$ slope flattened linearly. By contrast, it continued to flatten linearly from ages 15 - 30 years during visual attention, while steepening during rest. We also found that key brain regions involved in visual attention and memory showed differential relationships between the $1/f$ slope, age, and attentional state. The $1/f$ slope flattened during visual attention in extrastriate cortex (rho = .54, p < .001) and angular gyrus (rho = .51, p < .001), but showed no association with age during rest. By contrast, the parahippocampal gyrus demonstrated a linear steepening of the $1/f$ slope from ages 5 - 30 during visual attention (rho = -.27, p = .003), while the inverse was observed during rest (rho = .33, p = .008). These findings indicate that E/I balance varies non-linearly across development and differs by attentional state across cortical region. Next, we will model oscillations from 1 - 30 Hz. To comprehensively characterize functional brain development, we will further relate regional $1/f$ slope and oscillations to grey matter volumes and memory outcomes.

Title: Dissociable Fronto-Central Midline and Posterior Signatures of Mismatch Detection in Working Memory

Authors: ***J. B. YARBROUGH**[1], L. SHI[1], K. CHATTOPADHYAY[2], V. KOMMU[2], R. T. KNIGHT[3], E. JOHNSON[4];
[1]Northwestern Univ., Chicago, IL; [2]Univ. of California, Berkeley, Berkeley, CA; [3]UC Berkeley, el cerrito, CA; [4]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Working memory (WM) is a form of higher order cognitive control in which one must rapidly store and retrieve incoming information. Although literature supports the role of frontal midline theta activity (θ; 3-8 Hz) in organizing signals of novelty and error in a top-down manner, it is unclear whether this applies to WM. Additionally, event-related potentials (ERPs) such as the N200 (associated with frontal midline) and P300 (associated with posterior

topography) are key indicators of error detection and visual perception, respectively. Here we investigate mismatch detection in WM to understand the neural substrate of mismatch detection in real-world scenarios. We recorded EEG from 35 healthy adults (20 females, 15 males; M ± SD, age: 25.3 ± 7 years) performing a delayed match-to-sample WM task. Participants were given a sample sequence of three shapes followed by one of four test sequences, and asked whether the test sequence was a match or a mismatch to the sample sequence. Participants performed well overall (M ± SD, accuracy [hit - false alarm rate]: 0.85 ± 0.13). To isolate signatures of mismatch detection, data from correct trials were aligned to the onset of the mismatched shape and compared to match trials using cluster-based permutation tests. We hypothesized that frontal midline θ and N200 ERPs would act as mechanisms for mismatch detection. We observed fronto-central midline (FCM) θ activity during mismatch detection, consistent with previous literature. Surprisingly, the N200 was not present. Instead, we observed FCM late positive potential ERPs, as well as sustained negative ERPs in right frontal and left posterior channels. ERPs did not correlate with θ or behavioral performance. Furthermore, we found that increased posterior alpha-beta phase resetting on match trials predicted behavioral performance. These findings reveal that mismatch detection in WM involves dissociable FCM and posterior mechanisms and suggest a novel late positive potential signature for error detection and higher order cognitive control.

Title: Identification of pathway-specific local field potentials in the entorhinal cortical-hippocampal networks

Authors: *H. OSANAI, N. YAMAMOTO, I. R. NAIR, J. YAMAMOTO, S. K. OGAWA, T. KITAMURA;
UT Southwestern Med. Ctr., Dallas, TX

Abstract: Input of neural oscillatory activities from other brain areas have been proposed to play a crucial role in the brain area-area communication, but there is a technical limitation to investigate its neural mechanism in a cell-type specific manner. Lesion experiments have traditionally been conducted, but they cannot elucidate the original dynamics of lesioned neural pathways. Recently, independent component analysis (ICA), a blind-source separation technique, has started to be used as a mathematical tool to disentangle local field potential (LFP) signals to specific input-pathway's activities. The conventional technique separates independent components (ICs) from original LFP by ICA, and speculates that the separated ICs are of the specific input-pathway using the anatomical location information of ICs (Fernández-Ruiz et al., J Neurosci. 2012, Schomburg et al., Neuron 2014; Fernández- Ruiz, et al., Neuron 2017). However, this method may not easily be applicable when multiple inputs are on the overlapping layers since spatial distributions of ICs will be similar in this case. Also, selecting an IC based on spatial distribution may have limited interpretation of the data since a single cell-type pathway may generate multiple ICs. To overcome these limitations, instead of using the anatomical locations information in the conventional method, we propose a new method to investigate input-pathway specific activities by optogenetically 'tagging' the pathway associated ICs. In the current study, a 32-ch silicon probe and an optical fiber were implanted into hippocampal CA1 of the mice expressing ChR2 in MECII pyramidal neurons or MECIII neurons to record spontaneous and opto-responded LFP. After ICs are separated from the LFP using ICA, they are categorized as "tagged" when the IC's opto-response exceed z-score threshold. Then, pathway associated LFPs are reconstruct from all "tagged" ICs. We also demonstrate simultaneous identification of two pathways in single mice, LEC and MEC to DG. Compared with the conventional method, our method has advantages of cell-type specific and less-biased analysis.

Title: Hippocampal neural representation of food intake episode

Authors: *Y. OMURA[1], J. YAMAMOTO[2], T. KITAMURA[1];
[1]Psychiatry | Neurosci., [2]Psychiatry, The Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: The temporal organization of neural activity is a fundamental representation underlying hippocampal cognitive processes of episodic memory. Cumulative evidence suggests that the hippocampus, which has long been considered as a neural substrate critical for navigation and episodic memory, has certain role in regulating food intake behaviors by encoding and retrieving food intake events (M.B. Parent et al., 2014). Recent studies have identified a dedicated hippocampal reward cell population which encodes arbitrary spatial locations of consummatory reward (J.L. Gauthier & D.W. Tank, 2018). However, how the hippocampus operates the encoding and retrieving of reward information to guide navigation remains elusive. Furthermore, although awake sharp wave ripples (SWRs) have been linked to learning, recent finding revealed that awake replay content was decoupled from subsequent choice in spatial memory task, indicating a role in memory storage rather than in guiding subsequent behavior (A.K. Gillespie et al., 2021). To elucidate a hippocampal role in linking food intake episode and subsequent navigation, we recorded neural activity from hippocampal dorsal CA1 of mice while performing a delayed non-matched to place (DNMP) task. Here, we identified three distinct subsets of reward cells, 1) ramping down cells, 2) midst cells, and 3) ramping up cells, which coordinately represented temporal dynamics of sequential nature of feeding behaviors, each of phasic activity encoded, 1) approaching food, 2) food consumption, and 3) meal termination. These reward subpopulations were modulated by 6-Hz theta oscillations during food consumption, emitting robust synchronous spiking outside SWR time window. Strikingly, we found that co-firing of the ramping down and up cells was significantly stronger during food consumption followed by correct choice trials than that followed by either error choice or sample trials. Contrarily, we did not observe the enhanced activation within SWRs followed by correct choice trials, indicating novel neural subsets which encode reward information to guide subsequent navigation.

Title: Loss of Neuron-Specific Gene 2 (NSG2) alters long-term potentiation, learning and memory

Authors: *A. D. SERRANO RODRIGUEZ[1], A. ZIMMERMAN[2], S. WILSON[1], D. LINSENBARDT[1], J. BRIGMAN[1], J. WEICK[1];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: NSG2 is one of the three-member family of Neuron-specific genes (NSG1-3), which have been shown to regulate endolysosomal trafficking of a number of proteins critical for neuronal development and synaptic function. NSG2 is the least well-characterized of the family, but previous work in our laboratory has demonstrated binding to multiple AMPAR subunits and alterations in synaptic transmission following knockout and overexpression. Based on these studies, and the largely universal expression throughout mammalian brain, we predicted that genetic knockout of NSG2 would result in significant impairments across multiple behavioral modalities including motor, affective, and learning/memory paradigms. However, we were surprised to find that loss of NSG2 had highly selective effects on learning and memory modalities, leaving motor and affective behaviors intact. For instance, NSG2 knockout (KO) altered recall in the Morris water maze, without affecting acquisition rate during training. Similarly, NSG2 KO altered touchscreen reversal learning, but did not affect the initial acquisition phase of the association paradigm. In contrast, both acquisition and recall were significantly altered in a trace fear conditioning paradigm. Most surprising was the fact that in all cases where learning and memory were affected, loss of NSG2 caused *enhanced* recall and/or *accelerated* acquisition rather than impairments as predicted. These results paralleled alterations in Long-term potentiation (LTP) in acute brain slice preparations from hippocampus. Together, these data point to a specific involvement of NSG2 on certain types of associative learning, with endogenous NSG2 levels limiting the ability of particular circuits to create sensory-motor associations via changes in traditional models of synaptic plasticity.

Title: Long noncoding RNAs modulate spatial learning and motor activity

Authors: *S. J. JUNG[1], M. W. LUQMAN[1], L. M. ITTNER[1], F. DELERUE[1], J. MATTICK[2];
[1]Dementia Res. Ctr., Macquarie Univ., Macquarie Park, Australia; [2]Univ. of New South Wales, Sydney, Australia

Abstract: Long noncoding RNAs (lncRNAs) are being shown to play major roles in developmental and cell biology (https://doi.org/10.1038/s41580-022-00566-8). The greatest

diversity of lncRNAs is found in the brain, with most exhibiting region- and cell-specific expression patterns, and association with subnuclear or cytoplasmic domains (https://doi.org/10.1073/pnas.0706729105). Their potential roles in governing brain functions are only starting to emerge. Here, we have examined the role of selected lncRNAs with brain area-specific expression patterns on cognitive, behavioral and motor tasks in multiple mouse lines using CRISPR-Cas9 genome editing. All lines were subjected to a battery of functional tests to assess memory and motor performance, including Morris water maze, novel object recognition, rotarod, beam, pole and grip strength test. We found that loss of different lncRNAs resulted in differential cognitive, learning and motor deficits. Our results demonstrate that lncRNAs contribute to executive brain functions like spatial learning and motor coordination in distinct and specific ways, providing new insights into the regulation of brain function.

Title: Social experiences switch states of memory engrams through regulating hippocampal Rac1 activity

Authors: B. LEI[1,2], L. LV[1,2], ***S. HU**[1,2], Y. TANG[1,2], Y. ZHONG[1,2];
[1]Sch. of Life Sci., [2]McGovern Inst. of Brain Res., Tsinghua Univ., Beijing, China

Abstract: In pathological or artificial conditions, memory can be formed as silenced engrams that are unavailable for retrieval by presenting conditioned stimuli but can be artificially switched into the latent state so that natural recall is allowed. However, it remains unclear whether such different states of engrams bear any physiological significance and can be switched through physiological mechanisms. Here, we show that an acute social reward experience switches the silent memory engram into the latent state. Conversely, an acute social stress causes transient forgetting via turning a latent memory engram into a silent state. Such emotion-driven bidirectional switching between latent and silent states of engrams is mediated through regulation of Rac1 activity-dependent reversible forgetting in the hippocampus, as stress-activated Rac1 suppresses retrieval, while reward recovers silenced memory under amnesia by inhibiting Rac1. Thus, data presented reveal hippocampal Rac1 activity as the basis for emotion-

mediated switching between latent and silent engrams to achieve emotion-driven behavioral flexibility.

Title: Crest can bidirectionally regulate memory processes of the adult hippocampus via its CBP binding domain

Authors: *F. G. GARCIA, M. F. DE ALBUQUERQUE, V. G. JOHNSON, E. A. KRAMÁR, D. P. MATHEOS, M. A. WOOD;
UC Irvine, Irvine, CA

Abstract: The epigenome provides a powerful signal-integration system for transforming learning-induced gene expression into molecular changes for consolidating new information into long-term memories. The discovery of Calcium-RESponsive Transactivator (CREST) has provided a key candidate for a transcriptional regulator with the capacity to recruit multiple epigenetic machinery for histone modification (via CBP; a histone acetyltransferase) and nucleosome remodeling (via BRG1-containing BAF complex). In this study we examined whether CREST, and its function as a keystone (bridging histone acetylation and nucleosome remodeling) transcriptional regulator, is essential for long-term memory formation and synaptic plasticity in the adult hippocampus. When we used an anti-Crest vivo morpholino oligomer for focal knockdown of CREST expression in the adult C57BL/6J hippocampus, both males and females showed impaired long-term memory for the object location memory task. Antisense-mediated Crest knockdown also revealed decreased potentiation in theta-burst induced LTP. Notably, Crest protein and mRNA expression do not change during memory consolidation, but motif analysis of CREST peptide sequence for posttranslational modifications revealed a candidate tyrosine 397 (Y397) residue within the CBP binding domain. The JetPEI-mediated in vivo transfection of a Crest phosphomimetic (Y397D) into the adult hippocampus was sufficient to enhance both memory formation under subthreshold training conditions and synaptic plasticity compared to vehicle controls. Alternatively, when we expressed a CREST phosphonull (Y397F) in the adult hippocampus, animals showed both impaired long-term memory formation with threshold training and synaptic plasticity. When Cbp-floxed mice with empty vector or Cre recombinase AAV infusion received intrahippocampal JetPEI-mediate expression of Crest Y397D and subjected to subthreshold training in the object location memory task, animals with

Cbp deletion and Crest Y397D infusion did not show evidence of long-term memory formation. Together, this study highlights a critical role for CREST in regulating hippocampal-dependent memory processes via post-translational modification and CBP-dependent signaling during memory consolidation.

Title: Palmitoylated membrane protein 2 (MPP2) as a target for improving memory

Authors: *S. J. COHEN[1], R. W. STACKMAN, JR[2];
[2]Dept. of Psychology, [1]Florida Atlantic Univ., Jupiter, FL

Abstract: Episodic memory, the memory for personal events, is dependent upon a network of associated medial temporal lobe brain structures, including the hippocampus. Disturbances in hippocampal activity are associated with the memory impairments of Alzheimer's disease (AD). Progressive cognitive decline is a hallmark of AD, yet current treatment approaches are quite limited in efficacy to improve cognitive function. Discovering novel targets is essential in developing effective treatments for those suffering from learning and memory impairments. Thus, it is of broad interest to the field to better understand the neurophysiological and neuropathological changes that bring about age-related and AD-associated cognitive decline. Previous work has shown that the pharmacological blockade or genetic deletion of synaptic type 2 small conductance Ca2+-activated K+ (SK2) channels enhances hippocampal LTP and memory, while pharmacological activation or genetic overexpression of SK2 impairs LTP and memory. SK channels limit neurobiological mechanisms of long-term memory by shaping glutamatergic excitatory postsynaptic potentials and NMDA receptor-dependent synaptic plasticity within hippocampal and neocortical circuits that are critical for memory. SK channel activity also limits NMDA receptor mediated excitotoxicity. Membrane palmitoylated protein (MPP2) is a synaptic MAGUK scaffold protein that anchors SK2 channels in the postsynaptic density of hippocampal and cortical neurons. Our preliminary data indicate that knockdown of MPP2, via CRISPR/Cas9 gene editing, enhances glutamatergic excitatory postsynaptic potentials in the hippocampus, and improves spatial and non-spatial memory in adult male and female mice.

Title: Regulation of dopamine function by the gastrin-releasing peptide in stress-enhanced fear

Authors: *S. GONZALEZ[1], Y. MORISHITA[1], I. FUENTES[1], J. FAVATE[1], J. MEJAES[1], S. BUYSKE[1], S. SILLIVAN[2], C. A. MILLER[3], E. R. KANDEL[4], S. UCHIDA[5], D. BARKER[1], P. SHAH[1], G. P. SHUMYATSKY[1];

Abstract: The role of dopamine in fear learning and extinction is poorly understood compared to its role in reward-related behavior. A core symptom observed in post-traumatic stress disorder and phobias are deficits in fear extinction. Thus, identification of molecules that regulate dopamine function in stress-related memories would help our understanding of the mechanisms behind post-traumatic stress disorder and phobias. Our lab found evidence that the gastrin-releasing peptide (Grp) regulates dopamine signaling during Stress-Enhanced Fear Learning (SEFL). A prior history of stress can enhance subsequent learning of conditioned fear, making it more resistant to extinction. SEFL is a behavioral assay used in mice to assess the effect of an acute stressor over fear acquisition and extinction. We generated the *Grp* gene knockout (*Grp*-/-) mice and found that they exhibit delayed fear extinction and enhanced long-term memory recall after SEFL. When examining candidate genes in the basolateral nucleus of the amygdala (BLA) following long-term memory recall of SEFL, we found that transcription of dopamine-related genes was decreased in *Grp*-/- mice. Using fiber photometry approach to record dopamine signals, we also found enhanced signal of the dLight sensor in the BLA of *Grp*-/- mice during training and extinction. Altogether, our data suggest that the Grp may regulate dopamine function during stress-enhanced fear learning and extinction.

Title: Learning induces distinct modes of synaptic plasticity to balance memory discrimination and generalization

Authors: ***M. MENG**[1], J. DOUPE[1], D. FEITOSA TOMÉ[2], X. SUN[3], S. SADEH[2], C. CLOPATH[2], Y. LIN[1];
[1]Upstate Med. Univ., SYRACUSE, NY; [2]Imperial Col. London, London, United Kingdom; [3]Stanford Univ., Stanford, CA

Abstract: Memory engrams from past experiences are utilized to guide future behaviors, such as to discriminate or generalize contextual fear memory. Our recent study found that one way for the brain to achieve the balance between memory discrimination and generalization is to engage two distinct active neuronal ensembles within the contextual fear memory engram in the dentate gyrus (DG). These two active neuronal ensembles are each defined by the activation of the immediate-early gene *Fos* or *Npas4*, and they differentially drive the memory discrimination-generalization balance. We also found that they undergo distinct synaptic modifications following contextual learning. Synaptic modifications are believed to be the biological basis of memory. However, it is not known whether the distinct synaptic modifications associated with these two neuronal ensembles modulate memory expression differently. Here we show that *Fos* and *Npas4* directly regulate synaptic modifications beyond serving as markers of neuronal activity. *Fos* expression induced in a random population of neurons enhances excitatory drive onto those neurons, while *Npas4* expression recruits inhibitory inputs selectively from local cholecystokinin-expressing GABAergic interneurons onto *Npas4*-expressing neurons. These distinct synaptic reorganizations triggered by *Fos* and *Npas4* expression are consistent with synaptic modifications on *Fos*- and *Npas4*-dependent ensemble neurons after learning. In addition, we found that *Fos* knockout enhanced memory discrimination, whereas memory discrimination is impaired in the absence of *Npas4*. Finally, consistent with our experimental data, we developed a spiking network model that predicted that blocking *Fos*-mediated excitatory synaptic modifications or *Npas4*-mediated inhibitory synaptic modifications tips the balance of memory discrimination-generalization differently. These findings have not only

revealed critical roles of *Fos* and *Npas4* in mediating learning-induced synaptic plasticity, but also indicate that these synaptic modifications are responsible for the control of the memory discrimination-generalization balance.

Title: Pharmacologic activation of mTOR increases nucleolar activity and enhances memory

Authors: G. P. BAENA-CALDAS[1], M. REGIER[1], V. SEBASTIAN[1], J. KIM[3], C. ZHU[3], L. KOP[1], *J. LIBIEN[2], I. OJIMA[3], A. I. HERNANDEZ[1];
[1]Pathology, [2]SUNY - Downstate Hlth. Sci. Univ., Brooklyn, NY; [3]Chem., SUNY - Stony Brook, Stony Brook, NY

Abstract: The Mammalian Target of Rapamycin (mTOR) is composed of 2 different complexes (mTORC1 and 2) with distinct roles in mammalian cells. mTOR integrates diverse environmental signals in cells to respond to growth (mTORC1) or survival and proliferation (mTORC2). The role of TORC1 in synaptic plasticity dependent translation and RNA Pol II dependent transcription has been intensively studied. In contrast, the role of TORC1 activation of RNA Pol-I (Pol-I) dependent transcription and subsequent biogenesis of ribosomes in synaptic plasticity and learning and memory remains unexplored. Recently, we found that memory consolidation requires Pol-I dependent transcription, and therefore newly synthesized ribosomes. Since mTORC1 regulates growth including the biogenesis of ribosomes we asked: 1) can ectopic activation of mTORC1 have an effect in learning and memory beyond normal? and 2) Do mTORC1 changes in learning and memory require the biogenesis of ribosomes? In light of this, we seek to investigate the effect of mTORC1 activation by 3-benzyl-5-((2-nitrophenoxy) methyl)-dihydrofuran-2(3H)-one (3BDO) on learning and memory. Here, we show that a single dose of 3BDO shortly before a weak training accelerates learning and enhances 24 h long-term memory. These observations correlate with nucleolar activation.

Title: Neural epigenetic mechanisms of early life adversity and exercise intervention: a potential role for KDM7a.

Authors: N. E. NELSON[1], **S. VERMA**[2], A. MALIK[2], A. O. AGYEMANG[3], *A. S. IVY[4,5]; [1]Physiol. & Biophysics, Univ. of California, Irvine, Irvine, CA; [2]Biol. Sci., Univ. of California Irvine, Irvine, CA; [3]Pediatrics, Univ. of California- Irvine, Irvine, CA; [4]Univ. California-Irvine, Irvine, CA; [5]Neurol., Children's Hosp. Orange County, Orange, CA

Abstract: Background: Early-life adversity (ELA) can lead to long-term cognitive impairments, yet effective treatments to buffer against these consequences do not exist. Physical activity during adolescence can promote long term memory and enhance synaptic plasticity; thus, our experiments introduce adolescent exercise as a possible intervention after ELA. Our previously published data demonstrate that voluntary wheel running (Early Ex) during the 4th-6th postnatal weeks in mice results in lasting improvements in hippocampal memory and synaptic plasticity. Furthermore, we identified unique molecular signatures of Early Ex using TRAP-Seq analysis of translating mRNA expression. This included significant increases in hippocampal neuronal expression of multiple histone modifying enzymes, including the lysine demethylase KDM7A. *We hypothesize that Early Ex promotes a transcriptionally permissive epigenetic state via the activity of KDM7A, which may underlie the beneficial effects of Early Ex to mitigate cognitive impairments after ELA.* **Approach:** Emx1-cre female mice were crossed with NuTRAP reporter males (Raus et al., 2023) to generate experimental animals. Male and female Emx1-NuTRAP mice underwent ELA during postnatal days (P) 2-9 which consisted of limiting bedding and nesting material in the cage. On P21, a subset of juvenile mice were pair-housed in running wheel-equipped cages and running distances were monitored until P41. After removal from running cages on P42, mice underwent a battery of hippocampus dependent and independent behavior tasks in adulthood. Mice were sacrificed at P21, P42, or adulthood, and bilateral dorsal hippocampi were collected for molecular studies including mass spectrometry, RT-qPCR and western blot analysis to identify epigenetic signatures associated with ELA and Early Ex. **Results:** Object location memory was impaired in ELA mice, and partially rescued by Early Ex intervention. Mass-spec revealed opposing histone modification signatures of ELA and Early Ex. Specifically, the methylation status at H3K27 was uniquely altered depending on the early life experience (adversity vs. exercise). H3K27me2 state was found in a higher abundance in ELA, whereas in Early Ex the H3K27me1 and me3 state were found in a higher abundance. This specific histone residue is demethylated by KDM7a, which is increased after Early Ex, and may be responsible for this experience-induced epigenetic signature. **Conclusion:** These data implicate an epigenetic mechanism by which early exercise modulates hippocampal long term memory functions in adulthood, potentially through KDM7A activity on H3K27.

Title: Motor learning induced transcriptomic changes in motor engram neurons

Authors: *Y. SUN, R. H. ROTH, F.-J. HWANG, X. REN, S. WANG, J. B. DING;
Stanford Univ., Stanford, CA

Abstract: Motor learning induces profound dynamic reorganization of structure and activity in primary motor cortical (M1) neurons and striatal spiny projection neurons (SPNs). However, the molecular profile of motor engram cells and the underlying transcriptome regulation mechanism induced by motor learning remain unclear. Here, we combined activity-dependent genetic labeling tools (TRAP mice) and single cell RNA sequencing (scRNA-seq) to identify cell types and gene expression regulation mechanisms involved in motor learning and memory formation. TRAP mice were trained in a forelimb reaching task, and specifically activated cells in early and late training stages were TRAPed. Through scRNA-seq analysis, we identified TRAPed engram neurons in various neuronal populations, including glutamatergic corticostriatal projection neurons, and various types of GABAerigic interneurons. By quantifying the percentage of TRAP cells in each cell type, we investigated preferential activation during different stages of motor learning. Notably, we observed significant changes in the activation of a specific M1 interneuron type expressing 5-Hydroxytryptamine receptor 3a (Htr3a-Int). Using 2-photon Ca^{2+} imaging, we observed a selective Htr3a-Int activity coupled with reaching behavior. Furthermore, we detected significant differential expression of genes associated with synaptic functions and movement disorders during early and late learning stages in M1 and SPNs. Our scTRAP-seq findings, coupled with subsequent validations, identified novel cell types in corticostriatal circuits involved in motor learning, and provided mechanistic insights into coordinated pre- and postsynaptic gene expressions regulating synaptic plasticity induced by motor learning.

Title: Enhancement of cognitive function through HDAC inhibitor at dose increasing gene expression

Authors: K. MIYAMOTO, K. UNEMURA, K. HYAKKOKU, T. IZUMI, T. HATTA, N. SUZUKI, M. ITO, K.-I. KUSAKABE, *K. OGAWA, N. HORIGUCHI;

Abstract: Histone acetylation, particularly of histone H4K12, plays a crucial role in positively regulating gene expression, which is vital for various physiological functions, including learning and memory. Non-clinical studies using histone deacetylase (HDAC) inhibitors, the enzyme that causes histone deacetylation, have shown enhanced cognitive function, and increased spine number and density. However, the details of mechanisms and optimal dosage to show maximal efficacy remain unclear. In this study, we investigated gene alterations and their effects on cognitive function following HDAC inhibition using CI-994, a class I selective HDAC inhibitor. Oral administration of CI-994 in mice led to a dose-dependent increase in H4K12 acetylation and HDAC inhibition rate in the hippocampus. We then quantified gene alterations in the hippocampus after CI-994 administration at several dose. We demonstrated a transient increase of *cnih3* gene, which encodes for the auxiliary subunit protein of AMPA receptors, peaked at 7 hours after administration. AMPA receptors are known to play a significant role in the maintenance of long-term potentiation (LTP) induced following a learning stimulus. We hypothesized that aligning the peak of *cnih3* increase with the few hours from learning stimulus would efficiently induce cognitive function. When mice were given CI-994 four hours before a foot shock learning stimulus to align the peak of *cnih3* expression with three hours after stimulus, the freezing ratio in the recall test 24 hours after the foot shock increased in a dose-dependent manner. In contrast, administration of CI-994 four hours after the foot shock did not change the freezing ratio in the recall test. These results suggest that the increase and timing of *cnih3* expression could be important for enhancing learning and memory associated with HDAC inhibition. This study indicates the potential to define the optimal dosage of HDAC inhibitors by focusing on changes in gene expression as part of downstream mechanisms.

Abstract: The search for the memory engram has been a defining endeavor for the field of neuroscience. In the mammalian brain, the field has identified synaptic plasticity as a core mechanism for memory, and the coordinated activity of ensembles of neurons within relevant brain structures as the functional neuronal correlate for a memory trace (i.e., memory-associated neuronal ensembles). While the mechanistic basis of the engram is well-defined (i.e., synaptic plasticity), its mechanistic organization - the arrangement of molecular mechanisms supporting the memory trace within an neuronal ensemble - remains elusive. We wish to tackle this unknown by exploring the gene expression topography of hippocampal memory traces. Our goal is to identify and map networks of gene expression within memory-associated neuronal ensembles across the hippocampal network. The specific objective of this project is to explore whether gene expression profiles identified within memory-associated, immediate-early gene tagged neuronal ensembles exhibit different patterns of expression across the distinct sub-regions of the hippocampal network. We collected hippocampal tissue from mice trained in an active place avoidance memory task for RNA sequencing analyses. Samples were processed through: microdissected bulk RNA-seq and single nuclei RNA-seq to test for specific differences between hippocampal cells and regions; or spatial transcriptomics to assess the spatial distribution of gene expression profiles across the hippocampus. With these data we resolve the spatial organization of memory-associated gene expression profiles in the hippocampal network and provide a hitherto unknown gene expression map of memory, closing the gap between the molecular and network scales of memory.

Title: Voluntary wheel running in old mice reduces age-related inflammation in the colon

Authors: M.-L. EDERER[1], M. GÜNTHER[3], L. BEST[4], J. LINDNER[2], C. KALETA[4], O. W. WITTE[3], R. SIMON[1], ***C. FRAHM**[1];

Abstract: Inflammation is considered a possible cause of cognitive decline during aging. This study investigates the influence of physical activity and social isolation in old mice on their cognitive functions and inflammation. The Barnes maze task was performed to assess spatial learning and memory in 3, 9, 15, 24, and 28 months old male C57BL/6 mice as well as following voluntary wheel running (VWR) and social isolation (SI) in 20 months old mice. Inflammatory gene expression was analyzed in hippocampal and colonic samples by qPCR. Cognitive decline occurs in mice between 15 and 24 months of age. VWR improved cognitive functions while SI had negative effects. Expression of inflammatory markers changed during aging in the hippocampus (Il1a/Il6/S100b/Iba1/Adgre1/Cd68/Itgam) and colon (Tnf/Il6/Il1ra/P2rx7). VWR attenuates inflammaging specifically in the colon (Ifng/Il10/Ccl2/S100b/Iba1), while SI regulates

intestinal Il1b and Gfap. Inflammatory markers in the hippocampus were not altered following VWR and SI. The main finding of our study is that both the hippocampus and colon exhibit an increase in inflammatory markers during aging, and that voluntary wheel running in old age exclusively attenuates intestinal inflammation. Based on the existence of the gut-brain axis, our results extend therapeutic approaches preserving cognitive functions in the elderly to the colon.

Title: Long term memory consolidation in the hippocampus require the histone lysine demethylase KDM5B

Authors: L. PEREZ-SISQUES[1], S. BHATT[1], R. MATULEVICIUTE[1], T. GILEADI[1], E. A. KRAMÁR[3], A. GRAHAM[1], F. GARCIA[5], A. A. KEISER[4], D. P. MATHEOS[6], J. A. CAIN[1], A. PITTMAN[7], C. FERNANDES[2], M. A. WOOD[8], K. GIESE[1], ***M. BASSON**[9];

Calif, Irvine, IRVINE, CA; [9]Clin. and Biomed. Sci., Univ. of Exeter, Exeter, United Kingdom

Abstract: The histone lysine demethylase KDM5B has been implicated in recessive intellectual disability disorders and heterozygous, protein truncating variants in KDM5B are associated with reduced cognitive function in the normal adult population. The KDM5 family of lysine demethylases have developmental as well as homeostatic functions in the nervous system, some of which appear to be independent of lysine demethylase activity. In an attempt to distinguish between developmental and demethylase-dependent functions of KDM5B in hippocampus-dependent learning and memory, we studied mice homozygous for a *Kdm5b* allele (*Kdm5b*$^{\Delta ARID}$) that lacks demethylase activity and knocked down *Kdm5b* specifically in the adult, wildtype mouse hippocampus with shRNA. Demethylase-deficient *Kdm5b*$^{\Delta ARID/\Delta ARID}$ mice exhibited hyperactivity, mild anxiety, and long-term memory deficits in hippocampus-dependent learning tasks. The expression of immediate early, activity-dependent genes was downregulated in mice in the home cage (baseline) and hyperactivated upon a learning stimulus compared to wildtype mice. The expression of other learning-associated genes was also significantly altered in the

Kdm5b$^{\Delta ARID/\Delta ARID}$ hippocampus. *Kdm5b* knockdown in the dorsal hippocampus of adult, wildtype mice resulted in the induction of spontaneous seizures, hyperactivity and hippocampus-dependent long-term memory and LTP deficits. We conclude that KDM5B has a critical, direct function in regulating memory consolidation in the adult hippocampus. Together, these findings suggest that at least some of the cognitive deficits associated with KDM5B deficiency could be amenable to treatment in adults.

Title: Behavioral and transcriptomic analysis of Grin2b-3'UTR deletion mouse model

Authors: *A. HARVEY, P. NISSEN, M. KJÆRGAARD, H. POULSEN;
Mol. Biol. & Genet., Aarhus Univ., Aarhus C, Denmark

Abstract: NMDA Receptors (NMDARs) are calcium-permeable channels that drive learning and memory by activating downstream signaling pathways in a process called synaptic plasticity. The mRNA of the NMDAR2B subunit (*Grin2b)*, a known driver of neuronal development and differentiation, contains an unusually long 3'-untranslated region (3'UTR) of nearly 20kb, approximately 20 times the average mammalian 3'UTR length, but its exact role remains unknown. Many studies show that particular plasticity-related transcripts are trafficked to activated synapses for local protein synthesis, and in several cases, the process depends on RNA-binding proteins (RBPs) interacting with regulatory motifs in the 3'UTR. Recent evidence suggests that NMDAR transcripts are also trafficked to dendrites, but it is not clear what role local NMDAR protein synthesis may have. This study aims to better understand the post-transcriptional regulation of *Grin2b* mRNAs and how they may be transported in neurons. To investigate this novel concept of gene regulation, we have developed a mouse model, which harbors an 19kb deletion of the *Grin2b*-3'UTR, leaving the protein coding region unperturbed. In these mice we integrate animal behavioral evaluation with transcriptomic and proteomic analysis from hippocampal and cortical tissue. We find behavior deficits in 3'UTR knockout mice with underlying gene expression and proteomic changes. This marks the first assessment of the effect of the *Grin2b*-3'UTR deletion in adult mice, and further characterization of the expression

patterns and localization dynamics in this mouse model will aid in a better understanding of the post-transcriptional mechanisms that underlie synaptic plasticity.

Title: Mechanism of Padi2-mediated vimentin citrullination to promote microglial activation in the pathogenesis of AD

Authors: *J. ZHANG[1], J. ZHANG[2];
[1]Sch. of Basic Med. sciences Fujian Med. Univ., Fujian Med. Univ., Fujian Province, China;
[2]Fujian Med. university, Fuzhou, China

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by progressive cognitive impairment. The state and function of microglia play a key role in the occurrence and development of AD, making it important to investigate the reasons for microglia activation in early-stage AD. Citrullinated vimentin is typically found in the periphery, however, studies have found high expression of Padi2 and the presence of citrullinated vimentin in the brains of AD patients. To determine whether the high expression of Padi2 in AD mediates citrullinated vimentin, thereby promoting microglia activation and accelerating the occurrence and progression of AD, we first detected citrullinated vimentin in the hippocampus and cortex of young 5xFAD mice using mass spectrometry and western blot . Subsequently, we observed significant activation of primary microglia when they treated with citrullinated vimentin .When we injected with citrullinated vimentin in mice through the lateral ventricle, the mice showed impaired cognitive function and reduced postsynaptic density protein 95 (PSD95), a synaptic marker. When we administered a specific inhibitor of Padi2 to the mice, we found a significant reduction in citrullinated vimentin, along with a marked improvement in cognitive function. Our study reveals that Padi2-mediated citrullinated vimentin is a novel molecular driver of early-stage microglia activation in AD, which may provide new targets for the prevention and treatment of AD.

Autónoma de Nuevo León, San Nicolás de los Garza, Mexico

Abstract: Cognitive aging refers to the natural decline in brain processing and tasks that occurs with advancing age. It has been proposed that the presence of an inflammatory profile leads to the progression of cognitive impairment through increased levels of circulating proinflammatory cytokines and activation of microglial cells at the central nervous system. Although the molecular pathways that triggers systemic and central inflammation during aging are not clearly defined, several studies had shown that exposure to a hypercaloric diet may favor a proinflammatory state at earlier times than those observed in physiological aging. For example, our research group has identified that exposure of female mice to hypercaloric diet during pregnancy and lactation induces activation of microglial cells in the hypothalamus and increased systemic and central proinflammatory profile in the offspring. We identify whether nutritional programming with hypercaloric diet favors the onset of cognitive impairment at early ages through increased microglial phagocytosis. We exposed female C57/BL6J mice to a cafeteria diet for 9 weeks, and their male offspring of 2 and 6 months of age were cognitively evaluated using behavioral tests to determine deficits in memory and learning. Next, primary culture of microglia were obtained from hippocampus and cortex, phagocytosis was determined using myelin stained with BODIPY , the percentage of phagocytic cells was analyzed using flow cytometry. The results obtained show that nutritional programming increases the susceptibility of the offspring to present impaired spatial, recognition and working memory through increased phagocytic activity of hippocampal and cerebral cortex microglia at 6 months. We propose that Maternal nutritional programming could increase the phagocytic activity of microglia eliminating functional synapses and contributing to the development of cognitive impairment early in life

Title: Deletion of $Ca_v1.2$ from D1R expressing neurons is associated with sex-specific effects on long-term memory

Authors: *D. SCALA CHAVEZ[1], A. SEUNGHYUNG LEE[1], A. MARTINEZ-RIVERA[2], A. M. RAJADHYAKSHA[3];
[1]Pediatric Neurol., Cornell University: Weill Cornell Med. Col., New York, NY; [2]Weill Cornell Med., New York, NY; [3]Joan and Sanford I Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Dopamine signaling plays a key role in a variety of neuropsychiatric-related conditions including cognitive and emotional impairments. One downstream target of dopamine signaling is the $Ca_v1.2$ isoform of the L-type calcium channel. A variety of genome-wide association studies have found that single nucleotide polymorphisms (SNPs) of *CACNA1C*, the gene that codes for $Ca_v1.2$, are associated with schizophrenia, bipolar disorder, and a variety of other neuropsychiatric disorders. A previous study from our lab has shown that deletion of $Ca_v1.2$ channels in D1-expressing neurons (D1-Cre; $Ca_v1.2^{fl/fl}$) causes heightened contextual fear memory at long-term time points in male mice. To assess additional characteristics of these mice and potential sex-specific behavioral phenotypes, we performed a battery of behaviors. Here we report that deletion of $Ca_v1.2$ in D1-expressing neurons causes heightened contextual fear memory in both male and female mice when tested 30 days later, replicating and adding to our lab's previous findings. Of interest, females show higher sensitivity to the contextual fear, as the phenotype is present in heterozygote females (D1-Cre; $Ca_v1.2^{fl/+}$) but not males. Alongside these findings, we also report that deletion of $Ca_v1.2$ in D1-expressing neurons causes impaired learning in male but not female mice in the Water Y-maze task. Training consisted of five one-minute trials on day 1, with subsequent memory tests on days 2 and 7 post-training. At day 7, male heterozygous and homozygous mice showed significantly higher latency to find the platform compared to their wildtype counterparts. Female heterozygous and homozygous mice performed similar to wildtype mice. All groups reported normal locomotor activity, and there were no significant differences in social behavior or anxiety-like behavior, which we tested using the 3-chamber social assay and the elevated plus maze, respectively. Our results suggest that there are sex dependent effects of D1- $Ca_v1.2$ regulation and suggests that the male D1 expressing neurons modulate $Ca_v1.2$ differently than their female counterparts. Further studies will elucidate the brain region, circuit and molecular mechanisms that drive the sex-specific behavioral phenotypes in mice lacking $Ca_v1.2$ in D1-expressing cells. All experiments include a sample size of 7 or more animals, and differences among treated groups were established after performing the corresponding statistical analyses with significance defined as p values less than 0.05.

Abstract: Experience-dependent mechanisms underlying neurophysiological plasticity are required for the formation of long-term memories (LTMs). Epigenetic mechanisms are powerful experience-dependent regulators of gene expression needed for the processing of LTMs. One such epigenetic regulator, histone deacetylase 3 (HDAC3) works with transcriptional machinery to influence activity-dependent *de novo* DNA transcription. We build upon previous studies detailing increased auditory cortical plasticity and sound-specific behavior with HDAC3 inhibition (HDAC3i) by providing insight to molecular mechanisms underlying these changes. Our results reveal the auditory cortical effects of inhibiting HDAC3 in adult male rats during early acquisition of an auditory associative task (sound-reward learning) at the transcriptomic level. On a genome-wide scale, we found that HDAC3i produced large changes in learning-dependent transcription by further up- or down-regulating unique subsets of induced genes (relative to vehicle and sound-naïve groups). qRT-PCR performed on a separate cohort of animals that performed the same behavioral task verified effects seen in identified genes of interest (GOIs). While this work achieved bulk analysis of the auditory cortical transcriptome during learning, further investigation was needed to relate these profiles to cellular identity. To achieve anatomical specificity of gene expression events, we utilized single molecule fluorescent *in situ* hybridization (smFISH) to visualize GOI mRNA transcripts. Presumptive target genes regulated by HDAC3 identified from bulk RNAseq *Egr1*, *Per2*, and *Chrna7* were characterized within cortical tissue from a third cohort of animals that experienced the same sound-reward learning paradigm. GOI transcripts were colocalized with *CamkIIa* and *Rorb* transcripts to identify transcriptional changes within excitatory pyramidal cells and different cortical layers. Our findings characterize how HDAC3 regulates genes within subpopulations of cells to begin to

understand how changes in local cortical microcircuitry can support highly precise and lasting associative memories.

