changes associated with BTEX using a novel environmental exposure model. **METHODS:** Adolescent male Swiss-Webster mice (N=32; n = 8/group) were exposed on postnatal days (PND) 28-46 to one of three combinations of BTEX vapor representing 10x (ENV1) or 100x (ENV2) estimates of urban environmental levels or a comparison group exposed to occupational levels of exposure (OCC). A group exposed only to air was a control. Mice were exposed for 1.5 h/session, 2 sessions/day, 5 days/week, for 3 weeks. Locomotor activity (distance traveled) was measured during each exposure session and the two were averaged to represent a daily measure. Brains were collected and frozen immediately following the last BTEX exposure on PND 46. Brains were sliced at 2-mm thickness and tissue punches (1-1.5mm dia.) were collected from medial prefrontal cortex (mPFC) and nucleus accumbens (NAc). These tissues were then analyzed by high-performance liquid chromatography to quantify levels of monoamines (dopamine DA, serotonin -5-HT, and norepinephrine -NE) and their metabolites (DOPAC, HVA, 3MT and 5-HIAA). **RESULTS:** Repeated BTEX exposure altered the pattern of locomotor activity across each exposure day ($p < .01$) with differences observed between groups ($p < .001$) (control < ENV1 < ENV2 < OCC). Regionally specific effects on monoamine and metabolite concentrations were found between the mPFC and NAc. Specifically, the OCC group had significantly higher levels of NE within the mPFC ($p < .05$), but not within the NAc ($p = .232$). No other significant regional differences were observed between exposures. **CONCLUSION:** These results represent a first exploration of environmental patterns of BTEX exposure on neurobehavioral functioning in an animal model. The shifts in locomotor patterns and changes in neurotransmitter levels suggests that our environmental BTEX model can produce adverse long-term effects. Future studies should include both locomotor activity and neurochemical analyses as they were shown to be sensitive measures of the repeated effects of BTEX. This model should prove useful in future investigations of BTEX concentrations and exposure durations.

Title: Environmental enrichment increases brain derived neurotrophic factor and post-synaptic density 95 after lipopolysaccharide treatment in pubertal male and female mice

Authors: *M. S. MURACK, K. B. SMITH, J. DAVIDSON, A. KADAMANI, S. AL SHARANI, C. MESSIER, N. ISMAIL;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Puberty is a critical period of development marked by cortical reorganization and increased synaptogenesis. Healthy cortical reorganization and synaptic growth require sufficient environmental stimuli and minimal exposure to chronic stressors during pubertal development. Stimuli deprivation and/or exposure to stress significantly impacts cortical reorganization and reduces the expression of proteins that promote neuronal survival (BDNF) and measure synaptogenesis (PSD-95). However, previous investigations of pubertal cortical development use minimalized “standard” mouse housing conditions that rarely reflect the naturalistic environment. Environmentally enriched (EE) cages include improved social-, physical-, and cognitive stimulation that better simulate the naturalistic environment. We hypothesized that enriched and deprived environmental stimuli will significantly increase and decrease, respectively, the expression of BDNF and PSD-95 following stress exposure during pubertal development. Three-week-old male and female CD-1 mice (n=10) were housed for three weeks in EE, standard or socially deprived housing conditions. Pubertal mice were treated with lipopolysaccharide (LPS) or saline eight hours prior to tissue collection. EE mice displayed greater sickness behaviors than mice in other housing conditions. EE mice also displayed greater medial prefrontal and hippocampal BDNF and PSD-95 expression than standard housing and deprived housing mice. Only LPS-treated mice housed in EE cages displayed resilience to BDNF and PSD-95 reduction in the hippocampal CA3 and dentate gyrus. Interestingly, LPS-treated mice deprived of standard housing showed significant increases in BDNF and PSD-95 expression throughout the medial prefrontal cortex and hippocampus. Pubertal expression of neuroplasticity-promoting proteins is particularly susceptible to the introduction and removal of environmental stimuli and acute stress in CD-1 mouse models. Further investigations into the effects of stress on pubertal cortical reorganization should consider the inclusion of more ecologically valid housing conditions.

Title: The Long-Term Embedding of Traumatic Early-Life Experiences Within the HPA-axis: A p-curve Meta-Analysis

Authors: *N. HOSSEINI-KAMKAR, J. MORTON;
Psychology, Western Univ., London, ON, Canada

Abstract: Introduction: Traumatic early-life experiences including child maltreatment, sexual abuse, and neglect have been linked to negative health outcomes later in life. One mechanism by which life-experiences may result in lasting changes in the brain is via exerting a long-term influence on the calibration of the hypothalamic-pituitary-adrenal (HPA) system. The *differential susceptibility to context* model presents a U-shaped function to describe the relationship between adversity and biological reactivity, predicting heightened reactivity under both protected and traumatic environmental conditions (Boyce & Ellis, 2005). Empirically, while trauma has consistently been shown to predict HPA dysregulation, the direction of the association remains unclear. Some studies show that trauma is associated with cortisol hyper-reactivity, while others show that trauma is associated with cortisol hypo-reactivity. *P*-curve analyses are ideally suited to resolving apparent contradictions of this kind (Simonsohn et al., 2014a). **Methods:** Here, we used *p*-curve analyses to review evidence concerning the association between traumatic experiences and HPA-reactivity to a psychosocial stressor. Publications that reported blunted HPA-reactivity were included in the "cortisol hypo-reactivity" *p*-curve analysis, while publications that reported heightened HPA-reactivity were included in the "cortisol hyper-reactivity" *p*-curve analysis. **Results: Cortisol hyper-reactivity *p*-curve:** The *p*-curve for the 21 results in the cortisol hyper-reactivity analysis was not significantly right-skewed. A set of results contains evidential value if either the half *p*-curve (*p*-values below .025) is significantly right-skewed at $p < .05$, or if both the half *p*-curve and full *p*-curve are significantly right-skewed at $p < .10$. The *p*-curve for this set of results was not significantly right-skewed (half: $z = -1.5$, $p = .067$; full: $z = -1.14$, $p = .127$). Neither condition was met in this case, therefore, the *p*-curve did **not** indicate evidential value. **Cortisol hypo-reactivity *p*-curve:** The *p*-curve for the 41 results in the cortisol hypo-reactivity analysis was significantly right-skewed (half: $z = -5.3$, $p < .0001$; full: $z = -6.29$, $p < .0001$). In this case, both conditions are met, and the *p*-curve demonstrates evidential value. **Conclusion:** The *p*-curve analysis of the HPA hypo-reactivity literature demonstrates evidential value; in contrast, the *p*-curve analysis of the HPA hyper-reactivity literature was inconclusive. Taken together, these results provide greater support for the literature reporting an association between traumatic life events and blunted HPA-reactivity to stress.

Title: Mitochondrial dynamics in the nucleus accumbens control anxiety and depression-like behaviors through regulation of medium spinal neurons structure and function

Authors: E. GEBARA[1], O. ZANOLETTI[1], S. GHOSAL[1], J. GROSSE[1], B. SCHNEIDER[1], G. KNOTT[1], S. ASTORI[1], ***C. SANDI**[2];

Abstract: Mitochondria play central roles in psychiatric disorders, but the underlying molecular players that regulate neuronal structure and function are scarcely known. In this study, we assess the involvement of molecules involved in mitochondrial dynamics in medium spiny neurons (MSNs) from the nucleus accumbens (NAc) in rats selected for their high or low anxiety levels. We find that high anxious animals show increased depression-like behaviors in the forced swim and saccharin preference tests, along with lower expression of the mitochondrial GTPase Mitofusin 2 (Mfn2) in the NAc at the protein (Western blot) and mRNA (qRT-PCR, RNAscope) levels. They also show alterations in mitochondria (i.e., respiration, volume, interactions with the endoplasmic reticulum) and MSNs (i.e., dendritic complexity, spine density and typology, excitatory inputs). Viral AAV9-syn1-MFN2 overexpression in the NAc reverses all these behavioral, mitochondrial and neuronal phenotypes. Our findings demonstrate a causal role for accumbal Mfn2 on the regulation of anxiety and depression-like behaviors through actions on mitochondrial and MSN structure and function. Our work highlights the therapeutic potential of targetting Mfn2 to treat anxiety and mood disorders.

Title: Genomic signatures of corticosterone in dorsal and ventral hippocampus of males and females

Authors: ***S. G. CARADONNA**[1], H. KHALIL[2], N. R. EINHORN[1], F. S. LEE[3], H. AKIL[2], B. S. MCEWEN[1], J. MARROCCO[1];
[1]The Rockefeller Univ., New York, NY; [2]Univ. of Michigan, Ann Arbor, MI; [3]Weill Cornell Med., New York, NY

Abstract: Dorsal and ventral hippocampus are functionally distinct brain structures due to their unique anatomical connectivity and their role in distinct biological functions. More importantly, within the same brain areas, females and males may trigger distinct sets of genes in response to similar stimuli. We aimed to study the whole-genome transcripts of the dorsal (dHPC) and

ventral hippocampus (vHPC) in mice maintained on chronic low-dose (25mg/l) oral corticosterone (CORT), a mouse model that shows disruption of the hypothalamic-pituitary-adrenal axis associated with a blunted stress response. We used male and female mice that were wild-type (WT) or heterozygous for the brain-derived neurotrophic factor gene variant Val66Met (BDNF Val66Met) which increases susceptibility to stress. Differentially expressed genes (DEGs) of both vHPC and dHPC were generated using RNA-sequencing on an Illumina NextSeq 500 using 75-bp single-end reads. We found that CORT induced a greater number of DEGs in the vHPC than in the dHPC across experimental groups. After chronic CORT, WT males showed 184 DEGs in the vHPC and 119 DEGs in the dHPC. This difference was more prominent in BDNF Val66Met males compared to WT males because they showed 493 DEGs in the vHPC and 178 DEGs in the dHPC. Overall CORT induced a lower number of DEGs in females than in males. Curiously, WT females showed more DEGs in the dHPC than in the vHPC when treated with CORT. However, CORT had only a mild effect on DEGs in BDNF Val66Met females compared to WT females, especially in the dHPC. When investigating the common CORT-induced DEGs between males and females, the majority of DEGs were regulated exclusively within either sex across regions and genotypes. This suggests that chronic CORT modulates the genomic landscape of the dHPC and vHPC in a sex-, genotype-, and region-specific fashion. CORT-regulated DEGs of both the dHPC and vHPC were processed and grouped according to their GO terms, which showed unique gene sets in males, e.g., metabolism and cell signaling, and females, where CORT mainly induced immediate early genes. These findings show that discrete genomic signatures in the hippocampus associated with specific biological responses to CORT help to disentangle the separate biological role of the dHPC and vHPC as a function of sex and genotype.

Abstract: Neuroplasticity is a process that allows short to long-term brain remodeling in response to experiences and changing environment. This includes changes in synaptic remodeling and functional modification of neural circuitries. Acute and chronic stimuli (physical or emotional) trigger the activation of the stress system in which the acute stress allows organism to adapt; while chronic stress lead to a maladaptive response. Different animal models of stress show altered hippocampal-dependent behaviors; nonetheless, little is known about the molecular mechanisms involved.
Considering that miRNAs play a key role in gene expression regulation, we evaluated the miRNA profile expression in dorsal hippocampus and the object location task in acute (2.5 h of restraint), acute recovery (24 h after stress) and chronic stress (2,5 h of restraint for 14 days). We showed that hierarchical clustering of miRNA expression profile shows a similarity between acute and chronic stress. Consistently, acute and chronic stressed animals showed a decrease preference to explore an object in a novel position. Interestingly, acute recovery group displayed not only a similar miRNA profile, but also a similar preference for novel location both compared to controls. The enrichment analysis predicts functional relevance of miRNA roles in modulation of signaling pathways related to cell survival, protein metabolism, inflammation, during the transition between acute and chronic stress.

Abstract: Introduction: Psychological stressor is shown to activate inflammasome complex, which activates caspase-1. We investigated active caspase-1 distribution in hippocampal sub-regions in mice following exposure to chronic stress as a model of depression.Material Method: C57BL6 male mice were exposed to repeated predator , tail suspension and restraint stresses for 35 days (n = 7). Control group was left undisturbed except for the behavioral experiments (n =

4). Hippocampal sections, 35 µm thick, were immunostained with antibodies against p10 and p20 subunits of active caspase-1 and imaged under confocal microscope.
Results and Conclusion: Labeling with antibody against the p20 subunit reveals staining in the apical dendrites of stratum radiatum in proximal parts of CA2 region only in the chronic stress group. Similar staining was not observed with anti-caspase-1 antibody against p10 subunit. In cell somas, on the other hand caspase 1 labeling was observed with both antibodies in both chronic stress and control groups. Our findings indicate that p20 subunit of caspase 1 may have a yet unknown function in dendrites. Given the role of synaptic plasticity in the neurobiology of depression, functional significance of p20 subunit of active caspase1 in regulating synaptic plasticity requires further investigation.