Title: Effects of neuronal p27 genetic suppression on memory and cognition

Authors: *J. V. PATEL[1], X. WANG[2], X. ZHOU[3], T. MA[4];
[1]Intrnl. Med. – Geriatrics, Wake Forest Univ. Sch. Of Med. Neurosci. Program, Winston-Salem, NC; [2]Intrnl. Med. – Geriatrics, Wake Forest Univ. Sch. of Med., Winston Salem, NC; [3]Intrnl. Med. – Geriatrics, Wake Forest Univ. Sch. of Med., Winston-Salem, NC; [4]Intrnl. Medicine-Geriatrics, Wake Forest Sch. of Med., Winston Salem, NC

Abstract: p27 is a cyclin-dependent kinase (CDK) inhibitor of the kinase inhibitory protein (KIP) family. It interacts with and inhibits different CDK complexes (e.g., cyclin B/CDK1, cyclin A/CDK2, and cyclin D/CDK4) to arrest the cell cycle. Several cyclin/CDK complexes are potential upstream regulators of the kinase for eukaryotic elongation factor 2 (eEF2K), which phosphorylates eEF2 and results in repression of general protein synthesis. Substantial evidence has demonstrated that protein synthesis is required for long-term forms of synaptic plasticity and memory. We intend to investigate the neuronal effects of p27 using a transgenic mouse model with p27 conditionally suppressed in neurons. We performed a series of behavioral tests including open field (OF), novel object recognition (NOR) task, Morris water maze (MWM) to assess cognitive function in both the heterozygous p27 knock down and homozygous p27 knock out mice aging between 3-6 months. The results indicate that cognitive function is normal (compared to the wild type littermates) in the adult mutant mice with suppression of p27. We next will examine potential aging-related effects with genetic suppression of p27.

Title: Intensity dependent effects of transcranial direct current stimulation on memory performance and hippocampal protein abundance

Authors: *C. HATCHER-SOLIS[1], J. MARTIN[1], S. HARSHMAN[1], S. H. JUNG[2];
[1]Air Force Res. Lab., Wright-Patterson AFB, OH; [2]Infoscitex, Dayton, OH

Abstract: Transcranial direct current stimulation (tDCS) enhances cognitive performance and neuroplasticity, but its underlying mechanisms in the brain are still unclear. The purpose of this study was to investigate the effects of tDCS stimulation intensity on memory performance and examine the associated changes in hippocampal protein abundance. Two different current intensities (250 µA and 500 µA) of anodal tDCS were applied to Sprague-Dawley rats (male, 8-10 weeks old) for 30 min before training and 24 hours later before testing during the passive avoidance test (PAT). Memory performance measured by the PAT was enhanced by both current intensities. To investigate the underlying mechanisms for enhanced performance, hippocampal synaptosomes were isolated and profiled using Waters Acquity Ultra Performance Liquid Chromatography for bottom-up proteomics. Normalized proteomic abundance datasets were analyzed by multiple bioinformatics methods and advanced statistical analyses. Analysis of protein-protein interaction-related functions and pathways indicated that hippocampal synaptosomes were significantly modified by anodal tDCS at 250 µA and 500 µA. Based on the results of bioinformatics and network analyses, both current intensities enhanced glutamatergic and dopaminergic synapse pathways in addition to long-term potentiation (LTP) pathways in the hippocampus. However, a greater number of tDCS-induced modifications were detected after anodal tDCS at 250 µA including enhanced metabolic pathways, GABAergic and cholinergic synapse pathways. In conclusion, we report that although anodal tDCS at 250 µA and 500 µA both enhance memory performance, the underlying mechanisms may be different based on the pathways that were found to be significantly upregulated. Our findings have important implications for understanding the dose-dependent effects of tDCS and determining the optimal parameters for therapeutic applications. This study was completed under an approved IACUC protocol.

Sloan Kettering Cancer Ctr., New York, NY

Abstract: In the central nervous system, histone variants are critical for the precise control of neuronal gene expression and proper cognitive function. The histone variant H2BE was discovered in the mouse olfactory epithelium, where it affects olfactory neuron function and longevity. While H2BE was previously thought to be exclusively expressed in the olfactory system, our lab developed a highly specific antibody against H2BE and demonstrated that H2BE is present throughout the brain. However, despite the importance of histone variants in controlling neuronal function, to date, H2BE remains unstudied outside of the olfactory system. Using CUT&Tag-sequencing, we found that H2BE is specifically enriched at promoters in mouse cortical neurons. In addition, H2BE promotes open chromatin and is required for proper expression of synaptic genes and synaptic function. Lastly, we found that H2BE is critical for learning and long-term memory formation in young adult mice. This work contributes to our understanding of how neurons use chromatin to translate diverse environmental signals into a transcriptional profile that supports long-lasting memories and adaptive behavioral responses.

Title: Comparison of acute transcranial direct current stimulation effects on different brain regions

Authors: *S. H. JUNG[1], C. HATCHER-SOLIS[2];
[1]Cognitive Enhancement and Biodynamics Br., [2]Commander's Action Group, U.S. Air Force Res. Lab., Wright-Patterson Air Force Base, OH

Abstract: Accumulating evidence indicates that transcranial direct current stimulation (tDCS) affects cognition in a region specific and intensity-dependent manner. Our research group has provided some underlying molecular mechanisms by which tDCS enhances memory and learning. However, it is still needed to elucidate how tDCS modifies molecular regulation in the brain, especially in different regions with different intensities and polarities. Here, we examined the proteomics regulation in synaptic regions of different brain regions after one-time cathodal and anodal tDCS. One session of cathodal/anodal tDCS was applied to Sprague Dawley rats (male, 8-10 weeks old) for 30 minutes near bregma 0-5 mm at the current intensity of shame (0), 250 or 500uA. In 2-hour post-tDCS, different brain regions were collected in post 2 hours (n = 5/group). The brain regions we analyzed include cortex (the cognitive brain region and the nearest brain region from the stimulating electrode), hippocampus (memory & learning regions), and cerebellum (the farthest brain region from the stimulating electrode). Synaptoneurosomes were isolated and profiled by LC-MS/MS mass spectrometry. With a target false discovery rate of 0.05, proteomic data was determined, normalized, and analyzed. Different analytics methods, such as, clustering analysis, principal components analysis, classification analysis, functional enrichment analysis, protein-protein interaction analysis, Ingenuity pathway analysis, etc., were conducted to analyze the synaptoneurosomes data from different brain regions. Our data shows both brain region-specific and similar effects. Additionally, tDCS intensity and polarity dependent changes were also detected. Thus, our complicated data suggest that acute one-time tDCS affects regulations of synaptoneurosomes in different brain regions. Additionally, because we only present here the data collected from our project for which acute one-time stimulation was applied and tissues were collected after 2 hours, future studies should be designed to investigate different application of tDCS and exclude some limitations our study had.

Title: EGL-30/GNAQ activation rejuvenates memory in two-year-old mice

Authors: *M. E. STEVENSON[1], G. BIERI[2], R. KALETSKY[1], J. M. ST. ANGE[1], L. REMESAL[2], K. J. B. PRATT[2], S. ZHOU[1], Y. WENG[1], S. A. VILLEDA[2], C. MURPHY[1]; [1]Princeton Univ., Princeton, NJ; [2]Anat., Univ. of California San Francisco (UCSF), San Francisco, CA

Abstract: Age-related cognitive decline is debilitating. Memory decline with age has been identified across species, from worms to humans. We first found that the expression of gain-of-function Gαq/*egl-30* restores long-term associative memory in aged worms experiencing memory loss. EGL-30/GNAQ and Gαq signaling pathways are highly conserved between worms and mammals, so we wondered whether this pathway also has a role in mammalian cognitive decline. We found that GNAQ is enriched in excitatory neurons in the mouse hippocampus, and its expression declines with age. Next, we tested whether expression of GNAQ gain-of-function could improve memory in aged mice. When expressed in hippocampal neurons of 24-month-old mice, GNAQ gain-of-function significantly improved long-term memory performance. This demonstrates that the molecular and genetic pathways between *C. elegans* and other mammals are highly conserved, as increased GNAQ function is sufficient to rescue memory in two-year-old mice. Single-nucleus RNAseq showed cell autonomous and cell non-autonomous changes in genes related to synaptic structure and function, axon guidance, and pathways involved in learning and memory. We then tested worm orthologs of mouse genes upregulated by GNAQ(gof) overexpression for functional roles in EGL-30/GNAQ-dependent enhancement of worm memory. Several genes were found to be critical for improved memory. These findings demonstrate that EGL-30/GNAQ is a conserved regulator of cognitive decline and has therapeutic potential in the treatment of cognitive aging.

Title: Regulation of immediate-early genes by curcumin in scopolamine-induced amnesic mice

Authors: *A. GAUTAM;
Ctr. for Neural and Cognitive Sci., Univ. of Hyderabad, Hyderabad, India

Abstract: Several research studies have revealed curcumin's anticarcinogenic, antioxidant, and immunomodulatory properties. However, definite evidence on the molecular pathways triggered by curcumin against neurological disorders, particularly amnesia or memory loss, is unavailable. As the memory process involves an interaction of diverse synaptic plasticity genes (SPGs), we hypothesize that curcumin regulates the expression of these genes in brain areas linked with memory processing. To test this hypothesis, we looked at how curcumin affected behaviour and the expression of four SPGs (Arc, FMRP, c-fos and zif-268) in scopolamine-induced amnesic male mice. The Morris Water Maze test was administered for a week to assess their behavioural changes. Real-time PCR wand was used to examine the mRNA levels, whereas Western blotting was used to examine protein levels of SPGs in the hippocampus and prefrontal cortex. In both brain areas, we found a substantial downregulation of immediate-early genes (IEGs) during scopolamine-induced amnesia, which was upregulated by pre- and post-curcumin treatment. Surprisingly, we did not observe any significant change in the levels of other SPGs, i.e. non-IEGs. Our research indicates a molecular pattern for how curcumin alleviates amnesia, but more research on upstream signalling pathways would support the extract's medical utility in memory issues.

Title: Cey/ybx rna binding proteins regulate associative memory in c. elegans and play a previously unappreciated role in human cognitive health

Authors: *A. HAYDEN[1], K. BRANDEL[1], P. MERLAU[2], E. PIETRYK[3], R. AREY[2];
[1]Neurosci., [2]Mol. and Cell. Biol., [3]Genet., Baylor Col. of Med., Houston, TX

Abstract: RNA binding proteins regulate RNA metabolism, including the translation of target mRNAs. Translational control of mRNAs is especially important in the nervous system, as novel protein synthesis is necessary for cognition. However, despite their biological significance, many RNA binding proteins within the nervous system remain uncharacterized in cognition. We sought to determine the role of a conserved family of RNA binding proteins, the CEY/YBX RNA binding proteins, in cognitive health. We first identified that of the four CEY RNA binding proteins in *C. elegans,* CEY-1 is the primary ortholog to mammalian YBX's. We then determined that both truncated CEY-1 with a functional RNA binding domain and full loss of CEY-1 cause learning and associative memory deficits using positive associative olfactory

assays. To identify if this was due to a tissue-autonomous role of CEY-1 in the adult nervous system, we next tested whether adult-only, neuron-specific knockdown of CEY-1 using RNAi decreased associative memory. We identified neuronal CEY-1 as a regulator associative memory in adult *C. elegans*. To determine whether mammalian YBX RNA binding proteins are equally important for cognition, we next examined whether dysfunction of human YBX1, YBX2, and/or YBX3 are associated with neuronal symptoms. Using publicly available and institute-specific human variant datasets, we found that over 80% of patients with single nucleotide variants in any YBX RNA binding protein have severe neurological symptoms. Importantly, the most common symptom is intellectual disability, mirroring our findings in *C. elegans*. In summary, we found a new role for the CEY/YBX RNA-binding proteins in memory and cognition. In ongoing work, we are investigating the mechanisms of specific human variants using humanized *C. elegans* and what pathways are altered when CEY/YBX function is disrupted. These studies suggest that mechanisms in *C. elegans* can inform the molecular underpinnings of YBX-related neurological symptoms in human patients and underscore the importance of neuronal RNA binding proteins in cognition.

Title: Examining sex-differences in cognitive impairment in patients with Parkinson's disease

Authors: *K. PATEL[1], K. VAN HEDGER[1], S. PASTERNAK[1], M. MASELLIS[2], R. CAMICIOLI[3], O. MONCHI[4], P. MACDONALD[1];
[1]Univ. of Western Ontario, London, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]Univ. of Alberta, Edmonton, AB, Canada; [4]Univ. de Montreal, Montreal, QC, Canada

Abstract: Parkinson's disease (PD) is one of the fastest growing age-related, progressive, neurodegenerative disorders. Cognitive impairment, progressing to dementia, is the most common non-motor symptom of PD and can be debilitating to one's quality of life. Previous studies report sex-specific differences in cognitive impairment in patients with PD, with males having a greater prevalence and progression of cognitive impairment compared to females. However, there remains a need to further investigate these findings in larger samples with greater variability in age and disease duration. We gathered data from a large cohort (n=430, 117 female) of patients with PD who completed the Montreal Cognitive Assessment (MoCA) and self-reported biological sex, age, and disease duration. Participants had an average age of 69.50 (SD = 6.92), an average disease duration of 6.41 years (SD = 3.97) with no significant differences between males and females in age ($t(428) = -1.10$, $p = .27$) and disease duration ($t(428) = -.16$, $p = .87$). We used linear regression to investigate sex-specific differences in MoCA total score and found that sex significantly predicted MoCA total score after controlling for age and disease duration, $B = -1.44$, $t(426) = -3.66$, $p < .001$, $R^2 = .17$, $F(3, 426) = 29.44$, $p < .001$, with males having lower MoCA scores than females. MoCA total scores ranged from 5.00 to 30.00. Our results show sex-specific differences in cognitive impairment in patients with PD, as measured by the MoCA, after controlling for age and disease duration. In this large and varied sample of PD patients, we support previous findings that sex impacts the development of cognitive impairment in PD. Follow up analyses will investigate potential sex differences in specific cognitive domains, as measured by the MoCA sub-scales and other cognitive tests. Additionally, we are examining associations between cognitive impairment and brain structure using diffusion MRI. Overall, this study will provide a better understanding of how sex differences affect the cognitive profile of PD.

Title: Does Alzheimer's disease have a linear negative effect on thinking and emotion? From the six years of observation in the home environment

Authors: *A. ONZO[1], K. MOGI[2], Y. TATEWAKI[3], B. THYREAU[4], Y. TAKI[5];
[1]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [2]Sony Comp Sci. Lab., Shinagawa-Ku, Japan; [3]Inst. of Development, Aging and Cancer, Tohoku Univ., Sendai, Japan; [4]Inst. of Development, Aging and Cancer, Tohoku, [5]Inst. of Development, Aging and Cancer, Tohoku, Sendai, Japan

Abstract: Studies based on continuous and intimate observations of people with Alzheimer's disease can provide unique insights. Here we report the observation of six-year longitudinal changes after the initial diagnosis of AD in gray matter thickness from MRI images of the whole brain of the mother (KO) of the first author (AO) now with severe AD. The rate of accumulation of amyloid-beta and/or tau varies from region to region, and it is known that the primary sensory areas and primary motor cortex and the subcortical areas remain comparatively intact even many years after the initial diagnosis (Braak & Braak, 1991). It is also known that those remaining brain functions sometimes enable them to have lucid moments (Edvardsson, et al. 2008). If some conditions are met, such as having someone compensate for the abilities that they lost, or being in a secure environment, they may behave like the person they have always been, just as in the anecdotal BBC report of the case of Marta Gonzalez, a former ballet dancer. MG started dancing as she once did the moment the music came on, even after experiencing difficulty in verbal communication. Here we compared the six-year longitudinal changes after the initial diagnosis of AD in gray matter thickness from MRI images of the whole brain of KO (born 1950, 65 years old at the time of diagnosis) with severe AD, with longitudinal data from 45 non-demented people possessed by Tohoku University. KO showed changes typical of people with AD, with the medial prefrontal cortex and the temporoparietal junction atrophying exceptionally fast compared with non-demented people. KO has indeed difficulty in making and remembering autobiographical memories. However, surprisingly, compared with the non-demented, the speed of atrophy in the dorsolateral prefrontal cortex, which is said to correlate with IQ (Duncan, et al. 2000), and in the orbitofrontal cortex, which is involved in complex emotions such as regret and guilt (Camille, et al. 2004), were not exceptional. Moreover, the right Heschl's gyrus, which is related to pitch discrimination (Bermudez et al, 2009), atrophied exceptionally slowly even compared with the non-demented. It might reflect KO's 45 years of piano teaching and her remaining sensitivity to sound. It is as important for families to know what abilities remain as well as to know what abilities have been damaged. We will discuss changes in the brain and personality based on the six-year observation by the family member AO who has lived with KO. Our report would suggest a way to explore the remaining capabilities of individuals from information on longitudinal changes in regional cortical gray matter volumes (Thyreau & Taki, 2020).

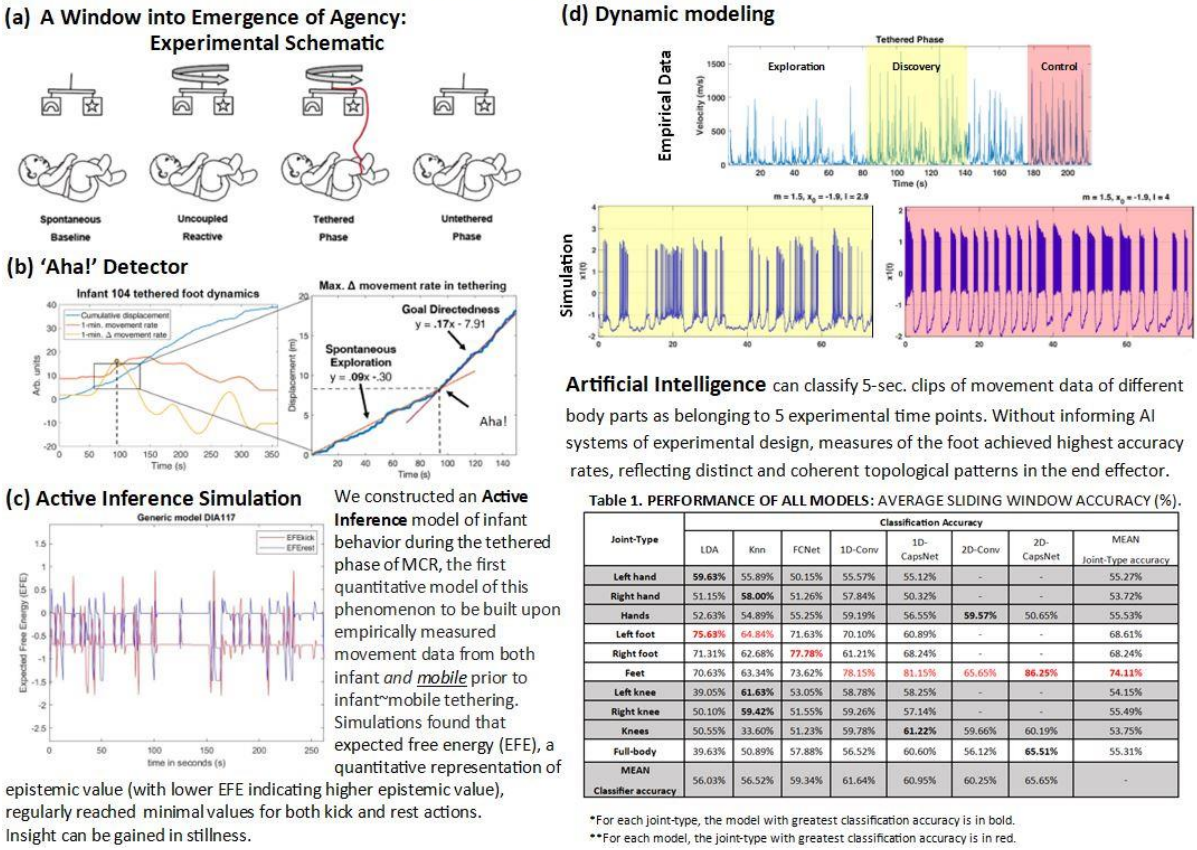
Title: Coordination Dynamics Meets Active Inference and Artificial Intelligence (CD + AI^2): A multi-pronged approach to understanding the dynamics of brain and the emergence of conscious agency

Authors: *A. T. SLOAN[1], N. A. JONES[1], N. BOITEN[2,3], K. J. FRISTON[3], M. KHODADADZADEH[4,5], D. COYLE[4,5], K. GUDIBANDA[6], V. K. JIRSA[6], J. A. S. KELSO[1,4]; [1]Ctr. for Complex Systems & Brain Sci., Florida Atlantic Univ., Boca Raton, FL; [2]Interdisciplinary Studies, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom; [4]Intelligent Systems Res. Ctr., Ulster Univ., Ulster, United Kingdom; [5]Bath Inst. for the Augmented Human, Bath, United Kingdom; [6]Inst. de Neurosciences des Systèmes, Aix Marseille Univ., Marseille, France

Abstract: How do humans discover their ability to act on the world? By tethering a baby's foot to a mobile (Fig. 1a) and measuring the motion of both in 3D, we explore how babies begin to make sense of their coordinative relationship with the world and realize their ability to make things happen (*N*= 16; mean age = 100.33 days). Machine and deep learning classification architectures (*e.g.*, CapsNet) indicate that functionally connecting infants to a mobile via a tether influences the baby movement most where it matters, namely at the point of infant~world connection (Table 1). Using dynamics as a guide, we have developed tools to identify the moment an infant switches from spontaneous to intentional action (Fig. 1b). Preliminary coordination dynamics analysis and active inference generative modeling indicate that moments of stillness hold important epistemic value for young infants discovering their ability to change the world around them (Fig. 1c). Finally, a model of slow~fast brain coordination dynamics based on a 3D extension of the Jirsa-Kelso Excitator successfully simulated the evolution of tethered foot activity as infants transition from spontaneous to ordered action. By tuning a small number of parameters, this model captures patterns of emergent goal-directed action (Fig. 1d). Meshing concepts, methods and tools of **A**ctive **I**nference, **A**rtificial **I**ntelligence and **C**oordination **D**ynamics at multiple levels of description, the **CD + AI^2** program of research aims to identify key control parameters that shift the infant system from spontaneous to intentional behavior. The potent combination of mathematical modeling and quantitative analysis along with empirical study allow us to express the emergence of agency in quantifiable, lawful terms.

Fig. 1. The CD + AI^2 Approach



Artificial Intelligence can classify 5-sec. clips of movement data of different body parts as belonging to 5 experimental time points. Without informing AI systems of experimental design, measures of the foot achieved highest accuracy rates, reflecting distinct and coherent topological patterns in the end effector.

We constructed an **Active Inference** model of infant behavior during the tethered phase of MCR, the first quantitative model of this phenomenon to be built upon empirically measured movement data from both infant *and* mobile prior to infant~mobile tethering. Simulations found that expected free energy (EFE), a quantitative representation of epistemic value (with lower EFE indicating higher epistemic value), regularly reached minimal values for both kick and rest actions. Insight can be gained in stillness.

Table 1. PERFORMANCE OF ALL MODELS: AVERAGE SLIDING WINDOW ACCURACY (%).

Title: Examining Differences in Amyloid and White Matter Hyperintensity in Older Adults with Distinct Cognitive Profiles

Authors: *S. MONIER[1,2], E. SMITH[2], J. P. HENNESSEE[2], J. BACCI[2], D. PARK[2];
[1]Univ. of Texas at Dallas-Center for Vital Longevity, Richardson, TX; [2]Univ. of Texas at Dallas, Dallas, TX

Abstract: While cognitive decline is commonly observed with age, there is significant individual variability. Additional research is needed to examine whether cognitively-normal (CN) older adults with diverse aging profiles also vary in Alzheimer's Disease (AD) pathology. We investigated differences in baseline amyloid (Aβ) among older adults with distinct cognitive profiles, characterized by initial memory performance and decline trajectory. Presence of white matter hyperintensities (WMH), believed to be associated with age-related cognitive decline, was also assessed. A total of 169 CN participants (ages 60-89; 61.5% F) with two time-points of cognitive data were included. Episodic memory (EM) was assessed using a composite score from multiple cognitive batteries and change was annualized. Participants underwent PET imaging with radiotracer AV-45 18F-Florbetapir to evaluate cortical Aβ levels. Mean cortical SUVR was computed across 8 cortical ROIs, normalized to cerebellar gray matter. Structural MRI was conducted and baseline global WMH levels were assessed. Group membership was based on baseline EM scores and the decline rates throughout study duration. To ensure sufficient statistical power, only groups of over 10 participants were included in subsequent analyses, leaving 4 groups: 1) participants with average baseline EM and decline rate (*Average-Normative,* N = 68); 2) those with average baseline EM and a decline rate greater than one SD above sample average (*Average-Accelerated*, N = 16)*;* 3) participants with below baseline EM and an average decline rate (*Low-Normative,* N = 13); 4) participants at one SD above the average EM and an average decline rate (*High-Normative*, N = 21). Analysis of variance controlling for age, sex, and education revealed group differences in baseline global Aβ (p = .002), with the *Average-Accelerated* group showing higher levels than both *Average-Normative* and *Low-Normative* groups. Cortical regions demonstrating this relationship included the precuneus (p < .001), lateral parietal (p = .002), and the posterior cingulate (p = .001), known as early Aβ accumulating regions. Baseline WMH also differed among groups (p = .029), with *Average-Accelerated* exhibiting higher levels than the *Average-Normative* group (p = .049). The results of this study suggest that baseline Aβ and WMH may serve as biomarkers for identifying older adults with distinct cognitive profiles and decline trajectories. These findings emphasize the importance of considering both baseline cognition and decline trajectories in assessing AD-related pathology to gain a broader understanding of risk factors associated with cognitive decline in older adults.

Title: Neurocognitive substrates of age-related impairment in search and foraging behaviours

Authors: *S. K. SALO[1,2], M. E. ROSER[1,2], A. D. SMITH[1,2];
[1]Sch. of Psychology, [2]Brain Res. and Imaging Ctr., Univ. of Plymouth, Plymouth, United Kingdom

Abstract: A prominent theory proposes that human cognitive control processes have their roots in foraging behaviour. This has been explored using simple 2D desktop tasks, and findings reveal that cognitive ageing may be revealed through inefficiencies in search behaviours before it is evident in other domains. However, whilst desktop tasks are generally considered to be simple and controlled models for naturalistic foraging, they lack key components that contribute to real-world behaviours, including the requirement to explore larger-scale environments and the integration of spatial reference frames. Since some visual search phenomena do not appear to transfer to large-scale search, it is important to ascertain how ageing affects foraging behaviour when it is enacted in a more authentic context. In addition, a finer grain of insight can be gained from relating change in the optimality of search behaviour to the cognitive and neural underpinnings of these behaviours. In the present study, younger (18-35 years) and older (>65 years) adults engaged in a simple foraging task in an immersive virtual environment. Participants were presented with multiple tables, each bearing a display of containers that were distinguished either by a single feature (colour) or a conjunction of features (colour and shape). Participants were required to search beneath each container for a target object (a ball) and to collect as many targets as possible within 60s. Participants also completed a battery of cognitive assessments, measuring executive function, spatial working memory, verbal and visual memory, reaction time, and rate maximisation. Finally, diffusion weighted imaging was employed to provide estimates of connectivity in frontal cortices.Analyses revealed that structural markers of ageing (fractional anisotropy and mean diffusivity) were predictive of decline in spatial working memory, visual learning, and executive function. Older adults displayed relative inefficiencies in their foraging decisions, both in the 2D rate maximisation task and in the 3D foraging task – their search was less organised, they collected fewer targets, and they displayed a tendency to exploit rather than explore. Together, these findings provide a more comprehensive account of the relationship between environmental search and its neurocognitive underpinnings. Further exploration of the relationship between neurodegenerative signatures and control processes will not only help to elucidate a major theory of human cognition but may also improve our abilities to provide early detection of atypical ageing in neurodegenerative conditions.

Title: Improvement of lifestyle and cognitive function through quantifying brain health

Authors: *K. KOKUBUN[1], Y. TOYAMA[2], M. OKAMOTO[1], Y. YAMAKAWA[1,3,4,5];
[1]Kyoto Univ., Kyoto, Japan; [2]bspr co., ltd., Shibuya, Tokyo, Japan; [3]Tokyo Inst. of Technol., Meguro, Tokyo, Japan; [4]Brain Impact, Kyoto, Japan; [5]Kobe Univ., Kobe, Japan

Abstract: In this study, the Brain Healthcare Quotient (BHQ: Brain Healthcare Quotient) (Nemoto et al., 2017), an index that quantifies brain health from MRI images, was used to evaluate whether it can promote good lifestyle habits for brain health in people. Participants were asked to use an app that promotes brain training and a healthy lifestyle. All participants were offered free access to the 'Estimated BHQ' function that enabled them to estimate their BHQ from the app's activities. In addition, Participants who actively used the app were provided with MRI BHQ measurements. Before and after using the app, participants were asked to answer a voluntary questionnaire on their motivation for participating, their medical history, lifestyle habits, and cognitive function test. 256 people participated in the study, 147 completed the questionnaire before using the app and 51 completed the questionnaire after using the app. The most common motivation for participation was “quantifying brain health seemed interesting”. 49% of the participants had a chronic disease, which was higher than the national statistic of 39.6% (White Paper on Health and Labour, 2014). An analysis of variance was conducted on nutritional intake and physical activity, with the presence or absence of chronic diseases and intervention timing as factors. The results showed a main effect of intervention timing for 'nutrition' ($p = 0.04$) and the interaction was significant ($p = 0.02$). A simple main effect was found that only the group with chronic diseases had significantly higher scores after using the app ($p = 0.01$). For 'low-intensity exercise', a main effect was found for both presence of chronic disease and intervention timing ($p = 0.03$, $p = 0.02$), and the interaction tended to be significant ($p = 0.08$). A simple main effect showed a significant increase in physical activity after using the app in the group with chronic disease ($p = 0.04$). Cognitive function test scores also increased after using the app, regardless of the presence or absence of chronic disease ($p = 0.04$). Based on the results of this study, it is assumed that people with chronic diseases actively participated in using the 'quantification of brain health status' as an incentive. Furthermore, people with chronic diseases may be more likely to improve their lifestyle through the brain healthcare app. Although the results of cognitive function tests are not able to remove learning effects, several studies have shown a relationship between diet and exercise and cognitive function (e.g., Titova OE et al., 2013; Colcombe SJ, et al., 2006). Hence, it is suggested that improving those habits in the participants with chronic disease may improve cognitive function.

Abstract: Cognitive decline is a common although not inevitable feature of aging. Identification of protective and exacerbating factors in the aging human brain is confounded by the presence of comorbidities, such as Alzheimer's pathology and cardiovascular disease, as well as the wide range of individual decline profiles. The cognitive aging field needs improved biomarkers which can be modeled in animals to identify and track the progression of age-related cognitive decline separate from pathological factors. Here we provide evidence that neuronal pentraxin 2 (NPTX2), an immediate early gene which mediates activity dependent homeostatic plasticity important for memory function, is a molecular marker of age-related cognitive decline which translates across species. Use of NPTX2 as a biomarker of cognitive health in an animal model of healthy aging will improve our ability to isolate factors contributing to age related cognitive decline in the otherwise healthy brain.

Title: The strength of LEC excitatory inputs into Dentate Gyrus PV-INs correlated with cognitive performance in aged rats

Authors: *C. MORENO NARANJO, D. SEVERIN, M. KOH, J. ZHOU, A. CONTREREAS, P. WORLEY, M. GALLAGHER, A. KIRKWOOD;
Johns Hopkins Univ., Baltimore, MD

Abstract: Aging impairs mental properties, including learning and memory. Recent studies have identified hyperactivity in the medial temporal lobe, particularly in the lateral entorhinal cortex (LEC) and the CA3/DG hippocampal subfields, as a dysfunctional condition common to cognitive impairment in aged rats and humans diagnosed with mild cognitive impairment. Previously we showed a reduction of feedforward inhibition elicited by LEC inputs onto DG granule cells, characterized as the ratio of synaptic excitation and inhibition (E/I ratio) in AI rats. A plausible mechanism to explain the reduction of inhibition recruitment is decreased LEC excitatory input onto DG PV-INs. We tested the possibility the overexpressing NPTXs in LEC neurons could rescue the DG granule cells' feedforward inhibition in AI rats. AI rats with comparable learning indexes were injected bilaterally in LECs with either AAV-CaMKII-NPTX2-SEP or AAV2-CaMKII-GFP as a control. We observed thus NPTX2 overexpression in LEC cells nearly doubles the strength of inhibition recruited by rescuing the E/I ratio in AI rats. By the AAV-DlMx-Td transfection approach to visualize DG-PV-INs. We identified PV-INs using immunofluorescence in slices and action potentials (AP) parameters (high firing frequency and AP half-width). We evaluated presynaptic and postsynaptic modification induced by aging, and we found a reduction of excitatory LEC inputs into dentate PV-INs in AI rats compared to AU rats.

Title: Deficits in force production during multifinger tasks demarcate cognitive dysfunction.

Authors: *R. G. CARSON[1,2], D. BERDONDINI[1], M. CROSBIE[1], C. MCCONVILLE[2], S. FORBES[2], M. STEWART[2], R. Z. X. CHIU[2];
[1]Trinity Col. Inst. of Neurosci. and Sch. of Psychology, Trinity Col. Dublin, Dublin, Ireland;
[2]Sch. of Psychology, Queen's Univ. Belfast, Belfast, United Kingdom

Abstract: The multifinger force deficit (MFFD) is the decline in (maximum) force generated by each finger as the number of fingers contributing to an action is increased. It is a measure of neural sufficiency that is larger in older persons than in the young, and associates with cognitive status. It was assessed here using a particularly challenging form of grip dynamometry that provides minimal tactile feedback via cutaneous receptors and requires active compensation for

reaction forces. It was hypothesised that these factors would accentuate the demands placed on the CNS and provide a particularly sensitive measure of functional brain integrity and cognitive impairment. Sixty-two volunteers took part in the study (42 females, 20 males; median age 72.5 years; range 65-87). Multifinger finger flexion dynamometry was undertaken using the approach described by Ohtsuki et al. (1981). Cognitive status was assessed using the Montreal Cognitive Assessment (MoCA). Eight neuropsychological evaluations (yielding eleven separate scores) and principal component analysis (PCA) was also used as a dimension reduction method to extract latent components of cognitive function. More than half of the 62 participants were unable to complete the dynamometry task successfully. Individuals who could perform the task were demarcated from those who could not, based on MoCA scores (Logistic regression estimate = 0.03, p = 0.044, 0.001 - 0.068 (95% c.i.)). Among 30 participants who complied with the task requirements, the MFFD (r = -0.51 (p = 0.003, -1 - 0.24 (95% c.i.)) and the rate-of-force (rof) MFFD (r = -0.47 (p = 0.007, -1 - -0.19 (95% c.i.)) were negatively correlated with MoCA scores - those with the highest MoCA scores tended to exhibit the smallest deficits, and vice-versa. It was indicated that only the first two PCs should be retained for further analysis. For the MFFD, there were corresponding associations with both latent components of cognitive function (PC1: r = -0.41 (-1 - -0.12 (95% c.i.), FDR = 0.021); PC2: -0.65 (-1 - -0.43 (95% c.i.), FDR = 0.0005)). To a lesser degree, this was also the case for the rofMFFD (PC1: r = -0.19 (-1 - 0.12 (95% c.i.), FDR = 0.169); PC2: -0.65 (-1 - -0.43 (95% c.i.), FDR = 0.0003)). The results add further weight to the assertion that deficits in force production during multifinger tasks are sensitive to cognitive dysfunction.

Title: Aging and depression trajectories on cognition

Authors: *J. R. BACCI[1], J. P. HENNESSEE[1], E. T. SMITH[2], S. MONIER[3], D. C. PARK[4]; [1]Univ. of Texas at Dallas, Richardson, TX; [2]Univ. of Texas at Dallas, Dallas, TX; [3]Univ. of Texas at Dallas-Center for Vital Longevity, Richardson, TX; [4]Ctr. For Vital Longevity, Univ. of Texas At Dallas, Dallas, TX

Abstract: In older adults the cross-sectional association of depression to cognitive impairments is well defined in the literature, but the relationship of depression to longitudinal cognitive declines is inconsistent. In this study, we investigated the relationship of depressive symptoms

with cognitive performance across the lifespan and predicted that the association of depressive symptoms to cognition would become stronger with age. Additionally, given the varying patterns of depressive symptoms across the lifespan, we explored the relationship of longitudinal depressive symptom trajectories to cognitive declines. The present study included 264 cognitively normal participants, aged 20-89, that completed two time-points of cognitive measures and depression questionnaires over an average of 3.92 years. Trajectory group membership was defined by the severity of depressive symptoms at baseline and the pattern of change over the course of the study. Five trajectory groups were identified: 1) participants with no depressive symptoms across the study ("Healthy Control", N = 34); 2) participants with depressive symptoms that emerged at the second time-point ("Emerging", N = 14); 3) participants with moderate baseline depressive symptoms that declined ("Moderate Declining", N = 82); 4) participants with moderate baseline depressive symptoms that increased ("Moderate Increasing", N = 66); 5) participants with moderate baseline depressive symptoms that remained stable ("Moderate Stable", N = 68). Using hierarchical linear regression, we found that baseline depressive symptoms demonstrated a quadratic age trend ($p < .001$), with depressive symptoms peaking in younger adulthood, declining through middle-age, and slightly rebounding at very late-life. A linear regression controlling for age, sex, and education revealed a significant age by baseline depressive symptom interaction on Reasoning ($p = .024$), where higher depressive symptoms had a more detrimental effect on Reasoning in older adults. Linear mixed effects models controlling for age, sex, and education revealed a significant depressive symptom trajectory group by time since baseline interaction on declines in Reasoning ($p = .008$), where only the Moderate Increasing trajectory group exhibited significant declines in Reasoning. This study provides evidence of the differential associations of depressive symptoms to cognition across the lifespan. While baseline depressive symptoms can be indicative of impaired Reasoning abilities in older adults cross-sectionally, trajectories of depressive symptoms over time can be used to predict longitudinal declines in Reasoning across the lifespan.