Title: A crosstalk between Transient Receptor Potential Vanilloid 1 and Cannabinoid Receptor 1 within the limbic system regulates anxiety and depression-like behaviors triggered by stress in rats

Authors: *W. NORZE[1], L. RODRIGUEZ[2], P. MUÑOZ[2], A. RAMOS[2], L. MENDEZ[2], C. MALDONADO[2];
[1]Biol., Univ. of Puerto Rico, University Of Puerto Rico Rio Piedras campus, Puerto Rico; [2]Biol., Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstract: Clinical studies provide strong evidence that stress is an environmental risk factor that can trigger the onset of several neuropsychiatric disorders such as anxiety and depression in humans. Pre-clinical evidence suggests that the endocannabinoid and endovanilloid system within the brain are important neuronal substrates involved in emotional responses to stress. Specifically, studies have proposed that the Transient Receptor Potential Vanilloid 1 (TRPV1) a member of the Transient Receptor Potential (TRP) superfamily, within the brain regulate anxiety and depression behaviors through its interactions with the cannabinoid receptor 1 (CB1R). However, little is known about the cellular mechanisms that regulate these receptors' interactions across the brain and its impact in neuropsychiatric disorders. We investigated the role of TRVP1R and CB1R within several brain regions including the medial prefrontal cortex as part of the dopamine mesocorticolimbic system, the hippocampus and the amygdala in anxiety and depression like-behaviors using rats as animal model. To modulate depression like-behavior, male Sprague Dawley rats were experienced a pretest session for 15 min, followed 24 h later by a 6 min test session in order to examine the effects of blockade of FAHH and its association with the olvanil in depression-like behaviors. One group of animals (acute exposure) received a single dose of URB597 [0; 0.1 ;0.2mg/kg/ip] 2 hours before testing in the FST for 6 min. The other group were treated for 4 days (repeated exposure) at the same doses. In order to examine the effects of the association of blockade of FAHH and the olvanil in depression like-behaviors, animals were treated for 4 days (repeated exposure) with URB597 [0; 0.1 ;0.2mg/kg/ip] and Olvanil [0; 0.3; 0.5 mg/kg/ip] only the last day (day 4^{th}) 2 hours before testing in the FST for 6 min to evaluate time spend in floating and swimming. However, to evaluate anxiety behavior, rats will be exposed to a repeat exposure for 4 days with either vehicle or URB597 at dose [0; 0.1mg;0.2mg/kg/ip] and Olvanil at dose [0; 0.3; 0.5 mg/kg/ip] only the last day (day 4^{th}) 90 min before exposed to 30 min acute restraint stress followed by 15 min light dark box test in order to measure the anxiety response. Our results suggest that the repeated exposure of URB597 significantly decreased depression like-behavior and tend to increase depression like-behavior when URB597 is associated with the olvanil. Ongoing biochemical analysis of the changes in expression of TRPV1 and CB1 receptors following treatment with URB597 alone and when it is associated with the olvanil will support mechanistic explanations for the present behavioral results.

Abstract: Exposure to prolonged stress in critical developmental periods induces heightened vulnerability to psychiatric disorders, which may have sex-specific consequences. Here we investigate the neuronal circuits mediating behavioral changes in males and females after being subject to chronic adolescent social isolation stress. Escalated aggression is exhibited in stressed males, while social withdrawal is shown in stressed females. *In vivo* multichannel recordings of free-moving animals indicate that pyramidal neurons in the prefrontal cortex (PFC) from stressed males exhibit the significantly decreased spike activity during aggressive attacks, while PFC pyramidal neurons from stressed females show a blunted increase of discharge rates during sociability tests. Chemogenetic and electrophysiological evidence shows that PFC hypofunctioning and basolateral amygdala (BLA) principal neuron hyperactivity contribute to the elevated aggression in stressed males, while PFC hypofunctioning and ventral tegmental area (VTA) dopamine neuron hypoactivity contribute to the diminished sociability in stressed females. These results establish a framework for understanding the circuit and physiological mechanisms underlying the sex-specific divergent effects of early life stress.

Abstract: Depression and anxiety disorders are comorbid in clinical populations and implicate overlapping neural systems that can be examined in validated animal models. We employed filial 8 female rats selectively outbred for extreme anxiety-like behavior and examined chronic mild stress-induced depression-like symptoms. We operationalized weight gain, sweet food consumption, piloerection, estrous cycling, and forced swim test coping behaviors as indices of depression-like symptoms (DLS). After a terminal forced swim test, brains were processed for immunohistochemistry for c-fos and serotonin 1A (5HT1A) receptor immunoreactive cells in the hippocampus and hypothalamus. We report evidence that F8 selectively outbred female rats exhibited extreme high (HAn) and low (LAn) anxiety-like behavior, similar to parental lines, on the elevated plus maze. An initial forced swim test revealed a differential response across extreme anxiety-like behavioral phenotypes, where HAn females exhibited more active coping styles than LAn females. On other DLS indices, chronic mild stress-treated HAn animals displayed enhanced active coping behaviors, attenuated weight gain, reduced sweet-food consumption, and stalled estrous cycling. Chronic mild stress treatment increased piloerection for all animals, independent of trait anxiety-line. Moreover, chronic mild stress treatment enhanced hypothalamic and hippocampal c-fos and 5HT1A receptor expression across HAn/LAn phenotypes—an effect that was greater in HAn animals. Thus, a female HAn phenotype conferred vulnerability to certain DLS indices (i.e., weight gain and attenuated sweet-food consumption) and resilience-like behavior to others (i.e., forced swim test coping behavior and increased consecutive estrous cycling). Together, our findings implicate the importance of using HAn lines to investigate neurobiological underpinnings of anxiety- and depression-like behaviors.

Title: Irisin suppresses acute stress-induced neurobehavioral impairment through hippocampal Akt/GSK3 pathway in a sex-dependent manner

Authors: *M. JODEIRI FARSHBAF[1], A. MONDAL[2], *K. ALVINA[3,2];
[1]Biol., [2]Texas Tech. Univ., Lubbock, TX; [3]Univ. of Florida, Gainesville, FL

Abstract: Acute stress is an immediate physical or psychological perceived threat that induces anxiety-like behavior and short-term memory impairment by affecting the hippocampus. The hippocampus is one of the most stress-vulnerable regions of the brain, it also controls emotion

and spatial memory in rodents and humans. Acute stress suppresses glucose uptake in the hippocampus of male mice which leads to imbalanced energy homeostasis. In contrast, the exercise-induced myokine Irisin, induces thermogenesis, browning of white adipose tissue and modulates glucose homeostasis. Further, Irisin rescues memory impairment in an Alzheimer's disease (AD) model. We have previously shown that Irisin injection into the hippocampus reverses memory impairment caused by acute stress in male mice. However, the neural mechanism of action for Irisin has not been discovered. Therefore, we aimed to determine the signaling pathway that mediates the resilience effect of Irisin in the hippocampus. To this end, we used an acute restraint stress protocol for 3h in C57BL/6J mice (male and female) that resulted in memory impairment and anxiety-like behavior in a combined open field/novel object recognition (OF-NOR) test. Injection Irisin into the hippocampus prevented these effects. We then found that Irisin modulated Akt/GSK3β and PGC-1α expression only in the hippocampus of male mice. Akt/GSK3β axis is the main sensor for energy homeostasis in neurons. We found that acute stress decreased Akt activity while activation and expression of GSK3β and PGC-1α were increased. In response to energy deprivation, PGC-1α expression is increased to preserve energy production. We showed that Irisin injection into the hippocampus reversed PGC-1α expression and activated Akt signaling pathway. Combined, our findings provide a possible molecular pathway that supports behavioral findings. We therefore propose that acute stress results in abnormal energy homeostasis in the hippocampus which is reversed by Irisin injection. Together, our findings demonstrate a potential avenue to connect the positive effects of exercise on brain function, healthy aging, and neurodegeneration. Key Words: Irisin, acute stress, hippocampus, memory, anxiety-like behavior

Title: Studying the effects of the pharmacological modulation of SERCA on behavior and monoaminergic neurochemical status in mice.

Authors: *A. BRITZOLAKI, C. C. CRONIN, P. R. FLAHERTY, R. L. RUFO, P. M. PITYCHOUTIS;
Biol., Univ. of Dayton, Dayton, OH

Abstract: The sarco/endoplasmic reticulum (SR/ER) calcium (Ca^{2+})-ATPase (SERCA) pump is a key regulator of intracellular Ca^{2+} homeostasis and subsequently essential for cell survival and function. Neurons are no exception to this; intricate pathways involving SERCA-mediated Ca^{2+} signaling are implicated in brain pathophysiology. Several studies have indicated that

dysregulation of SERCA pumps may be involved in the molecular mechanisms underlying debilitating brain diseases including Alzheimer's and Parkinson's diseases, schizophrenia, bipolar disorder, ischemia and alcoholism. Thus, this family of P-type ATPases comprises an emerging molecular target for developing efficient pharmacotherapies. Interestingly, recent studies proposed that chronic pharmacological stimulation of SERCA2, mediated by the quinoline derivative CDN1163, may rescue aberrant locomotor and cognitive deficits in rodent models of Alzheimer's and Parkinson's diseases, introducing CDN1163 as a novel pharmacotherapeutic target. However, the extensive effects of CDN1163 administration on mouse behavior and neurotransmission still remain elusive. Herein, we investigated the potential consequences of both acute (i.e., 60-90min) and chronic (i.e., 17 days; once daily) CDN1163 administration on the behavior and neurotransmission in adult (i.e., 2-4 month old) C57BL/6J mice. Furthermore, we extended the study to assess dose-dependent responses in both sexes using a low dose (i.e., 10mg/kg, i.p.) and a high dose (i.e., 20mg/kg, i.p.) of CDN1163. Interestingly, we observed that chronic SERCA activation exerts behavioral effects in mice. Present data indicated an anxiogenic effect of the chronic CDN1163 regimen, as assessed in the open field test, as well as a depressive-like behavioral effect in chronically treated mice subjected to the forced swim test. Furthermore, these behavioral alterations were accompanied by multiple brain region-dependent neurochemical effects, as assessed *ex vivo* using reverse-phase High-Performance Liquid Chromatography (HPLC) in mice of both sexes.

Title: Behavioural phenotype of novel sigma-1 receptor overexpression mouse line

Authors: K. MCCANN[1], P. CHUDALAYANDI[1], D. DEWAR-DARCH[2], R. BERGERON[2]; [1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Ottawa Hosp. Res. Inst., Ottawa, ON, Canada

Abstract: The sigma-1 receptor (S1R) is an endoplasmic reticulum chaperone protein implicated in psychostimulant addiction and neurodegenerative diseases such as Alzheimer's disease and Huntington's disease. The endogenous pharmacology of S1R suggests sex-specific roles as it is modulated by sex hormones. The known interacting proteins of S1R include membrane bound proteins such as voltage-gated sodium, potassium and calcium channels and intracellular proteins such as the inositol trisphosphate receptor. In light of its diverse interactome, the mechanism by which S1R can alter behaviour is not understood. As a novel approach to investigate S1R, we have developed a S1R over expressing (OX) mouse line. Given that S1R modulates multiple

proteins, it is unlikely that S1R saturates its binding partners. This novel transgenic mouse was developed with a linearized *Thy1a1.2* driving SIGMAR1 tagged with *myc* on the C-terminus. Transgene integration was confirmed by PCR. Founder tissues show an elevated amount of S1R protein in multiple brain regions (hippocampus, midbrain, cortex, cerebellum). Male and female animals were assessed for phenotypic behaviour. The behavioural assays used were, in order, elevated plus, Y-maze, open field, forced swim, tail suspension, Morris water maze and passive avoidance. Data was analyzed by two-way ANOVA with sex and genotype being the interacting factors (male WT n = 33, male Sig-1R OX n = 17, female WT n = 16, female Sig-1R OX n = 19). Tukey's and Sidak's post-hoc analyses were used when appropriate. Genotype was a significant main effect in Y-maze alternation, distance travelled in Y-maze, distance travelled in elevated plus, distance travelled in open field, forced swim immobile time, passive avoidance probe trial latency and tail suspension immobility. Sex was a significant main effect in Y-maze alternation, Y-maze distance travelled, time spent in open arm of elevated plus, distance travelled in elevated plus, open field location, open field distance travelled, passive avoidance probe trial latency and tail suspension immobility. Sex of the animal and genotype did not result in a significant interaction in any of the behavioural tests. These results suggest a trend where S1R OX provides resistance to certain stressors such as forced swim and passive avoidance. Further, S1R OX mice tend cover more distance in the Y-maze, elevated plus maze and open field. Spatial memory learning in the Morris water maze is unaffected. Future plans are to expand the use of this mouse line into disease models and incorporate S1R pharmacological approaches.

Abstract: Adverse experiences at different stages of life are relevant to promote vulnerable or resilient subjects. A vulnerable subject may develop mental diseases such as depression, anxiety or schizophrenia; a resilient subject will not. The development of these types of individuals could be due to several factors such as the nature of the experience, the stage of life at which the experience occurs, social support or genetics. However, there are no studies assessing the effect

of adversity during different stages of life and on synaptic plasticity. The present study aimed to evaluate if adverse events such as maternal separation (MS), mild social defeat in adult life (MSD) and maternal separation with mild social defeat (MS+MSD) promote vulnerable behaviors in the adult; and, whether these changes are associated with activity-dependent synaptic plasticity evaluated by c-Fos expression in the prefrontal cortex and hippocampus of rats. Behavioral results showed that conditions with MSD and MS+MSD promoted anhedonia and low motivation. Interestingly, the MS+MSD group increased the time spent in the area of social interaction. C-Fos analysis revealed greater number of positive cells in the prelimbic cortex of the MS+MSD group, which may be related to the increase of social interaction. A greater number of positive c-Fos cells were observed in the dentate gyrus when the animals underwent a single adverse event in adult life. These results suggest that medial prefrontal cortex and dentate gyrus could be systems involved in adaptive changes related to adversity.