Title: Levels of Blood Iron are Positively Related to Levels of Cognitive Performance in Women at the Menopausal Transition

Authors: *A. L. BARNETT, M. J. WENGER, L. K. BOOZARY, S. F. NEWBOLDS;
The Univ. of Oklahoma, Norman, OK

Abstract: Iron accumulates in the brain over time, and the amount of iron present in regions including hippocampus, putamen, caudate nucleus has been shown to be related to the deficits in cognition that are associated with aging. However, women have been shown to have lower levels of both serum iron and brain iron, a difference has been attributed to monthly blood loss during the reproductive years. This raises the question of what happens to brain iron levels at the menopausal transition. If higher serum iron levels are associated with higher brain iron levels and therefore increased oxidative stress, it is possible that women who have relatively lower blood iron levels may have an advantage in terms of brain structure and cognition relative to women who have higher blood iron levels. We examined this possibility in a small (n = 27) sample of women who were either in the earliest (n = 8) or latest (n = 19) stages of menopause. Blood measures of iron were obtained as were MRI-derived estimates of brain iron. Levels of sFt were converted to a percentile ranking based on race and age distributions obtained from the National Health and Nutrition Examination Survey (NHANES) data sets. Cognition was assessed using a set of four tasks, including a face-name associative memory task, which is the focus of this report. In this task, women learned to associate a set of faces with both a set of names and a set of occupations. Memory for these associations was measured both immediately and after an approximately 2 hr delay by presenting each studied face with (a) the associated name and a lure and (b) the associated occupation and a lure. Choice accuracy and reaction times (RTs) were measured and were analyzed using repeated-measures analysis of variance. There was an interaction between test type (face/name, face/occupation) and test time (immediate, delayed) for both accuracy and RT, such that performance was worse at the delayed test but only for the face/name associations. Accuracy for the face/name associations was predicted by age and the percentile of the sFt level at both test times, with the relationship with age being negative and the relationship with sFt being positive. RT for the face/name associations at both test times were predicted only by percentile of the sFt level, with the relationship being negative. This suggests that higher rather than lower levels of iron at the menopausal transition were associated with higher levels of cognitive performance. Further analyses of the blood iron levels will be needed to determine if higher levels of sFt are or are not related to the risk of oxidative stress. Funding: NIEHS, 1 R21 ES027909

Title: Novelty detection and stimuli discrimination in healthy and pathological ageing

Authors: *E. LANCINI[1], D. BERRON[2], E. DÜZEL[3], M. BETTS[4], D. HÄMMERER[5];
[1]Inst. of Cognitive Neurol. and Dementia Res. (IKND), Magdeburg, Germany; [2]Inst. of Cognitive Neurol. and Dementia Res. (IKND), Otto-von-Guericke Univ., Magdeburg, Germany; [3]Inst. of Cognitive Neurol. and Dementia Res., Magdeburg, Germany; [4]German Ctr. For Neurodegenerative Dis. (DZNE), Magdeburg, Germany; [5]Univ. of Innsbruck, Innsbruck, Austria

Abstract: Novelty detection and stimuli discrimination are particularly impaired in individuals with mild cognitive impairment (MCI) (Lagun et al., 2011, Zola et al., 2013, Crutcher et al., 2009) and individuals diagnosed with Alzheimer's disease (AD) (Daffner et al., 2001) and predict the progression from MCI to AD (Zola et al., 2013, Gaynor et al.,2019). Furthermore, memory for objects and scenes has been shown to decline differently (Güsten et al.,2021). In the present study, we investigate differences in novelty detection and stimuli discrimination among healthy (HC), subjective cognitive decline (SCD), MCI, and AD participants and across stimulus domains. Data for this study was collected from the DELCODE clinical trial. The analyses included 78 HC, 48 individuals with SCD, 15 patients with MCI and 7 patients with AD collectively referred to as the pathology (PAT) group. Participants underwent fMRI while performing a memory discrimination task (Berron et al., 2018). fMRI results were analysed on a study-specific template space to account for potential atrophy-related anatomical deviation in the PAT group. A significant main effect of group on “hits-false alarms" rate was found ($F(2)=279.64$, $p<.001$). The group difference was found between HC and both SCD and PAT ($p<0.001$). No effect of the type of object (room or scene) or interaction was found ($p > 0.05$). The analysis of hits and false alarms (FA) separately revealed no significant main effect of group, stimulus type or their interaction ($p > 0.05$) for FA. However, a significant main effect of group was observed for hits ($F(2) = 683.42$, $p<0.001$).The fMRI results for novelty contrast (*first presentation- repetition*) showed that compared to HC, SCD group showed reduced activation in the fusiform gyri ($T=5.08$, $Z_E=4.86$, $p_{unc}<0.001$). Similarly, the PAT group also showed a reduction in the same area ($T=6.67$, $Z_E=6.18$, $p_{unc}<0.001$), as well as bilateral hippocampus ($T=5.77$, $Z_E= 5.47$, $p_{unc}<0.001$) In conclusion, the findings suggest that: (1) the difference in stimuli discrimination in ageing may primarily stem from the ability to accurately recognise previously encountered stimuli, rather than a failure to identify a similar stimulus as new; (2) subjective complaints of memory problems may indeed indicate cognitive decline, despite not be easily detected using traditional diagnostic measures; (3) the reduced fMRI activation observed in the novelty contrast suggests a gradual decline in the task-related activation during the progression from a healthy state to pathology. These results highlight the importance of evaluating stimulus recognition and discrimination in ageing populations.

Abstract: Brain imaging using MRI has been used mainly by doctors. We have tried to convert brain images into a numerical value that is easy for everyone to understand. We normalized the degree of brain atrophy and named it BHQ (Brain healthcare Quotient) as the brain version of IQ, which was approved as an international standard. In this study, we developed the BHQ to show the individuality of the brain, and examined whether it could beused for education and human resource development in the future. MRI imaging was performed on 291 experimental collaborators (male; 174, female 117 /20-39 years old; 117, 40-49 years old; 77, 50-69 years old; 97). We normalized the values of 90 cerebral regions from the Local BHQs of 116 AAL brain regions obtained during the conversion of MRI images to BHQs. We selected 28 of these regions with relatively well-defined neuroanatomical roles, and used the bilateral averages as a single value. We named it the Brain Performance Quotient (BPQ) and defined it as a pattern of 14 value sthat indicate brain individuality. As a first step in examining whether the BPQ is indicative of individuality, we analyzed differences by sex and age. PCC and MPFC, part of the Default Mode Network, and Insula and ACC, part of the Saliency Network, were significantly larger for young people than for older people. The SPC and PFC, part of the Central Executive Network, were significantly larger in males than in females. The motor cortex was larger in the elderly, and the auditory cortex was larger in females. Hippocampus was larger in females and older adults, Amygdala was larger in females, and Putamen was larger in young adults. There were no differences insomatosensory or visual cortices or Pallidum according to sex or age.The BPQs generated from the BHQ were characteristically different for different genders and ages. This suggests that the BPQ partially shows the characteristics of each attribute due to differences in gender and age roles in Japan. In the future, we would like to clarify the relationship between BPQ and personality, strong subjects, and job performance, premised on ethical considerations.

Title: Neurobiology of age-associated changes in social cognition in rats

Authors: *S. DUTTA GUPTA, E. BURNS, J. M. LONG, E. PEREZ, P. R. RAPP; Neurocognitive Aging Section, Lab. of Behavioral Neurosci., Natl. Inst. on Aging, Baltimore, MD

Abstract: Aging is a multifactorial phenomenon that severely affects cognition over time and increases the risk for neurodegenerative disease. In addition, age affects the prioritization of social goals and subsequent preferences for social companions. These social network characteristics are identified as key elements of successful aging. However, it is unclear whether age-dependent deficits in social cognition mainly reflect the disruption of social network activity or are simply secondary to a more general impairment of cognition. In this study, we aimed to establish a better understanding of this fundamental issue using a Long-Evans rat model of neurocognitive aging. Aged rats (25-27 months) were classified as either aged-unimpaired (AU) or aged-impaired (AI) based on their spatial memory performance relative to young adults (Y; 6-8 months; n = 8-16/group). We assessed sociability and social novelty using a three-chambered social interaction test. In the sociability phase, rats from all three groups spent more time interacting with a trapped stranger conspecific versus an inanimate object on the other side of the apparatus. In the social novelty phase, rats chose between a familiar animal (from the sociability trial) and a novel animal. Y and AU rats spent more time interacting with the novel animal (p_Y = 0.01; p_{AU} = 0.02), however, the AI rats failed to show any preference, indicating a social novelty

deficit ($p > 0.99$). Interestingly, we observed marked individual differences in the social novelty index among the AI rats, with a robust effect size of mean difference compared to the Y rats (Cohen's d = 0.88). Rats from all three groups showed a gradual decline in the short (< 6s; curiosity-driven) and long (> 6s; mutual interaction-driven) bouts of social interaction with the novel conspecific along the test time course. However, the AI rats displayed a significant reduction in the long interaction bouts compared to the Y rats ($p = 0.02$) possibly due to a lack of social motivation. Further analysis indicated that social preference and spatial learning are uncorrelated and independent but overlapping cognitive domains affected in aging. To explore the neurobiology of individual differences in social cognition in aging, next, we quantified oxytocin (OXY) immunoreactive neurons in the hypothalamic paraventricular nucleus (PVN) and supraoptic nucleus, i.e., neuropeptidergic circuitry implicated in social behavior. We observed a lower OXY+ neuronal number in AI relative to Y in the PVN ($p = 0.02$). Together, our findings provide evidence of a successful preclinical model for studying the neurobiology of age-associated decline in socio-cognitive architecture.

Title: Amnestic Mild Cognitive Impairment And Alcohol Use Disorder Display Greater Functional Brain Network Similarities With Each Other Than With Healthy Controls

Authors: *G. WARNER, J. JOSEPH;
Med. Univ. of South Carolina (MU Neurosci. Inst. - Grad., Charleston, SC

Abstract: Alcohol Use Disorder (AUD) and amnestic mild cognitive impairment (aMCI) are both associated with altered functional connectivity in brain networks such as the episodic memory encoding network (EMN), default mode network (DMN), and frontoparietal network (FPN). AUD is also a risk factor for aMCI. Given this information it is surprising that so little has been done to directly compare network connectivity in these two groups. Such similarities could point to a mechanism through which AUD increases the risk of aMCI. To address this possibility, we conducted a study comparing resting-state fMRI networks of 22 AUD, 110 aMCI, and 84 healthy control (HC) to determine the similarities and differences of brain network connectivity based on independent component analyses (ICA) composition between these three groups. The hypothesis was that network composition in the AUD and aMCI group would be similar to each other while both being dissimilar to the HC group. Three ICA's were conducted, one for each of the three subject groups. The identified components were then manually labeled as part of the EMN, DMN, or FPN. Three series of cross correlations between the resulting

components, one for each group pairing, were conducted followed by chi-square analyses to compare the frequency of shared components. As predicted, the aMCI DMN components showed greater overlap with the AUD DMN components than with the HC DMN components (X^2=5.34, p=0.021). Similarly, the AUD DMN components showed greater overlap with the aMCI DMN components than with the HC DMN components (X^2=4.37, p=0.037). The aMCI EMN components showed a trend towards greater overlap with AUD EMN components than HC EMN components (X^2=3.82, p=0.051). In a second analysis, we performed a single ICA on the three groups (which were now matched by fMRI data acquisition TR) followed by a dual regression analysis which revealed that the FPN of both the AUD and aMCI groups included a region of the left hippocampus which was not included in the HCs. As the hippocampus is canonically associated with the EMN these findings suggest that perturbed resting-state networks may recruit regions from other networks in order to maintain functionality. These findings taken together indicate that aMCI and AUD show greater similarity of EMN, DMN, and FPN networks as compared to HCs.

Title: Cerebellar reserve mediates associations of educational attainment and cognitive performance in healthy older adults

Authors: *F. D'OLEIRE UQUILLAS[1], J. MERRIMAN[1], E. SEFIK[1], J. SEIDLITZ[2], V. ZHANG[1], M. KISLIN[1], J. D. COHEN[1], F. KRIENEN[1], J. SEPULCRE[3], S. S.-H. WANG[1], J. GOMEZ[1];
[1]Princeton Univ., Princeton, NJ; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]MGH, Harvard Univ., Charlestown, MA

Abstract: Greater educational attainment in older adults has been associated with greater cortical volume and lower risk for dementia and cognitive decline, with mixed findings. Associations of educational achievement (7-21, years) with brain volumes were examined in healthy older adults (age: 36-100 years) from the Human Connectome Project (N720, 56% F). All statistical models included sex at birth, estimated intracranial volume (eTIV), and age as covariates.

In separate robust regression models, greater number of years of education were related with greater Montreal Cognitive Assessment (MOCA) total scores (Cohen's f=0.23, p<0.0001), and greater cerebellar volume (Cohen's f=0.10, p=0.006), but not cerebral cortex volume (p=0.865). Greater cerebellar volume was also related to greater MOCA scores (Cohen's f=0.17, p<0.0001). Mediation models revealed that education exerted its effect on MOCA cognition scores through cerebellar volume (a*b: z=3.6, bca 95% CI=0.02,0.06, p<0.0001). Cerebellar volume was not a moderator of education (education x cerebellar volume effect: p=0.672), nor MOCA scores (MOCA x cerebellar volume effect: p=0.669).
LASSO regression on individual cerebellar lobules, controlling for sex and eTIV, found that years of education were most related to left lobules I-III, VIIB, VIIIB and X, as well as bilateral lobules VI and VIIIA, and right Crus II (Bonferroni-corrected, p<0.05). MOCA cognitive scores were most related to higher-order cerebellar regions: left Crus I, Crus II, and Lobule VI (Bonferroni-corrected, p<0.05).
This is the first study to show a relationship between educational attainment and the cerebellum, and that educational attainment is a predictor of cognitive performance in older adults by way of cerebellar volume.

Title: Proof of concept(POC) validation test for personalized near-infrared LED therapy based on QEEG

Authors: *U. PARK[1], J. KO[1], B. CHOI[1], H. KIM[1], H. LEE[1], H. GWAK[1], H. NA[1], J. KIM[2], D. KIM[1], S. KANG[1,3];
[1]iMediSync, Inc., Seoul, Korea, Republic of; [2]Dept. of Neurology, Ajou Univ. Hosp., Suwon, Korea, Republic of; [3]Natl. Standard Reference Data Ctr. for Korean EEG, Seoul Natl. Univ. Col. of Nursing, Seoul, Korea, Republic of

Abstract: Near-infrared LED therapy is being actively researched as a form of electroceuticals for enhancing brain neurology through photobiomodulation. In particular, 850nm near-infrared light has been found to stimulate the mitochondria of brain cells within the cerebral cortex, increasing ATP production and promoting activation, as well as facilitating increased blood flow and neurological activity. This study aimed to investigate the clinical impact of LED therapy on individuals with degenerative brain diseases at a community level and examine the positive effects of LED therapy on QEEG patterns. A total of 53 participants, including 12 males and 41 females, with an average age of 73.3, were enrolled in the study. Participants with a Clinical Dementia Rating (CDR) score of 0.5 or higher received expert counseling to confirm the presence of degenerative brain diseases. The intervention lasted for 12 weeks, during which baseline and post-intervention measurements of QEEG, CDR scores, quality of life scales, and individual interviews were conducted to assess the efficacy of the proof of concept. The iSyncWave, a 10-20 system EEG measurement device developed by iMediSync, was used to collect data. This device incorporated near-infrared LED light-emitting diodes into each electrode, enabling personalized therapy protocols based on the participant's QEEG patterns. LED therapy was administered three times per week, with the LED region and frequency adjusted based on individual patterns identified from the baseline brainwave measurements. The results showed significant improvements in cognitive function, as measured by CDR (Before: 0.542, After: 0.062, p-value < 0.001). The relative delta power, a key pattern associated with cognitive decline and degenerative brain diseases in the prefrontal cortex, also decreased (Before: 0.222, After: 0.189, p-value < 0.05). The small-worldness, a brain network index related to information exchange efficiency, increased significantly overall (Alpha; Before: 0.043, After: 0.05, p-value < 0.05), and the overall scores of the quality of life scale showed a significant improvement. Specifically, there were significant improvements in sleep (Before: 3.0, After: 4.0, p-value < 0.001) and energy (Before: 3.0, After: 3.5, p-value < 0.0001). These results demonstrate the effectiveness of personalized LED therapy in enhancing cognitive function, as evidenced by both cognitive function assessments and quantitative analysis of physiological signals. Non-invasive and free from side effects, personalized LED therapy protocols hold great promise in the prevention and treatment of cognitive impairment patients.

Title: Understanding the role of anterolateral entorhinal cortex in configural processing across the lifespan

Authors: *N. LADYKA-WOJCIK[1], S. D. ALLEN[2], J. C. LIANG[1], J. D. RYAN[1,3], R. K. OLSEN[1,3], M. D. BARENSE[1,3];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Florida State Univ., Tallahassee, FL; [3]Baycrest Hlth. Sci., Rotman Res. Inst., Toronto, ON, Canada

Abstract: The entorhinal cortex (ERC) is one of the earliest regions impacted in age-related pathologies like Alzheimer's Disease (AD), even before clinical diagnosis. Mounting evidence in humans and non-human animals has identified two subdivisions of ERC: an anterolateral (alERC) and a posteromedial (pmERC) subregion. Recent work also suggests that alERC volume in older adults, in contrast to pmERC volume, predicts intra-item configural processing (i.e., the ability to process arrangements between an object's features, reflected in eye movements). However, a functional role for the alERC in configural processing remains unclear, particularly in predicting cognitive decline associated with preclinical AD. In the current study, we used functional magnetic resonance imaging (fMRI) with simultaneous eye-tracking to investigate the relationship between functional patterns in alERC and intra-item configural processing across the lifespan. Our study included a large sample of younger (n = 48) and older (n = 51) adults, the latter demonstrating a range of cognitive performance from normal aging to at-risk for AD-related cognitive decline based on the Montreal Cognitive Assessment. Within each block of the experiment, participants were shown five repetitions of three computer-generated conjunctive objects comprised of distinct upper and lower halves. On the sixth and seventh repetitions of each block, we assessed the effect of novelty for whole objects by presenting participants with three possible configurations: (1) an old object configuration from prior repetitions in the block; (2) a reconfigured object in which the two halves had been presented as parts of different objects in the block; and (3) a novel object in which both halves were new. Finally, we used manually segmented subject-specific masks of the alERC and surrounding medial temporal lobe regions to constrain our functional analyses. Our results revealed an age-related pattern of activation along the ventral visual stream from early visual areas towards the alERC for novel and recombined objects compared to old objects. Overall, our results provide first evidence for the relationship

between functional activity in the alERC and configural novelty, mediated by age and cognitive performance.

Title: A Role for Cerebellum in Cognitive Aging and Brain Reserve

Authors: *J. MERRIMAN[1], F. D'OLEIRE UQUILLAS[1], E. SEFIK[1], J. SEIDLITZ[2], J. D. COHEN[1], J. SEPULCRE[3], J. GOMEZ[1];
[1]Princeton Univ., Princeton, NJ; [2]Univ. of Pennsylvania, Philadelphia, PA; [3]MGH, Harvard Univ., Charlestown, MA

Abstract: Cerebellar reserve refers to the capacity of the cerebellum to compensate for the cognitive effects of brain injury, including from biologically driven age-related processes. Here we sought to discover novel subtypes of cerebellar reserve for different cognitive domains in healthy older adults from the Human Connectome Project (n725, 56% F, age range: 36-100, years; mean=60.28).
Using LASSO regression, we first mapped associations between cerebellar regional volumes and specific cognitive domains: cognitive flexibility (Dimensional Change Card Sort, DCCS; and Flanker Inhibitory Control and Attention Task), reading decoding (Oral Reading Recognition Test, ORRT), and delayed memory recall (Rey Auditory Verbal Learning Test, RAVLT; and Face-Name Associative Memory Exam, FNAME Recall). We found that higher Delayed Memory Recall scores commonly related to greater volumes in left Crus I, II, and Lobule V, VIIb. Cognitive Flexibility commonly recruited a more distributed pattern of regions in addition to Crus I and II, while Right Lobule VIIIa only related to Oral Reading. We next averaged the relevant cerebellar regional volumes for each cognitive task to create cerebellar reserve signatures, which represented the relationship between cerebellar volume for that lobule and the cognitive task. We characterized the volumetric trajectories across the observed age range and found linear effects of age (RAVLT: β=-1.93, se=0.1, Cohen's f=0.72, p<0.0001; FNAME Recall: β=-2.29, se=0.11, Cohen's f=0.73, p<0.0001; DCCS: β=-1.86, se=0.1, Cohen's f=0.72, p<0.0001; Flanker: β=-1.77, se=0.1, Cohen's f=0.70, p<0.0001). We also found that among older adults, greater levels of cerebellar signature volume conferred greater cognitive scores (DCCS:

p=0.012).
Here we find overall evidence for cerebellar cognitive reserve and unveil age-related patterns of cerebellar volumetric associations with cognitive performance. Further work is underway to investigate how socioeconomic status and ethnicity may influence associations between cerebellar volume and cognitive performance.

Title: Nicotinamide riboside increases cognitive function and decreases microglial activation in aged mice.

Authors: *R. THIYAGARAJAN, R. BERMAN, Y. REDAE, O. TREANOR, A. DAVIS, K. SELDEEN, B. TROEN;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Abstract: As many as 1 in 6 people ages 60 or older exhibit cognitive impairment, representing major challenges for healthcare infrastructure as this demographic is projected to reach more than 75 million by 2030. Microglia undergo dramatic changes during aging and exhibit dysfunction that coincides with cognitive decline. Nicotinamide adenine dinucleotide (NAD+) is an essential co-enzyme for mitochondrial function, decreases with aging, and contributes to age-related declines in cellular metabolism and function. The NAD precursor, nicotinamide riboside (NR), restores cellular NAD+ levels in aged mice. But the impact of NR supplementation on microglia gene expression and cognitive function is yet to be elucidated. We provided 21-month-old male C57BL/6JNIA mice with chow containing placebo (PLB, $n = 10$) or NR at a dose of 400 mg/kg mouse weight (NR, $n = 10$). After 12 weeks, NR supplementation significantly enhanced the number of spontaneous alternations in Y-maze ($p < 0.05$), a measure of memory and exploratory activity, and prevented the age-related decline in nest-building ability, a measure corresponding to the housework component of the instrumental activities of daily living. NR also increased total NAD+ in muscle but not in the brain. Messenger RNA and microRNA sequencing were performed using NovaSeq 6000 System on magnetically sorted microglia from the whole brains of PLB, NR, and young mice. Gene expression analysis revealed greater activation, inflammation, and mitochondrial dysfunction in microglia from aged mice compared to young mice. In contrast, microglia from the NR-supplemented aged mice showed a lower activation status and a gene expression profile more similar to young mice. Therefore, NR supplementation enhances memory and an instrumental activity of daily living and concomitantly improves the microglia gene expression profile reflecting less activation and inflammation and better mitochondrial function. These findings support the translation of this work into clinical settings to ascertain the benefits of NR supplementation for maintaining and enhancing functional and cognitive activity during aging.

Title: Activation of the apelin receptor, implicated in a key aging pathway by analysis of longitudinal human data, ameliorates multiple mechanisms that drive neuroinflammation and neurodegeneration

Authors: *A. J. B. LUNDQUIST, Z. O'BROWN, N. SHAH, R. HUGHES, P. LEONG, E. MORGEN, K. FORTNEY;
BioAge Labs, Inc., Richmond, CA

Abstract: We developed a discovery platform based on analysis of multi-omic data from proprietary longitudinal human aging cohorts to identify novel targets for diseases of aging. Our analyses using the platform revealed a novel connection between higher circulating levels of apelin, and beneficial outcomes including delayed mortality and preservation of muscle and cognitive function. Apelin is a peptide hormone widely expressed throughout the body that signals through its Gi/o protein-coupled receptor APJ to exert beneficial effects on cellular function. Within the central nervous system, APJ is primarily expressed in astrocytes, which play important roles in age-related neuroinflammation and neurodegeneration. We observed that apelin pathway activity decreases with age. In multiple preclinical models of neurodegeneration, direct brain administration of apelin peptide has disease-modifying effects via modulation of apoptosis, inflammation, and autophagy. Based on the connection between apelin and cognitive aging, along with the established relationship between apelin, inflammation, and neurodegeneration, we hypothesized that apelin pathway activation could decrease inflammatory signaling in astrocytes. Using BGE-105, a highly selective, potent, orally available small-molecule agonist of the apelin receptor APJ, we demonstrated that astrocytic apelinergic signaling mediates potent anti-inflammatory and neuroprotective effects. We generated a model of the neuroinflammation associated with aging and neurodegeneration by stimulating primary mouse astrocytes using IL-1α/TNF-α/C1q. In these stimulated astrocytes, BGE-105 robustly inhibited proinflammatory cytokine release via downregulation of NF-κB. Activation of the astrocyte apelin pathway also increased glutamate uptake by increasing GLT1 expression. Because neuroinflammation causes breakdown of the blood-brain barrier (BBB), we examined the effect of BGE-105 on aged (26-month-old) mice. Daily oral administration of BGE-105 for 7 days suppressed circulating levels of age-related proinflammatory cytokines, increased levels of BDNF in the hippocampus, and reversed age-induced BBB dysfunction, suggesting that BGE-105 restores the BBB through its anti-inflammatory effects in the periphery. Taken together, our results suggest that apelin receptor agonism with an orally available small molecule represents a

novel approach for treating chronic age-related neuroinflammation and neurodegeneration, and for mitigating the effects of inflammation on the BBB.

Abstract: The fly visual system provides a unique opportunity to study neural networks solving known (or knowable) computational tasks. Decades of anatomical studies have carefully cataloged many of the cell types in the visual system, and in parallel, decades of behavioral and physiological experiments have examined the visual capabilities of flies. The wealth of interesting, high-performance visual behaviors coupled with genetic tools for targeted access to nearly any neuron type in the brain, have made *Drosophila* an outstanding system to study the neural circuit implementation of many computations. Janelia's FlyEM team has successfully imaged the complete nervous system of an adult, male fruit fly using Focused Ion Beam milling and Scanning Electron Microscopy (FIB-SEM). Subsequently, the entire volume was

reassembled and Google Research's connectomics group carried out automatic segmentation of the volume into neuron fragments, which were then proofread by connectome annotators at Janelia. The right optic lobe is the first brain region that was proofread. We then cataloged all neurons in the optic lobe, including the complete medulla (and accessory medulla), lobula, lobula plate, and approximately half of the lamina. Using first morphology analysis and then iterations of connectivity analysis, we identified and named all cell types of the optic lobe—over 51,000 neurons in ~700 cell types. Such that we now have access to a complete, curated, connectome of an entire fly optic lobe. For the first time, this data set allows a quantitative analysis of the flow of information across neuropils, such as the tracing of retinotopy from the retina and lamina through to the medulla, lobula, and lobula plate. Specifically, we examine the highly stereotyped columnar structure with its similarities and differences across the whole eye. Access to this wealth of information is critical for future analysis, particularly in the context of making strong inferences for predicting neuron function and for reevaluating prior experimental results. Here, we will detail a method to register single neurons to a specific address based on their morphology, location, and connectivity, and will demonstrate how to use this address space to enable new analyses.

Title: Investigating Human Cingulate Cortex Connectivity Through Intracranial Single Pulse Stimulation

Authors: *P. DEMAREST[1,2,4,3], M. ADAMEK[1,2], J. R. SWIFT[1,2,3], T. XIE[1,2,3], J. T. WILLIE[1,2,3], P. BRUNNER[1,2,3,4], E. C. LEUTHARDT[1,2,3,4];

Abstract: The cingulate cortex is widely recognized as a key locus that orchestrates various cognitive, perceptual, and behavioral processes. In humans, this region is an attractive target for neuromodulation to treat various disorders such as chronic pain or depression. This is specifically due to its intricate cortical connectivity, functionally and anatomically distinct sub-regions, and involvement in processes such as emotional affect and sensory integration. We recently conducted a six-week brain-computer interface intervention study with patients suffering from chronic pain and identified a significant relationship between pain symptom relief and patient-mediated increases in frontal theta power (Spearman's Rho 0.33, $p < 0.01$). Previous evidence suggests that this electrophysiological activity pattern indicates activity from the anterior cingulate cortex. While the clinical outcomes of this study are promising, they do not provide robust insight into the neurophysiological mechanisms driving patient symptom relief. The present study aims to provide direct, spatially specific, intracranial evidence of cingulate connectivity in humans through invasive single pulse stimulation to thus bolster our current understanding of the underlying physiology that may contribute to pain relief in humans. Five patients with intractable epilepsy invasively monitored using stereotactic electroencephalography underwent bipolar single-pulse stimulation of either the anterior cingulate cortex, midcingulate cortex, or posterior cingulate cortex at 3mA or 6mA. Cingulate sub-regional connectivity was then investigated by analyzing cortico-cortical evoked potentials at recording electrodes within the hippocampus, amygdala, frontal cortex, and somatosensory cortex. Evoked local activity within these regions was then represented by changes in high gamma. Finally, evoked potentials detected by electrodes on the patient's scalp provide valuable evidence linking evoked activity within the cingulate cortex, and electrophysiology recorded using surface EEG. The results of this study provide robust electrophysiological representations of cingulate connectivity and provide valuable insights into the nuanced inter-regional dynamics of this area.

Title: A scalable approach for mapping connectivity of transcriptomically defined neuron types

Authors: ***M. MOYA**[1,2], W. J. CUNNINGHAM[1,3], A. ZAMBON[1], T. WANG[6], M. N. ECONOMO[1,2,4,5];

Abstract: Large-scale transcriptomic atlasing projects have uncovered the vast diversity of cell types that compose each brain region. But defining the connectivity of the thousands of cell types in the brain remains challenging due to a lack of scalable methods. By combining high-sensitivity fluorescence voltage imaging and optogenetic photostimulation, we have developed an approach to map synaptic connectivity between brain regions with up to 100x greater throughput than existing techniques. Importantly, the all-optical basis of this method allows us to readily integrate synaptic connectivity measurements with highly multiplexed fluorescence *in situ* hybridization. In this way, we can molecularly identify large populations of neurons as well as describe their connectivity. Here, we demonstrate a proof-of-concept of this synaptic mapping approach (SYNMAP) in the motor cortex, providing a framework for performing high-throughput connectivity mapping across any brain region of interest. Population-level data acquired with SYNMAP have the potential to rapidly advance our understanding of how the diverse cell types of the brain are wired to form the functional circuits that underlie all cognition, learning, and behavior.

Abstract: Conventional imaging atlases of the human brain have been constructed using low spatial resolution MRI, rendering neuroanatomical delineations unsatisfactory compared to histological maps. **W**e aimed to construct an MRI atlas of the human brainstem using considerably higher resolution/contrast than currently available, with neuroanatomical delineations guided by those identified in our histological atlas of the human brainstem[1]. **P**ostmortem MR imaging was performed on a human brainstem of a 65-year-old male with no history of neurologic or psychiatric conditions in a 7T machine. Anatomic images were acquired using a 3D gradient echo pulse sequence, and diffusion data using a simple diffusion-weighted spin echo pulse sequence. Brain structures were manually traced in the transverse and sagittal planes. Delineations were informed by histology where available. **T**he 50μm GRE and 200μm DTI resolution images obtained to construct this atlas are 8000x and 1000x higher than the average clinical structural MRI and DTI, respectively. The high resolution of this data set enabled us to successfully delineate 363 structures (more than 80% of that identified in our histological atlas[1]) and produced 86 detailed diagrams across the transverse and sagittal planes using GRE, FAC, and DWI images. **W**e have constructed an MRI/DTI atlas of the human brainstem using data of unprecedented quality, that is also the first to present detailed diagrams in the sagittal plane, giving a unique perspective on brainstem organisation.

Title: Pattern of cortical white matter terminations across thalamus is conserved across primates.

Authors: *A. M. HOWELL[1], S. WARRINGTON[4], C. FONTENEAU[5], Y. CHO[2], S. N. SOTIROPOULOS[4], J. D. MURRAY[3], A. ANTICEVIC[1];
[1]Psychiatry, [3]Dept. of Psychiatry, [2]Yale Univ., New Haven, CT; [4]Univ. of Nottingham, Nottingham, United Kingdom; [5]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Corticothalamic anatomical connections vary between sensory and association systems along the cortical hierarchy (Harris et al., 2019). Previous work using diffusion weighted imaging (DWI) in humans and macaque monkeys has demonstrated that some cortical areas may project to multiple thalamic nuclei (Zhang et al., 2010; Phillips et al., 2019). However, the spread of thalamic connectivity patterns has not been systematically examined for every cortical area and so it remains unclear if such spread differs between sensory and association corticothalamic

circuits. In this study, we tested the hypothesis that the spread of thalamic connectivity patterns varied between sensory and association cortical areas in primates. Using probabilistic tractography data from healthy adults from the Human Connectome Project (n=828) and post-mortem macaques (n=6), the spread of each cortical area's tractography pattern across the thalamus was quantified using Principal Components Analysis (PCA) on Euclidean distance (ED) values across 100 thresholds for 360 cortical parcels (EDpc1) for each subject. Here, higher EDpc1 values correspond to more diffuse, or spread out, thalamic connectivity. The T1w/T2w ratio is a proxy measure of myelin and it is lower in association cortical areas (Burt et al., 2018). We correlated each subject's EDpc1 values and T1w/T2w ratio values using spearman correlation (rs). EDpc1 loadings dissociated cortical areas with focal and diffuse thalamic connectivity in humans and macaques. Notably, humans and macaques had similarly focal motor area 1 (M1) thalamic terminations, but human dorsolateral prefrontal cortex (DLPFC) thalamic terminations were more diffuse than that of macaques. EDpc1 loadings were significantly positively correlated with T1w/T2w values at the group-level in both humans ($p = 0.025$) and macaques ($p = 0.014$), such that sensory cortical areas had more focal thalamic terminations relative to association cortical areas. We characterized the variability of this relationship across subjects and, on average, there was a moderate correspondence between EDpc1 loadings and T1w/T2w values in both human (Mdn = 0.35) and macaque (Mdn = 0.34) subjects. Overall, we found that sensory cortical areas have more focal terminations across thalamus relative to association cortical areas in both humans and macaques. Additionally, we observed interspecies differences in the spread of some cortical areas (e.g. DLPFC). Future studies will further investigate these differences in homologous primate brain areas.

Title: High throughput molecular connectomics with barcoded rabies viruses

Authors: *A. BECALICK, A. BLOT, M. STROM, P. ZNAMENSKIY;
The Francis Crick Inst., London, United Kingdom

Abstract: Conventional approaches for determining the connectivity of individual neurons are extremely labor-intensive and limited to reconstructing connections between nearby neurons -

within 100s of microns. Recently, methods relying on DNA sequencing of unique oligonucleotide “barcodes” have been proposed for high-throughput reconstruction of neuronal connectivity. To date, they have been successfully applied to systematically characterize long-range projection patterns of thousands of neurons in parallel. However, existing approaches lack the resolution to identify individual synaptic connections. Taking advantage of the ability of rabies virus to spread between connected neurons, we developed a new method that has the potential to map thousands of synaptic connections within a single experiment. Infecting a population of starter cells with a library of rabies viruses expressing random barcode sequences enables these cells to transmit their barcodes to their direct presynaptic partners. These barcodes can then be matched to their respective starter cells to reconstruct synaptic connections. Towards this goal, we have generated libraries of barcoded rabies viruses with sufficient diversity to uniquely label >1000 starter cells within a single experiment. We used the CVS-N2c strain of rabies virus, which exhibits reduced cytotoxicity, in order to maintain viability of infected neurons. To preserve information about the spatial location of barcoded cells and avoid cell loss resulting from tissue dissociation, we used in situ sequencing to read out viral barcodes alongside endogenous transcripts of cell type marker genes from intact sections of mouse brain. This enabled us to classify the cell types of barcoded neurons, making it possible to relate their connectivity and molecular identity. As a proof-of-concept, we are currently applying this method to characterize cell-type specific connectivity rules in the mouse primary visual cortex. Our approach is highly scalable, does not depend on the availability of cell-type specific transgenic lines, and can be readily translated across brain areas, enabling the systematic characterization of connectivity between cell types in the mammalian brain.

Title: Automated neuropil segmentation of fluorescent images for Drosophila brains

Authors: *K. HSU[1], C.-T. SHIH[2], N.-Y. CHEN[3], C.-C. LO[1];
[1]Natl. Tsing Hua Univ., Hsinchu, Taiwan; [2]Tunghai Univ., Taichung City, Taiwan; [3]Natl. Ctr. for High-Performance Computing, Natl. Applied Res. Labs., Hsinchu, Taiwan

Abstract: The connectomic study is one of the most important research domains in today’s neuroscience. Connectomic analysis usually involves warping and registering individual brain images into a standard brain template. However, warping and registration often produce large spatial errors (1~3μm) and hence severely reduce the accuracy of the connectomic analysis. To address this issue, we have developed a method for automatically segmenting neuropils in individual fluorescent images of *Drosophila* brains obtained from the *FlyCircuit* database. This

technique enables future connectomics research to be conducted without the need for warping and registration to a standard brain template.Our method includes two stages. In the first stage, we use the YOLO model to locate neuropils and rapidly extract small-scale 3D images, which serve as input for the subsequent model in the second phase. In the second stage, we use the 3D-UNet model for neuropil segmentation. Our initial findings reveal a 99.4% accuracy rate in brain region localization during the first stage. In the second stage, we only use 3D images from 15 brains for training and achieve satisfactory accuracy in segmenting the antennal lobe (AL) and mushroom body (MB). For the test set performance, the F1 score is 0.93, and the 3D-IoU reaches 0.89. This outcome is comparable to the human labeling, which yields 3D-IoU between 0.85 and 0.89 3D-IoU for the same neuropils by two professional labelers. We also demonstrate that our method can be applied to other neuropils in *Drosophila*.Our method attains the proficiency of human labelers while taking only a mere 7 seconds to segment an AL or MB for one brain. Hence, the method constitutes a critical component in the high throughput connectome construction for optical imaging of the *Drosophila* brain.

Title: Structural Connectivity of the Posteromedial Cortex

Authors: *F. AGUILAR ORTEGA[1], Z. LIU[2], D. BULLOCK[3], J. ZIMMERMANN[2], S. R. HEILBRONNER[4];
[1]Dept. of Neurosci., Univ. of Minnesota, Twin Cities, Minneapolis, MN; [2]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]NSF Sci. & Technol. Policy Fellowship, Natl. Sci. Fndn., Washington, D.C., DC; [4]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The Posteromedial Cortex (PMC) is part of the brain's Default Mode Network (DMN). It is central to an impressive array of cognitive and emotional functions, but its structural connectivity has been relatively under-explored. Here, we utilize both anatomical tract-tracing (in macaques) and diffusion MRI tractography (in macaques and humans). In doing so, we are able to compare the ground truth of tract-tracing with the less invasive tractography approach. The qualitative comparison between tract-tracing and tractography data shows a substantial agreement, but there are glaring issues, particularly with regard to PMC-striatal

pathways. For tractography data, we ask three main questions: 1) What proportion of PMC fibers use each segmented bundle? 2) Where do each of these sets of fibers end? 3) How similar are the monkey and human PMC tractography fiber pathways? In both species, quantitative analyses reveal that PMC fibers primarily travel in the cingulum bundle and corpus callosum, with additional involvement of other bundles such as the middle longitudinal fasciculus and the internal capsule. Our findings offered valuable insights into the structural connectivity of the PMC, and ultimately we hope to enhance our understanding of its role within the DMN.

Title: Hippocampal Connectomics Revisited: An Improved (Para)Hippocampal Connectome Database Bridging Diverse Anatomical Nomenclatures

Authors: *N. M. VAN STRIEN[1], J. J. GEISLER[1], J. M. J. MURRE[1], M. P. WITTER[2], N. L. M. CAPPAERT[1];
[1]Universtity of Amsterdam, Amsterdam, Netherlands; [2]Norw. Univ. Sci. & Tech., Trondheim, Norway

Abstract: The wiring diagram of the brain, i.e. its connectome, contains fascinating insights into its function. However, creating a comprehensive network chart is challenging due to the abundance of anatomical nomenclatures that are in use. To address this, we previously constructed a connectome of the rat hippocampal formation, parahippocampal region and retrosplenial cortex (Van Strien, 2009). Here, we present an advanced version of this connectome, characterized by several key improvements. Brain connectivity is now stored in a MySQL database using the original nomenclature, while translations to standardized terminology are enabled by an integrated nomenclature dictionary. This dictionary was created by individually translating over 4,000 neuroanatomical terms that are used in over 18,000 curated connections, into standardized terms. The nomenclature dictionary allows for a more comprehensive understanding of brain connectivity by accurately consolidating multiple reports of a connection, even when they employ different nomenclatures. Moreover, our updated database can store brain connectivity data from all species, obtained through various visualization techniques, supplemented with relevant metadata. Types of connectivity that were previously impossible to catalogue, such as brain connectivity to the hemisphere contralateral to location of the cell body, are now also curated. Likewise, connections that were explicitly

reported as absent are stored as well. Finally, the curators now differentiate between connections that are explicitly reported and those that are suggested implicitly, and therefore inferred from the articles. Incorporating these changes required an extensive reworking of the entire connectome. The new dataset can be filtered on a variety of labels (e.g. gender, species, method, rating, hemisphere) to identify relevant experiments and connections. The temporal-lobe.com website offers new interactive tabulations to view and filter the connectome dataset, providing an invaluable resource for neuroscientists worldwide.

Abstract: Mapping hippocampal single-neuron projections is essential for understanding brain-wide circuit organization and diverse functions of the hippocampus. We reconstructed single-cell projectome of 10,100 mouse hippocampal neurons and identified 43 projectome subtypes, each with distinct collateral axon projection targets and preferential soma location along hippocampal longitudinal and transverse axes. Many projectome subtypes were enriched in selective hippocampal subdomains defined by spatial transcriptomic patterns. Although some neurons in

CA1 and subiculum complex exclusively projected to the hippocampal formation (HPF), most projected to both intra- and extra-HPF targets with varying targeting patterns and projection strengths. Furthermore, bi-hemispheric projecting hippocampal neurons generally projected to one pair of homologous targets with ipsilateral preference. Finally, the total arbor length of the axon correlated with that of dendrites of each neuron in CA3, CA1 and subiculum complex. These organization principles of single-neuron projectome provide a structural basis for understanding diverse but coordinated functions of hippocampal neurons.

Abstract: Oxytocin (OXT) is an evolutionarily conserved nonapeptide, which plays important roles in autonomic control and behavioral modulation, in species ranging from invertebrates to humans. OXT neurons localize to a number of brain regions, with the paraventricular hypothalamic nucleus (PVH) containing the largest number and most extensively arborized OXT neurons, likely holding the key to their central physiological functions. To better understand the

complex functions of OXT neurons, several previous studies analyzed the mesoscale projectomes of OXT neurons, especially PVH OXT neurons, using bulk labeling. While clearly illustrating the complexity of OXT neuron projection patterns, mesoscale experiments do not allow visualization of the diversity of individual OXT neuron projectomes, nor do they address whether the projectome of subtypes of OXT neurons have distinct patterns, possibly aligned with function. High resolution single-neuron projectomes, in addition to addressing the above questions, also allow analysis of co-projection relationships between brain regions, which is critical to understanding how projection patterns of individual neurons correlate with their functions.In order to label single OXT neurons brightly, sparsely and specifically, we designed and generated a Cre-dependent AAV construct which expressed cytoplasmic and membrane-bound fluorescent proteins in tandem. We used fluorescence micro-optical sectioning tomography (fMOST) technology to image the whole-brain projectome of single OXT neurons at submicron resolution, and Fast Neurite Tracer (FNT) software to reconstruct axons and dendrites of PVH OXT neurons. From 264 sparsely and brightly labeled PVH OXT neurons with complete 3D reconstructed axonal morphologies, by hierarchical clustering, we identified two main clusters, which projected to mutually exclusive targets and possessed distinct morphological features. Cluster 1 (C1) contained 177 reconstructed axons terminating in the median eminence (ME) and with few collaterals terminating within hypothalamic regions. Cluster 2 (C2), comprising of 87 neurons, in contrast, projected extensively throughout the brain. Some subtypes identified by our morphological characterization fitted neatly with previously described OXT functions. We also analyzed soma and dendritic morphological characteristics of PVH OXT neurons. Our single-neuron resolution observations provide comprehensive analysis of PVH OXT morphology and lay structural foundation for better understanding of the complex physiological function of OXT neurons.

Title: Mapping whole-brain activity in adult zebrafish by combining in-situ hybridization chain reaction with the adult zebrafish brain atlas and BrainGlobe

Authors: *N. RAJPUT, M. WONG, D. KANANI, A. SQUIRES, K. KUSH PARIKH, K. FIELDS, J. W. KENNEY;
Biol. Sci., Wayne State Univ., Detroit, MI

Abstract: Both adult and larval zebrafish have been increasingly used to study a variety of behaviors given their low cost, amenability to genetic manipulation, and genetic similarity to mammals. Adult animals are of particular interest because of their extensive behavioral repertoire; however, unlike larval animals, we lack the tools for mapping whole-brain activity mapping in adults. To map brain activity in adults we developed a method that combines *in situ* hybridization chain reaction (HCR) to detect the expression of the immediate early gene *c-fos*, with a tissue clearing technique, iDISCO+. Whole brains are then imaged using light sheet microscopy. To identify *c-fos* positive cells, we used CellFinder, a deep learning approach to cell identification that is incorporated into the BrainGlobe computational environment. Images were then registered to our recently created adult zebrafish brain atlas (AZBA) using advanced normalization tools (ANTs). We have successfully trained CellFinder to detect *c-fos* positive cells with high accuracy (96%) and found that *c-fos* expression peaks at 15-30 minutes following exposure to a novel tank. Utilizing this approach, we have begun to identify the neural mechanisms that underly exploratory behavior of adult zebrafish.

Abstract: The human insular cortex is considered the “fifth lobe” of the brain. Although it comprises less than 2% of the total cortical surface area it plays a crucial role in numerous functions. Previous in vivo neuroimaging studies in humans have identified three distinct functional subdivisions in the insular cortex: the dorsal anterior, ventral anterior, and posterior insula. These three regions exhibit different cytoarchitectonic characteristics. The anterior aspects of the insula are involved in the integration of complex autonomic, cognitive, and

emotional process, which are believed be important in interoceptive awareness. On the other hand, the posterior aspects are essential for integrating autonomic and interoceptive signals. However, the synaptic organization of this brain region is still unknown due to the challenges involved in studying the human brain. The current study focuses on analyzing the synaptic organization of the neuropil of layer III of these three different regions of the insular cortex: the agranular (anteroventral), dysgranular (anterodorsal) and granular (posterior) insular cortices. Human brain samples obtained from autopsies with short postmortem intervals (less than 3 hours) were utilized, and synaptic circuits were examined in 3D using Focused Ion Beam milling/Scanning Electron Microscopy (FIB/SEM). A specific software tool was employed to analyze synaptic density, morphometric characteristics, postsynaptic targets, and spatial distribution of the synapses. Preliminary results indicate that certain aspects of the synaptic organization are rather homogeneous, while others exhibit specific variations across the three insular cortices (such as the distribution of postsynaptic targets). This specific synaptic organization in these three brain regions could represent an anatomical basis of their distinct functions.

Title: Development of implantable 3mL micropump for preclinical and clinical applications, including controlled metronomic chemotherapy for brain cancers

Authors: *T. HOANG[1], S. LEE[1], E. MENG[2];
[1]Fluid Synchrony, LLC, Pasadena, CA; [2]USC, Los Angeles, CA

Abstract: Fluid Synchrony is developing a 3mL implantable drug delivery system for preclinical and clinical applications. For preclinical studies, the system will aid the discovery of new treatments and vaccines as well as drug-based neuromodulation therapies. Our microinfusion system consists of an implantable micropump, an external wireless programmer, and programmable dosing software. Newly-developed capabilities include a medical-grade primary battery and a programmable system-on-chip with Bluetooth telemetry transceiver, processor and memory. This automated microinfusion system will ultimately result in increased productivity

and reduced researcher exposure to potentially toxic drugs and disease vectors.
One specific clinical application that would greatly benefit would be for delivering chemotherapeutic drugs to the central nervous system (CNS) for the treatment of primary malignant and disseminated brain cancers. The blood-brain barrier (BBB) limits diffusion of high doses of systemic drugs into the cerebrospinal fluid (CSF). For those drugs that do cross the BBB, rapid CSF turnover reduces drug concentration in a matter of hours. The standard of care treatment results in CSF drug concentrations at initially toxic levels, which drop through the therapeutic window, then become sub-therapeutic. As a result of the limited efficacy of the standard of care, the CSF serves as a sanctuary for circulating tumor cells which disseminate in the CSF and form tumors on the leptomeninges. By using low concentration, tolerable, metronomic dosing regimen to increase AUC (Area Under the Curve), efficacy and outcomes may be significantly improved while reducing toxic side effects.The micropump fulfills an unmet need in brain cancer treatment, especially in pediatric applications where off-label use of adult pumps are not practical and not efficacious.
We present current progress on the development of the implantable micropump with 3mL drug reservoir. We will demonstrate a unique dual-needle fluid injection mechanism for percutaneous refill of the implanted micropump using negative-pressure syringe pull operation to avoid adverse pocket-fill events that plague other refill procedures for implanted infusion pumps.

Title: A urethane anesthesia protocol for robust recordings of bladder cystometrogram and visceromotor responses to bladder distention in mice

Authors: *E. WOON[1,2], S. ZHANG[1], L. CHEN[1], G. KUCHEL[2], B. FENG[1];
[1]Univ. of Connecticut Biomed. Engin. Dept., Storrs, CT; [2]Ctr. of Aging, Univ. of Connecticut Hlth. Ctr., Farmington, CT

Abstract: Bladder-related disorders, such as underactive or overactive bladder and chronic pelvic pain syndromes, are poorly managed in clinics, necessitating further mechanistic understanding of the underlying urodynamics and nociceptive neural circuitry. These disorders are usually studied through cystometrogram (CMG) and visceromotor responses (VMR) to urinary bladder distension (UBD) recorded in rats under urethane anesthesia. Here, we optimized a urethane anesthesia protocol to enable robust recordings of CMG and VMR in mice, offering a wider selection of disease models with the ease of genetic manipulations. Additionally, we assessed our anesthesia protocol on aged mice (18-22 months old), enabling geriatric studies on bladder-related disorders. In this study, C57BL/6 mice of both sexes were used: mature adults (10-12 months) and aged adults (18-22 months). Mice were first anesthetized with 1.75% isoflurane inhalation. A polyurethane (PE)-50 catheter was inserted into the dome of the bladder for delivering slow bladder filling (1.5 mL/hr) or stepped UBD (20, 40, 60, 80 cmH2O). Two stainless steel wire electrodes were sutured to the oblique abdominal muscles for recording the VMR. Another catheter was placed intraperitoneally (i.p.) for delivering urethane anesthesia. After the surgery, an initial dose of 0.6g/kg of urethane was administered, followed by a 30-minute period of reduced isoflurane to 0.25%. Then a 3-hour-long urethane infusion (0.15 g/kg/hr) was started. The micturition events were captured by measuring the urine weight with a force transducer. After establishing the baseline CMG and VMR, we assessed the effects of intravesical infusion of 0.5% acetic acid and 0.1% lidocaine on the CMG and VMR. Our anesthesia protocol, consisting of an initial dose of urethane and a 3-hour-long infusion, enabled robust CMG and VMR recordings for 3 hours in mice of both age groups. Intravesical acetic acid significantly enhanced the VMR to UBD and disrupted the regular micturition cycles in CMG, which were normalized by intravesical lidocaine. This new anesthesia protocol will enable focused studies to advance our mechanistic understanding of bladder-related disorders.

Title: Refining the use of general anaesthesia in embryo larval zebrafish: effective and tolerated concentrations of six commonly used fish anaesthetics

Authors: *S. DIMITRIADOU[1], M. C. M. MILLER[1], J. L. BAMSEY[1], D. HOGAN-BASSEY[1], A. PILEHVAR[1], A. RANDALL[1], A. TAKESONO[1], T. KUDOH[1], L. U. SNEDDON[2], M. J. WINTER[1], C. R. TYLER[1];
[1]Univ. of Exeter, Exeter, United Kingdom; [2]Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Zebrafish (*Danio rerio*) are one of the most widely used laboratory animals in scientific research worldwide, second only to the mouse in terms of regulated (invasive) procedures undertaken, for example, in the UK. Most experimental procedures are undertaken in the embryo-larval life stages, (typically <7 days-post-fertilisation or dpf), and many of these involve the use of anaesthesia, either as the first step towards euthanasia, or for procedures such as sedation for microscopic evaluation. Despite this, there is very little guidance available for humane and appropriate anaesthetic choices for fish, particularly for embryo-larvae. For example, limited research has been performed on establishing appropriate immersion concentrations (doses), lengths of induction and recovery times, or whether anaesthetic agents are poorly tolerated or aversive in embryo-larvae and as such may present a confounding factor. This knowledge gap has considerable implications both for the welfare of these animals, and for experimental design more widely. Our study used 4.5 dpf zebrafish embryos to explore the sedative and aversive characteristics of six of the most widely used fish anaesthetic agents: tricaine methanesulfonate, benzocaine, isoeugenol, 2-phenoxyethanol, quinaldine sulphate, and etomidate. The fully anaesthetic concentration for each agent was established by observing the effects of several different concentrations on heart rate, balance, and responsiveness to tactile stimuli, in addition to the induction and recovery times for each concentration/anaesthetic compound. Additionally, non-recoverable concentrations were established for each agent for application during euthanasia. Next, the aversive properties of each anaesthetic were assessed at a low (the highest concentration not causing anaesthesia) and a high (the highest concentration not eliminating heartbeat at recovery) concentration, using a novel behavioural avoidance test, combined with automated video analysis. Collectively, these studies revealed pronounced differences between the anaesthetic agents tested, both in their effectiveness and speed of induction, as well as in terms of their effect on the aversive behaviour of the larvae. Our findings indicate that certain anaesthetics are more effective and/or less aversive to zebrafish embryo-larvae and may, therefore, offer more ethical and scientifically appropriate alternatives in experimental procedures involving these widely used laboratory animals.

Title: An optimized and versatile Small Molecule based Cell Supplement for stress reduction in Primary and PSC-Derived Neural Cell

Authors: *M. A. DERR[1], R. E. SCOTT[1], A. IBRAHIMI[1], J. TANCREDI[1], K. LAHA[2], S. SHIN[1];

Abstract: Primary and pluripotent stem cell (PSC)-derived neural cell cultures are extensively utilized in neuroscience research to study basic neuronal function, development, morphology, disease modeling, drug development and neurotoxicity. However, the complex nature of these cells renders them particularly susceptible to the detrimental effects of stressful environments. In vitro workflows further exacerbate this vulnerability, potentially compromising experimental results and reducing the reliability of these models.Existing cell recovery supplements have shown improved survival in Pluripotent Stem Cells (PSCs), however, most are not recommended for neural cell applications and limited data is available. In this study, we aimed to address this issue by evaluating the efficacy of a small molecule based cell supplement (SMCS) in protecting neural cells from the stress induced during routine handling procedures such as recovery from the cryopreservation, dissociation and differentiation. To assess the versatility of SMCS, we included different neural cell types, namely primary neurons, PSC derived neurons and astrocytes. Our results demonstrate that SMCS can be widely employed to mitigate cell stress without compromising downstream applications. Furthermore, we conducted a comparative analysis to assess the performance of the SMCS in comparison to both the gold standard method specific to each application and a commonly used rho kinase inhibitor, which is a general reagent utilized for stress reduction. Remarkably, SMCS demonstrated superior performance, outperforming other compared reagents in terms of their protective capabilities.Overall, our study highlights the importance of addressing the vulnerability of primary and PSC-derived neural cell cultures to stress in order to enhance the reliability and utility of these models in neuroscience research. The introduction of the novel cell supplement, SMCS, provides a promising solution to protect these cells from the detrimental effects of routine laboratory manipulations, thus offering new opportunities for improved experimental outcomes and downstream applications.

Title: Alternative test of fearful temperament in non human primate

Authors: *M. KIM;
Korea Res. Inst. of Biosci. and Biotech., Cheongju-si, Korea, Republic of

Abstract: Non-human primate is widely used experimental animals due to its high similarity with human beings. However, this high correspondence between human beings requires more sophisticated research design. Unlike the rodent, non-human primate has higher cognitive capability and even each has personality or temperament as human beings. Traditionally, Human Intruder Test measuring the duration of bodily freeze in response to stranger is used for fearful temperament. However this method would accompany interpretation error and providing stress to the animals. Thus, standardized and sensitive test to assess temperaments among non-human primate is critical for further behavioral experiments. Here, we conducted a rigorous behavioral baseline experiment to identify each monkey's temperament and confirm whether they are right for further behavioral experiments. We conducted a reinforcement task with three cynomolgus monkeys with Cambridge Neuropsychological Test Automated Battery (CANTAB) and observed regular behavior in single-housed manner. First, the motivational behavior with CANTAB is conducted two to three times per week with a total time of 17 days. This behavior test is for measuring behavioral activation in response to novel stimuli. In the touchscreen, a particular shape appears in the monitor and the monkey is asked to touch the shape to get a reward, and their response time is measured— A: 2.50s, B: 6.89s, C: 8.90s. Then we also measured the abnormal behaviors with the various criteria: rapid orientation and flight behavior, sudden startle, visual tracking (eye gazing of invisible objects), grooming and circling with the mean time and total number of behaviors. Particularly, we focused on the stereotypic behavior; circling, which considered as monkey's typical anxious behavior. The total number of circling behavior of each is as follows A: 7.25 B: 11.75C: 14.75 with the two hours each for four days with the behavior measurement tool; observerXT. Based upon the results, we decided to exclude monkey C for future behavioral experiments due to its greater fearful temperament. We propose this touch-screen based task and behavioral observation would be more sensitive method for assessing fearful temperament of laboratory non-human primate.

Title: Comparison of viral vectors for retrograde transduction of dopaminergic neurons in rhesus monkey

Authors: *A. S. PLOTNIKOVA[1], W. LERCHNER[1], A. C. CUMMINS[1], L. SALHANI[1], B. J. RICHMOND[1], Z. M. KHALIQ[2], M. A. G. ELDRIDGE[1];
[1]Lab. of Neuropsychology, NIH, Natl. Inst. of Mental Hlth. (NIMH), Bethesda, MD; [2]NIH/ NINDS, Bethesda, MD

Abstract: Engineered viral vectors have been used to target the neuromodulatory systems of the brain, but a conspicuous obstacle is the inability of many retrogradely infecting viruses to transduce dopaminergic (DA) cells (Cushnie et al., 2020; Tervo et al., 2016). In a comparative analysis, we assess four viral vectors in their ability to drive expression in the somata of DA neurons of nonhuman primates (NHP) after injection into striatum. AAV2-retro and lentiviral vectors pseudotyped with rabies Fusion Glycoprotein B, C, and E (FuG-B2, FuG-C, and FuG-E) are viruses that have been engineered to confer retrograde transfection properties. A variant of AAV2, rAAV2-retro, is endowed with the ability to be internalized by axons, enhancing retrograde transfection (Tervo et al., 2016). FuG-B2 (‘HiRet’) transduces all brain cell types (glia and neurons), while FuG-C and FuG-E ('NeuRet') are neuron specific (Kato et al., 2020). To evaluate retrograde transduction of dopaminergic cells in the rhesus monkey, virus was targeted to striatum in stereotaxic surgeries. We injected between 70 and 150 µL (10 µL/site at a rate of 0.5 µL/min to 1.0 µL/min) unilaterally across three anterior-posterior levels of each NHP. Post-mortem immunohistochemistry was visualized with fluorescence and brightfield microscopy, and the transduction efficiency of the viral vectors in dopaminergic cells was quantified. Qualitative and quantitative analysis of the data revealed lentivirus-based vector, FuG-B2, produced robust retrograde transfection of DA cells, as evidenced by the neuronal co-expression of fluorescent reporter protein and tyrosine-hydroxylase (TH) antibody in substantia nigra. This finding is contrasted with the other three viral vectors, which do not transfect dopaminergic cells as efficiently. FuG-C expression was approximately two times lower than that of FuG-B2. FuG-E showed minimal expression, while AAV2-retro produced almost zero expression.

Title: Regional Specific Changes in Alpha Reactivity During Tonic Pain Stimulation

Authors: *Q. NGUYEN, J. PARK, R. HO, S. COOMBES;
Dept. of Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Alpha Reactivity (AR), characterized by alterations in alpha power between eyes-open (EO) and eyes-closed (EC) states, reflects the functionality and adaptability of the brain's attention system amidst varying cognitive demands. The attenuation of alpha power during the transition from EC to EO resting states — a change from a less attentive to a more attentive state — is well established and thought to rely on the cholinergic system, but the impact of pain on this transition is not well understood. The goal of the current study was to determine whether tonic experimental pain impacts AR. We collected 128-channel high-density electroencephalography (HD-EEG) from a cohort of young healthy adults. Data was collected during 2.5-minute pseudo-randomized rest periods, that varied as a function of the presence/absence of a tonic pain eliciting stimulus and whether their eyes were open or closed. Bootstrap paired t-tests on globally averaged AR revealed no significant differences ($p = 0.07$) between resting (mean ± SD: 0.46 ± 0.54) and pain conditions (0.41 ± 0.54). However, pre-planned region of interest (ROI) analyses using FDR corrected bootstrap t-tests revealed a significant decrease in AR during tonic pain in the left and right frontal electrodes ($p < 0.05$), but not in left and right occipital electrodes ($p > 0.05$). Our observations show that there are regional specific changes in AR when an individual is experiencing tonic pain. Prolonged thermal stimulation diminishes the brain’s capacity to modulate from EC to EO resting conditions in frontal electrodes, consistent with the mu rhythm, but less so in occipital electrodes. Our findings are consistent with task-based EEG studies in chronic pain that show deficits in the modulation of power in response to task demands. Whether attenuated AR during resting states translates to individuals with chronic pain remains an open question.

Title: Attention modulates synesthetic V4 photism salience

Authors: *L. C. WILLIAMSON, S. A. BAILEY;
Psychology, Texas Lutheran Univ., Seguin, TX

Abstract: Synesthesia occurs when stimulation of one sensory system induces spontaneous experiences in two or more perceptual systems. Chromesthesia is a form of synesthesia wherein hearing music evokes visual sensations, or photisms. Prior literature does not indicate whether photisms are fixed or dynamic for a given inducer. Photisms may be linked to trauma flashbacks. Cortical region V4 is involved in processing visual stimulus features. Neuroscientists have been

inconsistent at measuring chromesthetic activation of brain tissue. There are no published data on synesthesia using functional near-infrared spectroscopy (fNIRS) to measure cortical oxygenation as an activity indicator. Non-synesthetes viewed greyscale and color versions of the same images, and fNIRS captured V4 activation for only the colored stimuli. A blindfolded chromesthete listened to music clips and rated photisms while being measured using fNIRS, and V4 oxygenation measurements corroborated consistent subjective ratings over six months. For the present study, a blindfolded, experimentally naïve chromesthete listened to six song clips over 18 trials. The participant was instructed to increase photisms for four of the clips, and to decrease photisms for two clips. The participant's V4 and frontal cortex were monitored using fNIRS. Photism ratings were recorded before and after the trials. The participant increased oxygenation in V4 for the four stimuli targeted for increase while forebrain remained inactive. For decrease trials, V4 remained mildly active but was coupled with markedly increased forebrain activation. The absolute values of the differences between the pre- and post-trial ratings for the two targeted decrease condition ratings were calculated and added to the associated pre-test values, permitting analysis using a correlated samples t-test. Results indicated statistically significant changes across the two ratings with all values having moved in the predicted directions. fNIRS instrumentation reliably captured chromesthetic V4 activity. Efforts to increase photisms with directed attention resulted in significant ratings changes and concomitant oxygenation changes in V4. Efforts to decrease photisms resulted in reported reduction in photisms, though fNIRS did not detect reductions in V4 activity. Increased activity away from V4 may be responsible for the sense that photisms were reduced. These results suggest that chromesthetes may be able to modulate their photisms through attention. This finding may hold promise for people with comorbid PTSD and chromesthesia.

Title: A ST3DIO to Bridging the Gap between Cutting Edge Neural Networks and High Throughput Behavior Pipelines

Authors: *J. M. ROACH[1], I. A. WEAVER[1], S. S. X. LIM[1], J. H. WU[1], J. A. RAVENEL[2], A. CHOUDHURY[1], A. ANSHUMAN[1], S. SINGH[1], B. C. SHIELDS[1], T. W. DUNN[1], M. R. TADROSS[1];
[1]Biomed. Engin., [2]Neurobio., Duke Univ., Durham, NC

Abstract: Cutting edge neural networks have demonstrated a robust ability to track the 3D kinematic behavior of freely behaving marker less mice. This enhancement in feature detection has allowed researches to uncover novel correlations between neural mechanisms and kinematic behavior. However the application of these technologies has been stifled by the difficulty of their implementation within high throughput behavior analysis pipeline. The expertise required to implement these technologies often requires dedicated person to develop a multi-view open field arena, implement the required software packages, and maintain the system. Lack of standardization between arenas prevents standardization between behavioral analysis pipelines. To bridge the gap between recent advancements in neural networks and high throughput behavior pipelines we developed the ST3DIO (Singe-camera Tracking 3-D Integrated Open field) platform. We use both hardware and software solutions to reduce setup time and fully automate the prediction pipeline. IR lighting illuminates the behavior chamber, providing consistent lighting conditions across our 5 occlusion fields of view. Mirrors to reduce system complexity and spatial foot print. Highly controlled lighting and background ensure that imaging conditions and animal experience remain identical between arenas. This further aids in minimizing network training for separate arenas. The software platform we developed leverages the hardware to automate the pipeline. Acquisition is performed using a built in GUI started with a desktop icon. Our system is integrated into Dropbox to distribute local computational tasks such as camera calibration across the computers in the behavioral arenas. A decentralized handler automates the predictions pipeline by parsing the Drobox server to submit unfinished predictions. This handler automatically performs cloud based transfers from the cloud storage to University clusters, starts and manages predictions processes, and automates transfers back to a cloud storage. The ST3DIO platform aims to create a one click solution from acquisition to key point prediction. The solutions with software design were meant to allow for developers to work within the platform. Logic for handling predictions using different networks is being implemented to allow for a streamlined addition of new networks. We are implementing software to keep track of which recordings were predicted given network(s) in our current dataset of over 5000 recordings. We aim to develop a high resolution high throughput platform for characterizing of models of disease such Parkinson's and Levodopa induced dyskinesia.

Abstract: Manipulating Matrigel Concentration to Enhance Neural Network Formation and Electrophysiological Characteristics in Mouse Cortical Neural Stem Cells
In recent times, there has been growing interest in utilizing in vitro neural networks derived from neural stem cells (NSCs) for a variety of applications. However, there remains a need to develop neural networks with specific electrophysiological characteristics. The differentiation and neural network formation of NSCs are influenced by various factors, including the extracellular microenvironment and growth factors. Of these factors, the material properties of the microenvironment impact NSC differentiation and migration, leading to distinct electrophysiological characteristics. Therefore, our study aimed to investigate the effect of Matrigel concentration on neural network formation and electrophysiological activities using mouse cortical NSCs. We cultured mouse cortical NSCs in Matrigel at a seeding density of 0.5M cells/cm^2. The NSCs were then subjected to three weeks of differentiation using different concentrations of Matrigel: low concentration (LC) at 6mg/ml and high concentration (HC) at 10mg/ml. We measured the material properties of each condition, including diffusivity, storage modulus, and loss modulus, through FRAP analysis, frequency sweep, and strain sweep tests. Immunofluorescent images were captured to assess neural outgrowth and branching in both conditions, and neurons were reconstructed using IMARIS neural tracing. Additionally, calcium flux imaging was performed to examine neural activities, including calcium flux rises and synchronicity. The results showed that the LC condition exhibited higher neurite outgrowth, but lower branching compared to the HC condition. The mean neurite length was 95.59um for the LC condition and 66.72um for the HC condition ($p<0.05$). The HC condition displayed a greater number of Sholl intersections across a broader range of distances from the soma, indicating higher branching order. Furthermore, the calcium flux imaging revealed that the HC condition exhibited greater synchronicity of calcium flux, despite similar calcium flux rises. Our study supports the hypothesis that a higher concentration of Matrigel culture substrate accelerates neural branching and the formation of neural networks, leading to more synchronized intracellular calcium flux activities. Further investigations are currently underway to determine the extracellular microenvironment factors that can cooperate with chemical factors for the rapid and efficient fabrication of neural networks that closely mimic in vivo neural networks.

Abstract: In past studies, we have shown that mammalian cortical and hippocampal cells respond to mechanical stimulation through shear stress and local indentation by exhibiting two distinct response types: transient and sustained. Transient responses resemble spontaneous neuronal activity, while sustained responses last several minutes. Micrometer-sized bead stimulations evoke transient responses at low forces/pressures and sustained responses at higher forces/pressures. Axons exhibit predominantly sustained responses, while dendrites respond transiently. A synchronized approach combining atomic force microscopy (AFM), microelectrode arrays (HD-MEA), and fluorescence microscopy enables precise mechanical characterization and stimulation of individual neurons, revealing that mechanical stiffness does not correlate with electrophysiological activity. Transient mechanical stimuli evoke action potentials propagating along neurons. Spontaneously active neurons exhibit functional resilience to static compression but modulation of firing rate with transient/repetitive compression. Molecular investigations highlight the role of viscoelastic parameters and membrane-cytoskeletal coupling in differential neuronal responses. These findings advance our understanding of mechanosensitivity in neurons and open avenues for further exploration.

Title: Homecage assessment of complex behavioral phenotypes in adolescent mice

Authors: *K. M. NAUTIYAL;
Dartmouth Col., Hanover, NH

Abstract: Adolescence is a complex period for neural development and behavioral maturation of reward-related phenotypes. It is also a high-risk period for the development of neuropsychiatric disorders, including those which involve impulsive and reward-related behavior. In rodents operant behavioral paradigms provide rich data sets which allow for the careful analysis of reward, impulsivity, motivation, and learning phenotypes that are of high interest during adolescence. However, there are major barriers to performing these studies with commercially available equipment in adolescent rodents. First, rodents are generally trained on task-specific paradigms for at least a month which is incompatible for assessment during a 2-3 week long adolescent period in mice. Additionally, appetitive paradigms usually require prolonged food restriction during training which is not ideal for the physical growth occurring during adolescence. In order to address these issues, we developed an Arduino-controlled automated homecage, inexpensive and open-source behavioral testing system. It allows for the implementation of most standard operant paradigms in the homecage of rodents in shorter time frames without food restriction, and with much less experimenter effort. All construction and code for the DIY Nautiyal Automated Modular Instrumental Conditioning (DIY-NAMIC) system are open source. We used this system to delineate the trajectory of adolescent development of impulsivity in mice with a focus on premature responding and delay discounting measures. Overall, the DIY-NAMIC system allows for the comprehensive assessment of adolescent behavior in mice across multi-faceted complex phenotypes and throughout the extent of adolescent development. This is important for the study of neural development and behavioral maturation during this important developmental period.

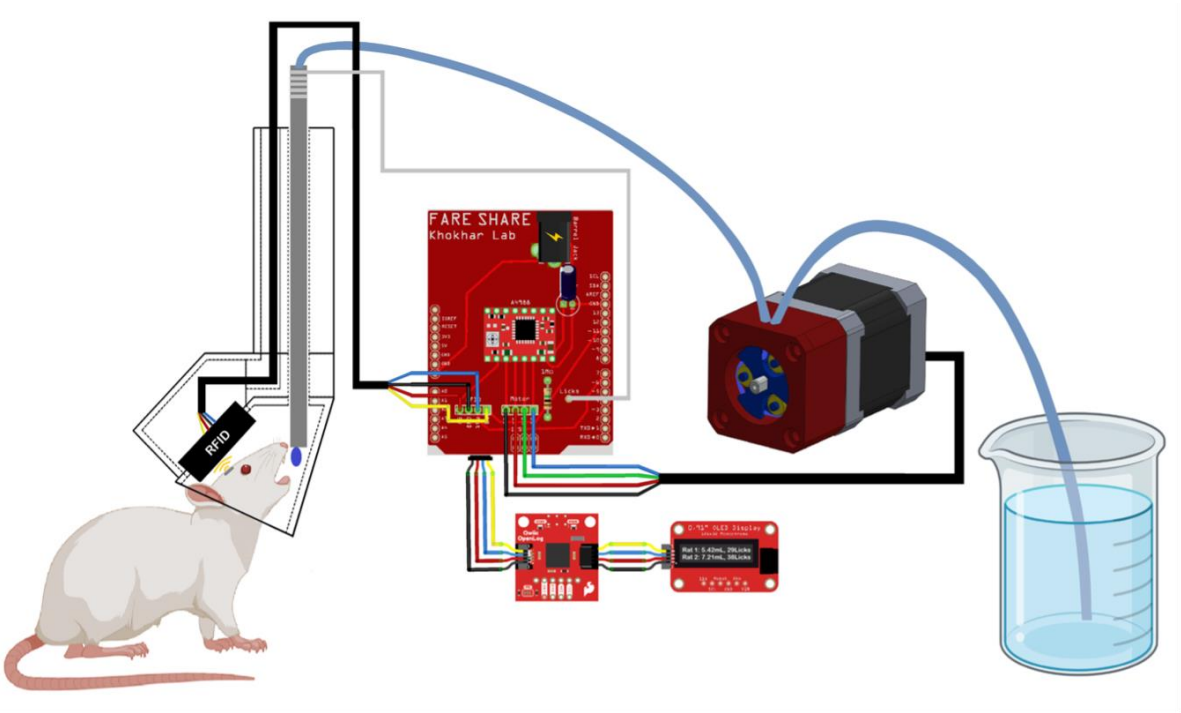
Title: An open-source device for measuring drinking microstructure in socially housed rats

Authors: *J. FRIE[1], J. Y. KHOKHAR[2];
[1]Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Anat. and Cell Biol., Western Univ., London, ON, Canada

Abstract:



Social factors have been shown to play a significant role in alcohol consumption. Studying the role of social context on alcohol drinking is important to understand the factors that contribute to initiation or maintenance of casual and problematic alcohol use. A large body of preclinical research has shown that social environment plays an important role in alcohol consumption and preference, though the extent of these effects have been obfuscated by methodological differences and technical challenges. Robust individual differences in alcohol intake in socially housed animals are difficult to track when animals share a common fluid source. Commercial solutions are prohibitively expensive and are limited by proprietary software and hardware. Here we describe an affordable, open-source solution for tracking fluid consumption in socially housed rats. The device uses RFID to identify rats, a lickometer to activate fluid delivery, a custom low-profile PCB that sits on top of an Arduino-based microcontroller, fluid delivery via custom peristaltic pump for accurate measurement of consumption volume, OLED display, and continuous data logging to an SD card. Here we validate our design via an alcohol two-bottle preference task. We use the data collected to determine fluid consumption, preference, and drinking microstructure of each of four rats housed in the same cage. Having a robust, affordable method for measuring drinking microstructure in socially housed animals will be of considerable use in preclinical addiction research and a step toward more translationally relevant animal models of fluid consumption. The added dimension of time allows for the analysis of circadian-linked consumption and the discrimination of continuous or binge-like drinking behaviours. Additionally, being open-source enables researchers to customize the device for more advanced applications such as sending signals to additional peripherals (e.g., optogenetic stimulation) or software on drinking initiation for time-locked or closed-loop interventions, manipulations, and measurements.

Title: Quantitative Balance Assessment with Wearable Pressure Insole in Patients with Brain Disorder

Authors: *W. CHANG, **J. LEE**, S. KIM, H. LEE, J. HWANG;
Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Introduction: Gait impairment can induce the risk of falls and reduced quality of life among survivors of brain disorder. Predicting outcome of gait function is critical to the treatment of patients with brain disorder. Although balance is a known predictor of independence of gait, the best tools for balance evaluation in patients with brain disorder are still under debate. Wearable pressure insoles can effectively collect data during a variety of activities and the wireless communication technology provides much more data acquisition. The objective of this study was to investigate the feasibility of the wearable pressure insoles to assess balance function in patients with brain disorder. **Methods:** We recruited total 48 patients with brain disorder (mean age 61.7±15.5 years, 14 females). NEUROGAIT Insole (SALTED Co., Ltd, Korea) was used for the balance assessment in this study. The coordinate system of the insoles was set up and used to calculate the center of plantar pressure (COP). Investigator guided each participant to perform functional reach test (FRT). The COP displacement and the shift speed of COP were calculated for analysis. The experiment should be repeated at least three times, the plantar pressure data of each experimental subject was recorded and the maximum COP displacement was taken as the analysis data. Trunk control test (TCT) was also performed in each participant to assess balance function. The feasibility of the proposed method with wearable pressure insoles was verified by comparing with the results obtained using the FRT and TCT. **Results:** There was no significant adverse effect such as falls during balance assessments. The pressure change curve was acquired from characteristic points of the insoles during FRT in all participants. Each parameter such as COP displacement in wearable pressure insoles was significantly correlated with FRT ($p<0.05$). However, there was no significantly correlation between parameters in wearable pressure insoles and TCT. **Conclusion:** These results demonstrated that the wearable pressure insoles might be used for quantitative balance assessment in patients with brain disorder. Further study with larger number of patients will be needed to clarify the useful additional balance assessment tool of the wearable pressure insoles in this study.

Title: Application of Focused Ultrasound to Macaque FEF Prior to Onset of Saccade Cue Elicits Neural Changes

Authors: *R. HAMPSON[1], M. R. RILEY[1], B. M. ROEDER[1], M. P. WEISAND[2], G. F. PINTON[3], A. O. BILIROGLU[3], F. Y. YAMANER[3], O. ORALKAN[3], P. M. CONNOLLY[2]; [1]Wake Forest Univ. Sch. of Med., Winston-Salem, NC; [2]Teledyne Scientific & Imaging, Research Triangle Park, NC; [3]NC State Univ., Raleigh, NC

Abstract: Low-intensity transcranial focused ultrasound (TFUS) is a promising method for non-invasive stimulation of brain tissue. TFUS has been used for neural stimulation in rodent, non-human primate, and human subjects. Herein we demonstrate TFUS stimulation that produces modulation of brain activity in the frontal eye field (FEF) while a macaque is performing a center-out task in which gaze fixation is followed by saccades to a left or right target.
In brief, we utilized a stationary transducer that provided 2.8 MHz pulsed TFUS to the FEF for 200 ms from a phased array of 4096 transducer elements. To dissociate TFUS-elicited and behavior-elicited neural signals, we stimulated 116 ms prior to a cue for the subject to saccade towards a left or right target. Local field potentials were recorded with multi-channel electrodes in FEF during task performance with sham or active stimulation.
Most importantly, we noticed that stimulation produced a sharp deviation of LFP signal as soon as stimulation started resulting in a higher level of activity following the saccade cue compared to non-stimulated trials. We were able to note that the signal reversed mid-way through the electrode shank, indicative that the stimulation-elicited neural activity was located near the FEF target and mid-way along the electrode shank. The neural activation was not observed when we stimulated with an air gap between the transducer and the surface of scalp or in sham trials.
These results indicate that TFUS stimulation can alter neural activity in a behaving primate. Additional work is underway to refine the parameters that are most effective in utilizing TFUS to influence neural signaling.

Abstract: Inducing a behavioral changes through activation of neural tissue is a key element in researching functions of brain regions. Brain activity in specific regions can be done invasively, for example, with electrode implantation or injected chemicals or viruses. We investigated the use of transcranial focused ultrasound (TFUS) to non-invasively stimulate brain regions. However, there remain many questions revolving around the properties of TFUS stimulation to influence behavior. Here, we report TFUS-elicited changes in a behaving nonhuman primate.
We delivered TFUS to the right frontal eye field (FEF) of a macaque performing a task requiring central gaze fixation followed by saccades to peripheral visual targets. In brief, we delivered 2.8 MHz pulsed TFUS to the FEF for 200 ms from a phased array of 4096 transducer elements. TFUS was targeted with phase delays calculated to correct for inhomogeneities from scalp, skull, and brain between transducer and the FEF target. TFUS was applied during central gaze fixation, 116 ms prior to the cue indicating the subject should saccade to left or right visual target locations.
We observed that TFUS induced a leftward bias of saccades compared to no stimulation trials. With stimulation nearly 10% more first saccades were leftward when the correct target was on the right side. In addition, there was a decrease in errant saccades toward the right target when the correct target was on the left. Finally, the median timing of saccades was slower in the stimulation condition compared to the non-stimulated trials.
Our results show that TFUS in our center-out task biased the saccade direction and the timing of the saccade. Additional work is underway to refine the parameters that are most efficacious in using TFUS to influence behavior.

Title: A cascade of binding and cell-based assays designed to characterize 5HT2A receptor ligands and aid the investigation of signaling pathway bias

Authors: *D. DALRYMPLE, L. GERRARD, J. KEWNEY, R. PRIHANDOKO, E. PARKER, G. CHAN, G. VREME, D. SMITH, I. MCPHEE;
SB Drug Discovery, Glasgow, United Kingdom

Abstract: Serotonergic psychedelics are substances which possess the ability to alter mood, perception and thought processes, with the serotonin (5-HT) 2A receptor subtype as their main pharmacological target. Psychedelics have been increasingly recognized for their potential therapeutic benefit however their investigation has been hampered due to possible adverse side effects such as disorientation, anxiety, hallucinations, seizures and even death.
5HT2A receptors have been proposed to signal via multiple intracellular signaling cascades, including the canonical Gαq-coupled pathway, resulting in calcium release from intracellular stores, and the β-arrestin pathway resulting in receptor internalization and desensitization as well as downstream signal transmission.
It has been suggested that ligands showing bias towards specific signaling pathways may allow separation of the desired therapeutic effect from any undesired side effects and offer the potential to develop effective ligands that can be used to target specific neuropathological conditions. A clearer understanding of the molecular mechanisms of 5HT2A ligands would help contribute to the development of therapeutic psychedelic-like compounds. To enable this, we have developed a cascade of in vitro binding and cell-based assays designed to identify and characterize 5HT2A receptor ligands in detail, allowing interrogation of receptor subtype selectivity and signaling pathway bias.
Cell-based assays measuring calcium mobilization, β-arrestin interaction, receptor internalization and pERK levels were developed and validated using a selection of standard reference compounds including psychedelic and non-psychedelic ligands. This panel of cell-based assays provides the basis for assessing compound effects on different signaling pathways and aids the discovery of ligands with preferential signaling bias.