Title: Nucleus Accumbens substance P underlies aversive learning

Authors: *T. C. FRANCIS[1], C. SANDERS[2], G. SCHOENBAUM[3], M. MORALES[1]; [1]Integrative Neurosci. Res. Br., [3]Cell. Neurobio. Res. Br., [2]Natl. Inst. on Drug Abuse, Intramural Res. Program, Baltimore, MD

Abstract: Responses to threat are an essential feature for animal survival and are a primary behavioral function of the Nucleus Accumbens (NAc). However, the synaptic and local circuit mechanisms in the NAc underlying these responses are not well known. In the NAc, highly aversive, stressful stimuli promote the release of the neuropeptide substance P from dopamine 1 receptor expressing medium spiny neurons (MSNs). We previously found substance P causes long-term potentiation (LTP) of excitatory inputs on dopamine 2 receptor (D2) expressing MSNs in the NAc core, which may provide a synaptic substrate for aversive learning. We hypothesized striatal substance P-driven LTP is required for aversive learning. To test this, we utilized a fear conditioning paradigm with a latent inhibition component and assessed how D2-MSN activity contributes to the learned association of a conditioned stimulus (CS, tone) with an aversive unconditioned stimulus (US, footshock). In the NAc core, c-fos-positive cell density in D2-MSNs correlated strongly with freezing behavior to the CS. In contrast, when a latent inhibition

procedure preceded conditioning and diminished cue salience, this resulted in decreased c-fos expression in D2-MSNs in response to the CS. This correlation was not observed in the NAc shell, in D1-MSNs, or in the context alone without the CS. Additionally, CRISPR-Cas9 knockout of NAc neurokinin 1 receptors (NK1R), the primary substance P receptor, diminished freezing to the CS during recall. These results suggest NAc core NK1Rs and D2-MSN activity contribute to the learned association between a cue and an aversive stimulus. In mice that underwent fear conditioning, electrophysiological measures for substance P release indicative of LTP in D2-MSNs were consistent with this finding and suggest plasticity is selective for the CS-shock relationship. We are currently examining *in vivo* D2-MSN activity to determine temporal dynamics of D2-MSN and relevant input activity during fear learning with and without substance P antagonism. Our work provides the foundation for a MSN crosstalk model for aversive learning and may suggest a cellular substrate for aberrant salience processing observed in mood disorders such as anxiety and behavioral depression.

Title: Stress alters rodent hippocampal neural dynamics

Authors: *A. TOMAR[1], D. POLYGALOV[2], S. CHATTARJI[3], T. J. MCHUGH[2];
[1]Univ. of Bristol, Bristol, United Kingdom; [2]Lab. for Circuit & Behavioral Physiol., RIKEN Ctr. for Brain Sci., Wakoshi, Japan; [3]Natl. Ctr. for Biol. Sci., Bangalore, India

Abstract: Adverse effects of chronic stress include loss of concentration, anxiety, depression, and impaired cognition including learning and memory deficits. Some of these deficits are mediated by stress-induced impaired hippocampal functionality at multiple levels of neural organization including dendritic shrinkage and neurogenesis and impaired synaptic plasticity. In agreement, studies in awake behaving rodents have reported that chronic stress alters place cell activity and disrupts global remapping which is the generation of distinct representations (place maps) across different surroundings. Surprisingly, it is not known if and how chronic stress alters hippocampal information processing during offline behaviour states, including quiet wakefulness/sleep, during which information consolidation takes place during sharp-wave ripples (SPW-Rs or ripples), high frequency (100-200 Hz) oscillatory events in the CA1 region. Here, we employed tetrode recordings in mice (N=17) and subjected them to chronic

immobilization stress (CIS), a well-established rodent model of chronic stress and assessed pyramidal cell activity and SPW-Rs in the dorsal CA1 of the hippocampus. We noticed a net decrease in pyramidal cell activity during the first exposure to a stress compared to the prior quiet wakefulness/sleep state. We also noticed lower firing rates and decreased participation by pyramidal cells during SPW-Rs, though pyramidal cell co-activity was enhanced during stress exposure. Interestingly, after repeated exposure to same stress, some of these stress-phenotypes were noticed during the rest-state on the last day of CIS, when no overt stress was delivered. These data indicate that chronic stress alters hippocampal neural dynamics and that disrupted ripple-spike interactions may underlie the impaired learning observed in chronically stressed subjects.

Title: Hippocampal modulation of hypothalamic circuits in the control of acute stress responses

Authors: ***V. S. TURNER**[1], F. STEFANINI[2], M. A. KHEIRBEK[1];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Ctr. for Theoretical Neurosci., Columbia Univ., New York, NY

Abstract: An essential adaptive function of the nervous system is to organize appropriate physiological and behavioral responses in the face of stressful situations. However, this process can become dysregulated in psychiatric disease. Characterizing the neural circuits that modify the adaptive stress response is essential to understand how the brain regulates responses to stressful stimuli and how that regulation can go awry. A population of neurons in the hypothalamic paraventricular nucleus (PVN) expressing corticotropin-releasing hormone (CRH) integrate information about stressful stimuli before initiating responses such as the release of corticosteroids. The ventral hippocampus (vHPC) is theorized to modulate neuroendocrine responses to threat, but how it may modulate CRH neuron activity to control acute stress responses remains unknown. Here we use optogenetics, chemogenetic, fiber photometry and 2-photon calcium imaging in male and female adult mice to investigate how the hippocampus acutely modulates PVN CRH cells in response to an acute stressor. Our results suggest the ventral hippocampus (vHPC) exerts top-down control over the paraventricular nucleus of the hypothalamus (PVN) in order to modulate moment-to-moment neural responses to acute stressors.

Title: Endocannabinoid Regulation of Innate Fear Responding

Authors: *V. KONDEV[1], A. MORGAN[2], M. S. NAJEED[1], S. PATEL[2];
[1]Vanderbilt Univ., Nashville, TN; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Anxiety disorders, including generalized anxiety disorder (GAD) and post-traumatic stress disorder (PTSD), are the most common mental illness in the United States. The endocannabinoid (eCB) system includes critical regulators of the processes involving fear responsivity and stress adaptivity and thus has been identified as an emerging therapeutic target to treat anxiety disorders. Recent evidence suggests that glutamatergic input from the ventral hippocampus (vHIPP) to the nucleus accumbens (NAc) underlies stress susceptibility. Here, using slice electrophysiology and optogenetics, we assess how eCBs modulate vHIPP-NAc activity ex vivo and in vivo and the role this plays in mediating stress responsivity. We have shown that optogenetic activation of vHIPP-NAc circuit increases avoidance of an innate stressor, the predator odor analog, 2MT. Avoidance of 2MT can be reduced by enhancing eCB signaling, and we have shown that eCBs negatively regulate glutamate release at vHIPP input onto specific interneuron populations in the NAc. This data ultimately increases our understanding of how eCBs mediate potentially therapeutic effects for stress-related behaviors.

Abstract: Currently, stress is considered a state in which the body responds to environmental demands. This response is essential and crucial for survival. Stress can even occur during the gestational period. When stress occurs during gestational, period, it can disrupt the hippocampus physiology, causing cognitive deficits in the adult body, altering several neurotransmission systems, such as the serotonergic system. Thus, the objective of this study was to evaluate the release of serotonin as well as serotonin transporter (SERT) content in the dorsal hippocampus, related with learning and spatial memory in prenatally stressed (PS) adult male rats. Control and PS, 3-month-old males were used. Serotonin release was assessed and dorsal hippocampus was dissected under basal conditions. This structure was also obtained from other rats after performing learning and memory tests, using the Morris Water Maze (MWM). Results show that cognitive deficits were confirmed in PS males, compared to controls groups. Basal SERT content was higher in the dorsal hippocampus of PS animals than in control males, which is in line with the low basal extracellular concentration of serotonin observed in the PS animals. No significant changes were observed in SERT content during cognitive tests in PS animals compared to controls, suggesting that serotonin reuptake during cognitive processes is similar in both groups, as s extracellular concentration of serotonin increased in control and PS males. In conclusion, the cognitive deficiencies observed in PS males seem to be related with low serotonin extracellular concentrations, but not with changes in SERT.

Title: Hypothalamic sex differences in basal reelin and sexually dimorphic effects of chronic stress induced by CORT.

Authors: *C. LIRIA SANCHEZ-LAFUENTE[1], R. ROMAY-TALLON[2], J. JOHNSTON[1], J. ALLEN[1], L. KALYNCHUK[1], H. J. CARUNCHO[1];
[1]Med. Sci., Univ. of Victoria, Victoria, BC, Canada; [2]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Introduction: Repeated exposure to the stress hormone corticosterone (CORT) can cause depressive-like behaviours paralleled by a downregulation of hippocampal reelin expression, a protein highly involved in neural plasticity. Reelin is also expressed in other key neural populations involved in the stress response, like the paraventricular nucleus (PVN), but

whether its expression is sex specific and involved in female's sex-specific vulnerability to stress and depression is not known.**Methods:** Male and female rats were treated with either daily vehicle or CORT injections (40mg/kg) for 21 days. Thereafter, they underwent the forced swim test and elevated plus maze to measure depressive-like behaviours before being sacrificed to permit quantification of reelin levels in hypothalamic nuclei using immunohistochemical techniques. **Results:** We found that the basal density of reelin-positive cells was significantly higher in males than female rats in the medial preoptic area ($p<0.01$) and PVN($p<0.05$). CORT treatment increased despair-like behaviour equally in both sexes compared to controls which was paralleled with a decrease in PVN reelin-positive cells in males ($p<0.001$) but not females ($p<0.581$). Interestingly, in male's PVN, 30% of basal reelin-positive cells co-stained for oxytocin while in females only 17.5%. Levels of CRF and AVP-IF cells were really low and barely co-localized with reelin and CORT did not affect co-localization of reelin with any of these markers. **Conclusion:** For the first time, this study shows that there is a sexually dimorphic subpopulation of reelin-positive neurons in the PVN that can be differentially affected by chronic stress. Further studies should be done to elucidate the potential role of these neural populations in individuals' susceptibility to stress and depression.

Title: Sex and regional differences in (3α,5α)3-hydroxypregnan-20-one (3α,5α-THP) regulation of hypothalamic and extrahypothalamic corticotropin-releasing factor (CRF).

Authors: *G. BOERO[1], R. E. TYLER[2], C. A. TODD[3], T. K. O'BUCKLEY[3], I. BALAN[3], J. BESHEER[4], A. MORROW[1];
[1]Psychiatry, Pharmacology, Bowles Ctr. for Alcohol Studies, [2]Pharmacology; Bowles Ctr. for Alcohol Studies, [3]Bowles Ctr. for Alcohol Studies, [4]Psychiatry; Bowles Ctr. for Alcohol Studies, UNC Sch. of Med., Chapel Hill, NC

Abstract: Corticotropin-releasing factor (CRF) is the main activator of the hypothalamic-pituitary-adrenal (HPA) axis in response to stress. CRF neurons are mainly in the hypothalamus, but CRF positive cells are also found in extrahypothalamic structures, including central nucleus of amygdala (CeA), hippocampus (HP), nucleus accumbens (NAc) and ventral tegmental area (VTA). An appropriate balance between inhibitory GABAergic and excitatory glutamatergic

inputs regulates CRF release and alterations in this system are found in several neuropsychiatric diseases, including drug addiction. 3α,5α-THP, the most potent positive modulator of $GABA_A$ receptors has previously been reported to attenuate basal and stress-induced hypothalamic CRF mRNA expression as well as ACTH and corticosterone serum levels in male rats. In this study, we investigated 3α,5α-THP regulation of CRF in hypothalamus and extrahypothalamic areas, in male and female Sprague Dawley rats, measuring CRF mRNA and peptide expression after 3α,5α-THP intraperitoneal administration (15 mg/kg). Sprague Dawley rats were injected with 3α,5α-THP (15mg/kg) in hydroxypropyl-beta-cyclodextrin (45%) or an equivalent volume of vehicle, sacrificed 45 min later, and brains were harvested for qPCR and western blot measurements of CRF mRNA and peptide. Data were analyzed statistically by 2-WAY ANOVA followed by the Tukey's post-hoc test. We found sex differences in hypothalamic CRF mRNA expression (females +74%, $p<0.01$) and CRF peptide levels (females -71%, $p<0.001$). 3α,5α-THP administration decreased hypothalamic CRF mRNA expression in males (-50%, $p<0.05$) and did not change CRF peptide expression in either sex. In HP and CeA, 3α,5α-THP administration decreased CRF peptide concentrations in male rats (HP -29%, $p<0.05$; CeA -62%, $p<0.01$). In VTA, 3α,5α-THP administration increased CRF peptide concentration in both males (+32%, $p<0.01$) and females (+26%, $p<0.01$). The results show sex and region-specific CRF signal regulation, at baseline and after 3α,5α-THP administration. This data may be key to develop sex-specific therapeutic approaches for stress-related disorders and addiction.