Title: Simultaneous spatial evaluation of IDH1, EGFR, IGF1R and Ki67 biomarkers in glioblastoma

Authors: A. OLIVER, J. HAGEN, K. TRUEMAN, G. LELAND, ***A. KALYUZHNY**; Bio-Techne, Minneapolis, MN

Abstract: Each year about 14,000 people in the United States are diagnosed with glioblastoma (GBM), the most aggressive primary neuroepithelial tumor. Patients with GBM have a poor prognosis and only 5% of these patients can survive for more than 5 years. Various biomarkers are used for Immunohistochemical (IHC) diagnosis of GBM including: Isocitrate dehydrogenase 1 (IDH1), Epidermal Growth Factor Receptor (EGFR), Insulin Like Growth Factor 1 Receptor (IGF1R), and a cell proliferating marker Ki67. Typically, IHC is done by using a single-biomarker HRP-DAB detection technique which is not suitable for the simultaneous spatial analysis of multiple biomarkers. The aim of this study was to develop a multi-color immunofluorescence protocol allowing for the spatial biology analysis of distribution and co-localization of biomarkers in GBM tissues. Paraffin-embedded tissue sections were incubated with a mixture of the following primary antibodies: monoclonal mouse anti-human IDH1 (MAB7049), polyclonal goat anti-human EGFR (AF231), monoclonal mouse anti-human IGF1R (MAB391), and monoclonal rabbit anti Ki67 (MAB7617). For detection, we used species specific secondary antibodies conjugated to fluorescent dyes with different excitation and emission spectra. At the qualitative level, we have observed about 80% of cells with strong immunoreactivity for EGFR and IDH-1 whereas IGF-1R labeling was confined to about 50% of cells. Immunoreactivity for Ki67 was the lowest and detected in about 5% of cells. About 80% and 50% of EGFR positive cells were also immunoreactive for IDH-1 and IGF-1R respectively. All Ki67 labeled cells were also immunoreactive for EGFGR and IDH1R but only 50% of Ki67 positive cells were immunoreactive for IGF1R. We applied a spatial biology methodology for co-detection of multiple GBM biomarkers which allowed us to analyze their spatial distribution as well as the extent of colocalization at the single-cell level. Co-detection of multiple biomarkers has a strong diagnostic potential especially when analyzing limited small-size biopsies.

Title: Overexpressed cytokines in cancer stem cells of rat and human glioma cells

Authors: *H. SHIN, L. NELSON, D. CASADO;
Rivier Univ., Nashua, MA

Abstract: Glioblastoma (GBM) is the most malignant and invasive brain cancer, and the average survival time of the patients is limited to 15 months, despite deep understanding of its genomic mutations and advanced medical therapeutics. Recent studies revealed that a unique subpopulation of cancer stem cells (CSCs) is the major cause of resistance to radiotherapy and chemotherapy and its recurrence of GBM. We aimed to compare differential cytokine expressions of the CSCs versus differentiated cancer cells. To this end, we employed the C6 rat glioma cell line and U251MG human glioma cell line due to their overall abilities to simulate the high growth rate, the high vascularization, and the highly infiltrative characteristics of GBM. We successfully isolated CSCs from the main population of the cell lines by utilizing conventional neurosphere assays, and properties of these CSCs were confirmed with immuno-fluorescence staining for a typical CSC marker, SOX2. The expression of SOX2 was observed only in CSC spheroids but not in the adherent differentiated cells. We harvested media of CSC-spheroids for the cytokine array on various dates. Repeated cytokine arrays detected several cytokines overexpressed in CSCs-spheroids as compared to adherent cancer cells. In the future study we will target those up-regulated cytokines with compounds to find potential therapeutics.

Title: Development and assessment of BBB-crossing capsids for enhanced gene delivery to the brain

Authors: *B. P. HEITHOFF, E. FIRNBERG, S. YOST, S. CHO, T. NGUYEN, A. MERCER, O. DANOS, J. SMITH;
Res. and Early Develop., REGENXBIO, Inc., Rockville, VA

Abstract: The blood-brain barrier (BBB) is responsible for the poor transduction of the brain by adeno-associated viruses (AAVs) following intravenous (IV) delivery, which is less invasive than intracranial parenchymal injections that require surgery. To improve brain transduction using the IV route, we and others have recently developed new capsids targeting specific BBB receptors to promote crossing. Here we present data on a novel approach fusing Designed Ankyrin Repeat Proteins (DARPins) to the AAV capsid to imbue affinity for BBB receptors. To better understand the BBB crossing capabilities of these vectors, we developed a battery of tests to assess biodistribution across different brain regions and cell-type specific transduction, used to initially characterize AAV9 and PHP.eB vectors at multiple doses (1e13, 5e13, 1e14, 2e14 GC/kg) in C57BL/6 mice after IV administration. Peripheral tissues and left-brain hemispheres were analyzed via ddPCR to quantify vector DNA and transgene transcripts (RNA). We measured the luminance of the fluorescent transgene in right brain hemispheres and immunohistochemistry to assess expression across different cells and neuronal subtypes. Biodistribution in brain for PHP.eB was found to peak at ~8 GC/cell at both medium and high doses (5e13 and 1e14 GC/kg), while AAV9 continued to increase at each dose level, reaching a maximum of ~2 GC/cell at the highest dose (2e14 GC/kg). Biodistribution in liver showed ten-fold lower vector DNA for PHP.eB compared to AAV9 at all doses. PHP.eB brains showed higher fluorescent luminance in all groups compared to AAV9. Histology for PHP.eB tropism in the brain revealed that expression was strongest in striatum, thalamus, and hippocampus, milder in cortex, and weakest in cerebellum. Conversely, AAV9 expressed best in cortex and brainstem, but weaker in subcortex. PHP.eB and AAV9 both targeted astrocytes in cortex. However, in striatum, thalamus, and hippocampus, PHP.eB primarily expressed in neurons, while AAV9 largely expressed in astrocytes. Neither capsid expressed in midbrain dopamine neurons. These *in vivo* experiments show the current capabilities and limitations of targeting the brain via the BBB. To develop a novel therapeutic vehicle, we created our own BBB-crossing capsids fused with DARPins that have strong affinity to different receptors enriched in BBB vessels. Initial *in vitro* studies with our first generation capsids show up to 38-fold higher transduction of receptor-expressing cells compared to AAV9 and are viable in terms of manufacturing. These pilot data demonstrate the utility of this approach in generating a novel class of BBB-crossing capsids with therapeutic relevance.

Title: Whole-brain quantitative 3D imaging of robot-assisted intracerebral AAV delivery: A Light sheet fluorescence microscopy study in mice

Authors: *T. TOPILKO, A. PARKA, F. L. SØRENSEN, J. PERENS, C. G. SALINAS, A. H. R. THOMSEN, J. HECKSHER-SØRENSEN;
Gubra, Hørsholm, Denmark

Abstract: Gene therapy using adeno-associated virus (AAV) as a vector has emerged as a novel therapeutic modality that has the potential to improve outcomes of diseases with currently no effective interventions significantly. Adeno-associated viruses (AAVs) have emerged as powerful tools for targeted gene delivery in various diseases, including CNS disorders. Various AAV serotypes have been identified, each exhibiting distinct transduction efficiencies and cell tropism. Researchers can achieve targeted and efficient transgene expression in a desired cellular population by selecting the appropriate AAV serotype. In combination with AAV delivery of Cre recombinase, this genetic strategy enables the visualization of cells with high precision and intensity. Light sheet fluorescence microscopy (LSFM), together with tissue clearing, have revolutionized the field of neuroimaging by enabling 3D imaging of intact biological specimens at cellular resolution. One of the primary advantages of LSFM imaging is its ability to provide an unbiased sampling of viral transfection throughout the brain. Here, AAVs (AAV9-CAG-eGFP, AAV9-hSyn-Cre-eGFP) were characterized in wildtype and Cre-tdTomato mice as visualized and quantified by LSFM coupled with deep learning computational analysis. To minimize human error and improve consistency, we used precise injections of AAVs, using the Neurostar stereotaxic robot, enabling precise injection of AAVs to CNS anatomical targets typically used in gene therapy (i.e., the ventricular system, hippocampus, entorhinal cortex, substantia nigra). We found that intracerebroventricular AAV injections resulted in widespread transfection of cells, notably in cerebellar Purkinje cells. On the contrary, intraparenchymal AAV injections labeled a local population of cells around the injection site. By harnessing the advantages of combined LSFM imaging-deep learning, we demonstrate how this unique pipeline enables whole-brain high-resolution visualization and quantification of fluorescently-labeled cells and AAV transduction patterns in preclinical gene therapy development.

Title: Design of an IQSEC2 minigene for AAV gene therapy

Authors: *A. LEVY[1], **V. BORISOV**[1], N. LEVY[1], M. SHOKHEN[2];
[1]Technion Israel Inst. of Technol., Haifa, Israel; [2]Bar Ilan, Tel Aviv, Israel

Abstract: Mutations in *IQSEC2* account for ~2-5% of children presenting with seizures, severe intellectual disability and ASD. Adeno-associated virus (AAV) is a promising means to perform gene therapy for CNS genetic disorders. However, a major limitation of AAV is the size of the gene that can be used. The *IQSEC2* open reading frame (ORF) far exceeds these limits. In order to design a reduced IQSEC2 ORF we modeled the wild type (WT) IQSEC2 protein and how its Sec 7 catalytic activity for ARF6 is allosterically regulated by the binding of apocalmodulin (ApoCM) to the IQ domain of IQSEC2. A structural model of IQSEC2 was prepared using the RaptorX server combined with molecular dynamics (MD) simulations. Our model suggests that when apoCM is bound to the IQ region, the N-terminal coiled coil domain pivots around a glycine hinge to interact with the Sec7 region, thereby blocking the accessibility of the Sec7 region to ARF6 and inhibiting the Guanine nucleotide exchange factor (GEF) activity of IQSEC2. However, Ca+2 binding to ApoCM destabilizes its binding to the IQ region of IQSEC2. With apoCM no longer bound to IQSEC2 the N-terminal fragment pivots away from the Sec7 region allowing free access of the Sec7 region to ARF6 and activation of the GEF activity of IQSEC2. We identified two regions of IQSEC2, one between the N-terminal region and the IQ apoCM binding region, and another between the IQ apoCM binding region and the Sec7 coding domain, which were structurally disordered and for which no function is known. After deletion of these fragments, we connected the amino acids bordering the deleted region using short flexible glycine loops. We demonstrate using MD that the stability of this IQSEC2 miniprotein and the thermodynamic stability of its protein-protein interactions with Arf6, apoCM and PSD95 are identical to that of the WT IQSEC2 protein. Moreover, as with the WT IQSEC2 protein we observed that when apoCM was bound to the miniprotein the N-terminal region interacted with the Sec7 region. When apoCM dissociated from the miniprotein the N-terminal region pivoted away from the Sec7 domain, thus showing an identical molecular regulatory mechanism for both the minigene and the WT protein. Using the Lumier protein-protein binding assay, the association of the IQSEC2 miniprotein with itself, CM, PSD95 and IRSp53 was comparable to that of the WT IQSEC. Future studies will evaluate whether the IQSEC2 minigene delivered by an AAV will rescue mice with IQSEC2 mutations.

Title: In utero systemic administration of engineered and natural rAAV serotypes reveals diverse expression profiles in fetal mouse brain.

Authors: *C. R. JACKSON[1], M. BORSOS[2], V. GRADINARU[3];
[1]Neurobio., [3]Biol. and Biol. Engin., [2]Caltech, Pasadena, CA

Abstract: In utero gene therapy (IUGT) holds promise for addressing disorders in the developing embryo and early intervention is particularly important for neurodevelopmental disorders. Recent technological advances have enabled genetic access to the mouse fetus as early as embryonic day 15 (E15), by injecting recombinant adeno-associated viruses (rAAVs) into the fetal circulation. rAAVs are well tolerated by the immature fetal immune system and their non-integrating cargo can be customized to deliver transgenes for functional protein expression, gene regulatory elements, and editing constructs. However, there are substantial challenges to overcome in enabling effective and safe genetic intervention during early developmental stages. Prenatal rAAV systemic delivery leads to ectopic organ transduction and low expression in the fetal brain, limiting the technology to treatment of multi-organ disease states. We set out to identify rAAV variants with reduced off-target organ transduction and develop delivery technologies for early systemic access using the developing mouse embryo as a model. To characterize genetic intervention at an even earlier developmental time point than previously reported, we used a delivery method for systemic access to the mouse embryo as early as embryonic day 12 (E12), when the fetus is roughly 30% the biomass of E15. We injected Ai14-TdTomato reporter mice with an AAV9 virus encoding a Cre-recombinase and eGFP linked by a P2A self-cleaving peptide, allowing us to identify cells that are currently transduced as well as those whose ancestors are transduced. E12 injected embryos when assessed at E18 showed broad neuronal coverage of the CNS and high expression in the periphery, when compared to E15 injected embryos. These results indicate that gene manipulation in the E12 embryo with rAAV has potential for high efficiency gene editing in the brain, but is lacking in organ specificity.To build a specialized toolbox for systemic delivery to the embryo brain, we compared the transduction profiles of seven rAAV capsids systemically injected into E15 mouse fetuses. In choosing capsids, we focused on a diverse array of natural serotypes, published brain-biased capsids, and unpublished capsids that have shown diverse transduction profiles. Using bulk DNA and RNA sequencing across tissues, we identified the rAAV capsids with the highest brain transduction and lowest ectopic organ expression to be used as a parent serotype in a capsid evolution library. Integrating capsid screening and gene regulatory elements with early systemic delivery can open the path to targeted, efficient, in utero gene therapy in mammalian disease models.

Title: Single-cell-resolution optogenetics for vision restoration

Authors: *P. RAMAKRISHNA, O. A. SHEMESH;
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Optogenetics has become a popular experimental strategy for vision restoration in blindness-causing retinal diseases, which result from either a loss of rods, cones or retinal pigment epithelium. However, conventional optogenetics has had limited success in achieving high-acuity vision restoration, with the acuity of vision restored in non-human primates only reaching up to 20/249. This is because conventional optogenetic molecules (opsins) were expressed in neurons that extensively overlapped surrounding neurons and led to significant cross-activation. This multicellular photo-stimulation translated to low-acuity vision restoration. To address this issue, we have developed novel opsins that enable single-cell-resolution optogenetics in the retina. By achieving single-cell optogenetic resolution, these molecules can potentially support an improved acuity of vision restoration for retinal diseases. These may include retinitis pigmentosa, macular degeneration, and diabetic retinopathy.

Title: Autohcs: automated ai-based scoring of dose-response high-content neuroprotectant screens.

Authors: *T. FINDLEY, H. DODKINS, J. DELANEY, I. GOLDBERG;
ViQi Inc, Santa Barbara, CA

Abstract: As the process of drug discovery scales rapidly, so does our ability to quickly and robustly identify novel neuroprotectants. These compounds have broad-reaching applications, namely the reduction or elimination of the degenerative effects of stroke, neurological disease, or medical treatments like chemotherapy. Such drug development increasingly depends on high-content compound screens where automation is the key to rapid, impactful discoveries. AutoHCS^{TM} is an AI-based system developed by ViQi Inc. that automatically detects and scores dose-dependent phenotypic responses to drugs in high-content screens. The only inputs to the analysis are images from any automated plate imager and a plate map specifying concentrations, replicates, and controls. Because the system does not depend on segmentation, it works non-parametrically with multichannel fluorescence, a combination of fluorescence and brightfield, or brightfield alone. With these inputs, AIs are trained by AutoHCS to score cellular responses to compound concentration within hours. Depending on researcher needs, results can include comparing phenotype across the dosages of each single compound, identifying the location of a compound in phenotypic space in relation to positive and negative controls, and mapping all compounds across phenotypic space in relation to one another. Among other pilot screens, AutoHCS was successfully run on a neuroprotectant screen provided by Anatomic Incorporated. Here, human induced pluripotent stem cell (hiPSC) derived sensory neurons were introduced to several compounds found in chemotherapy treatments that cause degeneration. Our analysis found that, when neurons were pretreated with the neural protectant SARM1 inhibitor DSRM-3716, the harmful phenotypes induced by these compounds were significantly lessened. This analysis from data upload to full report took less than a day. AutoHCS entirely determines its training parameters using experimental controls rather than user input, which eliminates subjective criteria selection that may bias phenotype scoring. This also makes it both user-friendly and extremely flexible to researcher needs. AutoHCS directly addresses the need for automation, objectivity, speed, and versatility in neuroprotectant research and development.

Title: Large-scale validation of open-source monoclonal antibodies geared toward generating a comprehensive whole brain 3D atlas of molecular targets

Authors: *K. THIRTAMARA, K. BOWYER, A. MALIK, V. SAXENA, A. SHIPMAN, J. XU, W. WANG, Z. WU;
Weill Cornell Med., New York, NY

Abstract: Lack of reliable and reproducible antibodies are a serious financial drain on research dollars in addition to wasted time and effort in generating unreliable and non-reproducible data. Only a subset of commercially available antibodies has been validated to recognize their intended targets. A large number of them are polyclonal antibodies that are not renewable to support desired reproducibility in large-scale and long-term applications. Monoclonal antibodies (mAb) on the other hand can offer more consistency and are also better suited for quantitative analysis. Furthermore, amino acid sequence of reliable mAbs can be defined and used to generate recombinant versions with the same epitope recognition regions, which in turn can lead to greater adoption, lowered costs and address ethical challenges of using animals in antibody production. Despite decades of community effort in producing and distributing mAb resources, their use is still limited by availability and lack of systemic validation in defined applications across different species. We are leading concerted effort to screen and validate mAb resources from both commercial vendors, as well as the libraries generated through partners (Addgene, NeuroMab, JHU/CDI) funded by National Institutes of Health, for robust immunolabeling application. Our goals are 3-fold. First, to generate a comprehensive and openly accessible mAb resource for the neuroscience community. Second, to extend the validation of these mAbs beyond mouse brain tissue and include both non-human primate and the human brain. Third, to scale the use of validated mAbs for whole mount labeling for both mouse and human tissue in order to generate a comprehensive 3D brain proteomic atlas cross species. 3D whole mount labeling on cleared brains (and other organs) presents a unique tool to study spatial distribution of different cell types as well as a platform to reliably perform quantitative marker analysis through the use of validated monoclonal antibodies. We have established a validation pipeline for immunolabeling compatible with advanced tissue clearing and labeling, and following initial validation screened over 100 antibodies on mouse and human brain samples from Addgene's collection of recombinant monoclonal antibodies. We have made this resource available on our own website (https://mab3d-atlas.com/) and shared it with our partners (Addgene) (https://www.addgene.org/antibodies/all/) complete with protocol information as well as high quality images. As we continue to screen more mAbs and curate the validated mAb 3D atlas, we aim to turn this into a comprehensive and open-source platform for the larger neuroscience community.

Title: Development of robust iPSC platforms for accurate predictions of efficacy and toxicity of new treatment modalities early in the development pipeline

Authors: *J. KOEPKE;
Ncardia Services B.V., Leiden, Netherlands

Abstract: With the discovery of induced pluripotent stem cells (iPSCs) by Shinya Yamanaka in 2006, iPSCs have become a powerful tool for drug discovery. A new era of nucleotide-based therapeutics offer a huge potential to specifically modulate cellular pathways in ways not previously possible. One example of such modality are Antisense Oligonucleotides (ASOs). ASOs are single-stranded nucleotides designed to bind complementary RNA targets which leads to reduced protein expression trough either RNA cleavage, altering splicing or blockage of translation. To enable cost effective screening in patient derived iPSC cells for ASO candidate identification and validation, we developed and optimized a scalable protocol for the differentiation of iPSCs to cortical neurons in sufficient quantities to support the various stages of the drug discovery process. Furthermore, we established an high throughput in vitro assay in 384-well format to study the effects ASOs on target gene knockdown in a fully automated setting which allows for fast and cost-efficient selection of preclinical candidates. During assay development, we tested two RT-qPCR kits and selected one based on PCR performance: assay linearity and curve fit, target and normalizer amplification efficiency and feasibility of multiplexing. Automation of all steps of the assay enabled the development of a highly robust assay with inter-plate variation (%CV) between technical and biological replicates being less than 5% CV. With ASOs being increasingly used to treat central nervous systems (CNS) disorders, neuronal toxicity is of major concern, primarily driven by neuronal toxicity and/or neuroinflammation. A recent publication has demonstrated that ASO-induced reduction in frequency and amplitude of calcium spikes are predictive of in-vivo acute neurotoxicity [Hagedorn PH et al, Nucleic Acid Ther. 2022 Jun;32(3):151-162]. Being able to predict acute side effects early in the drug development process, not only facilitates the confident selection of candidates with higher chances of success in preclinical and clinical stages, it also supports lead optimization to reduce toxicity which overall saves time and resources. To further aid, prioritize and optimize drug candidates and we developed iPSC-CNS cultures (a co-culture of different neuronal subtypes and astrocytes) in which we established an in vitro assay in 384-well plate format to detect changes in calcium transients. In conclusion, we developed two custom assays using stem cell-derived neuronal cell models which support drug developers during their mission throughout various stages of drug development while reducing the use of laboratory animals.

Title: Discovery of PSG07 for chemogenetic research: a candidate ultrapotent PSAM^4 actuator and PET reporter probe

Authors: S. NERELLA[1], S. TELU[1], J.-S. LIOW[1], S. ZOGHBI[1], J. GOMEZ[2], M. MICHAELIDES[2], C. MAGNUS[3], S. STERNSON[3], B. RICHMOND[4], *M. ELDRIDGE[4], V. W. PIKE[1], R. B. INNIS[1];
[1]Mol. Imaging Branch, NIMH, NIH, Bethesda, MD; [2]NIDA, NIH, Baltimore, MD; [3]Dept. of Neurosciences, Univ. of California, San Diego, CA; [4]NIMH, Bethesda, MD

Abstract: Chemogenetic technologies with expression targeted to specific neuronal populations are emerging as potential treatments for neuropsychiatric and neurological disorders. Chemogenetic tools have been widely used to prove a causal link between specific neural circuits and behavior in small animals. To apply these techniques to non-human primates, however, post-mortem analysis has been required to evaluate the location and expression of constructs, making such work expensive and logistically difficult. PET imaging monitors the initial and longitudinal expression of chemogenetic receptors non-invasively. This type of monitoring could be very valuable for the application of gene-delivery techniques to long-term behavioral studies and in clinical settings. The 'PSAM-PSEM' system is an example of such a technology. Pharmacologically Selective Actuator Modules (PSAMs) are chimeric ligand-gated ion channels. They comprise a modified α7 nicotinic acetylcholine receptor (α7-nAChR) ligand-binding domain coupled to either an excitatory 5-HT$_3$ receptor (PSAM-5HT$_3$) or an inhibitory glycine receptor (PSAM-GlyR). Pharmacologically Selective Effector Molecules (PSEMs) are small-molecule agonists that are intended to bind selectively with PSAMs [1]. The triple mutant PSAM ($\alpha7^{L131G,Q139L,Y217F}$, denoted PSAM^4) can be activated with varenicline. However, varenicline binds endogenous receptor and is not selective solely for PSAM^4. Further optimization of varenicline's structure resulted in four ultrapotent Pharmacologically Selective Effector Molecules (uPSEMs) (*e.g.*, uPSEM792; K_i, 0.7 nM, [2]). uPSEM 792 is selective for PSAM^4-GlyR over other endogenous receptors, except α4β2 nAChR. We labeled uPSEM792 with carbon-11 ($t_{1/2}$ = 20.4 min) as a candidate radioligand for monitoring PSAM^4-GlyR expression in animals with PET. However, we found [^{11}C]uPSEM792 to be limited as a tracer by high polarity that likely reduced brain entry. Through a medicinal chemistry campaign based on uPSEM792 as lead, we discovered PSG07 as a much less polar PSEM but with high-affinity for PSAM^4-GlyR (K_i, 4.6 nM) and also amenable for labeling with fluorine-18 ($t_{1/2}$, 110 min). Voltage sensitive FLIPR dye assay showed PSG07 to be a PSAM^4-GlyR agonist with α7-nAChR/uPSAM selectivity comparable to that of uPSEM792. We prepared an iodonium ylide precursor of

PSG07 for ^{18}F-labeling and obtained [^{18}F]PSG-07 in useful yields. [^{18}F]PSG07 showed good brain uptake and 27% higher uptake of radioactivity at the target site in a PSAM^4-GlyR monkey. PSG07 shows potential as a brain-penetrant PSAM^4 actuator and [^{18}F]PSG-07 as a PET reporter probe, with further characterization in progress.

Title: A reproducible and quantitative capillary electrophoresis immunoassay for eNOS protein expression measurements directly in human brain tissue homogenates

Authors: P. JOSHI, F. RAMIREZ, **M. MILICI**, C. HAITJEMA, I. EUGENIS, *K. GARDNER, C. HEGER;
Bio-Techne, San Jose, CA

Abstract: Detailed proteomic characterization of human brain tissue is needed to identify potential novel biomarkers and drug targets for a variety of neurological diseases. The enzyme-linked immunosorbent assay (ELISA) offers quantitative protein expression measurements with high specificity and sensitivity. However, ELISA is challenged by brain tissue samples, which can have significant interference by matrix effects due to the high content of lipids and lipoproteins, as well as sheer protein intricacy that results from the brain's complexity. As a result, ELISAs for studying protein biomarkers of neurological diseases are limited primarily to peripheral blood and CSF samples.
Here, we developed a capillary electrophoresis immunoassay (CE immunoassay) for measuring a biomarker of the cerebrovascular system, eNOS, directly in human brain whole tissue homogenates. We show that the size-based separation provided by the CE immunoassay identified differential expression of eNOS isoforms in brain tissue compared to cultured endothelial and cervical cancer cells which could not be detected by ELISA. Compared to a commercial ELISA kit, the CE immunoassay demonstrated increased sensitivity and dynamic range of detection. Furthermore, differences in tissue homogenization and storage buffer conditions impacted the ability of ELISA to detect eNOS in brain tissue samples but had no observable effect on the CE immunoassay. Finally, the CE immunoassay consumed less brain tissue for analysis, needing only 3 µL of homogenate compared to 50 µL for ELISA. Because the CE immunoassay requires only one target-validated antibody for detection, we anticipate that the CE immunoassay will enable the analysis of additional protein biomarkers in brain tissue samples that historically have been challenging to detect by traditional ELISAs.

Title: Phenotypic screening using waveform analysis of synchronized calcium oscillations in primary cortical cultures

Authors: ***R. SAKAGUCHI**[1], S. NAKAMURA[2], H. IHA[3], M. TANAKA[4];
[1]Dept. of Lead Discovery Research, New Drug Res. Div., Otsuka Pharmaceut. Co Ltd, Tokushima, Japan; [2]Dept. of Res. Management, New Drug Res. Div., [3]Office of Bioinformatics, Dept. of Drug Discovery Strategy, New Drug Res. Div., Otsuka Pharmaceut. Co., Ltd., Minoh-shi, Japan; [4]Dept. of Lead Discovery Research, New Drug Res. Div., Otsuka Pharmaceut. Co., Ltd., Tokushima, Japan

Abstract: At present, *in vitro* phenotypic screening methods are widely used for drug discovery. Fluorescence measurements of calcium oscillations in neurons are commonly used for measurement of neuronal activities, and some drugs have been evaluated using this assay technique. Here, we have developed a high-throughput screening system containing a new analysis method for quantifying waveforms, and our method has successfully enabled simultaneous measurement of calcium oscillations in a 96-well plate. Features of waveforms were extracted automatically and allowed the characterization of some anti-epileptic drugs using principal component analysis. Moreover, we have shown that trajectories in accordance with the concentrations of drugs in principal component analysis plots were unique to the mechanism of drugs. Finally, we successfully scaled up this method to 384-well plates to evaluate compounds which have other indications or mechanism of actions. We believe that an approach that focuses on the features of calcium oscillations will lead to better understanding of the characteristics of existing drugs and allow to predict the mechanism of actions of novel drug candidates.

Title: Nu-Serum™: A superior media supplement for SH-SY5Y cell culture

Authors: *Z. B. KAYA[1], V. SANTIAGO-PADILLA[2], P. MCLEAN[1];
[1]Mayo Clin., Jacksonville, FL; [2]Univ. of Puerto Rico, San Juan, Puerto Rico

Abstract: Understanding the underlying mechanisms of neurological diseases is crucial for developing effective treatments and potential cures. Studies aimed at unraveling complex interactions between genetic, molecular, and environmental factors often focus on key pathological cellular processes with in vitro cell culture experiments playing a vital role in advancing our understanding of these diseases. Neuronal cell lines are invaluable tools because they can mimic the properties and behaviors of cells of neuronal origin. The SH-SY5Y human neuroblastoma cell line is one of the most widely used cellular models. SH-SY5Y cells can be differentiated into neurons and offer the advantage of studying impaired dopamine metabolism and other pathologies. However, these cells are extremely sensitive, and proliferation rates tend to be slow. Typical culture conditions involve DMEM F12 + 10% Fetal Bovine Serum (FBS). Herein, we performed a study to evaluate the utility of serum alternatives to test the hypothesis that an alternative serum supplement will aid and promote SH-SY5Y cell proliferation and differentiation when compared to traditional serum. Nu-Serum (NuS) is a low-protein alternative for newborn calf and fetal bovine sera. To compare the effect of NuS to FBS SH-SY5Y cells were cultured in DMEM F12 +10% FBS, DMEM F12 + 10% NuS, or serum-free (SF) conditions. Cell counting, cell size, and viability were evaluated by automated cell counter on days 2, 4, and 6 of culturing (n=6) and cell proliferation measurements were assessed by WST-1 assay on days 1 through 6 (n=8). Cells were observed under a brightfield microscope each day and imaged on days 2, 4, and 6. Cells were observed to develop neuron-like morphology faster in the NuS-treated group. Higher cell numbers were detected in the NuS-treated group, compared to the FBS-treated group (day 6 cell number $p=0.017$) and the SF-treated group (day 6 cell number $p<0.0001$). Both sera treated groups showed higher viability, but only NuS-treated group had significantly larger cell size compared SF-treated group. Cell proliferation was higher in the

NuS-treated group compared to FBS-treated ($p<0.0001$) and SF-treated groups ($p<0.0001$). Our data support NuS as a suitable serum alternative for SH-SY5Y cell culture. Overall, NuS offers an advantage with improved cell proliferation, viability, and morphology. Adjustments to cell culture protocols for this cell line may yield better cell health and positively influence the quality of research, especially in the neuroscience field.

Title: Novel platforms to investigate Central Nervous System diseases for discovery purposes

Authors: M. BSIBSI[1], M. ZANELLA[1], B. TORROBA[1], M. DA SILVA[1], *L. RITSMA[1], D. MAGNANI[2], M. IOVINO[2], R. REDIS[1], M. HERVA MOYANO[2], L. BUTI[1], M. VLAMING[1]; [1]Charles River Lab., Leiden, Netherlands; [2]Charles River Lab., Saffron Walden, United Kingdom

Abstract: Robust, reproducible and upscalableplatforms to discover and develop disease modifiers for Central Nervous System(CNS) diseases, in high throughput formats, are urgently needed. In recentyears, significant advances in technology, particularly in the areas of 2D and3D stem cell research and gene/RNA editing, have translated into newopportunities to better understand brain diseases. Applying them within a drugdiscovery setting enables discovery of potential treatments on the mostrelevant cell models.Both induced pluripotent stem cells (iPSCs)and organoids represent promising resources for modeling CNS diseases. iPSCshave the ability to differentiate into various CNS cells and can be used togenerate patient-specific neurons or glial cells either as single cell typesor, with increasing complexity, in co-cultures. Organoids offer athree-dimensional representation of the brain, enabling the investigation ofCNS development and architecture, connectivity, and function; thus, allowing toclosely mimic in vivo conditions.Our recent results confirm thatiPSC-derived neurons and microglia are indeed a robust platform to studyneurodegenerative disorders, such as Amyotrophic lateral sclerosis (ALS) andAlzheimer's Disease (AD). First, we showed that these models possessphenotypical and functional properties similar to what observed in the humanbody, including electrical activity (neurons) and cytokine release (microglia).Next, we observed that some of these properties differed between healthy anddiseased cell lines and mimicked pathological conditions, for example a reducedneural firing activity in neurons with mutations in key ALS causative genes. Inaddition, we successfully applied the antisense oligonucleotide (ASO)technology in iPSC-derived neurons, by reducing the overexpression of genesresponsible for Dup15q Syndrome.Finally, we investigated the presence ofmultiple cell types (neurons, astrocytes, microglia and oligodendrocytes) in abrain 3D model, through immunostaining of canonical

markers and high resolutionconfocal imaging.Takentogether, these platforms and associated assays can help identify noveltherapeutic targets and improve our understanding of disease mechanisms, withthe ultimate goal of establishing effective treatments for CNS diseases.

Title: A Web Application for Identifying Critical Protein Regions from Human Genetics Data

Authors: *A. W. LEHR, K. W. ROCHE;
Neurosci., NINDS, Bethesda, MD

Abstract: The increased availability of human genomic sequencing data has allowed for the association of genetic variations to disease. With large genetic heterogeneity in the human population, it is important to understand which residues/domains of human genes are tolerant or intolerant to variation. A disproportionate number of mutations in synaptic proteins have been implicated in neurological disorders such as autism spectrum disorder, schizophrenia, and epilepsy. Historically, neurological disease variant studies relied on finding patient mutations and characterizing how the mutation disrupted the protein (i.e., trafficking deficits, disrupting protein-protein interactions, and affecting post-translational modification sites). With a recent abundance of human genetic variant data, of both unaffected and neurologically impacted individuals, we can use low-powered statistics to determine critical regions of proteins and predict functional impacts of mutations.
We have developed a website that generates variant alignment graphics that display the location of variants in both unimpacted and impacted populations along a single protein domain map. Our program automatically pulls variants from ClinVar, an aggregated database of human genomic variants maintained by NCBI, as well as from gnomAD, an exome and genome sequencing database from unimpacted individuals maintained by the Broad Institute. These charts are then aligned to a functional domain map of the protein, allowing the user to map loci of variants along the protein alignment. Equipped with these data, we have developed an algorithm that compares loci of variants in unimpacted populations versus impacted populations, revealing protein regions that are significantly enriched with disease-associated variants and *in absentia* of unimpacted population variation. Users can enter a gene of interest and examine clusters of disease-associated variants and unimpacted-population variants to determine critical residues/regions/domains in the gene of interest to inform hypothesis generation. Additional filtering tools sort by disease, mutation type, and hetero/homo/hemizygosity to glean specific

insights into the impacts of various mutations. Our website is now publicly available at [comparagene.com].
With additional publicly available resources such as Protein Data Bank and AlphaFold providing models of protein structure, we can corroborate critical regions by comparing human genomic data to the protein structure, and even overlay deleterious mutations onto our structures to create predictive models of impacted protein structures.

Title: Improved Alzheimer's Disease diagnosis with structural brain MRI using 3D deep learning architectures and knowledge transfer across domains

Authors: *N. DHINAGAR, A. SINGH, S. OZARKAR, K. BUWA, S. THOMOPOULOS, E. LALTOO, P. THOMPSON;
USC, Los Angeles, CA

Abstract: According to the Center for Disease Control and Prevention, 5.8 million people were living with Alzheimer’s disease (AD) in the U.S. alone during 2020 - a number expected to increase threefold by 2060. Artificial intelligence (AI) methods have recently shown vast progress for healthcare applications as well as neuroscience research. In this work, we demonstrate performance improvements in AD diagnosis based on 3D T1-weighted brain MRI scans (T1w), using novel 3D deep learning architectures pre-trained using diverse strategies known as transfer learning. We studied a total of 4,098 T1w from 1,188 participants in Alzheimer’s Disease Neuroimaging Initiative (ADNI) - ADNI1, GO, 2 - (55.7-92.8 years, 418F/461M) for AD classification; data was respectively split into 2577, 302, and 1,219 T1w for training, validation and testing sets, with unique subjects restricted to a specific fold, thus avoiding data leakage given repeat scans. We used 600 T1w (43.5-97.0 years, 341F/359M) from the Open Access Series of Imaging Studies (OASIS) as an out-of-distribution test dataset. The pre-training data included 38,703 T1w (44.58-82.75 years, 20,216F/18,487M) from the UK Biobank (UKBB), 100,000 (44-82 years, 50,123F/49,877M) synthetic T1w generated using a Latent Diffusion model (LDM) trained on UKBB and Kinetics-400, a publicly available dataset with 276,708 separate videos. The use of natural videos and synthetically generated data to pretrain 3D models are emerging transfer learning techniques to natively learn generic features for computer vision tasks based on large-scale data. For our experiments, we used the SwinT vision transformer, DenseNet121 convolutional neural network (CNN), MiNiT Transformer, and

Tiny-DenseNet CNN. The SwinT, MiNiT, TinyDenseNet and DenseNet121 trained from scratch respectively achieved test ROC-AUC of 0.8498, 0.8497, 0.8852, 0.8940 on ADNI, and 0.8327, 0.8130, 0.8348, 0.8158 on OASIS. The SwinT pre-trained on Kinetics-400 boosted the test ROC-AUC to 0.9235 (+7.4%) on ADNI and to 0.8501 (+1.7%) on OASIS. The DenseNet121 pre-trained on LDM, ADNI (self-pretraining), UKBB with contrastive learning weakly-supervised by age, achieved a test ROC-AUC of 0.8916, 0.9006 (+0.7%), and 0.9159 (+2.2%) on ADNI and test ROC-AUC of 0.8194 (+0.3%), 0.8175 (+0.2%), and 0.8409 (+2.5%) on OASIS, respectively. Our results show that pre-training with large scale datasets, i.e., UKBB for the DenseNet121 CNN and Kinetics-400 for the SwinT, yields an improvement in AD diagnostic accuracy. The pre-training pipelines proposed here could provide an initialization for training AI models for neuroimaging tasks with limited data and data heterogeneity.

Title: Emergence of Fronto-Cerebellar Connectivity During Infancy

Authors: W. LYU[1], K.-H. THUNG[1], L. WANG[1], W. LIN[1], S. AHMAD[1], ***P.-T. YAP**[2];
[1]Dept. of Radiology, [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: Although the cerebellum is widely recognized for its involvement in motor and non-motor functions, the timing and extent of its involvement in motor and higher cognitive functions during early development remain unclear. Here, we show evidence of the emergence of fronto-cerebellar connectivity between birth and 5 years of age using functional MRI data acquired from 285 children (M/F:137/148).
Using independent component analysis, we identified the spatial maps of 5 networks that are associated with the frontal lobe. Using the AAL template, we then investigated the connection strength to these 5 frontal networks in cerebral regions consisting of the bilateral precentral area, supplementary motor area, superior frontal gyrus, middle frontal gyrus, inferior frontal gyrus and in cerebellar regions consisting of the bilateral Lobule III, Lobule IV-V, Lobule VI, Crus I, and Crus II.
We found that the connections between the cerebral regions and the frontal networks peak between 9 and 18 months. Additionally, we discovered that the frontal network exhibits stronger connections with Lobule VI, Crus I, and Crus II, which are believed to be involved in higher

cognitive functions, compared with Lobule III and Lobule IV-V, which are associated with motor functions. This pattern is already evident in the first few months after birth.

Title: A new fNIRS measurement equipment for improving spatial resolution and removal of systemic components by using near skin blood flow as a reference signal

Authors: *R. TANIGUCHI, T. KOHAMA, H. YOSHIDA;
Grad. school of biology oriented science and technology, Kindai Univ., Wakayama, Japan

Abstract: fMRI is widely used in academic research and clinical settings as a standard method for studying brain function activity. On the other hand, fNIRS has also been increasingly utilized in various fields of brain function measurement in recent years. fNIRS has the advantage of being less restrictive compared to fMRI, allowing for measurements in more natural environments. However, it cannot measure the entire brain like fMRI can. Additionally, there are limitations such as the potential inclusion of scalp blood components.
The holder generally used for fNIRS measurement has transmitting and receiving probes arranged at intervals of 30 mm so that brain activity in the cerebral cortex can be measured. The authors have proposed a new measurement holder and data cleansing method, which has another grid on one axis of the conventional grid arrangement with a 15mm shift, enabling measurement of brain function components at double density, and at the same time measuring skin blood flow at 15mm intervals, which is used as a reference signal. In this study, in order to confirm the effectiveness of this proposed holder, we report the results of a comparative experiment described below with a conventional holder.
In this experiment, we performed finger tapping on subjects whose brain activation area by finger tapping was known in advance. During the finger tapping, we measured the activation area of the motor cortex using both a conventional fNIRS measurement holder and our proposed double density/skin blood flow simultaneous measurement holder. In order to clarify the difference between the two, we first performed a finger tapping experiment by placing the fNIRS measurement holder channel appropriately at a predicted motor cortex activation site. Next, the fNIRS measurement holder was moved 15 mm to the parietal side, and the finger tapping experiment was conducted in the same way as the first experiment.
As a result, in the first experiment, it was possible to identify the activation site of brain activity by finger tapping with both the conventional and the proposed holders. On the other hand, in the second experiment in which the position of the holder was changed, the proposed holder was able to identify the activation site, but the conventional holder with a spatial resolution of 30 mm was unable to confirm the brain activity observed in the first experiment. These results indicate that the proposed holder improves the spatial resolution and makes it easier to identify the

activation sites. In addition, unlike other double-density holders, the proposed holder can be used together with a new data cleansing method that uses skin blood flow near the measurement site as a reference signal.

Abstract: A supplemental receiver coil recovers frontal and subcortical fMRI signals under half-volume head coil configuration
Authors: Yucong Yuan, Toshiko Tanaka, Daisuke Nishiyama, Yasuhiro Shimada, Ichiro Fujimoto, Tomoki Haji, Atsushi Wada, Masahiko Haruno (all NICT CiNet)
Recent advances in virtual reality (VR) technologies have started to impact human emotion and cognition. However, little is known about underlying neural mechanisms. Although fMRI experiments using VR devices are essential, and a VR goggle in front of the eyes is required, it is impossible to locate a standard receiver coil on the front side with the goggle. Absence of the anterior coil leads to a considerable reduction in the signal. In other words, there is the space-signal tradeoff in the VR-fMRI environment. To solve this problem, we tested the co-use of a commercially available elliptical 4-channel receiver coil placed on the participant's forehead with a half-volume posterior head coil to capture brain activity in the frontal and subcortical areas during emotional and cognitive processing. To explore the potential benefits of the frontal 4-channel receiver coil, we first compared the S/N ratio using full (64ch), half-volume (posterior coil part, 40ch) and half-volume + frontal 4ch receiver coils using resting-state fMRI (N=12). We confirmed that adding the frontal 4-channel coil to the back half-volume coil increases the signal-to-noise ratio. Next, we conducted a task-fMRI experiment using an emotional face discrimination task (N=12). This task allowed us to obtain the BOLD signal in the subcortical and prefrontal areas for emotional and cognitive processing. We found that the addition of the frontal 4-channel coil allows us to detect the activity in the amygdala, the striatum, and the ventromedial and lateral prefrontal cortices during the task. These results clarified the benefits of the frontal 4-channel receiver coil to detect BOLD signals in the frontal and subcortical areas, which should be useful in the fMRI experiments of emotion and cognition in VR environments.

Title: Regularized partial correlation provides reliable functional connectivity estimates while correcting for widespread confounding

Authors: *K. L. PETERSON[1,2], R. SANCHEZ-ROMERO[1], R. D. MILL[1], M. W. COLE[1]; [1]Ctr. for Mol. and Behavioral Neurosci., [2]Behavioral and Neural Sci. PhD Program, Rutgers Univ., Newark, NJ

Abstract: Functional connectivity (FC) analyses allow us to investigate the brain's communication network, but the quality of inferences depends on the chosen method of FC estimation. One promising method is partial correlation, which can estimate theoretically valid FC from functional magnetic resonance imaging (fMRI) data. Unlike the field-standard FC method of pairwise Pearson correlation, partial correlation considers all measured brain regions when determining the connectivity weights of each pair, allowing it to discard confounded (i.e., false) and indirect connections. However, recent studies have shown partial correlation FC to have extremely poor repeat reliability, which substantially limits its accuracy. We hypothesized that this could be remedied with regularization, which increases estimate stability by reducing overfitting to noise. We therefore tested several established regularized alternatives - graphical lasso, graphical ridge, and principal component regression - against unregularized partial correlation as well as pairwise correlation. They were applied to both empirical fMRI (N=236 participants) and simulated data (N=100 simulations). As expected, all regularized methods substantially improved on the repeat reliability seen with partial correlation, as measured by between-session similarity and intraclass correlation. This stability also increased the accuracy of FC estimates generated by regularized methods, as indicated by their higher similarity to structural connectivity (empirical data) and higher similarity to ground truth networks (simulated data). Graphical lasso achieved especially high accuracy, likely because it better preserved the valid network structure of partial correlation. We then proceeded to test the robustness of the methods to number of timepoints, noise levels, and motion artifacts, with graphical lasso again

performing best. Lastly, we demonstrated the advantage of graphical lasso over pairwise correlation and unregularized partial correlation for two applications of FC: predicting fMRI task activations and predicting individual differences in intelligence and age. Based on these results, we recommend broad use of regularized partial correlation or similar multivariate methods for calculating FC, as they can more validly estimate unconfounded connectivity than field-standard pairwise correlation while overcoming the instability seen in unregularized partial correlation.

Title: Time-domain Signal Alignment Method for Cross-dataset Transfer Learning in Event-Related Potential based Brain-Computer Interface

Authors: *M. SONG[1], D. GWON[1], K. WON[2], S. C. JUN[2], M. AHN[1];
[1]Handong Global Univ., Pohang, Korea, Republic of; [2]Electrical Engin. and Computer Sci., Gwangju Inst. of Sci. and Technol., Gwangju, Korea, Republic of

Abstract: Recently, more and more electroencephalogram (EEG) datasets have been shared in the Brain-Computer Interface (BCI) field. However, direct use of public datasets for implementing well-working BCI systems is not easy due to the high sensitivity of EEG to equipment and environment [1]. To tackle this issue, we propose a signal alignment (SA) method for transforming an Event-Related Potential (ERP) from one dataset to another. ERPs are slightly different in phase (or time delay), amplitude scale, and direction (positive or negative peak) across datasets due to the differences in the recording environment (paradigm, device, referencing, etc.). Thus, with the basic assumption, we propose a method that makes a linear transform with optimal latency, scale, and reverse factors. Given template ERPs from two different datasets, the latency and reverse factors can be computed using cross-correlation, and the scale factor can be obtained by the ratio of standard deviations of two template ERPs. We evaluated the proposed method with three datasets. First (P3A)[2] and second (P3B) [3] datasets are from the conventional 6 by 6 P300 Speller BCI system where each row/column flashes at a time. The third (P3Face)[4] is also the P300 speller data, but face stimuli were used during

flashing with a random presentation. We attempted to classify targets from non-target epochs with a trained model in two approaches. In the Standard approach, we trained Step-Wise linear discriminant analysis (SWLDA) with one dataset and evaluated it with the other two datasets. But in the proposed approach (SA), signal alignment was conducted before testing a model. The performance was estimated with average precision. As results, standard and SA approaches yielded, for each pair of datasets, 41.9%/46.8% (P3A to P3B), 18.0%/36.5% (P3A to P3Face, $p<0.05$), 31.2%/44.7% (P3B to P3A), 17.4%/35.5% (P3B to P3Face, $p<0.05$), 17.3%/20.2% (P3Face to P3A) and 35.8%/25.6% (P3Face to P3A, $p<0.05$) respectively. These results demonstrate the feasibility of the proposed signal alignment across different datasets and imply that the outcomes may depend on the datasets and type of stimulus.[1] A. Biosystems Dynamics Res., RIKEN, Kobe, Japan; [7]Integrative Brain Imaging Ctr., Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

Abstract: Introduction:The Human Connectome Project (HCP)-style surface-based brain MRI analysis is a powerful technique that allows precise mapping of the cerebral cortex. However, the strength of the surface-based analysis is yet to be tested in aged people who often show white matter hyperintensities (WMHs) on T2-weighted (T2w) MRI. Here we tested the effects of WMHs on surface-based brain MRI analysis. Methods: We analyzed T1-weighted (T1w) and T2w structural MRI acquired from 43 healthy participants. We removed the effects of subcortical WMHs with two different WMH masks: hand-edited WMH masks and Brain Intensity AbNormality Classification Algorithm (BIANCA)-predicted WMH masks. To evaluate the quality of surface-based analysis, we used stereological quality control (QC) by two blinded radiologists and automated surface QC based on an HCP-YA database. We compared the QC scores across the default pipeline and customized pipelines with hand-edited WMH masks and BIANCA-predicted WMH masks. Results: We found substantial surface estimation errors in the default pipeline in which WMHs were mislabeled as part of the GM due to the relatively low and high intensities of WMHs in T1w and T2w MRIs, respectively. The proposed pipeline improved the quality of surface estimation. Two blinded raters indicated a reduction of the surface estimation errors in the proposed pipeline. The surface QC metric supported better surface analysis quality of the proposed pipeline with the reduction of outliers in the surface metrics. Discussion: We show that WMHs may result in surface estimation errors, yielding erroneous values in the surface metrics such as cortical thickness and myelin maps. Because WMHs are common in the aged population, we recommend intensive QC in the surface analysis of MRI data in the aged population. The incorporation of WMH masks is expected to improve the quality of surface based analysis.

Title: YAEL: Yet Another Electrode Localizer for iEEG

Authors: *Z. WANG, X. ZHANG, J. F. MAGNOTTI, M. S. BEAUCHAMP;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Intracranial electroencephalography (iEEG) provides a unique opportunity to measure human brain function with implanted electrodes. We describe the YAEL (Yet Another Electrode Localization) software package for accurately determining electrode locations, a key step in neuroscience inference.
Existing workflows require manually selecting each electrode from the patient's computed tomography (CT) scan, a time consuming and error-prone process. YAEL expedites this process with automated electrode localization. In modern clinical practice, iEEG patients are implanted with stereotactic (sEEG) electrode shafts, each containing many contacts. YAEL users may click on only two contacts on a given shaft and YAEL will automatically select all remaining contacts, accounting for any bends in the shaft introduced during the surgical insertion process.
After identifying the approximate location of each electrode, YAEL applies a refinement process. Electrode locations are automatically adjusted using nearby CT densities. While some workflows downsample the CT to match the resolution of the pre-surgical MRI, YAEL uses the original CT for more accurate localization. This is important for identifying the location of the electrode relative to cortical lamina or small subcortical structures.
A common source of error is the confusion of contacts on nearby sEEG shafts. To ensure that electrodes are mapped correctly, YAEL provides simultaneous viewing of 3D cortical surface models and 2D MRI slices, together with all electrode positions. Both penetrating sEEG electrodes and grids and strips of surface electrocorticographic (ECoG) electrodes are supported, along with the brain shift compensation sometimes required for accurate ECoG localization. Viewer parameters, such as CT threshold, can be adjusted on-the-fly for quick troubleshooting. YAEL's integrated graphical-user-interface (GUI) is designed to be flexible and easy to use. Installing YAEL automatically installs Advanced Normalization Tools (ANTs) and NiftyReg for CT-MRI co-registration (FSL-FLIRT is also supported). Users may export the completed table to comma-separated value (CSV) files that contains electrode locations in three coordinate systems; four anatomical labels estimated from different anatomical segmentations and parcellations; and MNI template coordinates for group analyses. YAEL is fully integrated with the RAVE iEEG analysis suite and is freely available at https://rave.wiki .

Title: Identifying and combining homogenous signals for better brain parcellation in functional neuroimaging analysis

Authors: *R. E. WAUGH, P. B. SEDERBERG;
Psychology, Univ. of Virginia, Charlottesville, VA

Abstract: Many analyses of fMRI data rely on clustering multiple voxels into discrete regions and producing representative mean time series. Hierarchical agglomeration techniques, such as the Ward method, combine voxels into clusters by optimizing a similarity metric between potential merges. There are two potential issues with this approach. First, the standard approach merges clusters based on a Euclidean distance metric, which assumes that signals are similar in magnitude, rather than simply exhibit correlated activity patterns. Secondly, without a principled stopping point, clusters may be over-combined, such that anti-correlated signals are averaged together. Here, we assess the relative performance of Euclidean distance compared to homogeneity (mean correlation) as a similarity metric, and develop a method for determining the best number of clusters in the parcellation. We collected resting state fMRI data from 29 subjects. Following standard preprocessing, we compared cluster construction using the Ward agglomeration method to two custom variants of hierarchical clustering. In the first variant, Euclidean distance was the metric for assessing potential cluster mergers, as in the standard Ward method, however, the distance was divided by the correlation of averaged signals (or homogeneity) between the proposed clusters. Zero and negative homogeneity values were reassigned to a tiny value. This modification dramatically increases the distance metric of poorly correlated cluster distances, creating a clear stopping criterion based on a standard elbow approach. A second variant replaces the Euclidean metric with correlation distance, which, as stated above, no longer requires clusters to have similar magnitudes to combine. To ensure the merged features are on equal footing, the time series are Z-scored before clustering.To assess how these variants affected the clusters we examined N=200 clusters produced for each method. The correlation distance variant increased the mean cluster size, by producing fewer small clusters, and reduced the cluster size variability compared to the original Ward method or the homogeneity-scaled Euclidean variant. We will present examples from these solutions and a comparison of differential outcomes for a functional connectivity based analysis using each of these methods. Our method of defining and aggregating neuroimaging signals improves on current practices by producing more homogenous solutions and implementing a data-driven stopping mechanism. These changes are not trivial, as many neuroimaging projects investigating a diverse range of topics are reliant on accurate signal aggregation.

Title: Deep learning-based feature extraction from intracranial electroencephalography recorded from epilepsy patients

Authors: *S. YAMAMOTO, T. YANAGISAWA, R. FUKUMA, S. OSHINO, N. TANI, H. KHOO, K. EDAKAWA, M. KOBAYASHI, M. TANAKA, Y. FUJITA, H. KISHIMA; Neurosurg., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Background
Although advancements in deep learning (DL) techniques have identified which parts of an image are essential for classification, revealing electrophysiological signal features extracted by DL remains a difficult task. Signal classification has been reported to help doctors diagnose disease and determine the treatment approach for epilepsy patients. However, due to lacking of methods that understandably disclose the detected feature by DL model, those classification studies rarely lead to improved comprehension of epilepsy electrophysiology. To address this problem, we developed a new method to clarify a feature DL model learned from intracranial electroencephalogram (IEEG) signals from epilepsy patients. The revealed feature was evaluated by comparing it with other conventional signal features.
Methods
IEEG signals recorded from 21 refractory epilepsy patients with multiple etiologies (including 109 seizures) were analyzed retrospectively. The early phase signals of epileptic seizures (EPES) (0 to 10 seconds after onset) and interictal states were classified by two models, and their classification accuracies were compared: a one-dimensional convolutional neural network model named Epi-Net and a support vector machine (SVM) model using a spectral power of 8 frequency bands (δ, θ, α, β, low, high-γ, HFO, and 250–500 Hz) and phase amplitude coupling between the γ amplitude and the α and β phases. Then, a modified integrated gradients (mIG) method was applied to Epi-Net to reveal the relative contribution of each frequency amplitude to characterizing EPES. Next, we defined the product of powers multiplied by the contribution as a data-driven epileptogenicity index (d-EI). By comparing the d-EI with other features, its accuracy in detecting EPES was assessed. Finally, we compared the d-EI among the electrodes to estimate how it affects seizure onset zone identification.
Results
Epi-Net outperformed the SVM, with an AUC of 0.944 ± 0.067, which was significantly larger than that of the SVM (0.808 ± 0.253; p = 0.025). The mIG disclosed that Epi-Net focused on increased powers of 17–92 Hz and >180 Hz when classifying IEEG signals of EPES. Seizure detection accuracy of d-EI was the highest among all features. Moreover, the surgical resection of areas showing a larger increase in d-EI was significantly associated with seizure outcomes.
Discussions
D-EI, a new IEEG feature learned by Epi-Net, was extracted with mIG. Identifying the pattern of contribution of each frequency component to detecting epileptic seizures is expected to lead to an enhanced understanding of epilepsy electrophysiology.

Title: Toward a deep neural network simulator of brain activity on fast time scales: Correspondence between EEG and Transformer-based model responses to naturalistic audio stimuli

Authors: *H. KURASHIGE, J. KANEKO;
Sch. of Information Telecommunication Engin., Tokai Univ., Minato-ku, Japan

Abstract: A functional correspondence between the brain and deep neural networks (DNNs) may allow DNNs to be used as simulators of the brain, which can be used to evaluate the effects of specific sensory and physiological stimuli on the brain. This could lead to the development of novel interventions based on DNN models for the treatment and enhancement of cognitive abilities. Brain oscillation ranging from a few to over 100 Hz is involved in various healthy and pathological brain functions. Indeed, methods have been developed to intervene in such oscillatory activity using external stimulation. Therefore, interventions where DNNs are used as brain simulators also need to handle such fast activity. However, fMRI cannot capture this. In addition, most of the existing studies on the correspondence between the auditory brain and DNNs have focused only on speech. Therefore, the correspondence of their responses to more general auditory stimuli is still unknown.
Here, therefore, we used electroencephalography (EEG) to measure fast brain activity from native Japanese speakers listening to a variety of naturalistic auditory stimuli. During the EEG recording, they were exposed to documentary videos containing Spanish or Russian narration and environmental sounds, as well as short video clips to which various sound materials used in TV programs were randomly attached. The power spectral density of the obtained brain responses was predicted by linear regression from the responses of the self-supervised audio spectrogram Transformer. This is a DNN model that takes a mel spectrogram as input and is pretrained on various sound data in a self-supervised learning framework.
The results showed that, as a whole, the predictions were accurate to a certain degree for both the data from the experiments with documentary and short video clip stimuli. In addition, the data from the short video clip experiment showed a dependence of prediction accuracy on electrode position. Specifically, prediction accuracy was lower for the posterior electrodes. This is reasonable because the occipital lobe is mainly responsible for visual processing, and auditory stimuli are difficult to access there. On the other hand, no such dependence was observed in the data from the documentary video experiment. This may be due to the fact that in the short clips, there is no relationship between video and sound, whereas, in the documentary video, they are originally associated. In both conditions, there was no dependence on the frequency band of the

EEG.
The present results provide insights into the brain regions and frequency ranges in which it is appropriate to model brain activity responses to auditory stimuli in DNNs.

Abstract: The complex and heterogeneous nature of major depressive disorder (MDD) has sparked ongoing debates regarding the association between morphological brain alterations and the clinical manifestation of the disorder. Previous attempts to differentiate MDD patients from healthy controls (HC) using linear machine learning approaches based on segmented cortical features have yielded low accuracies. However, deep learning techniques applied to more refined neuroimaging data show promise in identifying diagnostic and predictive biomarkers for MDD by capturing intricate non-linear patterns. In this study, we leveraged a globally representative dataset from the ENIGMA-MDD working group, comprising individuals with MDD (N=2,772) and HC (N=4,240), which allowed for a robust analysis with generalizable outcomes. Our objective was to assess the classification performance of two methods: DenseNet and Support Vector Machine (SVM). We hypothesized that integrating vertex-wise cortical features - thickness, curvature, and sulcal depth - would increase classification accuracy compared to individual features, and that DenseNet would outperform SVM. To mitigate potential confounding effects across multiple sites, we utilized the ComBat harmonization tool. Both classifiers demonstrated performance close to chance when evaluated on unseen sites (DenseNet: 51% balanced accuracy; SVM: 53% balanced accuracy). Slightly improved classification accuracy was achieved when cross-validation folds included participants from all sites (DenseNet: 58% balanced accuracy; SVM: 55% balanced accuracy), indicating the influence of site-related factors. Overall, the integration of vertex-wise morphometric features and the utilization of non-linear classifiers did not facilitate clear differentiation between MDD and HC. These findings underscore the current limitations in utilizing these techniques in this particular combination of vertex-wise brain features for the classification of MDD. Future research will explore more sophisticated approaches to integrating information from other MRI modalities, such as functional MRI and diffusion MRI, in an attempt to increase the accuracy of diagnostic tasks related to MDD.

Title: Improving MEG Inverse Model Identification for Brain Cortical Connectivity Analysis

Authors: B. SOLEIMANI[1], E. B. MARSH[2], J. Z. SIMON[1], *B. BABADI[1];
[1]Univ. of Maryland, College Park, MD; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: State-space models find extensive applications across various scientific domains, including econometrics, controls, and neuroscience. In computational neuroscience, they play a crucial role in solving the neuromagnetic inverse problem by estimating latent activity from out-of-scalp recordings. While sparsity-aware state estimation techniques have significantly enhanced source localization accuracy, precise identification of state-space model parameters remains a challenging task. Current solutions, such as the Expectation-Maximization (EM) algorithm and its variants, face difficulties due to non-convex optimization and slow convergence. Reliable model identification is essential for studying network-level properties of cortical activity. In this work, we present an improved sparsity-aware EM-based source localization technique that surpasses existing methods. We introduce adaptive sparse state-space modeling, which incorporates a data-driven adaptation method to enhance convergence rate, thereby making it more applicable in real-world scenarios. We showcase the efficacy of our proposed methodology through realistic simulation studies, focusing on the magnetoencephalography (MEG) inverse problem as a use case. Our results demonstrate the substantial improvements offered by the proposed method, consolidating its superiority in neuroscience applications. In addition, we apply our method to a set of experimentally recorded MEG data from stroke patients undergoing clinical rehabilitation and successfully demonstrate the network-level changes correlated to their cognitive improvements across recovery checkpoints.

Title: When brain-phenotype associations are studied, it is crucial to know the intraclass correlations of the measured variables

Authors: *M. K. BASINSKA;
Med. Univ. of Gdansk, Gdansk, Poland

Abstract: Linking behavioral phenotypes to brain structure and function is a persistent challenge in mental health research. Some phenotypes, like cognitive ability, are known to be relatively stable over time, while others, like suicidality, are much less stable. Mental health phenotypes are often measured with assessment scales and questionnaires that aim to target inter-individual differences, with the assumption that the phenotype is relatively stable over time. I used a computer simulation to find to what extent the use of questionnaire data can hinder attempts to establish reproducible brain-phenotype associations by reducing test power. In the simulation, I considered predictors (independent variables, IV) and phenotypes (dependent variables, DV) with intraclass correlations (ICC) equal to 0.3 and 0.6 (as calculated over measurements separated by days rather than minutes or seconds). Inter and intra-individual variance of the IV contributed to the same extent to the inter and intra-individual variance of the DV in a linear fashion (r = 0.1, 0.2, and 0.5). Samples of 50, 100, 200, 500, and 1000 individuals were simulated, with 10 time points for each individual. Each combination of parameters was simulated 1000 times. The average level of the DV (ADV) over all time points was calculated for each individual. Since averaging over multiple time points cancels out intra-individual variance, ADV was considered a proxy of questionnaire measurement. I considered the correlation of not averaged IV and DV at one time point a reference to compare the correlations of the ADV with one measurement or the average of 2, 5, and 10 measurements of the IV. For a pair with ICCs = 0.3, the correlation of one measurement of IV with ADV underestimated the true correlation by 37.7-41.5% of the reference effect (for ICC = 0.6 by 17,6%-21,3%). As a consequence, power was reduced by up to 41 p.p. For ICC = 0.3 using 10 averaged measurements of the IV as a predictor made the effects well estimated. For ICC = 0.6 and 5 averaged measurements, there was nearly no underestimation. The above results show that for variables with low ICCs, when DV is measured with a questionnaire and IV with a direct behavioral or neuroimaging measure, some variance is left unexplained. The results also suggest that this challenge can be addressed by the use of longitudinal designs along with direct behavioral measures of phenotypes. It is not obvious how the results will generalize to multivariable models, but it seems unlikely that the consequences of averaging of the DV may disappear entirely. This issue may be explored in further work, along with different combinations of IVs' and DVs' ICC and varying timescales.

Title: Unveiling the neural symphony: EEG-based song classification and enjoyment assessment

Authors: *I. AGARWAL[1], P. PANDEY[2,3];
[1]Biol. Sci., Indian Inst. of Sci. Educ. and Research, Mohali (IISER Mohali), Mohali, India; [2]Univ. of Rhode Island, South Kingstown, RI; [3]Computer Sci. and Engin., Indian Inst. of Technol. (IIT) Gandhinagar, Gandhinagar, India

Abstract: Music has a profound impact on the human brain, influencing emotions and eliciting diverse responses. Understanding the neural correlates of music perception and enjoyment can have far-reaching implications in fields such as music therapy, personalized music recommendations, brain-computer interfaces (BCI), etc. In this study, we investigate the feasibility of classifying songs and assessing their enjoyment levels using electroencephalogram (EEG) data collected during music listening sessions. To conduct our research, we leverage the publicly available Naturalistic Music EEG Dataset—Tempo (NMED-T) obtained from the Stanford Digital Repository. This dataset consists of EEG recordings, familiarity ratings, and liking scores provided by 20 subjects aged 18-29 years, with a mean age of 23 years and six female participants. All participants reported normal hearing, fluency in English, and no cognitive or decisional impairments. Moreover, 17 of the participants had received music training for an average duration of 8.4 years. On average, participants reported listening to music for 14.5 hours per week. The analysis of the EEG data involves several steps. Initially, we apply a cross-frequency coupling (CFC) method called phase-amplitude coupling (PAC) to examine the inter-sensor brain dynamics across seven brain rhythms. PAC provides valuable insights into the coordination and communication between different frequency bands within the brain. Next, we utilized dynamic graph centrality, specifically focusing on broadcast and receive measures, to investigate the connectivity patterns among brain regions. By analyzing how information propagates and is received within the brain network, we can better understand the underlying neural mechanisms associated with music perception and enjoyment. We utilized feature selection techniques to extract relevant features from EEG data, specifically focusing on gamma rhythm data and identifying features with positive relief scores. We utilized Support Vector Machine (SVM) for training the model on the selected features, and developed a binary classification framework designed to identify the songs being played based exclusively on EEG data. Additionally, we employ SVM classification to predict the liking scores of the songs. Together, this study sheds light on the intricate relationship between music enjoyment and brain activity. Overall, our investigation demonstrates the potential of EEG-based song classification and enjoyment assessment in various domains, ranging from clinical applications to music recommendation systems.

Title: Preserving gastric peristalsis during motion correction for abdominal cine-MRI data - A low-rank tensor-based approach

Authors: *R. SCLOCCO[1], J. COLL-FONT[2], C. NGUYEN[2], B. KUO[2], V. NAPADOW[1]; [1]Spaulding Rehabilitation, Harvard Med. Sch., Boston, MA; [2]Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA

Abstract: Evaluation of gastric function is important for the clinical diagnosis of multiple disorders. Recently, magnetic resonance imaging (MRI) applications to the study of gastric function in humans have started to incorporate dynamic volumetric imaging. These approaches allow for continuous 3D coverage of the gastric region without requiring breath holding, hence providing measurements of gastric emptying and motility with a single, non-invasive test. However, motion artifacts (e.g., respiration) require techniques to mitigate inter-frame misalignments. Most standard off-line motion compensation methods use a fixed motion-free template as reference to register the motion-corrupted images. However, while this approach can mitigate undesired sources of motion, it can also impact gastric peristaltic estimates. We propose to overcome this limitation by generating a respiration-free template of the original images that eliminates respiratory motion, while preserving gut dynamics. Our Gastric Low-Rank Tensor-based approach uses a low-rank tensor (LRT) model to separate the temporal components that correspond to breathing motion from those related to gut motion. The key assumption of the approach is that the two main sources of motion (i.e. respiration and peristalsis) are uncorrelated and, hence, appear as orthogonal components of the LRT decomposition. The algorithm includes three main steps, namely (i) LRT decomposition, (ii) separation of the respiratory and gut motion components, and (iii) registration to the respiratory-free template. We perform subject-specific separation between peristaltic and respiratory motion by taking advantage of the spatially localized nature of the peristaltic motion - i.e. respiratory motion affects the entire abdomen,

while peristaltic motion is concentrated on the stomach. As a proof of concept, we applied the algorithm on gastric cine-MRI data in fasted and fed state. Images were collected on a 3T scanner using a real-time 3D cine sequence not requiring breath holding (2.4 s/volume, 72 abdominal coronal slices, 125 volumes), preceding and following the ingestion of a contrast meal. Application of the proposed algorithm showed successful recovery of clean gastric peristalsis both in the fed and fasted state, as demonstrated by the data profile showing oscillations at 3cpm, and by the reduced fluctuations in the position of the gastric center of mass over time. Our motion correction approach effectively removes respiratory noise from abdominal cine-MRI data while preserving gastric peristalsis, thus providing a useful pre-processing tool for the non-invasive evaluation of gastric functional impairments.

Title: A denoising filter for the simultaneously recorded EEG-fMRI data by using an autoregressive model with exogenous input with carbon-wire loop signals

Authors: *T. OGAWA[1], T. KURODA[1], R. KOBLER[1,2], M. TSUTSUMI[1], T. KISHI[1], M. KAWANABE[1,2];
[1]Cognitive Mechanisms Labs., ATR, Kyoto, Japan; [2]RIKEN-AIP, Kyoto, Japan

Abstract: Artifact removals for electroencephalography (EEG) data measured in the magnetic resonance imaging (MRI) scanner have been developed to extract and study brain dynamics. In highly magnetic fields, EEG sensors capture not only brain activity but also artifacts of mechanical (gradient, vibration of the helium pump) and physiological (ballistocardiogram: BCG, head movements) origin. Carbon-wire loops (CWLs) placed on the EEG cap capture a majority of these artifacts independently from brain activity, thereby being suitable for reducing the artifacts with an adaptive regression technique (van der Meer et al., Neuroimage, 2016). Nonetheless, this technique has been limited to recording EEG and CWL signals simultaneously. Here, we propose a machine learning technique to predict CWL-denoised EEG signals. In particular, we use noisy EEG as input and the target as the CWL-denoised EEG. The noise reduction model consists of autoregressive models with exogenous input (ARX) to fit the training EEG data. We primarily examined 63-ch EEG data recorded from a phantom as a baseline and also applied the method to 63-ch EEG datasets from four subjects. To estimate the

model's generalization capabilities, we considered within-subject and day, within-subject across days, and subjects' train/test split scenarios. We found that the trained model could accurately predict time courses of CWL-denoised EEG signals from the noisy EEG on held-out test data. Additionally, we confirmed that the residuals were sufficiently whitened with a Kolmogorov-Smirnoff test. Altogether, our preliminary findings suggest that our approach has the potential to improve EEG data denoising for legacy EEG-fMRI datasets that were recorded without CWLs.

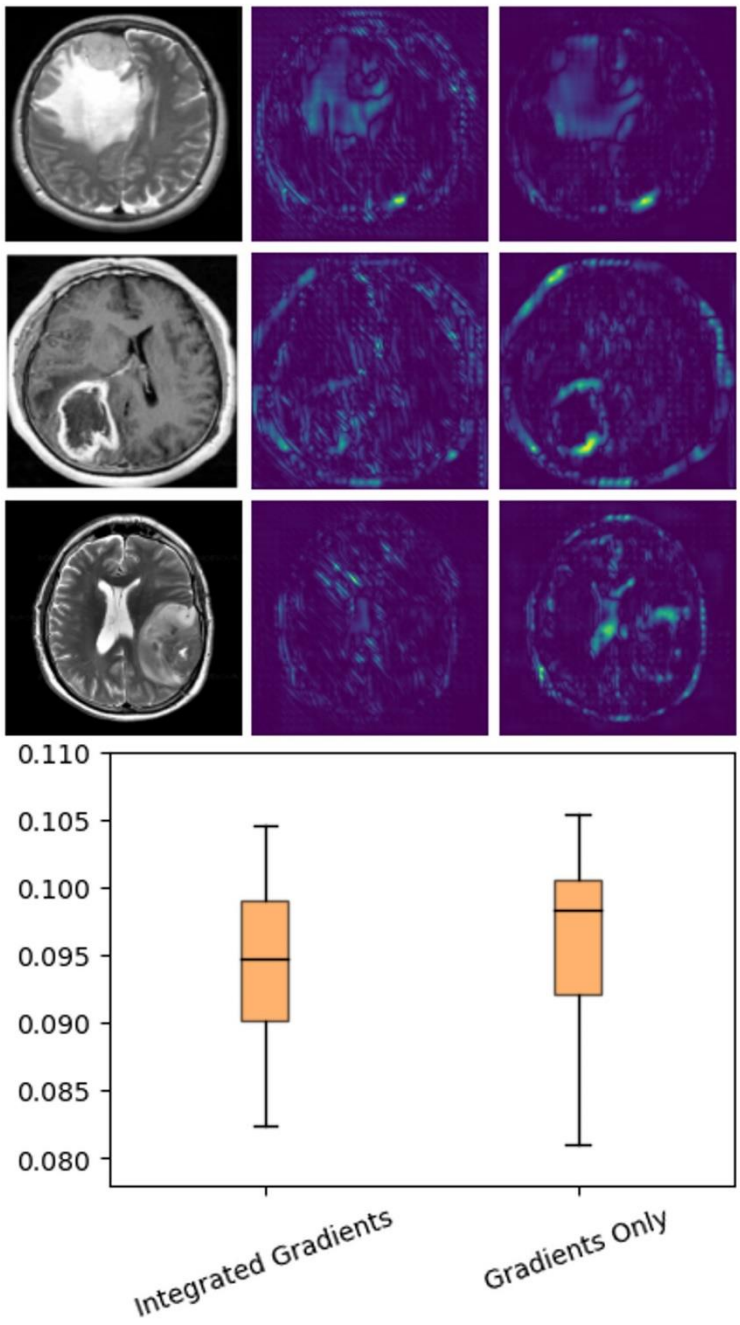
Title: A showcase of faults in gradient-based deep learning explanations for Neuroimaging

Authors: *N. LEWIS[1], A. FAGHIRI[2], V. CALHOUN[3];
[1]Georgia Tech., Atlanta, GA; [2]Georgia State Univ., Atlanta, GA; [3]Georgia Inst. of Technol., Decatur, GA

Abstract: Explainable AI in the medical field has exploded in the last few years. However, recent work in the broader field of explainability has revealed extensive problems with various XAI methods, particularly post-hoc gradient-based methods. First and foremost, gradient-based saliency methods have been found to be unreliable, unable to capture all correlations learned by the model, and generally problematic. In this paper, we will elucidate some of these issues that are particular to the medical field.
We will show some of these problems by experimenting with a single dataset of sMRI data containing controls and patients with brain tumors. We train a state-of-the-art resnet model to classify the patients vs. controls and then compute the gradients-only saliency and integrated gradients (IG), and compare these relevancy maps with a ground truth representation of the patients with brain tumors. The ground truth representation is a mask that covers only the tumor location. Beyond the ground truth estimation, we will also test the maps' stability over differently seeded models to investigate a phenomenon known as underspecification. This is a phenomenon in which two models can be equally optimal, but also be entirely different functions with different weight values. This phenomenon can impact both performance on holdout data and any explanation associated with the model. In order to showcase this effect, we used the same dataset for 20 separate models and tested how similar the saliency maps were over all 20 models.
Our results show, even with a generally accurate model, the saliency maps capture only a small percentage of the truly relevant information. Additionally, we found that the maps themselves vary wildly over the 20 models. Overall, this poster presents some of the drawbacks behind gradient-based explanatory methods and showcases some of the pitfalls, in the hopes of generating discussion on how best to improve these explanatory methods.



Top: 3 examples of subject MRI scans with tumors (left) along with the corresponding IG maps (middle) and grads-only maps (right).
Bottom: the percentage of the IG (left) and grads-only (right) maps that overlap with the ground truth regions, the tumors themselves.

Title: Strategies for Motion- and Breathing-Robust Estimation of fMRI Intrinsic Neural Timescales

Authors: *A. GOLDBERG[1], J. D. POWER[2], G. HORGA[1,3], K. WENGLER[1,3];
[1]New York State Psychiatric Inst., New York, NY; [2]Weill Cornell Med., New York, NY;
[3]Psychiatry, Columbia Univ. Med. Ctr., New York, NY

Abstract: Intrinsic neural timescale (INT) is a resting-state fMRI (rs-fMRI) measure reflective of the time window of neural integration within a brain region with relevance to neuropsychiatric disorders. Despite its relevance, physiological artifacts, which can impinge on the validity of fMRI findings, have not been systematically considered in INT estimation. Two such artifacts, head motion and respiration, pose serious issues in rs-fMRI studies. Here, we analyzed how two preprocessing strategies targeting these artifacts—frame censoring and global signal regression (GSR)—affect INT estimation. We used a subset of the HCP Young Adult dataset with runs annotated for breathing patterns (Lynch et al., 2020) and at least one "clean" run that was free from breathing artifacts and head motion (frame displacement<0.2 mm for >1000/1200 frames). The subset of analyzed data comprised these "clean" runs and other "non-clean" runs from the same participants (n = 46). All data were preprocessed using the HCP minimal preprocessing pipeline and nuisance regression was performed with the average WM and CSF signal, plus 6 motion parameters and their 1st derivatives. For non-clean runs, nuisance regression also included: 1) both frame censoring and GSR; 2) only frame censoring; 3) only GSR; or 4) neither. INT maps were calculated from autocorrelation functions (ACF) estimated in three ways: 1) a standard approach using the full timeseries after despiking frame censoring (when applied) (Wengler et al., 2020); 2) using blocks of contiguous frames after frame-removal censoring (when applied) (Raut et al., 2020); or 3) using Lomb-Scargle periodograms (VanderPlas, 2018) after frame-removal censoring (when applied). We evaluated the ability of frame censoring and GSR to correct for artifacts by comparing the non-clean runs to their respective clean run within a subject. We found that using both frame censoring and GSR yielded the lowest INT estimation error. We also found that GSR significantly improved INT estimation for runs with deep breaths ($t=-2.5$, $p=0.021$). Randomly applying frame censoring to the clean runs revealed for all three ACF-estimation methods that frame censoring itself biased INT values regardless of motion (more censored frames caused more INT underestimation; $t=-14.3$, $p<0.001$), with the standard approach being least susceptible to this bias. Importantly, bias correction is possible through regression-based adjustments for subject-level frame censoring. Overall, these results simultaneously reflect the utility of frame censoring and GSR in minimizing physiological artifacts, as well as the importance of accounting for potential confounds in INT estimation.

Title: Innovative imaging techniques in the study of balance and the brain in autistic youth

Authors: ***A. R. BLOCK**[1], O. SURGENT[3], B. TRAVERS[3], J. GUERRERO-GONZALEZ[4], N. ADLURU[2], D. DEAN, III[4], A. L. ALEXANDER[4], G. R. KIRK[4], S. KECSKEMETI[4]; [1]Kinesiology, UW-Madison, Madison, WI; [2]UW-Madison, Verona, WI; [3]Univ. of Wisconsin-Madison, Madison, WI; [4]Waisman Ctr., Madison, WI

Abstract: Motor challenges, including decreased postural control and balance ability, are prevalent features of autism spectrum disorder (Harris, 2017; Travers et al., 2013), and yet, the neurobiological mechanisms driving these challenges remain largely unknown. Evidence suggests that the brainstem may strongly contribute to autism features and motor behavior (Dadalko & Travers, 2018; Rimland et al., 1964), making it a key area for further investigation. Despite this evidence, the low resolution of traditional brain imaging techniques makes it difficult to image the brainstem *in vivo*. Previous voxel-based analyses revealed autism-specific changes in the brainstem as a result of a balance intervention (Surgent et al., 2021); however, the study's use of conventional brain imaging methods limited its ability to capture the anatomical complexities of the brainstem. This study employs a novel post-processing method for brain imaging (TiDi-Fused processing) to enhance quantification of brainstem structures (Guerrero-Gonzalez et al., 2021) with the purpose of investigating if neuroplasticity in the brainstem is related to balance improvement in autistic individuals. We utilized data from a randomized control trial (#NCT02358317) involving balance intervention and brain imaging in autistic and non-autistic adolescents. Outcome variables included balance improvement and corresponding brain plasticity as a result of balance intervention. The TiDi-fused method proved to be an effective form of post processing brain images, decreasing the coefficient of variance by an average of 3.7%, in addition to demonstrating sharper gray-white matter boundaries and improved apparent resolution. Further, we were able to replicate previous voxel-based analysis findings, showing autism specific brainstem changes in FA ($t(11) = 1.915$, $p = 0.0819$) and ICVF

($t(11) = -1.958$, $p = 0.0761$) in the brainstem, and, with the TiDi-fused method, we were able to confirm that these changes were located in the left SCP. Together, these results suggest not only that the TiDi-fused method is an accurate and reliable post processing technique for enhancing visualization and quantification of brainstem structures in traditionally acquired DWI datasets, but also that neuroplasticity in the SCP plays an important role in balance for autistic individuals in a way that is distinct from their non-autistic counterparts.