Title: Androgen and androgen receptor regulation of corticotropin-releasing factor receptor 1 in the mouse forebrain

Authors: *K. A. RYBKA, K. STURM, R. M. DE GUZMAN, S. BAH, J. S. JACOBSKIND, Z. J. ROSINGER, D. G. ZULOAGA;
Psychology, Univ. At Albany State Univ. of New York, Albany, NY

Abstract: Stress related mood disorders such as anxiety and depression are two times more prevalent in women than men. Sex differences in these disorders are often associated with dysregulation of HPA axis function and have been demonstrated across multiple species including both rodents and humans. Androgen actions through androgen receptors (AR) have been shown to produce actions that decrease the HPA axis response and anxiety behaviors. Corticotropic releasing factor (CRF) and its binding to the CRFR1 receptor has been shown to

play a major role in the regulation of the HPA axis as well as anxiety and depression. We first tested whether CRFR1 neurons co-localize with AR and whether this differed by sex by using dual label immunohistochemistry. Using CRFR1-GFP mice, we found high co-localization of AR in CRFR1 neurons within the paraventricular nucleus (PVN), bed nucleus of the stria terminalis (dorsal and ventral divisions; BSTd, BSTv), medial preoptic area (MPOA), and posterodorsal nucleus of the medial amygdala (MePD). To test whether androgens are capable of altering CRFR1 levels, male CRFR1-GFP mice were sham operated, castrated (GDX), or castrated with supplementation of dihydrotestosterone (GDX-DHT), a non-aromatizable androgen that preferentially binds to ARs. The PVN showed a decreased CRFR1 cell number after GDX, but DHT treatment reversed this effect. In the BSTd, GDX-DHT treated mice showed a decrease in CRFR1 compared to both sham and GDX groups. No other brain regions showed differences in CRFR1 resulting from either GDX or DHT treatment. Our lab also assessed neural activation of CRFR1 neurons in mice that experienced 30-minute restraint stress. We found that there were fewer c-Fos CRFR1 co-localized neurons in GDX males compared to both sham and DHT treated mice in the MePD. No statistical differences were found in other brain regions. When assessing plasma corticosterone (CORT), we replicated previous findings that GDX males showed increased CORT levels when compared to GDX-DHT treated or sham operated males at both 30- and 90-minutes following restraint stress. Finally, we showed a negative correlation between the number of PVN CRFR1+ neurons and CORT levels at 90 minutes following restraint stress. Together these findings indicate androgens can directly alter levels of CRFR1 in the brain and has potential implications for sex differences in regulation of the HPA axis and stress-related mood disorder prevalence.

Title: Regulation of stress-induced pair bond formation impairments in the socially monogamous prairie vole (Microtus ochrogaster) by extended amygdala corticotrophin-releasing hormone neurons

Authors: *M. C. TICKERHOOF, A. S. SMITH;
Dept. of Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: Although social interaction is typically a beneficial experience, social conflict can have a significantly negative effect on normal social behavior. The effect of social conflict on social withdrawal is a subject of significant investigation, but the impact of social conflict on the

formation of close social connections is not well understood. The primary goal of this study was to use the social defeat model of social conflict to investigate its effect on social bonding in the prairie vole (*Microtus ochrogaster*), a socially monogamous rodent species that forms strong social bonds between mating pairs known as a *pair bond*. One week after a three-day social defeat protocol, male prairie voles demonstrated an impairment in pair bond formation, but pair bond formation was accelerated in female prairie voles. Using chemogenetic manipulation, we have identified corticotrophin-releasing hormone (CRH)ergic neurons in the bed nucleus of the stria terminalis (BNST) as a novel neurobiological mechanism regulating pair bond formation in prairie voles. Since CRH in the BNST has been demonstrated to have a role in the behavioral response to social defeat and stress-dependent motivation, we hypothesize that this system would be a key modulator for the effect of social defeat on pair bond formation. Similar to BNST CRHergic neuronal activation leading to accelerated pair bond formation in male prairie voles, chemogenetic inhibition of these neurons in stress-naïve voles inhibits pair bond formation, demonstrating the sufficiency and necessity of this system in prairie vole pair bond formation. In contrast, inhibition of BNST CRHergic neurons in socially defeated prairie voles reverses the deleterious effect of defeat on pair bond formation. These results suggest a stress-dependent "switch" function of BNST CRHergic neurons that has an essential role in the impact of social stress on future social interaction and relationship formation.

Title: Role of corticotropin-releasing factor (CRF) neurons in the oval nucleus of the bed nucleus of the stria terminalis on anxiety-like behavior

Authors: *R. CHUDOBA[1], V. OLIVERA[2], P. LIS[2], C. EDMONDSON[2], S. H. LOSEE OLSON[2], J. A. DABROWSKA[3];
[1]Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]Rosalind Franklin Univ., North Chicago, IL; [3]Chicago Med. Sch. RFUMS, North Chicago, IL

Abstract: Corticotropin-releasing factor (CRF) is a neuropeptide responsible for regulating autonomic, endocrine, and behavioral responses to stress. A significant population of CRF-producing neurons is found in the oval nucleus of the bed nucleus of the stria terminalis (BNSTov), a brain region that mediates behavioral responses to stressors such as fear and anxiety. We used a Cre-CRF transgenic rat model expressing Cre-recombinase driven by the CRF promoter to investigate the role of CRF neurons in the BNSTov in modulating anxiety-like behavior. We infused AAV driving inhibitory or excitatory, Cre-dependent designer receptors

exclusively activated by designer drugs (DREADDs) fused to reporter protein, mCherry, into the $BNST_{OV}$ of Cre-/- and Cre+/- male adult rats. We then silenced or activated these CRF neurons with DREADDs selective ligand, clozapine-N-oxide (CNO), and measured the corresponding effects on anxiety-like behavior via elevated plus maze (EPM) and acoustic startle response (ASR). We also investigated the effect of additional stressor with light-potentiated startle (LPS) and startle sensitization (SS) experiments.
Inhibition For EPM, percentage time spent in open arms did not differ between Cre- and Cre+ rats post CNO injection. For ASR, we tested baseline ASR (pre test) and ASR after CNO (post test). Although no time or genotype effect, we observed a significant interaction between the two, suggesting that systemic injection before post test affected ASR differently in Cre- vs Cre+. With SS, we measured ASR before and after a series of sensitizing footshocks. Analysis revealed a significant time (P=0.0046) and genotype (P=0.0166) effect. In Cre- rats, we observed heightened ASR post shock compared to pre shock, an effect significantly attenuated in Cre+ rats. In addition, Cre- rats post shock ASR were significantly higher than those of Cre+ with CNO.
Activation For EPM, percentage time spent in open arms did not differ between Cre- and Cre+ rats after CNO. For ASR, there was no time or genotype effect. For LPS, we compared ASR in dark/dark and dark/light phases. Light exposure did not heighten ASR; however, it revealed a significant effect of genotype (P=0.0224) showing Cre- rats startling more than Cre+. For SS, shocks significantly heightened ASR in both groups (P=0.0329) and Cre- rats showed higher ASR overall compared to Cre+ (P=0.0343).
Overall, our results suggest that although silencing CRF neurons in the $BNST_{OV}$ does not affect baseline anxiety-like behavior in male rats, it attenuates stress-induced startle sensitization. Activating CRF neurons does not potentiate baseline anxiety-like behavior nor stress-induced startle.

Title: Chronic social defeat stress increases ghrelin infiltration in the arcuate nucleus in mice

Authors: ***A. SMITH**, L. HYLAND, A. ABIZAID;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Ghrelin is a stomach-derived peptide hormone that increases food intake through the central activation of the growth hormone secretagogue receptor (GHSR). Circulating ghrelin

levels rise in response to chronic social stress, inducing increased feeding and weight gain in mice. Ghrelin primarily functions in the brain to exert its orexigenic effects, however, ghrelin movement into the brain is extremely limited due to the blood brain barrier. Notably, social stressors have been found to increase permeability of the blood brain barrier. In this study, we investigated the effect of chronic social defeat stress on ghrelin movement into the brain in mice. Male mice underwent 21-days of chronic social defeat stress before being peripherally injected with fluorescently labelled ghrelin, Cy5-ghrelin. The results showed that stress exposure increased Cy5-ghrelin fluorescence in the arcuate nucleus of the hypothalamus, compared to non-stressed controls. Despite increased Cy5-ghrelin accumulation in the arcuate nucleus, stressed mice did not exhibit changes to ghrelin movement in other brain regions. Overall, the results suggest that increased food intake during stress may be facilitated by the increased ghrelin accumulation in the arcuate nucleus.

Abstract: Declining levels of estrogens during menopause are associated with increased risk of anxiety, depression, diabetes, obesity and cancer. Similarly, removal of estrogens by ovariectomy increases weight gain and anxiety in rodents. Mounting evidence suggests gut microbiota influence anxiety and metabolism via the gut microbiome-brain axis. The present study investigated the effects of estradiol (E) and high-fat diet (HFD) on anxiety, gut microbiota and metabolism. Adult C57BL6J mice were ovariectomized and implanted sc with capsules containing E (50 μg) or vehicle (V). Within each treatment group, mice were fed a standard diet (SD) for 10 days and maintained on SD (n=16) or switched to HFD (n=16) for 26 days. Anxiety behavior was assessed with Light-Dark (LD) and Elevated-Plus Maze (EPM) tests at the end of the study. Following perfusions, whole brains were labeled for c-fos using iDISCO. Fecal DNA was sequenced for 16s rRNA genes to identify bacteria that correlated with E treatment, body

weight or were most predictive of anxiety. As reported previously, V mice on HFD became obese, while E mice remained lean, indicating that E protected against HFD-induced obesity. E reduced anxiety behavior on the LD and EPM tests. Interestingly, in HFD-fed mice, E decreased c-fos expression in the paraventricular hypothalamic nucleus and the subparafascicular thalamic nucleus, regions involved in anxiety, as well as the lateral hypothalamic and medial preoptic areas, which regulate energy homeostasis. E increased relative abundances of the families Bacteroidaceae, Alcaligenaceae and Verrucomicrobiaceae, namely the genus *Akkermansia*. E decreased relative abundances of Peptostreptococcaceae, Mollicutes and Clostridiales of the phylum Firmicutes. *Akkermansia* levels were negatively correlated with body weight, and positively associated with E treatment, suggesting this microbe protects mice from HFD-induced obesity. Increased abundances of Clostridiales and Alcaligenaceae (just prior to behavioral testing) and Peptostreptococcaceae and Erysipelotricaceae (longitudinally) were associated with low anxiety. Taken together, these findings provide insight into gut microbiota-based therapies for anxiety and metabolic disorders associated with declining estrogens in menopausal women.

Title: Examining male and female vulnerability to chronic social defeat stress

Authors: *A. MORGUNOVA[1,2], **A. MAHMUD**[1,2], M. GIROUX[2], S. ZHAO[1], C. FLORES[1,2]; [1]McGill Univ., Montreal, QC, Canada; [2]Douglas Mental Hlth. Inst., Verdun, QC, Canada

Abstract: Background: Major depressive disorder (MDD) is a chronic disabling disorder often induced by stress, affecting over 300 million people worldwide. Females are twice as likely to experience depression as males. The goal of this study was to characterize stress-induced

behavioral and molecular changes in adult male and female mice in the recently developed chronic non-discriminatory social defeat stress (CNSDS) model, in which a male and a female mouse are simultaneously subjected to social aggression.
Methods: The CNSDS was carried out to measure vulnerability to stress-induced behavioral abnormalities associated with depression-like traits in male and female mice. After 10 days of the social defeat paradigm, mice were assessed in the social interaction test and were segregated into susceptible and resilient phenotypes according to their interaction ratio. Mice then underwent behavioral tests, including the dark-light test. Trunk blood and brain samples were collected at the end of the experiment to quantify microRNA expression using Real-Time PCR analysis. **Results**: Female mice received very few attacks compared to males (4 versus 15). Nonetheless, a small percentage of females exposed to stress showed social avoidance, indicating stress hypersensitivity. Indeed, these susceptible females, but not susceptible males, showed increased anxiety-like behavior in the light dark-test, in comparison to their controls and resilient counterparts. **Conclusions**: Our results suggest that a subgroup of female mice are particularly sensitive to stress-induced social avoidance and anxiety-related behaviors. Results from microRNAs analysis will shed light into possible mechanisms underlying this trait.

Abstract: Several studies have demonstrated sex differences in neuroendocrine and behavioral responses to stress, where females have showed more impairment than males, which could explain the higher prevalence in females to develop stress related disorders. Additionally, most neural and behavioral studies not included females, however, the pattern suggest that stressed males have downregulation on neural activity while stressed females have not alter or have

upregulation of neural activity. The above, supports the idea of sex specific stress effects on behavior. The aim of this study was to compare female vs male responses to a predator scent stress (PSS). Male and female Wistar rats 12 weeks old were used (n=10 per group). PSS groups were exposed for 10 minutes in an exposure box that contained a bottle with scent tag impregnated with predator urine. Behavior was assessed with novel object recognition, open field, zero maze, and saccharin preference tests 24 hours after the final stressor. The results obtained in saccharine preference test were PSS-exposed females had lower preference for saccharine in comparison with control females and control males had a lower preference than control females. PSS-exposed females and males had a highest water consumption than control females and males. Saccharine consumption were higher in females than males no matter if they were stressed or not. In novel object recognition test the results were females had lower recognition index than males. PSS females spent more time explore the familiar object while PSS males explored more time the novel object. PSS females and males had higher latencies to explore the novel object for the first time than control females and males. In open field test PSS females and males spent less time in center area than PSS males. As well, females had more crosses in open field arena than males, but PSS females and males had fewer total crosses than control females and males. Additionally, lower locomotor activity can be explained by the increased time of grooming and immobility in PSS females and males. In zero maze test the results were PSS males had fewer entries and time in open arm than PSS females and control males even though none of the results in zero maze were statistically significative. The above suggests that PSS induced impairment on recognition memory in females and males but not in the same way. Also, PSS induced depression- and anxiety-like behaviors. That impairments could be associated with sex-specific alterations in areas important for learning and memory like the prefrontal cortex and hippocampus and for areas mediating mood and anxiety such amygdala.