Title: Modeling neural features predictive of cognitive performance with a gamma generalized linear model

Authors: *M. HEDLUND, B. REID, J. PARVIZI, T. COLEMAN, V. BUCH;
Stanford Univ., Palo Alto, CA

Abstract: Identifying neural features that modulate cognitive performance is a core question in cognitive neuroscience. Intracranial electroencephalography (iEEG) provides unique and unparalleled insights into rapid human brain state dynamics. We aimed to study the predictive effect of subsecond spontaneous neural features on upcoming single-trial reaction times (RT). We collected data from 13 adult human subjects undergoing iEEG monitoring for epilepsy as they answered basic true/false math questions. RT was used as a measure of cognitive performance. Spectral power and phase-locking value-derived communicability, which is a graph theoretic measure of network-wide information flow in and out of each node, were calculated in four canonical frequency bands for every electrode. Features that have a statistically significant relationship with RT were found using a univariate gamma GLM and comparison linear regression model. To assess goodness of fit for each distribution, we calculated the empirical and theoretical cumulative distribution functions and compared the Kolmogorov-Smirnov (KS) statistics. We showed that the conditional distribution of the RT given neural features is better modeled using a generalized linear model (GLM) with a gamma distribution and log link function than with linear regression, which assumes a Gaussian distribution. The mean KS statistic was .349 (.069 SD) for the Gaussian distribution and .241 (.130 SD) for the gamma

distribution. On average, the gamma KS statistic was lower than the Gaussian by .107 (.150 SD), indicating that the gamma distribution was a better fit for the data. Using the significant features as regressors, a multivariate gamma GLM was trained with an 80/20 train/test split and 5-fold cross-validation. The number of features used as regressors were varied in order to find the optimal prediction error, selecting the features with the highest weights as the number of features. The average standard prediction error is 1.36s (.352 SD). Without knowledge about the neural features, the best prediction for the RT is the sample mean. In all subjects, conditioning on the neural data reduced the standard prediction error, with a mean improvement of 19.32% (7.48 SD). Therefore, conditioning on the neural features exhibits higher predictive power than the marginal distribution of RTs. We conclude that spontaneous neural features, prior to trial onset, can predict upcoming RT using a gamma GLM. This modeling approach may be used in the future to create a closed-loop cognitive neural state decoder and empower therapeutic strategies for cognitive disability.

Title: Leveraging EEG Signals and Motion Artifacts for Accurate Gait Event Prediction: A Machine Learning Approach

Authors: *R. KANKAR[1,2], H. HUANG[1];
[1]Univ. of Central Florida, Orlando, FL; [2]Univ. of Central Florida, Orando, FL

Abstract: EEG, a primary mobile brain imaging technique, often contends with motion artifacts—large electrical signals generated by movement, which mask underlying brain activity. Traditionally, these are removed using signal processing methods. Our lab uses a dual-layer EEG system to record standard scalp electrical activity and isolated motion artifacts, providing an expanded toolset for signal processing. This dual-layer system includes an inner layer to measure electrical activity from scalp-interfacing electrodes (like standard EEG), and an outer layer to measure activity from outward-facing electrodes in contact with a conductive fabric cap—presumably mainly noise and motion artifacts.The purpose of this study was to determine whether gait events could be accurately predicted using machine learning techniques. Our dataset is from mobile brain imaging study in the lab that recorded dual-layer EEG as human participants (n=14) responded to small discrete surface treadmill belt perturbations while walking. The belt perturbations were brief increases and decreases in treadmill belt speed at

either left heel strike or left mid-stance. The experimental protocol included periods of unperturbed (normal) and perturbed walking. The dataset used here includes both perturbed and unperturbed walking conditions from 14 subjects. The perturbed dataset represents instances of unexpected obstacles during walking, while the unperturbed dataset captures regular, unobstructed walking. We were interested in predicting typical gait events, the left and right heel strikes and toe offs..Machine learning models—Random Forest, Logistic Regression, and SVMs—were trained using the motion artifact layer alone, the full inner layer (both good and bad channels), and only the good inner layer channels. Models trained on the outer/motion artifact layer showed the highest performance, highlighting the artifacts' value in gait event prediction. Models trained on both good and bad inner layer channels outperformed those trained only on good channels, indicating even perceived EEG noise can have gait prediction value.Further evaluation of advanced neural networks showed LSTM-equipped RNNs effectively utilized the temporal dependencies in EEG and motion artifact data, significantly boosting prediction accuracy.This study revolutionizes our understanding of brain dynamics and walking biomechanics, suggesting EEG, when fully leveraged, can offer insights beyond traditional brain dynamics assessments. This could facilitate research into age and disease-related mobility and cognitive impairments, broadening neuromechanics research's future scope.

Title: Surgical and Neurophysiological Analytic Methods for Human Single-Neuron Recordings with DIXI Medical Microdeep Micro-Macro Depth Electrodes

Authors: *M. L. DARWIN[1], J. ZHENG[2], U. RUTISHAUSER[3], S. OJEMANN[4], D. R. KRAMER[4], J. A. THOMPSON[4];
[1]Neurosurg., CU Anschutz Med. Campus, Aurora, CO; [2]Boston Children's Hosp., Boston, MA; [3]Neurosurg., Cedars Sinai Med. Hosp., Los Angeles, CA; [4]Neurosurg., Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Single neuron recordings offer unparalleled temporal and spatial resolution to advance the field of cognitive neurophysiology as never before afforded. Recently, DIXI Medical (Besancon, France) became an FDA-approved manufacturer stereotactic electrophysiology (SEEG) depth electrodes that can record from single units. This electrode variant is novel in both surgical and analytic techniques compared to other depth electrodes used for single-unit analyses (i.e., described in Minxha et al., 2018). Thus, the aims of the current study are to describe and

discuss the methodologies surrounding the use of DIXI Medical Microdeep® Micro-Macro depth electrodes (DIXI MME) that have the capability to record from single neurons in cognitive neuroscience research. Implantation techniques unique to this electrode and useful for others interested in this research will be detailed to allow for replication by other groups. Furthermore, OSort, a semi-automatic spike sorting program (Rutishauser, 2021), was modified for single unit analyses with DIXI MMEs; the modifications of which will be detailed for replication by other groups as well. To demonstrate the utility of DIXI MMEs with a real-world example, we implemented these electrodes to advance the understanding of episodic memory. We were afforded a rare opportunity to record eye movements and activity from single neurons from the medial temporal lobe in humans during the encoding and retrieval process. Patients with medically refractory epilepsy (N=4, M_{age} = 41.5 ±8, 75% female) admitted for intracranial monitoring of seizure activity via SEEG depth electrodes completed the study during their inpatient stay in the Epilepsy Monitoring Unit at University of Colorado Hospital. Patients were implanted with 1 DIXI MME in either the hippocampus or amygdala to record single neuron activity. Eye movements were recorded binocularly from a desktop mounted EyeLink 1000 Plus System (SR Research, Canada) while patients completed a computerized episodic memory paradigm. Using cognitive and computational models to relate both behavioral performance and eye tracking processes to the underlying neural mechanisms will ultimately inform the design of targeted interventions for causal disruptions in these systems.

Title: A Pose-Informed De-Noising Diffusion Model for Infant and Adult Naturalistic EEG Signals

Authors: *A. DUTTA[1], M. H. ANDRE[1], L. COVARRUBIAS[1], S. GEORGIEVA[1], C. GERLOFF[2], B. LI[1], V. LEONG[1];
[1]Nanyang Technological Univ., Singapore, Singapore; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Artifact contamination in EEG signals poses a persistent challenge, owing to the diverse sources of artifacts (including ocular, muscular, sweat, and electrical), which exhibit limited commonalities among individuals. These challenges are amplified when EEG data is collected under naturalistic settings permitting free movement in paediatric and adult

participants. Existing denoising methods, such as Independent Component Analysis assume linearity between artifact and artifact-contaminated EEG signals. Also, the quality of the clean signal extracted from such methods is contingent on the dominance of one noise source over others. These assumptions are not always held, leading to poor noise segregation. Further, existing EEG cleaning methods require subjective judgments to label noise components, often without the aid of objective ground truth data. To address these issues, we present a new EEG-denoising model that is able to utilise body pose data to perform more effective denoising of movement-contaminated EEG signals and is therefore suitable for application with naturalistic EEG datasets. Our contribution is twofold: 1) we introduce ground truth constraints from - pose coordinates - extracted from the participant's video data and represented as x and y coordinates of 25 body keypoints (e.g., wrists, eyes, ankles) to guide the denoising process and 2) a denoising diffusion model (Song et.al 2021) (EEG_DDM) which takes both the artifact contaminated EEG and pose coordinates as input to denoise the EEG signal. To ensure generalisability, the model accommodates denoising scenarios both with and without pose coordinates and is thus applicable for common EEG datasets without pose coordinates. Experiments on adult EEG demonstrate that the model achieves a cosine similarity of nearly 0.85 to the ground truth data when utilising pose coordinates and still maintains a similarity ~ 0.80 in the absence of pose data. Furthermore, our model performs comparably to the current automated state of the art methods such as ICLabel (Tonachini et.al 2020), RELAX (Bailey et.al 2022), EEGDenoiseNet (Zhang et.al 2022) and GANS (Brophy et.al 2022).

Title: Improvement of accuracy in predicting subacute stroke functional outcome by machine learning with increased clinical indicators: A retrospective study

Authors: *Y. MIYAZAKI[1,2,3], M. KAWAKAMI[3,2], K. KONDO[2,3], M. TSUJIKAWA[2,3], K. HONAGA[4,2], K. SUZUKI[5], T. TSUJI[3];
[1]Dept. Physical Rehabil., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Dept. of Rehabil. Med., Tokyo Bay Rehabil. Hosp., Chiba, Japan; [3]Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan; [4]Dept. of Rehabil. Med., Juntendo Univ. Grad. Sch. of Med., Tokyo, Japan; [5]Dept. of Rehabil. Med., Waseda Clin., Miyazaki, Japan

Abstract: The prognosis of post-stroke functional recovery is important in early hospitalization because the Activities of Daily Living (ADL) of stroke patients affect the lives of patients and their caregivers after discharge. Many previous studies reported improved prediction accuracy by adding various clinical findings to Multiple Linear Regression analyses (MLR). However, the prediction accuracy of stroke patients, which is nonlinear data, may have decreased by MLR, which assumes linear data. Therefore, the purpose of this study is to examine whether the prediction accuracy can be improved by using machine learning, which can analyze nonlinear data. We also examine whether prediction accuracy can be improved by adding clinical indicators as explanatory variables.In this study, 980 participants who met the inclusion and exclusion criteria were included, and prognostic models were developed using the total Functional Independence Measure (FIM) motor scores at discharge as the objective variable. From the Electronic Health Record, age, number of days from onset to admission day, and FIM at admission were collected and used as explanatory variables to develop prediction models. In addition, prediction models were also developed by adding the Stroke Impairments Assessment Set (SIAS), grip strength, Body Mass Index (BMI), and Geriatric Nutritional Risk Index (GNRI) as explanatory variables. Decision trees (DT), Ensemble Learning (EL), Support Vector Regression (SVR), Artificial Neural Network (ANN), and Gaussian Process Regression (GPR) were adopted as machine learning in addition to the conventionally used MLR. The coefficients of determination were used as prediction accuracies and compared.The coefficients of determination for prognosis based on patient background and FIM at admission were 0.69 for MLR and 0.75 for GPR; when clinical findings such as SIAS were added, the coefficients of determination improved to 0.72 for MLR and 0.77 for GPR.This study suggested that GPR may improve prediction accuracy more than MLR. In addition, the prognostic model with the addition of SIAS and GNRI was more accurate than the prognostic model based on patient background and FIM at admission.

Title: Genetic and cellular decoding of cortical region and its association to psychiatric disorders

Authors: *Y. ZHAN, C. LIU;
Inst. of Neurosci., Shanghai, China

Abstract: The spatial distribution of cell types is critical in determining their functional properties and has significant implications for understanding psychiatric disorders. However, the regional cellular composition in the neocortex and its association to genetic risks for psychiatric disorders remains largely unknown. In this study, we first integrated brain-wide microarray gene expression data from Allen Human Brain Atlas (AHBA) with single-nucleus (sn) RNA-sequencing data to attribute expression-driven cell types to specific regions. We then examined whether illness-related genes are more prevalent in regions where specific cell types are preferentially localized. Our results reveal that the neocortex can be divided into sensory, anterior association and posterior association subgroups, with each subgroup comprising similar constituent cells. The sensory subgroup, encompassing the primary visual cortex, somatomotor cortex and posterior cingulate cortex, shows a preferential expression of excitatory neuronal subclasses and parvalbumin interneurons in the granular layer (layer 4). The posterior association subgroup, encompassing the lateral, ventrolateral prefrontal cortex, and posterior association cortex, exhibits a preferential expression of excitatory neuronal subclasses in the spuragranular (layers 1-3) and granular layers. In contrast, the anterior association subgroup, comprising the anterior association cortex, demonstrates a preferences of glia cells and excitatory subclasses in the infragranular (layers 5 and 6), along with excitatory and inhibitory subclasses in the supragranular layer. The regional distribution of neuronal cell types was correlate with the cortical layer-specific thickness. The granular layer neuronal subtypes-dominant sensory and posterior association subgroup regions tend to have a relative thicker granular layer. Conversely, the anterior association subgroup regions, dominated by infragranular and supragranular layer neuronal subtypes, exhibits thicker supargranular and infragranular layers. Additionally, by integrating psychiatric disorder-associated gene sets, we find the anterior association subgroup region exhibited enrichment for up-regulated and primary sensory cortex exhibited enrichment for down-regulated genes associated with autism spectrum disorder, bipolar disorder and schizophrenia. These findings advance our understanding of the cellular underpinnings of brain functional specialization and the neural basis of psychiatric disorders, potentially paving the way for the development of more targeted and effective treatments.

Title: Contrastive graph representation learning of brain functional networks improves prediction of CSF amyloid-beta in Alzheimer's disease

Authors: *K. ZHAO[1], R. S. OSORIO[2], Y. ZHANG[1];
[1]Lehigh Univ., Bethlehem, PA; [2]New York Univ. Grossman Sch. of Med., New York, NY

Abstract: Contrastive graph representation learning of brain functional networks improves prediction of CSF amyloid-beta in Alzheimer's disease

Authors: Kanhao Zhao[1], Ricardo Osorio[2], Yu Zhang[1,3*1] Department of Bioengineering, [2] Department of Electrical and Computer Engineering, Lehigh University, Bethlehem, PA, USA[2] Department of Psychiatry, New York University Grossman School of Medicine, New York, NY, USA* Corresponding author: Email: yuzi20@lehigh.edu

Disclosures: K. Zhao: None. R. Osorio: None. Y. Zhang: None.

Abstract: Contrastive learning has shown significant promise in distinguishing the representative variants between the background and target datasets. However, existing contrastive strategies were not specifically designed for graph data, limiting the utilization of the topological information. In this study, we proposed a novel framework, Contrastive Graph Variational Autoencoder, tailored for graph data-based contrastive learning. We aim to fully utilize the topological information in brain functional graphs to identify target-specific salient latent features from target dataset, contrasting the background shared features. Moreover, we introduce a prediction loss to enhance the predictive ability of the target-specific latent features, ensuring they correlate with clinical scores. Cerebrospinal fluid (CSF) levels of amyloid-beta is a crucial biomarker for drug development of Alzheimer's disease (AD) and categorizing neurodegenerative conditions. The relationship between brain dysfunction and the accumulation of amyloid-beta pathology remains unclear. We aim to utilize brain functional connectivity graphs to shed light on this association. Specifically, we extracted the resting-state function connecitivity graph from healthy controls and the patients with Alzheimer's disease from the Alzheimer Disease Neuroimaging Initiative dataset and PResymptomatic EValuation of Experimental or Novel Treatments for AD dataset. Then employing brain functional connectivity features from healthy subjects as the background and Alzheimer's disease as the target, we demonstrate the superiority of our model in predicting CSF amyloid-beta, compared to other state-of-the-art approaches. Further investigations indicated that the Alzheimer's disease-specific features and the healthy-shared features decomposed by our model are significantly distinguishable. This indicates that our model successfully disentangle the disorder-specific representations for Alzheimer's disease from healthy-control-shared representations, providing valuable insights into the neurobiological characteristics of the disease.

Abstract: Tourette Syndrome (TS) is a neuropsychiatric disorder characterized by repetitive and involuntary motor and phonic tics. Deep Brain Stimulation (DBS) has shown promise as a therapeutic option for refractory TS, particularly in alleviating motor tics. This study explores the identification of targets of tic detection and suppression in the Centromedian (CM) Nucleus of the Thalamus and the Anterior Globus Pallidus Interna (aGPi) using closed-loop DBS. The study spans nine months, comprising several phases: identifying the best nuclei for tic detection and suppression, optimizing adaptive settings, and testing the optimized settings. Data collection involves rest periods, voluntary movement of hands upon cue presentation, and periods of tics while recording video and streaming data from the Medtronic Percept implants and Delsys Wearable Sensors. The recorded data is aligned and marked for analysis, comparing Local Field Potential (LFP) power and time domain data recordings during different conditions. The study involves eight subjects, with one patient fully implanted at present. Our preliminary results are from a female subject with bilateral DBS electrodes targeting CM and aGPi, and bilateral Percept Neurostimulators. Our analysis reveals that lower frequency bands (1-10 Hz) show consistent separability of tics from rest for this subject (p-value < 0.1). However, due to hardware limitations, the lowest observable range for closed-loop DBS is 7.81 ± 2.5 Hz. Despite this constraint, we have successfully initiated closed-loop DBS using the LFP signal. Future directions include periodic evaluation of stimulation thresholds to maintain therapeutic efficacy, prevent subject habituation, and improve closed-loop DBS parameters optimization techniques based on real-time and chronic monitoring of neural activity and symptom progression. Additionally, investigating the impact of CM and aGPi stimulation on TS-associated psychiatric comorbidities is crucial. While the first subject does not present with psychiatric comorbidities, future subjects will shed light on the effects of DBS on these conditions. Lastly, we aim to explore alternative approaches for efficient tic detection and marking during patient visits, as the current video labeling technique is time-consuming. In conclusion, our study demonstrates the potential of closed-loop DBS targeting CM or aGPi for TS treatment. Further research is needed to optimize DBS parameters and monitor symptom progression, ultimately leading to tailored therapies that account for individual patient characteristics.

Title: An Error-Correction for Augmented Reality Based Steady State Visually Evoked Potential to Improve Information Transfer Rate

Authors: *J. HA[1], S. PARK[2], H. JANG[1], L. KIM[1,3];
[1]Bionics Res. Ctr., Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of; [2]Industry-Academy, [3]Dept. of HY-KIST Bio-Convergence, Hanyang Univ., Seoul, Korea, Republic of

Abstract: Nowadays, augmented reality (AR) devices enable portable steady-state visually evoked potential (SSVEP) experiments by presenting visual stimuli wherever the user is. However, users' gaze remains within the stimulus field because the visual stimuli in AR follow head movement. Inconvenience caused by wearing AR devices and fatigue resulting from continuous visual stimuli could lead to low accuracy and low information transfer rate (ITR) for SSVEP. Recently, many researchers have conducted AR-based SSVEP studies to improve performance. However, none of these studies have considered the components or situations on SSVEP errors. In this study, we aimed to increase the ITR by applying an error correction, unlike previous studies that focused on improving algorithms to increase accuracy and ITR or reducing window time to increase ITR. Seven subjects of both genders (3 males, 4 females; mean age: 24.6 ± 2.3 years) participated in this experiment. EEG data were recorded using a 64-channel Brain Vision actiChamp. All subjects wore an EEG cap with Microsoft Hololens 2, stood up, and performed the experiment for SSVEPs every 4 seconds for a total of 100 times using flickering visual stimulation under 4 target frequencies (6.6, 7.5, 8.57, 10 Hz). EEG data acquired from eight occipital electrodes were selected for SSVEP classification. In this study, SSVEP classification adopted an extended multivariate synchronization index (EMSI) algorithm, which calculates the synchronized index between EEG signals and reference signals and applies time-delay embedding to the EEG data. Regarding the error correction strategy, we hypothesized that participants would gaze at the target correctly. If error trials with similar synchronization indexes occurred, it was considered that participants did not gaze at the target correctly. We used 4 seconds of data for EMSI, and this time range was used to determine the original accuracy and ITR. On the other hand, the ITR for corrected trials was based on 5 seconds (time range [4 seconds] + error recognition time [1 second]). The original accuracy and ITR were 89.07% and 25.83 bits/min, respectively, while the corrected accuracy and ITR were 94.71% and 31.80 bits/min, respectively. We hypothesized that cases where the synchronization index on the target was not the highest occurred due to delayed onset time in gazing at the target or the effect of flickering light from other targets. In future studies, the inclusion of an eye-tracking device would allow for a more accurate analysis and the development of more effective error correction methods for all trials, unlike the current study.

Title: Covid-19 prevalence is modified by specific diagnoses and antipsychotic exposure in psychiatric patients

Authors: *H. TENDILLA-BELTRÁN[1], Á. RIVAS-RAMÍREZ[2], F. FLORES[2], L. CARBAJAL-RIMOLDI[2], L. GÓMEZ-MENDOZA[2], G. LOAIZA[2], G. FLORES[1,2];
[1]Meritorious Autonomous Univ. of Puebla, Puebla, Mexico; [2]Hosp. Psiquiátrico Dr Rafael Serrano, Puebla, Mexico

Abstract: Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2), the biological agent for Coronavirus disease 2019 (COVID-19), has brain tropism and induces neuroinflammation, which also is a core mechanism of psychiatric disorders such as schizophrenia, depression, and bipolar disorder. In this sense, patients diagnosed with psychiatric diseases seem to be vulnerable to COVID-19 outcomes. Interestingly, some drugs employed for the treatment of psychiatric diseases, including antipsychotics, have anti-inflammatory and antioxidant properties, suggesting that they can be protecting the brain against neuroinflammation. The clinical records of 170 inpatients were analyzed during the COVID-19 outbreak (June-September 2020) and a year followed up, to determine the effects of sex, age, psychiatric/neurological diagnosis, comorbidities, and antipsychotic exposure on COVID-19 prevalence. The prevalence of COVID-19 in hospitalized patients with psychiatric disorders was increased compared with that of the general population; however, a lower mortality rate was detected. Furthermore, inpatients with intellectual disabilities had higher COVID-19 prevalence (OR 2.2, 95% CI: 0.2-0.8; P = .0434) than those with schizophrenia, which was lower (OR 0.4, 95% CI: 0.2-0.8; P = .0250). Regarding antipsychotic effects, inpatients exposed to first-generation drugs (FGA) have reduced COVID-19 prevalence, specifically in the group of 18-65 years of age (OR 0.37, 95% CI: 0.17-0.81, P = 0.0202) and diagnosed with intellectual disabilities (OR 0.23, 95% CI: 0.16-0.55, P = 0.0039). While the second-generation antipsychotics increased COVID-19 prevalence in the general hospital population (OR 2.11, 95% CI: 1.13-3.86, P = 0.0207), in inpatients 18-65 years of age (OR 2.38, 95% CI: 1.2-4.92, P = 0.0156) and in inpatients diagnosed with intellectual disabilities (OR 2.87, 95% CI: 1.3-6.19, P = 0.0108). Also, reduced Long COVID prevalence, in comparison with the general population, was detected in these inpatients. These results indicate that the prevalence of COVID-19 in hospitalized patients with psychiatric disorders is modified by multiple factors including the specific diagnosis and the presence of comorbidities. Additionally, FGA seemed to have protective effects against COVID-19 effects, including long-term ones. Our data greatly advance the body of information regarding how antipsychotics alter COVID-19 outcomes, albeit

preliminary, in which their antiviral, antioxidant, and anti-inflammatory properties also impact the pathophysiology of psychiatric diseases.

Title: Blocking Aδ- and C-fiber neural transmission by sub-kilohertz peripheral nerve stimulation

Authors: *S. ZHANG, L. CHEN, J. LIU, A. SEFERGE, B. FENG;
Univ. of Connecticut, Storrs, CT

Abstract: Peripheral nerve stimulation (PNS) has emerged as a non-drug alternative for managing chronic pain and other neurological disorders. The pain-managing effect of PNS is usually attributed to the activation of myelinated A-fiber afferents, which causes a non-painful tingling sensation known as paresthesia that masks the pain sensation from the same area. We recently showed that sub-kilohertz electrical stimulation of the dorsal root ganglia (DRG) reversibly blocks afferent transmission via activity-dependent conduction slowing. In this study, we further investigated whether electrical stimulation of the peripheral nerve trunk can also cause neural transmission block. To that end, we explored the mechanisms and parameters of PNS to block axonal neural transmission by conducting *ex vivo* single-fiber recordings from harvested mouse sciatic, saphenous, and vagal nerves. In a two-compartment tissue chamber, we evoked action potentials from one end of the harvested nerve in the tissue chamber perfused with Krebs solution and conducted single-fiber recordings from split nerve filaments approximately 20 μm thick in the adjacent recording chamber filled with paraffin oil. PNS was delivered in the middle of the nerve trunk using a glass suction electrode at frequencies of 10, 50, 100, 500, and 1000 Hz. Similar to DRG stimulation, suprathreshold PNS reversibly blocks axonal neural transmission of thinly myelinated Aδ-fibers with a conduction velocity (CV) of 1-4 m/s and unmyelinated C-fibers with a CV less than 1 m/s. PNS leads to a progressive decrease in CV until transmission blockage, suggesting activity-dependent conduction slowing. The blocking efficiency is dependent on the axonal conduction velocity, with Aδ-fibers efficiently blocked by 50-100 Hz stimulation, while C-fibers are blocked by 10-50 Hz. This frequency-dependent blocking effect is consistently observed in the sciatic, saphenous, and vagal nerves. The current study provides direct evidence of reversible Aδ- and C-fiber transmission blockage by low-

frequency (<100 Hz) electrical stimulation of the nerve trunk, a previously overlooked mechanism that can be harnessed to enhance the therapeutic effect of PNS.

Title: Vagus nerve stimulation for EEG modulation in rats

Authors: *Y. LEE[1], S.-Y. MOON[2,3], J. SUNG[4], S. JUN[2,5];
[1]Ewha Womans Univ., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Dept. of Electronic and Electrical Engineering,, [3]Grad. Program in Smart Factory, [4]Dept. of Communication Disorders, [5]Dept. of Brain and Cognitive Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Recently, vagus nerve stimulation (VNS) has been studied as a therapy for various diseasesincluding epilepsy, depression, cardiovascular illness, obesity, diabetes, and traumatic brain injury.The treatment effects are attributed to the widespread connections of vagus nerves. Since VNSalso regulates the autonomic nerve system, it is well known that heart rate can be modulated byVNS application. In addition, the possibility of improving cognitive function is suggested, andprior studies have shown that norepinephrine and dopamine levels have increased in the frontallobe (cognitive integrated center) and hippocampus (memory center) . In this study, we aim toverify which brain regions and which frequency bands of EEG are affected by VNS in the rat brain.Along with heart rate recording, EEG power spectrums are obtained in different brain regions(both left and right medial prefrontal cortex (mPFC) , somatosensory (S1) , and parietal associationcortex (PtA)) when various stimulation frequencies are applied on vagus nerve of Sprague-Dawleyrats. For VNS, a bipolar cuff electrode was wrapped around the vagus nerve and connected to acurrent stimulator. When it was ON for 1sec, biphasic current square pulses (amplitude: 0.8mA;width: 0.8ms; frequency: 1, 10, 30, 60Hz) were delivered under light isoflurane anesthesia. EEGpower spectrums was analyzed for each stimulation frequency. As a result, this study confirmedthat VNS can modulate brain EEG signal and identified the most effective stimulation frequencyfor modulating brain signals.

Title: Unlocking the Potential of Transcutaneous Vagus Nerve Stimulation: Circuit-Inspired Approaches for Locus Coeruleus Activation and Noradrenergic Modulation

Authors: *K. MORE[1], C. GONZÁLEZ-CABRERA[1,2], A. M. JARAMILLO[1], M. BETTS[3], M. PRIGGE[1,2,4];

Network, Chevy Chase, MD; [3]Inst. für Kognitive Neurologie und Demenzforschung (IKND), Magdeburg, Germany; [4]Ctr. for Behavioral Brain Sciences, CBBS, Magdeburg, Germany

Abstract: One-Sentence-Summary: Transcutaneous stimulation of the auricular branch of the vagus nerve induces a stimulation-locked increase in firing rate in noradrenergic brain stem neurons, which persists for an extended period.Non-invasive electrical stimulation offers a sophisticated method to selectively manipulate neuronal circuits with greater accuracy and spatial resolution compared to pharmacological interventions. Transcutaneous Vagus Nerve Stimulation (taVNS) has the potential to activate specific neuronal circuits, leveraging our understanding of the neural circuitry that has emerged in recent years. The auricular branch of the Vagus Nerve, which innervates the inner ear, serves as a gateway to various neuromodulatory networks that exert significant control over sensory, spatial, and higher cognitive cortices. However, the exact connectivity between the auricular branch of the vagus and brainstem nuclei, such as the Locus Coeruleus (LC) and Dorsal Raphe, remains unclear. It is believed that auriculo-vagal afferents converge in the nucleus of the solitary tract, which has an excitatory connection to the LC via the nucleus paragigantocellularis, thereby activating the ascending LC-NA system. However, there is a lack of systematic studies investigating how specific stimulation parameters at the ear level translate into the activation of the LC.
Therefore, we conducted taVNS experiments in anesthetized mice to engage the LC-NA system and study stimulation parameters that can maximize activation in the LC. Initially, we measured cFos activity in the LC and peri-LC regions after administering taVNS at the cymba concha or the outer ear, using both high and low current regimes. The mice were stimulated for 15 minutes with a duty cycle of 30s ON and 60s OFF. Acute taVNS resulted in a significant increase in cFos-positive neuronal density in the LC bilaterally, compared to the sham groups, under both stimulation regimes (unpaired t-test). We consistently observed cFos-positive neurons in close proximity to the medial LC region.
Next, we aimed to map the stimulation parameters to the activation of individual LC neurons with higher temporal and spatial resolution. To achieve this, we employed the juxtacellular recording-labeling technique to monitor the activity of a single LC neuron during taVNS. We observed increased firing activity in the neuron during the stimulation bouts (parameter-free

ZETA-test), with a spike latency of 15-20ms following pulse delivery. Additionally, we noted an increased effectiveness of stimulation after several repeated stimulation bouts. The responsive neurons did not exhibit any topographic bias within the LC.

Title: Evaluating targeted stimulation patterns for artificial sensory feedback with in-silico rodent dorsal column model

Authors: *R. RADHAKRISHNA[1], A. P. YADAV[2];
[1]Biomed. Engin., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Neurolog. Surgery, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Spinal cord stimulation (SCS) has evolved from its original purpose as a treatment for chronic pain, to a means of restoring motor function in individuals with spinal cord injury (Miller et al., 2016). SCS also holds promise in delivering sensory feedback to the cortex via activation of the dorsal column pathways (Yadav & Nicolelis, 2017). Studies have successfully generated artificial sensations in rats and primates via SCS (Yadav et al., 2021, Slack et al., 2022). However, optimal stimulation parameters to reliably induce biomimetic sensory feedback are yet unknown (Formento et al., 2020), limiting clinical translation. Numerical methods and biophysical models provide an opportunity to simulate stimulation parameters and study their impact on neural structures. We coupled finite element (FE) simulations with the Izhikevich model, to explore how axons behaved under different stimulation conditions (Izhikevich, 2003). This approach allowed us to rapidly simulate and study different stimulation patterns. A CAD model of the rat spinal cord was created from *The Spinal Cord* atlas in Shapr3D (Watson et al., 2009). The modelled bodies included extradural tissue, neuronal tissue, electrodes, and 850 axons randomly distributed in dorsal column. Two stimulation patterns varying in periodicity were simulated for five seconds. Five axons were randomly selected for the simulation using the Izhikevich model generated in MATLAB. Stimulation involved biphasic, bipolar current

injection of 350uA. This was delivered firstly as a periodic pulse train at 50Hz for two seconds, followed by an aperiodic pulse train generated from a gamma distribution with mean frequency of 50Hz. The stimulation period comprised 100 pulses for both patterns, followed by three seconds with no stimulus. The axons reacted differently to the simulated pattern injection. For pattern 1 (periodic 50Hz), the total number of spikes elicited was 64. For the aperiodic pattern, the number of spikes across all axons totaled 85. There was a change in the activity of axons #2, 4 and 5. By coupling established numerical methods, we have demonstrated that temporally different stimulation patterns influence spiking activity. The difference in response to the patterns may influence how sensory information is transmitted to the cortex. Apart from unit activity, there is also a prospect to study peak-to-peak voltages, excitatory and inhibitory behavior between neighboring axons, etc. Comparative analysis between the various stimulation parameters will allow us to identify potential candidate patterns that can then be tested in-vivo to specifically provide biomimetic sensory feedback for individuals with SCI.

Title: Efficiency of high-frequency modulated stimulation waveforms in sensory and motor pathways

Authors: *R. KEESEY[1], L. LOMBARDI[1], R. HAWTHORN[1], N. BRYSON[1], U. HOFSTOETTER[2], K. MINASSIAN[2], I. SEÁÑEZ[1];
[1]Biomed. Engin., Washington Univ. in St. Louis, St. Louis, MO; [2]Med. Univ. Vienna, Ctr. for Med. Physics and Biomed. Engin., Med. Univ. Vienna, Ctr. for Med. Physics and Biomed. Engin., Vienna, Austria

Abstract: Spinal cord injury (SCI) leads to permanent motor function loss and reduced autonomy for approximately 12K individuals in the United States each year. Transcutaneous spinal cord stimulation (tSCS) has emerged as a promising non-invasive technique for restoring residual function post-injury. However, potential discomfort associated with the high stimulation amplitudes necessary for producing strong muscle contractions for an orthotic effect poses a critical barrier to its clinical translation. To mitigate this issue, some applications of tSCS have advocated the use of 5-10 kHz high-frequency modulated waveforms that are believed to reduce discomfort during stimulation. However, emerging evidence suggests that these high-frequency

modulated waveforms do not offer greater tolerability compared to conventional stimulation when adjusted for motor response amplitudes. Additionally, the neural mechanisms underlying the recruitment of motor and sensory fibers by high-frequency waveforms remain poorly understood. This study aimed to investigate the neural mechanisms of recruitment for high-frequency stimulation in afferent and efferent fibers through peripheral nerve stimulation. We hypothesized that high-frequency stimulation would be less efficient at recruiting sensory and motor fibers than conventional waveforms. Furthermore, we hypothesized that high-frequency waveforms would rely on temporal summation processes to elicit muscle responses and exhibit preferential recruitment of motor efferent pathways over proprioceptive afferents. Tibial nerve stimulation was used to evoke H-reflexes and M-waves recorded at 50 kHz in the soleus muscle of neurologically intact participants to analyze the recruitment of proprioceptive afferent and motor fibers, respectively. We describe the stimulation responses of motor and sensory pathways, providing insights into the distinctive recruitment characteristics of conventional and high-frequency modulated waveforms. By focusing on peripheral nerve stimulation, this study offers a simplified system to examine the recruitment mechanisms of tSCS while allowing for the direct analysis of H reflexes and M waves, which appear as separate potentials in the EMG recordings. These results contribute to the understanding of high-frequency stimulation in SCI rehabilitation, promoting the translation of tSCS to further enhance and accelerate recovery.

Title: Decoding high-density supraspinal representation of spatial and spatiotemporal patterns of spinal cord stimulation

Authors: *J. SLACK[1], A. YADAV[2];
[1]Biomed. Engin., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Neurolog. Surgery, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: A promising method of providing sensory feedback to neuroprosthetic devices and brain-computer interfaces (BCIs) is spinal cord stimulation (SCS). However, the relationship between evoked supraspinal response and temporal, spatial, or spatiotemporal parameters of SCS is not well understood, limiting the ability to generate naturalistic sensory feedback. Investigating whether SCS parameters can be decoded from evoked response is critical for developing a neuroprosthesis that induces reliable and reproducible sensory percepts. Here, we examined brain responses to spatial/spatiotemporal SCS patterns using high-density recordings and developed deep neural network (DNN) models which classify evoked responses to these

SCS patterns. 5 anesthetized rats were implanted with a Neuropixel probe and a 16-channel electrode array. The probe targeted the somatosensory cortex (S1) and the ventral posterolateral thalamic nucleus (VPL), allowing for local field potential and action potential (AP) recording on 384 channels acquired by SpikeGLX. The electrode array was positioned epidurally at the thoracic level and used the Ripple Neuro Scout processor and Trellis software to control SCS. A MATLAB interface controlled SpikeGLX and Trellis to simultaneously record brain activity and deliver SCS. During recordings, 1-1.2 sec biphasic/bipolar pulse-trains were delivered at 15 unique cathodes while anode was kept constant (spatial variation) and 10 unique anode-cathode patterns (spatiotemporal variation). Spike sorting of AP recordings was performed using *ecephys spike sorting* which incorporated *Kilosort2* and curated in *phy*. To train DNN models, peristimulus time histograms (PSTHs) were generated in MATLAB using the first pulse of each SCS pulse-train. Two DNNs were developed in Python following convolutional architecture to learn both time- and depth-dependent features of the neural recordings. Models were evaluated using 5-fold cross validation. The DNN trained on neural response to spatial variation (15 classes) had testing accuracy of 66.56 ± 4.51% and training accuracy of 85.08 ± 2.39%. The DNN trained on neural response to the 10 spatiotemporal patterns, achieved testing accuracy of 83.14 ± 2.97% and training accuracy of 98.46 ± 1.25%. These results demonstrate that SCS modulates neural activity in S1 and VPL. DNN models learned to effectively classify evoked responses, highlighting that spatial/spatiotemporal patterns of SCS can be decoded from supraspinal responses. SCS can be an effective method to transmit sensory information to the brain and generate sensory feedback that can be optimized by manipulating spatial/spatiotemporal parameters.

Abstract: Enhanced Selectivity of Transcutaneous Spinal Cord Stimulation by Multielectrode Configuration

***Noah Bryson[1,2]**, Lorenzo Lombardi[1,2], Rachel Hawthorn[1,2], Jie Fei[1,2], Rodolfo Keesey[1,2], J.D. Peiffer[1,2], Ismael Seáñez[1,2,41] Biomedical Engineering, Washington University in St. Louis[2] Division of Neurotechnology, Washington University School of Medicine in St. Louis[3] Neurosurgery, Washington University School of Medicine in St. Louis

Spinal Cord Injuries (SCI) are devastating events impacting sensory, motor, and autonomic nervous function caudal to these lesions. Spinal cord stimulation (SCS) has emerged as an effective tool to aid in the restoration of motor function. A barrier to translation of spinal cord stimulation is the highly invasive nature and cost of implanted systems, coupled with the low functional selectivity of transcutaneous SCS (tSCS). Our study aims to enable simultaneous rostrocaudal and unilateral selectivity of tSCS in leg muscles by one electrode configuration. We hypothesize that using a multi-electrode array placed over the lumbosacral spinal cord will enhance the selectivity of tSCS conventional tSCS. A single electrode and the multi-electrode array were placed centered over the T11/T12 interspinous ligament. Paired biphasic pulses of increasing amplitude were delivered through the single and each multi-electrode to elicit evoked responses in the rectus femoris (RF), semitendinosus, vastus lateralis (VL), tibialis anterior (TA), medial gastrocnemius and soleus (SL) muscles. EMG sensors were placed on each muscle to record responses (fs: 2000 Hz). Selectivity was calculated from the recruitment curves generated by the stimulation sweep. Nineteen neurologically intact individuals and two individuals with SCI took part in this study. Simultaneous rostrocaudal and ipsilateral selectivity of tSCS increased significantly with multi-electrode tSCS in the RF, VL, TA and SL. We found significant post-activation depression across all neurologically intact subjects, verifying that multi-electrode tSCS is mediated by the posterior root muscle (PRM) reflex. In individuals with spinal cord injury, multi-electrode tSCS enabled the recruitment of muscles that were unable to be recruited by the single electrode configuration. Multi-electrode tSCS enables significantly higher selectivity than conventional tSCS in neurologically intact individuals and allows for an enhanced profile of stimulation targets in individuals with SCI. The reflex pathway enabling these effects suggests a promising path to translation that allows the interaction between stimulation effects and residual neural inputs in people with SCI.