Background. Adversity during development (e.g. child abuse and neglect) is linked to multiple behavioral and cognitive conditions observed in later life, such as impulsive behavior and attention deficit/hyperactivity disorder (ADHD) in which the prefrontal cortex (PFC) are implicated. The PFC undergoes protracted development through adolescence and early adulthood. As such, adversity in early life could have a profound impact on this brain region, leading to disorders like ADHD. The underlying neural mechanisms of this process, however, are still unclear. The purpose of the present study was to establish a rat model to study attention deficits caused by chronic stress during development.

Materials and Methods. Four- to seven-week-old male and female Sprague Dawley rats underwent a mild chronic unpredictable stress (CUS) procedure for two weeks. Eleven different stressors (e.g., cage vibration, cage tilting, soiled bedding, restraint, and food deprivation) were applied once or twice in an unpredictable fashion. The rats then underwent a 2-choice reaction time (2-CRT) task, which could detect major attention deficits, including action impulsivity and lapses of attention. In addition, an open field test was conducted to examine if the CUS procedure also led to increased anxiety.

Results. In the 2-CRT task, both male and female rats that underwent the CUS procedure displayed increased action impulsivity, exhibited by elevated premature responses, compared with controls. Augmented lapses of attention were observed in female but not male CUS rats, shown by increased incorrect responses. Furthermore, both male and female CUS rats spent less time in the center area of the open field, indicating heightened anxiety.

Conclusion. Chronic unpredictable stress during development leads to increased attention deficits in both male and female rats. The deficits are more severe in females than in males. The rats undergoing CUS also show increased anxiety-like behavior. The elevated anxiety could exacerbate the attention deficits in these animals.

Nacional Autonoma de Mexico, Mexico City, Mexico; [5]Univ. Nacional Autonoma De Mexico. Fac Psicologia, Mexico City, Mexico

Abstract: Stress is a systemic response for a real or perceived threat, that enhance the survival probability of an organism. Several mechanisms have been proposed as modulators of this response, however, when those mechanisms are not enough, and the stress response is sustained (chronic stress), it becomes dangerous for the organism. It is well recognized that a history of adverse experiences could be a risk factor for develop psychiatric disorders such anxiety or depression, this population is considered as susceptible to stress effects. Although, it is also well known that not all the subjects exposed to stress develop any disorder, this individuals are considered as resilient. In basic research, resilience and susceptibility to stress are highly studied in posttraumatic stress models and there are different classification methods to recognize each phenotype. But in other models (e. g. depression induced by stress) there are no ways for classify the effects of stress. Due this, the aim of this research was to investigate the behavioral effects of chronic stress in male Wistar rats to identify the set of altered behaviors to get a better classification of animals according to the severity of their alterations. First, we applied a chronic unpredictable stress battery (CUSB) in different lifetime periods (during adolescence, postnatal day 40, PND40) and during adulthood (PND 60) in four groups. Control group (without stress), stress during adolescence, stress during adulthood and stress in both periods (PND 40 and 60). Once the stress exposure finished, behavioral tasks were applied, saccharine preference (SP) and Forced Swim Test (FST) for evaluate depression-like behaviors and open field test (OFT) for anxiety-like behaviors. Finally, the classification method known as k-means was used. Results showed that in all the groups depression and anxiety like-behaviors are modulated by stress exposure. Also k-means classification method showed three clusters of altered behaviors: 1) No effects, 2) Moderate alterations and 3) Severe alterations. This data suggests that an exposition to stress during different periods could increase anxiety and depression-like behaviors but that changes are not present in all the subjects of the exposed groups. That means that as in human situations, individual differences (resilience and susceptibility) also happen in animal models of depression and it is an important factor to consider in future research.

Title: Chronic stress causes transient microglia-mediated neuronal remodeling that contributes to persistent synaptic and behavioral consequences

Authors: *S. C. WOODBURN, J. L. BOLLINGER, E. S. WOHLEB;
Pharmacol. and Systems Physiol., Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: Chronic psychological stress causes dendritic atrophy and synapse loss in the prefrontal cortex (PFC), leading to aberrant PFC function. This is important because these neurobiological changes promote the development of working memory deficits and behavioral despair. Our recent work indicates that that functional changes in microglia contribute to stress-induced synaptic deficits in the PFC. Indeed we showed that 14 days of chronic unpredictable stress (CUS) increased microglial phagocytosis of neuronal elements via CSF-1 signaling. However it is unclear if these changes reflect a permanent shift toward a dysfunctional microglia phenotype, or transient responses to adapt to stressors. In these studies male and female mice were exposed to varied durations of CUS to assess temporal dynamics of neuron-microglia interactions and associated behavioral effects. After 14 days of CUS male mice showed increased immobility in the forced swim test (FST) and reduced discrimination in temporal object recognition (TOR). These behavioral changes coincided with increased *Csf1* expression in whole PFC and *Csf1r* expression in sorted PFC microglia. Confocal imaging in Thy1-GFP mice showed that CUS decreased apical spine density for PFC pyramidal neurons and increased microglial phagocytosis of neuronal elements in layer I of the medial PFC. Notably, these changes were not evident in female mice. After prolonged CUS exposure (28 days) both male and female mice showed CUS-induced behavioral changes in FST and TOR. Interestingly, *Csf1* levels in the PFC and microglia-specific expression of *Csf1r* were normalized at the 28 day time point. Confocal imaging in Thy1-GFP mice revealed that apical spine density was still diminished in the PFC of males, but microglia-mediated neuronal remodeling returned to baseline levels after prolonged CUS. Furthermore, while female mice showed behavioral changes after 28 days of CUS, they did not show changes in microglia function or synaptic markers. Collectively these results suggest that stress-associated alterations in microglia function are dynamic, with increased microglia-mediated neuronal remodeling observed after 14 days, but not after 28 days. Additionally these studies indicate that while males and females have similar behavioral phenotypes after prolonged CUS exposure, they show divergent neurobiological

responses to stress within the PFC. Future studies will investigate whether changes in neuron-microglia interaction are directed by stress-induced changes in neuronal activity.

Title: Effect of stress on the procedural memory in adrenalectomized male rats

Authors: *M. A. GONZALEZ, E. A. RENDON-OCHOA, M. R. A. GONZALEZ-LOPEZ, N. L. GARCIA-SALDIVAR, S. E. CRUZ-MORALES;
FACULTAD DE ESTUDIOS SUPERIORES IZTACALA. UNAM, Tlalnepantla, Mexico

Abstract: In response to stress, corticosterone (CORT) is released from the adrenal glands through the hypothalamic-pituitary-adrenal axis. In adrenalectomized animals (ADX), the role of glucocorticoids in memory has been evaluated; training rats under such conditions has been shown to interfere with memory formation for several tasks. Therefore, the effect of stress by restraint 15 min (R), or the injection of CORT 1mg / kg pre-training, was studied in ADX male rats, which performed the elevated T maze task (ETM). The ETM evaluates acquisition and retention of procedural memory. Thirty-two male Wistar rats were assigned to different groups: one subjected to ETM without adrenalectomy (ETM), and three adrenalectomized groups, one exposed to ETM, another to restraint 15 min before ETM (R-ETM) and another injected with corticosterone 1 mg / kg before ETM (CORT-ETM). In adrenalectomized subjects, glucose was taken at different times and the weights of the gonads were measured. In the ETM and R-ETM adrenalectomized groups impaired retention was detected. In adrenalectomized subjects decreased testicular weight, hypoglycemia was observed on days 1 and 2, which gradually recovered. Adrenalectomy caused memory impairment in the ETM task, when pre-training CORT was administered, the subjects performed similar to the group without adrenalectomy, so CORT is necessary for memory processing and with a dose of 1 mg / kg it was sufficient to regulate their processing. The restraint causes an increase in CORT and has been related to impairment of different types of memory. The restriction induced memory impairment in the R-LET group, it is likely that this effect is associated with the activation of other circuits. However, it has been observed that in adrenalectomized subjects there is gradual recovery of plasma CORT level, but not sufficient concentration for memory to be formed.

Title: Blockade of dorsal striatal glucocorticoid receptor prevents memory acquisiton impairment induced by corticosterone

Authors: *A. O. FLORES SÁNCHEZ, E. A. RENDON-OCHOA, N. L. GARCÍA-SALDÍVAR, M. R. A. GONZÁLEZ-LÓPEZ, S. E. CRUZ-MORALES;
UNAM, Tlalnepantla, Mexico

Abstract: Response to stress is characterized by the release of glucocorticoids from the HPA axis. Corticosterone (CORT) the main hormone released by HPA, modulates adaptative responses and behavior, including learning and memory in rats. The behavioral outcome depends on the type of stressor, the moment and stress exposure time, and the type of memory. Several studies indicate that CORT administrated after training enhanced declarative and procedural memory, and administrated before training could impair declarative memory, although exist some discrepancies in procedural memory. Therefore, the present work aims to evaluate the effects of restraint stress or CORT administration before training on procedural memory in elevated T maze (ETM). ETM test consists of training the rats to avoid and escape from the open arms. On day 1 there are three trials of avoidance and one of escape. Avoidance and escape latency are measured on the second day. Wistar male rats were stressed for 15 min (restraint stress) or injected with CORT (i.p. 5 mg/ml) and the glucocorticoid synthesis inhibitor, metyrapone (ip, 40 mg/kg in 1 ml). On day 1, we found that CORT but not restraint, impaired acquisition in ETM. Metyrapone administration returned latencies to baseline in the group injected with CORT. On day 2 it was observed that CORT and restraint groups impaired retention. These results suggest that glucocorticoid inhibition is sufficient to block the acquisition impairment induced by CORT administration. The dorsal striatum has been implicated in the modulation of procedural memory formation; therefore, to determine its participation in CORT memory impairment, we implanted cannulas in rat's dorsal striatum to deliver the glucocorticoid antagonist, mifepristone. No significant differences were found in acquisition latencies among vehicle, CORT or restraint in the avoidance latencies. The CORT and restraint groups improved retention latencies. Together, these results suggest that activation of glucocorticoid receptors in the striatum before training is enough to impair the acquisition in ETM test.

Title: Glucocorticoid receptor binding contributes to cocaine-induced disruptions in goal-directed decision making

Authors: *M. K. SEQUEIRA, S. L. GOURLEY;
Pediatrics, Neurosci. Program, Emory Univ., Atlanta, GA

Abstract: Many addictive drugs increase stress hormone levels. They also weaken the ability of organisms to select actions based on their consequences, biasing behavior towards stimulus-elicited habits. We hypothesized that chronic cocaine causes habit biases by increasing circulating stress hormone levels and activating the low-affinity glucocorticoid receptor (GR). We first confirmed that cocaine increases circulating corticosterone (CORT) in mice. We next trained mice to generate two nose pokes for food and then required them to update action-consequence associations when one response was no longer reinforced. Cocaine delivered in adolescence or adulthood impaired the capacity of mice to update action strategies, and inhibiting CORT synthesis prior to cocaine blocked cocaine-induced response biases. Next, we reduced *Nr3c1,* which encodes GR, in the orbitofrontal cortex, a region of the brain responsible for interlacing new information into established behavioral routines. *Nr3c1* silencing protected against cocaine-induced response biases. Both CORT and cocaine destabilize dendritic spines in the orbitofrontal cortex, and we lastly found that inhibiting actin polymerization selectively in the orbitofrontal cortex blocked the ability of mice to update action strategies – mimicking the behavioral effects of chronic cocaine and CORT alike. Future experiments will determine whether cocaine-induced CORT release disrupts reward-related decision making via the destabilization of dendritic spines on excitatory neurons in the orbitofrontal cortex.

Title: Immune cell types in murine stellate ganglia identified by single-cell sequencing mirror immune cell diversity in the brain.

Authors: *D. CARRERA[1], V. VAN WEPEREN[2,1], R. LITTMAN[1], X. YANG[1], O. AJIJOLA[1]; [1]Univ. of California - Los Angeles, Los Angeles, CA; [2]Utrecht Univ., Utrecht, Netherlands

Abstract: Objective To define immune cell populations in healthy, murine stellate ganglia using single-cell RNA sequencing (scRNA seq). **Rationale** Microglia are the resident macrophages of the nervous system and play a crucial role in neuronal development, immune response, and homeostasis. Like microglia, CNS-associated macrophages (CAMs) are derived from the embryonic yolk sack but are found in CNS border zones. While microglia and CAMs have been studied in the CNS, little is known about their role in the peripheral nervous system. Inflammation in stellate ganglia has been reported in patients with cardiomyopathy, severe ventricular arrhythmias, and inherited arrhythmia syndromes. The role of microglia and CAM in promoting inflammation and hyperadrenergic states in sympathetic ganglia remains poorly understood. Using scRNA seq, we explored the transcriptomic heterogeneity of immune cell populations in murine stellate ganglia. **Methods** Stellate ganglia from eight wildtype male mice were used for scRNA seq. A total of 1290 immune cells were identified by expression of known gene markers (Fcrls, Cxcr6, Cd209a, etc.) and analyzed. Cell clusters were determined through unsupervised clustering, visualized using a bi-dimensional T-distributed stochastic neighbor embedding (t-SNE) dimension reduction analysis and studied using pseudotime trajectory analysis and biological pathway analysis. **Results** Murine stellate ganglia contain diverse immune cell types consisting of microglia, CAMs, monocyte-derived macrophages, dendritic cells, and T-cells. More CAMs were present than microglia, and 4 subclusters of CAMs were identified, mirroring the heterogeneity found in the CNS using deposited data. Pseudotime analysis revealed a basal CAM state transitioning to an inflammatory state, and subsequently to a stressed CAM state. Another lineage downregulates overall gene expression but upregulates mitochondrial and oxidative phosphorylation genes possibly suggesting a terminal, apoptotic state. Finally, both CAMs and microglia expressed genes associated with sympathetic signaling, such as NPY, DBH, MAO-A, COMT, NET and VMAT2. This suggests immune cell interactions with sympathetic neurons in the stellate ganglion. **Conclusion** In murine stellate ganglia, immune cell types mirror the diversity seen in the brain. CAMs might represent the predominant immune cell type in stellate ganglia. Both CAMs and microglia express genes associated with sympathetic signaling and may be involved in modulating inflammation and local adrenergic signaling at the stellate ganglion. Targeting CAMs and microglia might be an innovative strategy for treating cardiac diseases.

Title: Organization of contractile proteins in pericytes suggest different flow regulatory functions

Authors: *G. KURELI, E. ERDENER, T. DALKARA;
Inst. of Neurolog. Sci. and Psychiatry, Hacettepe Univ., Ankara, Turkey

Abstract: Although it is known that capillary pericytes contribute to regulation of blood flow, the contractile proteins involved and their role in these processes are unclear. We examined the expression of alpha-smooth muscle actin (α-SMA) and myosin heavy chain-11 (Myh11) as well as their structural organization and functional coupling in pericytes located on retinal capillary network. α-SMA and Myh11 were detected by immunofluorescence on mice retinas fixed with ice-cold methanol to prevent α-SMA depolymerization. We evaluated the structural and functional coupling of the two proteins by confocal microscopy, FRET, pharmacological inhibition of the actomyosin cross bridge cycle and, evaluated the contractile force generation by 3D modeling of pericytes after α-SMA/lectin co-labeling. We found that Myh11 tightly colocalized with α-SMA in stress-fibers and is present in all pericytes along the microvasculature. However, the organization of contractile fibers differed: circular fibers in upstream pericytes were gradually replaced by oblique and horizontal orientations toward downstream branches, suggesting that upstream pericytes regulate blood flow distribution by constricting capillaries, whereas downstream ones modulate the flux rate by varying capillary resistance. Tight association of α-SMA interaction site with Myh11's head domain was confirmed by high FRET efficiency, pointing to a less than 10 nm distance between them. Suggesting a functional coupling between the two proteins, noradrenaline-induced vasoconstriction was prevented by pharmacological inhibition of actomyosin cross bridge cycle. In conclusion, capillary pericytes express Myh11 along with α-SMA and contract via actomyosin cross bridge cycle. Differential orientation of the stress fibers along the capillary segments suggests specialized blood flow regulatory functions for up- and down-stream pericytes. Legend: 3D rendering of a contracted pericyte from Z-stack images. Note the steep reduction in luminal diameter from periphery toward pericyte soma. Cooler colors indicate lower luminal area.

Abstract: High altitude (HA) is characterized by hypobaric hypoxia, reducing effective availability of oxygen for respiration. This compromises tissue oxygenation and causes cognitive, cardiovascular and metabolic dysfunction, often with long-lasting effects even after return to normoxic conditions. In addition, HA can cause significant disruptions to normal sleep. We previously identified enhanced angiogenic activity, disruption of the blood-brain barrier, alterations in brain glucose metabolism, and increased microglia phagocytosis after HA, as well as functional deficits in hippocampal mediated behavior (Cramer et al. 2019). HA was simulated by placing ~7 week old mice in a hypobaric chamber to a simulated altitude of 5000 m (10-11% O_2, ~60% SpO_2) for chronic exposures ranging from 3-7 weeks. Assessment of vasculature was achieved through transcardial perfusion of the high contrast agent BriteVu (Scarlet Imaging, UT) followed by ex-vivo microCT imaging and analysis using Vesselucida software (MBF, VT) to quantify vascular changes including surface area, volume, diameter, length and tortuosity. We found that HA had an effect on vasculature morphology, with HA brains showing increased total blood volume of vessels, likely due to increased average vessel diameter and tortuosity. In order to assess sleep, polysomnographic recordings were carried out using EEG/EMG DSI telemetry system with HD-X02 implants (DSI, MN; n=6 per group). Throughout the 3 weeks of HA exposure animals spent increased amount of time awake during the light cycle, showed increased rapid eye movement (REM) sleep in dark cycle, and decreased slow wave sleep (SWS) in dark and light cycle (2-way ANOVA, $p < 0.001$). We also evaluated arteriolar pulsatility with use of *in vivo* 2-photon imaging and cranial windows and preliminary results suggest that penetrating arteriolar pulsatility may be reduced in the HA group. These results suggest the possibility that HA exposure may attenuate perivascular glymphatic flow. In summary, it appears that HA exposure significantly impacts vasculature and sleep architecture and can be a serious health concern and unexplored risk factor for the development of progressive neurodegenerative conditions.

Magnetic resonance imaging (MRI) can answer questions about the neural underpinnings of behaviour and perception. To answer questions about the evolutionary origins of the brain´s organization, in terms of both structure and function, comparative neuroimaging, i.e., looking at brain organization similarities and differences between species, is an important and promising avenue. In canine neuroimaging, human knee coils are often used for image acquisition. However, they cannot be expected to yield the best possible data quality as they are not designed for canine cranial anatomy. A specific canine headcoil was developed (K9 Coil, Vienna MR Apps, Austria), optimized for the canine anatomy. Here, we compare structural (n = 9) as well as functional (resting state n = 7, and a simple visual paradigm, n = 9) imaging data collected from the K9 Coil to data collected with a human knee coil, the previous state of the art in canine MRI, while keeping the sequence settings identical. Our results show that the K9 Coil significantly outperforms the human knee coil, improving the signal-to-noise ratio across the imaging modalities by at least 35%. For structural images, increases of roughly 43% (for white and gray matter collectively) are noted, while in the functional domain, increases of roughly 74.5% in the temporal signal-to-noise ratio of resting state data, and increases of 44% of task-related functional data. These findings demonstrate that hardware improvements are instrumental in driving data quality, and thus, quality of imaging results, for modern comparative neuroimaging.

Abstract: Substantive endeavors have been made for the study of cerebral blood flow (CBF) regulation mechanism and numerical modeling of oxygen transfer and delivery within cerebral microvascular networks. The reconstruction of absolute blood flow velocity distribution over a high-resolution cerebral microvascular network contributes to the better understanding and improved modeling of those mechanisms, but it is still a challenging task because the anatomical vascular structure and blood flow measurements are typically collected using nonconcurrent optical imaging techniques such as two-photon microscopy (TPM) and dynamic light scattering optical coherence tomography (DLS-OCT) which demand data co-registration to account for the differences in imaging setup and distortions. We propose a framework for rodent model to map a large set of CBF velocity measurements down to the capillary level from DLS-OCT on the corresponding anatomical microvascular structure obtained using TPM. The cerebral angiograms and absolute blood flow velocities were obtained from three anesthetized young-adult female C57BL/6 mice with sealed glass cranial windows installed. Dextran-conjugated Alexa Fluor 680 was administered to each subject as the vascular contrast agent for TPM. A global 3D and multi-layer 2D co-registration operations were employed on the TPM and DLS-OCT angiograms to obtain transformation matrices from the TPM space to the DLS-OCT space. Graph-based vascular structures were retrieved from TPM angiograms and transformed into the DLS-OCT space. Finally, accurate cerebral blood flow speed distributions were established on the graph-based high-resolution cerebral microvascular networks. Using the proposed framework, we were able to collect the mean red blood cell (RBC) velocity distributions from over 1000 microvascular segments of the three mice in arterioles, venules, and capillaries as a function of the branching order from precapillary arterioles to postcapillary venules. The proposed framework in this work can be applied for quantitative analyzing the dense data sets from OCT and multiphoton microscopy and pave the way for improved performance in the numerical modeling of CBF regulation mechanisms, oxygen transport, and delivery with realistic microvascular networks in both healthy and diseased rodent brains.

Title: Atlas-based spatial analysis and quantitative assessment of the rat hindbrain regional response to glycemic challenge

Authors: *G. TAPIA[1], L. J. AGOSTINELLI[2], S. D. CHENAUSKY[1], J. V. SALCIDO[1], J. E. ESQUIVEL[1], A. M. KHAN[3];

Abstract: Hypoglycemia unawareness may result from a failure of hindbrain glucosensing neurons to effectively respond to decreases in circulating glucose. Hindbrain epinephrine and norepinephrine neurons are necessary to prompt the glucose counter-regulatory response (CRR) that protects against hypoglycemic conditions, but there is limited knowledge of the precise atlas-based distribution of glucosensing neuronal populations. To address this, hindbrain regions were surveyed in glucoprivic (2-deoxyglucose, 250 mg/kg, i.v.) and saline-control rats. Single- and double-labeled neurons processed using antibodies against phospho-ERK1/2, dopamine β-hydroxylase, and choline acetyltransferase were photographed. These images were aligned with those of an adjacent series of Nissl-stained tissue that served as a cytoarchitectural reference, enabling the data to be mapped to a rat brain atlas (Swanson, *Brain Maps 4.0*, 2018). Additional animal cases have been surveyed, mapped, and an assessment of the hindbrain regional response to 2-DG comparing phospho-ERK1/2 labeled cell bodies 15 minutes after treatment was conducted. Cell counts were tallied to quantify the rostrocaudal distribution of activated neurons per region. In glucoprivic animals, we found increased cellular activation in hindbrain adrenergic/noradrenergic regions, suggesting these areas are associated with rapid responses to glycemic challenge. In the anterior hindbrain (e.g., Swanson Levels 51-53) phospho-ERK1/2+ neurons were distributed in the locus coeruleus and sub-coeruleus. More caudally (e.g., L55-63), activation was observed in the nucleus ambiguus and cholinergic cell groups in the vicinity of the facial nucleus. At the most caudal hindbrain atlas representations (e.g., L67-71) activation was observed in the nucleus of the solitary tract, dorsal motor nucleus of the vagus nerve, and the hypoglossal nucleus. These data indicate that rapid responses to glycemic challenge are chiefly mediated by hindbrain adrenergic/noradrenergic and cholinergic centers.

Title: Identification and analysis of controlling nodes in a neural network regulating feeding behavior

Authors: *S. MILLER[1], A. BORZOU[5,2], N. SMITH[3], J. KASPER[4], J. HOMMEL[4];
[1]Ctr. for Addiction Res., [3]Sch. of Med., [4]Pharmacol. and Toxicology, [2]Univ. of Texas Med. Br., Galveston, TX; [5]Syracuse Univ., Syracuse, NY

Abstract: Dysregulated eating carries a substantial economic and societal toll both in the United States and globally. Eating disorders like anorexia nervosa, bulimia nervosa, and binge-eating disorder can have severe effects on all body systems and are difficult to effectively treat. Currently, most treatments for these disorders rely on behavioral modification or surgical interventions, with few pharmacotherapeutic options. Because of this, a more detailed understanding of how the brain functions to regulate food intake is necessary. While multiple brain regions have been implicated in various aspects of food intake, to date, there is no systematic approach to quantitatively analyze the relative importance of each brain region to the overall function and control of the neural feeding network. Using the Allen Mouse Brain Connectivity Atlas combined with targeted literature searches, we identified 64 brain regions (or nodes) implicated in control over different aspects of feeding and constructed an *in-silico* model of the resulting mouse brain structural neural network. Network control principles were then applied to the feeding network, allowing us to identify key controlling nodes, as well as nodes that act as network hubs. *In-silico* lesioning of controlling nodes and the resulting effects on overall network controllability identified distinct brain regions that influence overall feeding network function. By applying network control principles to create a model of the mouse feeding network, we created an unbiased *in silico* tool that identified network nodes controlling food intake for future *in vivo* confirmation. This provides a connectome-driven strategy to identify central targets for pharmacotherapies to treat eating disorders while minimizing potential effects on overall brain function.