Title: Short-term changes in neural excitability of cortico-reticulo-spinal circuits induced by spinal cord stimulation and activity-based training

Authors: *R. HAWTHORN, H. NIE, R. KEESEY, L. LOMBARDI, I. SEÁÑEZ;
Biomed. Engin., Washington Univ. in St. Louis, St. Louis, MO

Abstract: Spinal cord injuries (SCI) lead to long-lasting paralysis, affecting hundreds of thousands of individuals in the United States. When combined with training, spinal cord stimulation (SCS) has been shown to induce significant functional improvements in individuals with SCI. However, the neural mechanisms that mediate this neurorecovery remain poorly understood. This study aims to quantify short-term changes in neural excitability of the corticospinal, reticulospinal, and spinal motoneurons induced by transcutaneous SCS and activity-based training, both independently and in combination. We used transcranial magnetic stimulation (TMS) to record motor evoked potentials (MEPs) to examine the contributions of the corticospinal tract, the StartReact response (a shortening in response time after a startling auditory cue) for the reticulospinal tract, and F-wave responses in the soleus to tibial nerve stimulation for the spinal motoneuron tract. Pre- and post-evaluations were conducted after three distinct 30-minute training sessions: activity-based training; SCS only; and a combination of activity-based training and SCS. Activity-based training involved a non-invasive body-machine interface (BoMI), where participants used their legs to control a 2D cursor to play video games. Twelve wireless EMG sensors (Delsys Trigno Avanti & Avanti Mini), sampled at 4370 Hz, were placed bilaterally over the muscle belly of the sternocleidomastoid, rectus femoris, tibialis anterior, medial gastrocnemius, soleus, and flexor hallucis brevis muscles. MEPs, startle response times (indicative of reticulospinal tract gain), and F-wave persistence and amplitudes were used to characterize changes in excitability within their respective neural tracts following each condition. This study validates a robust framework for quantifying short-term changes in neural excitability of the cortico-reticulo-spinal circuits in able-bodied individuals by targeting lower limb muscles. The findings of this research will enable future investigations into neural plasticity in individuals with SCI undergoing SCS-assisted neurorehabilitation.

Title: Neuronal Outcomes of Different Coil Configurations in Cerebellar Transcranial Magnetic Stimulation: A Computational Study

Authors: *X. ZHANG[1], R. HANCOCK[2], S. SANTANIELLO[1];
[1]Univ. of Connecticut, Storrs, CT; [2]Yale Univ., New Haven, CT

Abstract: The cerebellum is a common target of transcranial magnetic stimulation (TMS) for studying various brain processes and diseases. However, there has been insufficient evidence to support coil type selection, and empirical methods of coil placement, which are based on fiducial markers and do not specifically target the cerebellar region of interest, contribute to variability and suboptimality in outcomes. To tackle these issues and provide quantitative predictions on the neuronal effects under different coil types and placements, we used a previously developed multi-scale pipeline to place a variety of coil types (i.e., MagStim D70 and DCC; MagVenture DB80; Deymed 120BFV) across 28 targets (i.e., a 7×3 grid across the lateral cerebellum along with optimized positions for targeting lobules from V to VIII) on the BigBrain atlas [1, 2], which provides a highly precise reconstruction of the cerebellar cortical surface (average mesh resolution: 126 μm) and enables accurate estimation of the locations and orientations of Purkinje cells [3]. For each of the 112 setups, we predicted the corresponding local activation of Purkinje cells in each lobule and systematically compared the potential effects on the major functional areas usually explored via TMS. Altogether, our study supports identification of the most effective coil setup for targeting the desired cerebellar target and offers guidance for more precise and effective cerebellar TMS studies.

Title: Pattern of synchronization between nucleus basalis of Meynert and its cortical targets helps to choose DBS parameters

Authors: *E. LEVICHKINA[1], X. WU[2], L. WESTON[2], T. VIDYASAGAR[1], **C. FRENCH**[3];

Abstract: Deep brain stimulation (DBS) effectively prevents motor dysfunctions in Parkinson disease but whether it can alleviate cognitive decline co-occurring with PD (Lewy body dementia) is unknown. Several clinical attempts to use DBS for that purpose reported inconclusive effects. At the same time, DBS experiments in rodents focussed on stimulating nucleus basalis of Meynert (NB) largely resulted in cognitive improvement. While tonic

stimulation was used in clinical studies, the effective stimulation in animal studies is known to be intermittent which includes both low and high frequencies. We hypothesized that communication between NB and cortex involves frequencies in both delta-theta and gamma ranges, making nested frequency patterns potentially more effective. In addition, human clinical studies opted for tonic stimulation across the sleep-wake cycle. We also hypothesized that NB stimulation during sleep can lead to sleep disturbances.
We studied preferred frequencies of neuronal synchronization within NB as well as between NB and its cortical targets in B6 mice (N=6, age 4-6 month) by recording neuronal spiking and local field potentials (LFP) from 2 NB and 4 cortical sites simultaneously across multiple sleep-wake cycles (115 NB cells and 210 cortical cells). Spike-field coherence (SFC) between NB cells and NB LFP revealed natural synchronization tendencies of NB - all animals demonstrated significant SFC at delta-theta range and multiple gamma peaks, largely similar in sleep and wakefulness with higher low frequency SFC in slow wave sleep (SFC > 95% jackknife confidence interval at frequency range > 2*bandwidth). SFC between cortical cells and NB LFP, which reflects cortical feedback, in all but one animal peaked at low frequencies. We conducted a preliminary study of NB stimulation effects on cortical LFPs across sleep-wake cycles (N animals = 3), and compared nested frequencies (5Hz & gamma <100Hz), random and tonic (20Hz) stimulation types. All types of stimulation lead to a significant decrease in delta activity immediately after the stimulation in all states of vigilance even at the lowest intensity (Wilcoxon $p<0.05$), indicating a potential for sleep disturbance. Only nested frequency pattern induced gamma activation during wakefulness, and prolonged suppression of delta activity was more likely to occur with this pattern as well.
We conclude that communication between NB and cortex occurs at gamma bursts nested within delta-gamma oscillations, and NB stimulation using this pattern can be more effective in supporting wakefulness. However, NB stimulation during sleep may lead to sleep disturbances.

Abstract: Dopamine release and neural ensemble activity in the nucleus accumbens (NAc) play crucial roles in reward-guided learning, motivation, and decision making. Electrical deep brain stimulation (DBS) is an important tool for the causal manipulation of neural circuits and the treatment of diseases such as Parkinson's disease. The effects of DBS on neural activity and neuromodulator release are complex and incompletely understood. In addition, traditional DBS utilizes fixed inter-pulse intervals at fixed frequencies. This is potentially sub-optimal as neurons and neural circuits are often responsive to unpredictable input. Therefore, this study investigated how inter-pulse variability of DBS applied to the medial forebrain bundle (MFB), the axon bundle connecting ventral tegmental area to the NAc, impacts single-neuron and neural ensemble activity as well as sub-second patterns of dopamine release. **Methods**: Isoflurane-anesthetized male Sprague-Dawley rats (310-400 g) were implanted with a Neuropixels probe (n = 4 rats) and a carbon-fiber microelectrode for measuring dopamine concentration (fast-scan cyclic voltammetry, FSCV). Both probes targeted the NAc (AP: 1.5, ML: 1.4, DV: >6.2 mm). A bipolar stimulating electrode was placed in the MFB. Ten-second biphasic stimulation trains (~300 µA) with varying inter-pulse statistics (tonic to bursting) and mean frequencies of 10 or 20 Hz were delivered. **Results**: Stimulation reliably increased extracellular NAc dopamine concentration, and the time course of release was strongly correlated with the stimulation sequence. Preliminary analyses of neural ensemble recordings indicate that the effects of stimulation varied by neuronal subtype. During stimulation, regardless of frequency or inter-pulse variability, putative medium spiny neurons (MSNs, n = 138) initially increased firing and returned to baseline in <20 seconds. In contrast, putative fast-spiking interneurons (INs, n = 41) were suppressed during stimulation and exhibited a large rebound in firing at stimulation offset that lasted ~2 seconds. Moreover, IN firing rates remained elevated for >2 minutes following stimulation offset. At the network level, stimulation reduced network sparsity and increased overall population activity for tens of seconds to minutes following stimulation offset. These findings suggest that MFB stimulation produces opposing effects on distinct NAc neuronal subgroups, and these effects can persist for minutes after stimulation offset. Further research will explore sub-second relationships between neural ensemble activity, dopamine release, and inter-pulse variability.

Title: An investigation of the effects of transcranial direct current stimulation on the rat somatosensory evoked potential

Authors: *L. CHEN[1,2], B. ASAMOAH[1,2], M. MC LAUGHLIN[1,2];
[1]KU LEUVEN, LEUVEN, Belgium; [2]Leuven Brain Inst., Leuven, Belgium

Abstract: Transcranial direct current stimulation (tDCS) is a non-invasive neuromodulation method that uses scalp electrodes to deliver low-amplitude direct currents (DC) which creates a weak electric field (<1 V/m) in the cortex. Anodic tDCS is believed to have a depolarizing effect, leading to cortical excitation; while cathodic tDCS has a hyperpolarizing effect, leading to cortical inhibition. tDCS is used to boost cognitive and motor function in healthy volunteers and is under investigation as a treatment for many neurological and psychiatric disorders. However, the underlying mechanisms behind tDCS remain poorly understood and a number of recent studies have failed to reproduce some previously reported tDCS effects. One approach to address these issues is to develop animal models that can reproduce tDCS neural effects previously observed in humans. These animal models can then be used to study and understand basic tDCS mechanisms. In 8 male Sprague Dawley rats we implanted a 32-channel silicon probe in the somatosensory cortex to measure evoked potentials (SSEPs) elicited by fore-limb stimulation (0.25Hz, 1mA). A screw electrode was implanted over the somatosensory cortex to deliver DC stimulation (3mins, 0.005 to 0.3 mA). To quantify cortical excitation, we normalized SSEPs during stimulation to SSEPs collected before stimulation. The effect of tDCS on normalized SSEP (nSSEP) amplitude was then analysed using a linear mixed model. We found that anodic tDCS significantly increased nSSEP amplitude (i.e. excitation, p <0.01), while cathodic tDCS significantly decreased nSSEP amplitude (i.e. inhibition, p <0.01). The linear model showed that for every 0.1mA step change in anodic tDCS amplitude, cortical excitability increased by 3%, while for every -0.1mA step change in cathodic tDCS cortical inhibition increased by 3%. We showed that animal models can be developed which reproduce some of the basic tDCS effects, similar to those previously reported in humans. This rat model can now be used to accurately quantify the electric field strengths and determine how this corresponds tDCS electric field strength in humans.

Abstract: Transcranial electrical stimulation (TES) is a non-invasive neuromodulation technique consisting of injecting electrical currents via electrodes placed on the scalp showing promising clinical applications. Commonly, currents are injected using two electrodes with the anode placed above the region of interest and the cathode at a distant location on the head. It has long been held that external electric fields stimulate neurons more effectively when oriented along the axons that are being stimulated. While this effect has been studied for transcranial *magnetic* stimulation, it has not been rigorously verified for TES. Doing so is important, e.g., in order to optimize high-density (HD) TES. HD-TES has recently gained prominence as an attempt to improve the focus of the fields generated in the brain by using HD electrode montages, with a central anode surrounded by equidistant cathodes. While the resulting E-fields are more confined, these montages typically result in larger E-field components normal to the cortical surface and lower tangential components, compared to the two-electrode montages.
In the present study, we applied pulsed TES (100 μs monophasic pulses of amplitude 65-145 mA) to the motor cortex of awake healthy humans (n=4 participants) while monitoring evoked motor activity in hand flexor and extensor muscles using high-density surface electromyography (EMG). Two stimulation electrodes (1 cm diameter gold cups) separated by 7 cm were used to inject the current. The anode was fixed above the forearm representation of the motor cortex (2 cm medial from C3, determined in previous experiments), while the cathode was moved in 22.5° increments to achieve different orientations of the electric field. We found that the motor evoked potential (MEP) amplitude in the contralateral limb is maximized when the two electrodes are aligned with the medio-lateral (ML) axis, with an angular full-width at half-maximum (FWHM) of 48.5°±8.2°. In one participant, we additionally performed small movements of the anode in 7 mm steps to assess whether the observed change in MEP could be due to shifts in the spatial location of the electric field caused by the changing cathode location. We observed similar changes in MEP amplitudes as a function of the field direction independently of the anode location, confirming that the electric field direction drives the motor response.
The results shown demonstrate that TES of the hand motor area exhibits strong directional selectivity. Since directionality in the motor cortex may be a consequence of the orientation of the central sulcus, the strength of this effect on other brain areas is not known and requires further experimentation.

Title: Varying the inter-pulse interval of electrical brain stimulation in the MFB and mPFC alters the time course of dopamine release

Authors: *A. HAMILTON[1], N. C. WEINTRAUB[1], A. VISHWANATH[2], C. J. STOPERA[3], S. L. COWEN[2], M. L. A. V. HEIEN[1];
[1]Chem. and Biochem., [2]Psychology, [3]Neurosci. GIDP, Univ. of Arizona, Tucson, AZ

Abstract: Dopamine release in the striatum is crucial for reward-guided learning, decision making, and motor control. Electrical deep brain stimulation (DBS) is used in research and for treating Parkinson's disease. DBS typically uses fixed frequencies and fixed inter-pulse intervals, but previous research has shown that neurons and neural circuits are more responsive to variable inter-pulse intervals, or more burst-like pulses. In this study, we seek to understand the effects of increasing the variability of inter-pulse intervals on downstream dopamine release in the nucleus accumbens (NAc). We also investigated whether these effects differ depending on whether stimulation was applied to the medial forebrain bundle (MFB) or the medial prefrontal cortex (mPFC). MFB stimulation directly activates dopamine axons while the mPFC activates a multi-synaptic circuit that ultimately triggers dopamine release. We hypothesized that increased inter-pulse variability, which appears more 'bursty,' will release the most dopamine in the NAc. **Methods:** Anesthetized (isoflurane), male, Sprague-Dawley rats (310-400 g, n = 5 each stimulation region) were implanted with a carbon-fiber microelectrode in the NAc to measure extracellular dopamine concentration at a sub-second resolution using fast-scan cyclic voltammetry. A bipolar stimulating electrode was placed in the MFB or mPFC. Stimulation trains lasted 10 seconds, were generated with differing degrees of inter-pulse variability, and constrained to have an average frequency of 10 Hz or 20 Hz. Local variance (Shinomoto et al. 2003) quantified variability in the inter-pulse intervals. **Results:** Data indicate that increasing stimulation frequency in the MFB increases dopamine release. In the mPFC, dopamine release did not significantly increase when the stimulation frequency increased. Conversely, pulse variability caused opposite trends in the MFB and mPFC as a result of increasing local variance. We observed that increasing local variance in the MFB increased dopamine release while increasing variance of mPFC stimulation evoked less release than fixed inter-pulse interval sequences. The time course of dopamine release followed the time course of variable stimulation sequences more closely when the MFB was stimulated relative to the mPFC. This was further supported by the observation that correlations between MFB stimulation and dopamine release were highest when time was binned using 200 ms intervals while correlations between mPFC and dopamine release peaked when 600 ms intervals were used. These results enhance the understanding of inter-pulse variability and its effect on the time course of dopamine release.

Title: Different direct electrical stimulation paradigms to upregulate and downregulate low-frequency (7-12 Hz) rhythms in human cerebral cortex

Authors: *D. OSWALT, W. BOSKING, M. S. BEAUCHAMP, D. YOSHOR;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Neuromodulation is a rapidly growing tool in research and clinical practice, with potential for large impact in both realms. The devices used for interfacing with the brain are becoming increasingly advanced, however the electrical stimulation strategies used to modulate brain activity have not seen the same development. Low frequency oscillations in the alpha and beta range, a prominent attribute of ongoing neural activity, are a frequent target for modulation. Being able to manipulate these rhythms in a patient-specific manner would be extremely useful for the development of brain computer interfaces. Here we have focused on electrical stimulation strategies to either enhance or suppress these rhythms.

Testing was conducted with 4 patients undergoing invasive monitoring for epilepsy, implanted with stereo-EEG electrodes. Monopolar electrical stimulation was delivered to one electrode per patient. A large surface electrode placed on the patient's thigh served as the return. Electrodes were selected based on whether they exhibited prominent low frequency oscillations (7-12Hz). Three of the electrodes were in temporal lobe, and 1 electrodes was in occipital lobe. Pulse trains were comprised of charge-balanced, biphasic, symmetric, cathodal first pulses, with 0.1ms duration per phase delivered at 1mA.

To enhance low frequency oscillations, we delivered pulse trains comprised of short bursts of high frequency (200Hz) pulses delivered at a regular, lower frequency interval. For example, to entrain an oscillation at 8Hz, we delivered a burst of 4 pulses every 125ms for total duration of 1s. Using this strategy, we were able to enhance the power in the 7-12Hz range by 49% on average across the 1s train, without corresponding changes in other low frequency bands (10 trials, 1 subject). Similar effects were seen in 2 other subjects.

To disrupt low frequency oscillations and suppress low frequency power, we delivered a pulse train with irregularly timed pulses. 200 pulses were delivered over a 1 second interval, with the random inter-pulse timing obtained from a Poisson distribution. This paradigm reduced oscillatory power by an average of 32% across the 1s pulse train, without a significant change in power in the 1-6Hz range (15 trials, 1 subject).

These results show the viability of using electrical stimulation to up or down regulate low frequency rhythms in the cerebral cortex. This could be a useful tool for use in future BCI and neuroscientific research.

Fairview, Minneapolis, MN

Abstract: Depression is the leading cause of disability worldwide. Half of these patients have treatment-resistant depression (TRD). Because of the high dimensionality of symptom presentation, numerous models have been proposed to explain patterns of depressive symptoms. These models have focused on large-scale networks that include combinations of the Default Mode Network (DMN), Fronto-Parietal Networks (FPN), the Salience Network (SN), and several other sub-cortical systems related to mood and the limbic system. Thus far, there have been limited efforts in direct cortical stimulation for TRD. Despite its relatively easy access and success in other domains of cortical stimulation, the substantial variability in cortical network topography makes precise targeting of the model systems difficult. New approaches using Precision Functional Mapping (PFM) now allow for such precise localization within individuals and provide an opportunity for personalized targeting for direct cortical stimulation in TRD. Here we report the first case of an individually-targeted Prefrontal Cortical Stimulation (PCS) informed by PFM for TRD. PFM was conducted with both a supervised or unsupervised approach network mapping algorithm based on two 40 minute resting-state functional connectivity runs. Surgical planning leveraged PFM to isolate areas of pathology in the SN (larger relative to controls, $t=-2.93$ $p<0.01$), and DMN (smaller relative to controls, $t=2.39$ $p<0.01$). PFM was also leveraged to carefully plan electrode placement. An 3D model of four multicontact electrodes(Abbott Laboratories) was placed on the 3D pial surface along with the PFM, to simulate final placement targeting SN, DMN, and FP network motifs, consistent with prior models of pathology . A volume image with the desired placements was then used for stereotactic neuronavigation during craniotomy. A follow up CT scan confirmed accurate placement with pre-surgical targets. Proclaim Elite SCS System stimulation system was implanted 4 days later. Stimulation of the right dorsal medial prefrontal cortex provided immediate feelings of joy. Critically, optimization of stimulation parameters showed distinct positive modulation of emotions and attention which was (59% improvement in mood using the

HRSD24 after 17 week follow-up). Our approach establishes PFM-informed PCS targeting as a viable method for modulation of affected networks in TRD as a therapeutic intervention.

Abstract: Transcranial magnetic stimulation (TMS) is a safe, effective and non-invasive treatment for several psychiatric and neurological disorders. TMS is FDA approved treatment for depression and obsessive-compulsive disorders [1]-[3]. Lately, there has been a research surge in utilizing this novel technology in treating other neurological and psychiatric ailments. The application of TMS on other several neurological disorders requires the magnetic flux density

and electrical field to be focal and targeted to a small region in the brain [4]. Multiple coil designs have been introduced in the literature to improve the focality of TMS coils, whereas, slight few numbers of these designs have adapted soft magnetic materials as coil cores to focus the magnetic flux. In this study, some new core configurations will be tested in Finite Element Simulations on a rat head model while some of them will be tested experimentally.Finite element analysis of the rat head model is done using Sim4life and Ansys Maxwell while investigating variations associated with changing the coil core material and design. Materials proposed for the analysis in this study include but not limited to Iron Cobalt Vanadium alloy (FeCoV), Iron (AISI 1010 Carbon Steel) and Manganese Zinc ferrites (MnZn Ferrites). Simulation results are presented below in (Fig. 1), comparing the generated magnetic field distribution of 4 types of cores. Furthermore, a novel parabolic coil design with a sharpened tip was developed to concentrate the E-Field to the targeted region in the rat head model without stimulating adjacent regions (Fig. 2) [5]. Further analysis will be done for this novel coil.Acknowledgment: Authors acknowledge Commonwealth Cyber Initiative Central Virginia Node Grant # FP00010500.:

Title: Direct current onset excitation controlled through electrode positioning

Authors: *Y. DU[1], C. CHENG[1], G. FRIDMAN[2];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Johns Hopkins Univ., BALTIMORE, MD

Abstract: Direct current (DC) delivered to a nerve can block action potential (AP) propagation in individual axons. This block has been shown to be useful by us and others, to control chronic peripheral nociceptive pain. The onset of DC however evokes undesired APs. These are commonly controlled by lengthening or ramping up the duration of the DC onset. This tendency to evoke APs also depends on the distance of the axon to the stimulation site. The conventional

technique to control neural excitation is to use tripolar stimulation. The current from the side anodes that hyperpolarize the neuron is driven to the center cathode to prevent depolarizing the neuron further downstream of the electrode site. While this technique has been used to control the neural response over a longer duration, it has been less effective in suppressing undesired excitation for DC onset. Here we hypothesize that the main origin of undesired APs is at the center of the stimulation site in response to strong cathodic depolarization. The high amplitude of cathodic current causes AP to form in the center, while the hyperpolarized sidelobes due to the anodes are too weak to suppress it from propagating. In our computational model, we demonstrated this effect for three axons positioned at different distances from the stimulation site (a1, a2, a3, a4). Our solution is to move the cathode further away from the nerve to reduce the depolarization effect of the cathodic electrode. Panels b1, b2, b3, and b4 demonstrate the effect and the reduction of the undesired AP formation in the center. With increased the cathode distance by 1mm in the model, and the threshold of DC onset neural excitation increased from 0.23 mA to 1.59 mA for axon 1, from 1.35 mA to 5.85 mA for axon 2, and from 4.10 mA to 9.75 mA for axon 3.

Abstract: Freeform Stimulator (FS): Stepper motor-integrated implant design for non-pulsatile arbitrary waveform neuromodulation**Authors**Alexandra Cheng[1], Yangsheng Xu[2], Gene Fridman[1,21]Johns Hopkins University, Department of Biomedical Engineering, Baltimore, USA[2]Johns Hopkins Medicine, Department of Otolaryngology, Baltimore, USA**Disclosure**Research was funded by NIH R01NS110893 and Australia NHMRC Ideas Grant APP1187416.**Abstract**In contrast to conventional pulsatile stimulation that evokes action potentials in phasewith pulse presentations, ionic direct current (iDC) or low frequency neuromodulationis capable of axonal excitation, inhibition, and synaptic sensitization. Despite itsversatility, iDC cannot be delivered safely via metal electrodes for safety concerns suchas pH changes, electrolysis, and corrosion. Our lab and others published extensively onthe applications of iDC neuromodulation for improving vestibular implants, blockingpain in the peripheral nerve, and modulating cortical processing.[1] We previouslyproposed several designs of a microfluidic device that rectifies electrical pulses deliveredto metal electrodes into an ionic DC current delivered to the neurons. The architectureallows each electrode to alternate between charging and driving current to the tissue orbeing discharged to avoid electrochemical reactions. The main reliability concern inthese designs has been shape memory alloy actuation due to its thermal and structuralinstability. In this work, we propose a novel design that uses a miniature stepper motorinstead of shape memory alloy as the actuator. The motor rotates an inner cylinderhousing the two hydrogel-coated metal electrodes within another concentric outercylinder. As the electrodes encounter the hydrogel reservoirs on the wall of the outercylinder, a gel bridge is created to allow ionic current to pass through. This rotatingmechanism greatly improves the reliability and efficiency of the device compared withprevious generations.[1]F. P. Aplin and G. Y. Title: Investigating Test-Retest Reliability of TMS-Evoked Potentials (TEPs): Exploring TMS Protocols Across Distinct Target Sites

Authors: *C. SAYALI[1], D. JARO[1], G. LOFLAND[1], S. DARCY[1], E. WEISMAN[1], F. S. BARRETT[2];
[1]The Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Johns Hopkins Univ. Sch. of Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Concurrent Electroencephalography (EEG) and Transcranial Magnetic Stimulation (TMS) has been recently utilized to assess the effects of various treatments on brain function, yet the test-retest reliability of TMS-evoked potentials (TEPs) remains inadequately understood. Test-retest reliability is crucial for evaluating the magnitude of effects of a given intervention on an outcome measure, particularly in TMS studies as intrinsic neural fluctuations and uncontrolled extrinsic factors can contribute to variability in TEPs across sessions, impacting the reliability of TEP-based outcomes. While previous research has focused mainly on motor evoked potentials (MEPs) and standardized TMS target locations, limited studies have assessed the test-retest reliability of TEPs and generalizability to other stimulation protocols and target sites. This study aims to fill this gap. Neurologically and clinically healthy participants (n=11; data collection is ongoing) underwent magnetic resonance imaging to obtain anatomical and resting-state functional brain images for neuronavigation-guided TMS. Resting-state data were separately decomposed into canonical network maps for each participant using independent components analysis (ICA). Two concurrent EEG and TMS sessions were then completed, with at least one week between sessions. In each session, TEPs were generated across distinct brain regions (the motor cortex, DLPFC as a node of the fronto-parietal task control network, and angular gyrus as a node of the default mode network) using literature-derived target coordinates as well as individualized target coordinates based on ICA-derived resting-state networks. TEPs were compared between literature-derived and individualized coordinates, and between a single pulse TMS protocol and paired-pulse TMS protocols with interstimulus intervals of 3ms (to stimulate cortical inhibition) and 11ms (to stimulate cortical excitation) at each coordinate. Preliminary results showed that concordance correlation coefficients (CCCs) for all protocols were moderate (0.34 - 0.52) with single-pulse protocols showing the greatest reproducibility. Additionally there was no significant difference in CCCs between individualized versus standardized targets (individualized: 0.43 [0.19 0.61]; standardized: 0.51 [0.29 0.68]). By investigating the test-retest reliability of TEP measurements across various brain regions and TMS protocols, this study contributes to the understanding of the reliability of TMS measurements, which may advance our understanding of the underlying neurophysiological processes associated with TEPs.

Title: Terminating ECoG high-gamma activity increases the effectiveness of ECS during speech production

Authors: *C. KAPELLER[1], K. KAMADA[3], M. MOHAMMADPOUR[1], K. MAYR[1], **C. GUGER**[2];

Abstract: Electrical cortical stimulation (ECS) of the brain can change our behavior and the way how our brain works. This phenomenon has been demonstrated by observing stimulation-related symptoms such as involuntary movements, visual illusions, or transient aphasia while stimulating the motor, visual, or language cortices. It turned out that the resection of those areas often led to postsurgical function deficits, and, thus, ECS is a valuable method for pre- or peri-operative functional mapping. Especially for language mapping, where ECS became the gold standard technique for preserving the ability to speak. Stimulation protocols during a language task like the Boston naming test have been well established, but are mainly created based on empirical observations and greatly differ from patient to patient. Hence, it is important to better understand the causality of the applied stimulation settings and the behavioral symptoms. An additional biomarker, broadband high-gamma activity (HGA) in the electrocorticography (ECoG), was demonstrated to reflect language neural activity with a great spatial resolution. The aim of this study was to determine whether the onset time of ECS during a naming task affects the frequency of symptoms and, if so, how it aligns with the HGA time course. Two epilepsy patients of the Megumino Hospital in Japan gave informed consent to participate in this extension of the routine clinical ECS language mapping prior to a resective brain surgery. A picture naming task was performed without ECS to observe task-related HGA. The clinical routine ECS revealed locations where stimulation with 5-7mA elicited transient aphasia, paranomia, or paraphasia. Thus, the location with the strongest HGA was selected as the stimulation target for variable ECS onsets between 0.35 and 1s after picture onset. Stimulation at 50Hz lasted for 1s and each trial was labeled either with ‘no symptom’ if the speech was not disturbed, or ‘symptom’ if any of the aforementioned symptoms arose. The HGA reached a top of 5.44 and 4.72 z-scores at 684 and 454ms, and the full-width-half-maximum was 383-955 and 333-764ms for P1 and P2, respectively. The ECS symptom rate of P1 and P2 was 92 and 47% before the HGA peak and reduced to 37 and 13% afterward. The ECS symptoms reduced once the HGA reached its top, indicating a strong relationship between speech production, HGA, and the effectiveness of ECS. Furthermore, it shows that patients that respond faster require earlier ECS compared to slower ones. Such personalized stimulation protocols can make functional

mapping more efficient by reducing the time of stimulation, which can improve time-critical mapping during awake craniotomies.

Title: The influence of stimulus pulse duration on corticospinal excitability in neuromuscular electrical stimulation

Authors: *K. HAYASHIDA[1], J. USHIBA[2], M. TAKEMI[1];
[1]Grad. Sch. of Sci. and Technol., [2]Fac. of Sci. and Technol., Keio Univ., Yokohama, Japan

Abstract: Neuromuscular electrical stimulation (NMES) is a neurorehabilitative method utilized for improving motor function in individuals with post-stroke paralysis. This method involves the application of electrical currents to the skin, which depolarize sensory nerves underlying the stimulating electrodes. NMES has been shown to increase the excitability of corticospinal projections in a frequency- and duration-specific manner. However, the specific impact of pulse width on this process remains unclear. This study aimed to investigate the effect of NMES pulse width on corticospinal excitability. Twenty-four healthy subjects were recruited for this study. Robotic transcranial magnetic stimulation was used to assess corticospinal excitability before and after 40 min of median nerve stimulation at a stimulation frequency of 100 Hz. The pulse widths of 0.3 ms and 1 ms were selected for the experiment. Motor-evoked potential amplitudes of the abductor pollicis brevis muscle were fitted to a stimulus-response curve (SRC) to estimate the dependent variables reflecting neurotransmission efficiency. The results showed that NMES could transiently increase corticospinal excitability regardless of the pulse width. An ANOVA demonstrated a significant interaction between the presence or absence of NMES application and the time course after NMES for the SRC-dependent variables reflecting neurotransmitter efficiency ($F(3,66) = 3.403$, $p = 0.023$) but not for the factors NMES application, time after NMES, and the pulse width ($F(3,66) = 2.62$, $p = 0.058$). Post-hoc pairwise comparisons indicated a difference in neurotransmitter efficiency between immediately after 40 min of NMES and after 40 min of Rest ($t(23) = 3.156$, $p = 0.044$). Furthermore, although ANOVA did not reveal

significant interaction with the factor pulse width, there was a marginally large difference in the percentage increase in neurotransmitter efficiency immediately after NMES application for a pulse width of 1 ms compared to 0.3 ms (1 ms: 156% increase, 0.3 ms: 114% increase). Consistent with previous findings, our results demonstrated that NMES is capable of enhancing corticospinal excitability. However, the differential impact of NMES on corticospinal excitability between pulse widths of 1 ms, which are believed to effectively induce afferent volleys, and 0.3 ms, which is less painful, was not evident. These findings suggest that NMES utilizing less painful parameters could be used as a plasticity-inducing protocol in clinical practice.

Title: Topography heat maps to visualize the source of EEG-based biomarkers for deep brain stimulation in Parkinson’s disease

Authors: J. PEETERS[1], T. DEMBEK[2], A. BOOGERS[1], T. VAN BOGAERT[1], R. GRANSIER[1], J. WOUTERS[1], B. NUTTIN[1], ***M. MC LAUGHLIN**[1];
[1]Neurosci., KU Leuven, Leuven, Belgium; [2]Fac. of Med., Univ. of Cologne, Cologne, Germany

Abstract: Subthalamic deep brain stimulation (STN-DBS) is a well-established therapy to treat Parkinson’s disease (PD). The wide parameter space and time constraints can make the programming of patients challenging. One solution could be to use EEG-based evoked potentials (EP) to guide programming. Previously, we have investigated EEG-based evoked potentials (EPs) as a biomarker to guide programming. We found that a 3-millisecond peak (P3) was strongest in contacts closest to motor STN and could predict the best DBS-contact configuration. Together with evidence in literature, these results led to the hypothesis that P3 may be caused by hyperdirect pathway (HDP) activation. Alternatively, we found that a 10-millisecond peak (P10) was related to substantia nigra (SNr)-related side effects. Here, we investigated in the scalp location where P3 and P10 are strongest by calculating EEG-based topographic heat maps. Stimulation was delivered at 10Hz for 50s at each contact of a directional lead, while EPs were recorded using 64-channel EEG. Next, right hemispheric stimulations were transformed to the left hemisphere and all EPs were averaged across hemispheres for each EEG channel resulting in an average 64-channel dataset. Lastly, topographic heat maps were calculated at the latency for P3, P10, and the stimulation artifact.Data from 12 hemispheres were grouped for P3 and the stimulation artifact, and from 13 hemispheres for P10.

The topographic heat map for P3 shows strongest activity in the primary motor and premotor cortex ipsilateral of stimulation, while the through of activity was observed in the parietal cortex ipsilateral of stimulation. The topographic heat map for P10 shows strongest activity in the prefrontal cortex ipsilateral of stimulation and lowest activity in the occipital area. As a control, the topographic heat map for the artifact represents a deep source.
The P3 topography strengthens the hypothesis that P3 may be caused by HDP activation. Next, the P10 topography supports the previously published data that P10 is probably related to SNr activity as a SNr-to-prefrontal connection has been described in literature. These results strengthen our previous hypotheses that P3 and P10 are important biomarkers to facilitate the DBS programming of PD patients.

Title: A machine learning-based approach to select parameters for safe electrical neural stimulation

Authors: Y. LI[1], R. FREDERICK[2], D. GEORGE[1], S. COGAN[1], J. J. PANCRAZIO[3], L. BLERIS[3], ***A. HERNANDEZ-REYNOSO**[1];
[1]The Univ. of Texas At Dallas, Richardson, TX; [2]Univ. of Oregon, Eugene, OR; [3]The Univ. of Texas at Dallas, Richardson, TX

Abstract: Stimulation of the nervous system can be used to restore function after neurological injury or disease. The safety of delivering currents to neural tissues depends on the stimulation parameters. The Shannon equation is an accepted linear model to separate damaging from non-damaging parameters based on log10 values of charge and charge density. However, this equation was developed based on a small dataset for cortical macroelectrodes and may not accurately predict outcomes beyond this limited space. Here, we report on a machine learning approach to more reliably predict stimulation-induced tissue damage in response to different parameters.A literature search was conducted using keywords including “neuromodulation”, “damage”, “safe”, “neural interfaces”, as well as literature cited in previous neural stimulation reviews. Stimulation parameters were extracted from each publication. Tissue responses were either reported by the included studies or scored by two blinded investigators as damaging or non-damaging. Then, we calculated the accuracy of the Shannon equation on the entries of this database. Subsequently, we used ordinal encoding and Random Forest for feature selection and then developed a machine learning model based on One-Hot encoding and Random Forest classification. Finally, we compared these results against the accuracy of the Shannon

equation.We compiled a database with 387 unique stimulation parameters collected from 58 studies. There was a discrepancy between the two investigators scores in only 3% of database entries. Tissue response scores in the database were balanced showing 195 (51%) entries as non-damaging and 190 (49%) as damaging. The features selected were pulse waveform, geometric surface area, pulse width, frequency, pulse amplitude, charge per phase, charge density, current density, stimulation train duration, daily stimulation duration received, daily number of pulses delivered and daily accumulated charge. The Shannon equation yielded an accuracy of 63.9% using a k = 1.79. In contrast, the random forest algorithm was able to robustly predict whether a stimulation parameter was damaging or non-damaging with an accuracy of 89.6%.The use of this model for prediction of stimulation parameters on neural tissue outcomes can facilitate informed decision-making in selection of neuromodulation parameters for research and clinical practice. This is the most comprehensive database to date for stimulation parameters and neural tissue outcomes and the results indicate high generalization to new parameter combinations. Future work will further validate this model against novel electrode designs and stimulation parameters.

Title: Identification of controller parameters for closed-loop deep brain stimulation

Authors: *J. ORLOWSKI, M. LOWERY;
Univ. Col. Dublin, Dublin, Ireland

Abstract: Deep Brain Stimulation (DBS) is a widely used treatment for Parkinson's disease (PD). It has proven effective in reducing the symptoms of PD, however, conventional DBS treatments are not always sufficient to meet the needs of patients in the long-term. Adaptive DBS (aDBS) is an emerging technology that improves upon conventional DBS by automatically adjusting the stimulus parameters in response to the patient's condition in real-time.
In recent years, the majority of the proposed aDBS solutions have utilized the magnitude of beta (13-30 Hz) oscillations as a biomarker with which to adjust either stimulation amplitude or frequency. Proportional-Integral-Derivative (PID) control is a well-established approach for controlling a wide range of systems and is effective even when the systems are very complex, have unknown internal dynamics and are subject to noise.
While powerful and responsive, PID controllers need to be tuned to realize their potential. A

range of techniques exist to help select the controller parameters; however, many of them require precise knowledge of the internal dynamics of the controlled system and are poorly suited to situations where the underlying dynamics change over time as is the case with neural systems e.g., due to diurnal variation of symptoms or the disease progression.
In this study we examine the use of iterative feedback tuning (IFT) to identify and update DBS controller parameters in a way that minimizes a specified objective function using only data recorded during controller's operation. An IFT-tuned PI controller is applied within a computational model of cortico-basal ganglia loop to suppress pathological beta activity in subthalamic nucleus local field potentials. We run the simulations for a range of initial controller parameters through multiple iterations of the IFT algorithm. We show that the resulting update of the controller parameters results in a reduction in the value of the objective function compared to the initial condition.
The results demonstrate a method for automatic identification and updating of controller parameters for use in closed-loop neuromodulation systems including DBS, with potential for further development and optimization of aDBS technology. In addition, the testing framework developed provides a means with which to compare the efficacy and efficiency of novel aDBS algorithms.

Title: How to optimally stimulate to modulate phase-amplitude coupling?

Authors: *B. DUCHET, R. BOGACZ;
Univ. of Oxford, Oxford, United Kingdom

Abstract: Phase-amplitude coupling (PAC), which involves the coupling of the phase of slower brain oscillations with faster oscillations, plays a significant role in brain activity and has been implicated in various neurological disorders. For example, in Parkinson's disease, PAC between the phase of the beta rhythm (13-30 Hz) and the amplitude of the gamma rhythm (50-200 Hz) in the motor cortex is exaggerated compared to patients with dystonia and humans without a movement disorder. Conversely, in patients with Alzheimer's disease, PAC between the theta (4-8 Hz) and gamma rhythms is diminished compared to healthy controls. Modulating PAC levels (i.e. reducing or enhancing PAC) using brain stimulation could therefore open new therapeutic avenues. However, while it has been previously reported that phase-locked stimulation can increase PAC in the motor cortex, it is unclear what the optimal stimulation strategy to modulate

PAC might be. Here, we provide a theoretical framework to narrow down the experimental optimisation of stimulation aimed at modulating PAC, which would otherwise rely on trial and error. We make analytical predictions using a Stuart-Landau model, and confirm these predictions in a more realistic model of coupled neural populations, the Wilson-Cowan model. Our framework specifies the critical Fourier coefficients of the stimulation waveform which should be tuned to optimally modulate PAC. Depending on the impact of stimulation on the mean-field, these components may include the slow frequency, the fast frequency, combinations of these, as well as their harmonics. We show that the optimal balance of energy between these Fourier components depends on the relative strength of the endogenous slow and fast rhythms. Furthermore, we demonstrate that phase locking the stimulation to the slow rhythm is only necessary if stimulation is weak and overriding the existing PAC is detrimental. Together, our theoretical framework lays the foundation for guiding the development of innovative and more effective brain stimulation aimed at modulating PAC for therapeutic benefit.