Abstract: The advent of endothermy, which is achieved through the continuous homeostatic regulation of body temperature and metabolism, is a defining feature of mammalian and avian evolution. However, when challenged by food deprivation or harsh environmental conditions, many mammalian species initiate adaptive energy-conserving survival strategies—including torpor and hibernation—during which their body temperature decreases far below its homeostatic set-point. How homeothermic mammals initiate and regulate these hypothermic states remains largely unknown. We discovered that entry into mouse torpor, a fasting-induced state with a greatly decreased metabolic rate and a body temperature as low as 20 °C, is regulated by neurons in the medial and lateral preoptic area of the hypothalamus. We show that restimulation of neurons that were activated during a previous bout of torpor is sufficient to initiate the key features of torpor, even in mice that are not calorically restricted. Among these neurons we identify a population of glutamatergic *Adcyap1*-positive cells, the activity of which accurately determines when mice naturally initiate and exit torpor, and the inhibition of which disrupts the natural process of torpor entry, maintenance and arousal. Taken together, our results reveal a specific neuronal population in the mouse hypothalamus that serves as a core regulator of torpor. This work forms a basis for the future exploration of mechanisms and circuitry that regulate extreme hypothermic and hypometabolic states, and enables genetic access to monitor, initiate, manipulate and study these ancient adaptations of homeotherm biology.

Title: Comparison of rostral and caudal prelimbic cortical connections with the forebrain in the adult male rat

Authors: K. NEGISHI[1], L. P. MONTES[1], M. S. PONCE[1], Y. C. WELLS[1], *A. M. KHAN[2]; [1]Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Connections of the cingulate region are engaged when changing environments demand adaptive control of habitual behaviors; these functions are studied as subprocesses such as attention, executive control, and working memory. The prelimbic area (PL) is frequently

identified as a key anatomical locus for these functions. However, studies usually focus on the caudal half of the PL, despite its 3 mm span, and leave the rostral PL unexamined. A comparison of rostral and caudal PL connections will help us judge when these omissions are especially problematic. To this end, we targeted the PL with co-injected anterograde (Phaseolus vulgaris leucoagglutinin) and retrograde (cholera toxin subunit B) tracers and performed high-spatial resolution analysis to compare its forebrain connections within an atlas framework (Brain Maps 4.0; Swanson, 2018, J. Comp. Neurol.). Among cerebral nuclei, pronounced differences were seen in the nucleus accumbens (ACB). Projections from the caudal PL densely targeted both ACB shell and core divisions whereas terminals from the rostral PL were restricted to the core. Rostral PL projections appeared to target matrix compartments whereas more patch innervation was observed for caudal PL projections. Bidirectional PL connections with anterior basolateral amygdala (BLAa) showed topographic differences. Hypothalamus received light projections from the rostral PL whereas caudal PL innervated several hypothalamic structures, most of which were found in the lateral hypothalamic area. In thalamus, PL connections were bidirectional. Rostral and caudal PL connections showed remarkably little spatial overlap despite having similar target structures. Caudal PL was strongly connected to the mediodorsal nucleus medial part whereas rostral PL mainly connected with its central part. The paratenial nucleus connected with the caudal PL in its rostral part, but not its caudal extension, whereas rostral PL primarily connected with its caudal part. Overall, our work demonstrated that functional experiments involving the PL could produce variable effects depending on which rostrocaudal segment was targeted. Further anatomical and functional characterization will help fine-tune experimental design and contribute to better division schemes for the rat prefrontal cortex.

Title: Sex differences in binge eating behavior and expression of pituitary adenylate cyclase-activating polypeptide in the thalamic paraventricular nucleus in rodents

Authors: *G. R. CURTIS, A. T. GARGIULO, A. GUPTA, B. E. PIRINO, J. R. BARSON; Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Binge eating disorder, characterized by the overconsumption of food in a discrete time period, is the most common eating disorder in the United States and affects women more than men. Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuropeptide implicated in feeding and is independently processed into PACAP-27 and PACAP-38. We have recently

identified high levels of PACAP-27 (more than PACAP-38) in cells of the paraventricular nucleus of the thalamus (PVT), a limbic brain region involved in feeding. To better understand the sex difference in the rate of binge eating disorder, we used a limited access home cage model with Milk Chocolate Ensure Plus® to induce binge eating behavior in adult male and female mice. Under this 6-week paradigm, female mice (n = 7) demonstrated greater binge eating than male mice (n = 5), consuming more Ensure both as a function of bodyweight (BW) (0.22 kCal/g BW vs. 0.17 kCal/g BW, $p < 0.001$) and as a percent of total daily calories consumed (33.4% vs. 25.7%, $p < 0.05$). Next, we used quantitative real-time PCR (qRT-PCR) to examine PVT PACAP mRNA in adult male and female mice (n = 5/group) with no history of binge eating, and found that females had higher levels of PVT PACAP mRNA than males (+100%, $p < 0.05$). In adult male and female rats, both qRT-PCR and immunohistochemistry further supported this finding. Gene expression of PACAP was higher in females by 97% in the anterior PVT and 28% in the posterior PVT. Protein levels of PACAP were also higher in females (n = 5/group), for both PACAP-27 (52% vs. 44% of all cells, $p < 0.01$) and PACAP-38 (13% vs 10%, $p < 0.05$) across the entire PVT. In summary, our results indicate that females have higher levels of PACAP in the PVT and are more prone to binge eating, suggesting that PACAP in the PVT could drive binge eating behavior.

Title: High-spatial resolution atlas-based mapping of insular cortical connections to the amygdala and thalamus in the adult male rat

Authors: *L. P. MONTES, K. NEGISHI, A. M. KHAN;
Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: The insular cortex is known to be a hub that receives and sends information to different brain regions. It integrates autonomic and limbic responses, and is anatomically connected to amygdalar and thalamic subregions. The insular cortex, in turn, receives somatosensory, visual, gustatory, and auditory information from thalamic regions. Similar to the amygdala, the insular cortex plays a role in processing signals encoding emotional responses. Early tract-tracing studies have shown that injections in limbic areas displayed anterograde and retrograde labeling in the insular cortex. These connections have not yet been mapped in a standardized, high-spatial resolution atlas. Here, we focus on mapping the anatomical connections between portions of the insular cortex, mainly in the dorsal agranular insular area

(AId), and subregions in the amygdala and thalamus; using a standardized reference atlas (*Brain Maps 4.0* (*BM4.0*); Swanson, 2018, *J. Comp. Neurol*.). Cholera toxin B subunit (CTB) and *Phaseolus vulgaris* leucoagglutinin (PHAL) were injected in the AId. The injection site was from *BM4.0* atlas levels 9-13 (AP= +2.80 to +1.20 mm from Bregma, β) and the core was from level 10 to 11 (AP= +2.15 to +1.70 mm from β). Diaminobenzidine (DAB) was used to visualize PHAL labeling and a nickel-enhanced DAB reaction was used for CTB labeling in coronal rat brain sections. Adjacent tissue series were Nissl-stained, and boundaries were assigned based on cytoarchitecture, as described in *BM4.0*. Results were consistent with previous studies showing projections from the insular cortex to the anterior and posterior basolateral amygdalar nucleus (BLAa and BLAp), lateral amygdalar nucleus (LA), and central amygdalar nucleus (CEA). The LA had the highest expression of PHAL, followed by the CEA, BLAa, and BLAp. Cell bodies expressing CTB were only present in the LA. The AId also showed projections to subregions of the thalamus, specifically to the mediodorsal thalamic nucleus medial part, mediodorsal thalamic nucleus lateral part (MDl), paraventricular thalamic nucleus (PVT), and the intermediodorsal thalamic nucleus (IMD). Cell bodies expressing CTB were present in the MDm, IMD, MDl, with very few also present in MDc. Subregions of the amygdala and the thalamus were analyzed for *BM4.0* atlas levels 25-31. These data provide high-spatial resolution maps of the connectivity between the insular cortex and the amygdala or thalamus that can greatly aid in targeting for functional experiments using methods such as optogenetics.

Title: Fibrinogen-induced oxidative stress and inflammatory responses in astrocytes

Authors: *N. H. SULIMAI, J. BROWN, D. LOMINADZE;
Univ. of South Florida, Tampa, FL

Abstract: Neuroinflammation is the hallmark of traumatic brain injury (TBI), which may progress years beyond the trauma causing cognitive decline, particularly reduction in short-term memory (STM). TBI is associated with elevated blood levels of fibrinogen (Fg) called hyperfibrinogenemia (HFg). We found that HFg resulted in Fg extravasation, deposition in vasculo-astrocyte interface and activation of astrocytes via interaction with astrocyte cellular prion protein (PrP^C). These effects were associated with neurodegeneration and STM reduction during TBI. However, mechanisms of HFg-induced astrocyte activation-mediated neurodegeneration is unclear. We hypothesized that HFg, via Fg-PrP^C interaction, stimulates astrocyte inflammatory responses and causes increase in nitric oxide (NO) production and

generation of reactive oxygen species (ROS). Cultured mouse brain astrocytes were treated with either serum-free medium, 4 mg/ml of Fg, or with Fg (4 mg/ml or 1 mg/ml) in the presence or absence PrP blocking peptide overnight or for 3hrs for detection of Fg and astrocyte PrP^C interaction and generation of ROS. Possible formation of fibrin was prevented by the presence of hirudin. Effects of Fg on expression of astrocyte proinflammatory genes (assessed by q-PCR) and proteins (assessed by ELISA), and Fg and PrP^C interaction assessed by proximity ligation assay (PLA) (Duolink™PLA, Millipore Sigma) were tested. Astrocyte ROS and NO were detected using carboxy-H2DCFDA (Image-IT™ LIVE Green ROS Detection Kit, Invitrogen) and Griess assay (Promega), respectively. We found that HFg caused an increase in interleukin 6 (IL-6), C-X-C motif chemokine 10, and chemokine (C-C motif) ligand 2 gene and IL-6 protein expressions. It did not affect IL-10 gene expression. PLA positive signals revealed that Fg was in close proximity (< 40nm) to astrocyte PrP^C. HFg caused an increase in ROS and NO productions. Inhibiting of PrP reduced all these Fg effects. These results confirm our hypothesis that Fg interacts with astrocyte PrP^C inducing release of inflammatory agents, production of ROS and NO, which contribute to oxidative stress and possibly trigger neurodegeneration. The latter can be a result of cognitive decline previously seen during mild-to-moderate TBI in our studies.

Title: Alterations in blood brain barrier permeability after chronic allergen exposure in a mouse model of mild cow's milk allergy

Authors: *D. L. GERMUNDSON, N. A. SMITH, A. BRISHTI, K. NAGAMOTO-COMBS; Univ. of North Dakota SMHS, Grand Forks, ND

Abstract: Food allergy has been implicated as a risk factor for various neurodegenerative disorders. However, the connection between allergic hypersensitivity and neurodegeneration remains elusive. We hypothesized that repeated consumption of offending allergens by mildly allergic individuals could sustain chronic inflammation, which in turn would promote degenerative pathology via neuroinflammation. To test our hypothesis, we developed a mouse model of non-anaphylactic cow's milk allergy, in which 4-week old male C57BL/6J mice were sensitized to a bovine whey allergen, β-lactoglobulin (BLG), for 5 weeks and then subsequently placed on a whey-containing diet for 2 weeks. The BLG-sensitized mice were able to consume the allergen diet without weight loss or obvious anaphylactic symptoms despite their

significantly increased levels of serum IgE. Mice were then sacrificed to investigate changes in glia, blood brain barrier permeability, and peripheral immune cell migration into the central nervous system. After BLG-sensitization, GFAP-immunoreactive astrocytes in the brain were increased in number around larger blood vessels and showed more reactive morphology. Vascular permeability in the brain was also assessed by immunostaining with an anti-IgG antibody to determine transendothelial extravasation. While sham mice showed strong positive staining within the vessels, the brains of BLG-sensitized mice were diffusely stained, likely due to a 'leaky' blood brain barrier. Additionally, in highly vascularized regions of the brain, such as the choroid plexus, BLG-sensitized mice showed increased numbers of mast cells as we have previously reported. The increase of mast cells suggested that these innate, proinflammatory immune cells may have contributed to the observed changes in blood brain barrier permeability. Taken together, these results indicated that chronic exposure of sensitized mice to BLG significantly altered brain physiology even without typical anaphylaxis symptoms. Furthermore, these findings support the notion that food allergy may serve as a risk factor for the development of neurodegenerative disorders and highlight the possibility for food allergy management as a preventative approach for reducing chronic neuroinflammation.

Title: Reduced Folate Carrier 1 is Present in Cerebral and Retinal Microvessels

Authors: *G. GURLER[1], G. URUK[1], N. BELDER[1], M. YEMISCI OZKAN[1,2,3];
[1]Inst. of Neurolog. Sci. and Psychiatry, Hacettepe Univ., Ankara, Turkey; [2]Fac. of Medicine, Dept. of Neurology, Hacettepe Univ., Ankara, Turkey; [3]Neurosci. and Neurotechnology Ctr. of Excellence (NÖROM), Ankara, Turkey

Abstract: Microvessels of the brain and retina are encircled by pericytes and vascular smooth muscle cells, called mural cells. These cells have several roles in health and disease. Recently, a meta-analysis of five transcriptomic studies of cerebral mural cells showed three genes were enriched, one of which was the reduced folate carrier 1 (RFC1, SLC19A1) gene. However, to date, RFC1 protein in mural cells of the brain has not been demonstrated. Here, first, we aimed to detect RFC1 protein expression of cerebral mural cells. Second, since retina is considered as the extension of the brain in terms of microcirculatory properties, we hypothesized that RFC1 should also be present in retinal microvessels. We used brain sections, isolated brain

microvessels, whole mount retinas and retinal digest preparations obtained from male and female naïve adult Swiss albino mice to immunohistochemically characterize RFC1 expression in microvessels and pericytes. We used 2 commercially available RFC1 antibodies targeted to 2 different regions. As positive controls we used mice liver, kidney and gut sections where RFC1 protein expression is already abundant and determined immunohistochemically. We colocalized RFC1 marker with the accepted pericyte markers such as platelet-derived growth factor receptor beta (PDGRFR-beta), Aminopeptidase N (CD13) and Neural/glial antigen 2 (NG2). Vessels were visualized by 'Fluorescein' or 'Texas Red' labeled Lectin. Hoechst 33258 was used to label cellular nuclei. We also applied methotrexate (MTX); which is used clinically as an antineoplastic and antirheumatic agent inhibiting folic acid uptake by acting as a non-covalent inhibitor of RFC1 intraperitoneally and obtained brains, as well as intravitreally and obtained retinas, to study if RFC1 protein changes. We showed immunohistochemically that RFC1 protein was present in cerebral mural cells widely, and is colocalized with accepted pericyte markers. In literature, RFC1 was determined to be present only in the retinal pigment epithelium constituting the outer blood-retinal barrier. However, for the first time, we detected RFC1 protein in the microvessels of inner blood retina barrier - the endothelium and pericytes, in line with the transcriptomic studies. Our preliminary data showed that MTX administration changed the RFC1 protein in acute or chronic time points. Therefore, we suggest that RFC1 protein, which is overlooked in microvasculature until know, is widely expressed in retinal and cerebral pericytes, and may have a critical role in health and disease.

Title: A subset of smooth muscle actin-negative microvascular pericytes transition to smooth muscle actin-positive pericytes in the brain during normal aging or HIV/SIV infection

Authors: ***D. G. BOHANNON**[1], H. R. OKHRAVI[2], J. KIM[3], M. J. KURODA[4], E. S. DIDIER[4], W.-K. KIM[1];
[1]Microbiology and Mol. Cell Biol., [2]Glennan Ctr. for Geriatrics and Gerontology, Eastern Virginia Med. Sch., Norfolk, VA; [3]Cedars-Sinai Med. Ctr., UCLA, Los Angeles, CA; [4]Ctr. for Immunol. and Infectious Dis., Univ. of California, Davis, Davis, CA

Abstract: Historically, the presence of both alpha-smooth muscle actin-positive (SMA+) and SMA- brain microvascular pericytes have been repeatedly referenced throughout literature, but a lack of in-depth characterization of these cells has hindered our understanding of their role(s) in neurological diseases and disorders. In this study, we found that SMA- primary human brain microvascular pericytes transition to a SMA+ phenotype in culture after two 16-d passages. Compared to untreated controls, treatment with HIV-1 BAL gp120 recombinant protein (10-20 ng/mL) for 3 d induces an increase in the number of SMA+ cells. Similar changes in SMA +/- pericyte populations were observed in the frontal cortex of male and female rhesus macaques during natural aging (juvenile, adult, aged; n=10/group) and in young adult males with SIV infection with or without encephalitis (n=5/group). The percentage of the pericytes that were SMA+ (type-2 pericytes; PC2) was found to be increased in macaques both with aging and SIV status. Furthermore, PC2-associated vessels had significantly less claudin-5 ($p<0.0001$) and significantly more fibrinogen extravasation ($p<0.0001$), resulting in a strong positive correlation between the percentage of PC2 and percentage of vessels with fibrinogen extravasation in each animal regardless of animal group or infection status ($r^2=0.76$, $p<0.0001$). Ultimately, our findings demonstrate that the in vitro observed transition from SMA- type-1 pericytes (PC1) to PC2 can occur in vivo, providing a potential explanation for the increased percentage of PC2 in the brain of naturally aging rhesus macaques and SIV-infected macaques. These results also suggest that PC2 may play an important role in BBB disruption in various neurological disease and that the PC1-to-PC2 transition may be a pathologically more relevant change in the BBB than pericyte loss.

Title: Oat1 expression in murine and human leptomeninges

Authors: *V. HULL, Y. WANG, D. PLEASURE;
UC Davis, Davis, CA

Abstract: The organic anion transporter (OAT) family of transmembrane proteins have high clinical relevance because of their essential role in regulating the blood concentration of important drugs like antivirals, nonsteroidal anti-inflammatory drugs, and antibiotics. The OAT family of proteins are membrane transporters, exchanging one molecule of hydrophilic organic anion for dicarboxylates such as glutarate or ketoglutarate. This exchange system is seen most

classically in the kidney, where OAT1 (encoded by Slc22a6) is highly expressed in the basolateral membrane of the proximal tubular cells and functions to absorb anions from the blood thereby regulating renal secretion of soluble drugs. Studies involving knockout of OAT1 and OAT3 (encoded by Slc22a8) also point to roles for the transporters in regulation and maintenance of gut microbiome homeostasis. Beyond the kidney, OATs have also been identified at various other blood-fluid barrier sites including liver, retina, choroid plexus, brain endothelium and placenta. We have recently localized OAT1 to the arachnoid layer of murine and human brain tissue. In this study we use layer- and cell-specific markers in mouse and human tissue, along with quantitative methods in mice, to better understand the location and expression level of OAT1 and OAT3 in the brain. In mice we find that the expression level of OAT1 is 1.3 times higher in the leptomeninges than in the kidney. Additionally, we find that OAT3 expression in murine meninges is drastically less than that of OAT1. The expression of OAT1 in cerebrospinal fluid (CSF) facing arachnoid mater could potentially point to a role for OAT1 in CSF filtration within the subarachnoid space which has important implications for the regulation of drug pharmacokinetics. Furthermore, meningeal expression of OAT1 is important to understand as this protein also participates in the exchange of dicarboxylic acids, the brain specific accumulation of which is a hallmark of several currently incurable genetic metabolic diseases like Canavan disease, the glutaric acidurias and others.

Title: Brain microvascular endothelial cells are sensitive to hypoglycemia, and partially rescued by ketone bodies

Authors: *I. PERVAIZ, A. AL-AHMAD;
Pharmaceut. Sci., Texas Tech. Univ., Amarillo, TX

Abstract: Introduction: Glucose represents the main source of energy of the central nervous system (CNS), as 20% of daily glucose intake is directed towards the brain. Glucose transport inside the CNS is occurring mostly via the blood-brain barrier (BBB) via the presence of several glucose transporter isoforms (GLUTs). Although glucose metabolism has been mostly investigated in the lens of the astrocyte-neurons axis, the fate of glucose and its metabolism at the BBB remains elusive. GLUT1 deficiency syndrome (GLUT1DS) is autosomal dominant haploinsufficiency characterized by mutations in *SLC2A1* resulting in impaired GLUT1 expression and/or activity. Patients suffering from GLUT1DS suffer from epileptic seizures, intellectual disabilities, and movement disorders. As of today, medical intervention involving the

adoption of a ketogenic diet (KD) remains the main course of action with satisfactory clinical outcomes. Yet, the effect of hypoglycemia and ketone bodies on the BBB function (including its glucose metabolism) remains unclear. This study investigates the effect of hypoglycemia and ketone bodies on the barrier function and glucose metabolism in vitro. Methods: CTR90F and CTR65M iPSC derived BMECs were used in this study. Changes in GLUTs expression was assessed by immunofluorescence and flow cytometry, change in glucose uptake was assessed using 14C-glucose, change in glycolytic flux using SeahorseXF24 flux analyzer, and changes in the barrier function by transendothelial electrical resistance (TEER) and permeability to fluorescein. Cells were supplemented ketone bodies (KB, 4microM beta-hydroxybutyrate, and 1mM acetoacetate) for 24 hours. Results: Our data suggest that a decrease in glucose level upregulates the expression of GLUT1 and GLUT3 isoforms in our BMECs monolayers, such decrease was accompanied by a decrease in glucose uptake, alterations in tight junction complex, as well as a decreased cell metabolic activity and glycolytic flux resulting in a partial recovery of the barrier function under mild hypoglycemia and a partial recovery of the glycolytic flux. No significant changes in glucose uptake was observed in our model following treatment with KB. Discussion: Our study suggests that BMECs may rely on glycolysis as the main source of energy, a decrease in blood glucose may have a detrimental effect on the barrier function. Supplementation with Ketone body (beta-hydroxybutyrate and acetoacetate) partially relieved such symptoms.

Title: Exploring the relationship between functional ultrasound and neuronal activity

Authors: *A. O. NUNEZ-ELIZALDE[1], M. KRUMIN[1], C. B. REDDY[1], G. MONTALDO[2], A. URBAN[2], K. D. HARRIS[1], M. CARANDINI[1];

Abstract: Functional ultrasound imaging (fUSi) is an appealing method for measuring blood-volume signals from the brain. However, the blood-volume signal measured by fUSi bears an unclear relationship to the underlying neuronal firing. Is this relationship linear, and stable across brain regions, subjects, and time?
To answer these questions, we performed simultaneous fUSi measurements and Neuropixels recordings in awake mice. Eight recording sessions were performed across four mice (~4 coronal slices per session). We inserted one or two Neuropixels probes per session, and related firing recorded from these probes to fUSi signals from the corresponding regions of interest.

A linear model provided a good estimate of fUSi signals based on neuronal firing. We measured the multi-unit activity (MUA) from the Neuropixel probes and convolved it with a hemodynamic filter. The filter was estimated using a linear regression model using half the data from one recording, and tested on the second half. Model predictions were accurate ($r > 0.5$). Furthermore, this model generalized across mice: it increased prediction accuracy relative to an instantaneous MUA model with no delay in all sessions in all three held-out mice. The hemodynamic filter resembled one measured optically, peaking ~1.5 s after neural activity (Pisauro, et al., *J Neurosci* 2013).
These results indicate that the relationship between neuronal firing and fUSi is stable and linear. Our current efforts aim to optimize the processing of fUSi signals so that they best capture variations in neuronal firing across both time and space.

Title: Simultaneous functional imaging of hemodynamic and mechanical properties changes during neuronal activation in the rodent brain with Ultrafast Ultrasound

Authors: ***F. LASZLO**, C. RABUT, S. PEZET, T. DEFFIEUX, M. TANTER;
Physics For Med. Paris, paris, France

Abstract: *Introduction*
Advances in neuroscience are closely tied to the development of neuroimaging techniques. Functional ultrasound imaging (fUS), based on ultrafast Doppler, permits to image the Cerebral Blood Volume (CBV) variations and thus to monitor brain activity through the neurovascular coupling. The hemodynamic response to a functional stimulus is slow and may conceal faster transient phenomenons. A recent study (Patz, Science Advances, 2019) formulated the hypothesis that brain activity would also lead to a fast local change in tissue stiffness and therefore would give access to faster functional imaging. By merging fUS and Shear Wave Elastography (SWE), we investigate here this neuromechanical (NM) coupling hypothesis that could serve as a new functional contrast.
Methods
To study simultaneously hemodynamics and tissue mechanical properties in the brain, we programmed for the first time an ultrafast research scanner with a hybrid ultrasound sequence that combines SWE, by generating a shear wave with radiation force and monitoring its propagation with ultrafast imaging (framerate of 5000 Hz) and fUS by ultrafast imaging (framerate of 500 Hz) for power Doppler. In vivo experiments were conducted on 6 rats under perfusion of ketamine/medetomidine with craniotomy centered on Bregma - 6.2mm. Functional

visual stimulation was controlled by a chaining of 30 s of 3 Hz blinking green LED and 30 s of rest during 3 minutes to activate the Superior Colliculus (SC).

Results

High-quality Doppler movies were obtained on rats and show strong correlations between stimuli and vascular response in SC (β - 6.2 mm) with an average CBV increase of 18 % during activation. SWE proved its robustness with a reproducibility under 5 % and relevant tissue stiffness values (17,7 ± 0,4 kPa) in SC. In this zone, the difference in stiffness between stimulation and rest remained under 0.1 % indicating the absence of a fast NM effect in the activated area and thus contravening the fMRI study. However, we showed that stiffness significantly changes solely in SC with an average 6 % decrease ($p = 0.0018$) after 3 minutes of activation. In conclusion, we designed a novel reliable tool that could be used to investigate a NM coupling and showed that a functional activation leads to a slow, localized and reversible decrease in brain stiffness.

Title: Simultaneous functional ultrasound and electrophysiological recordings of awake and behaving monkeys in Supplementary Eye Field.

Authors: ***J. CLARON**[1], F. ARCIZET[2], *T. DEFFIEUX[1], M. TANTER[1], P. POUGET[3]; [1]ESPCI Paris, PSL Res. University, Physic for Medecine Paris, INSERM U1273, Paris, France; [2]Inst. de la Vision, Paris, France; [3]Paris Brain Inst., Paris, France

Abstract: Introduction To date most whole brain imaging techniques such as fMRI are based on the use of neurovascular coupling. However its combination with electrophysiological recording for a direct assessment of local brain electric activity remains complex due to electromagnetic compatibility issues. Here, by coupling functional ultrasound (fUS) and electrophysiological recording, we were able to directly compare the hemodynamic blood flow at high spatiotemporal resolutions and the local neuronal activity, we were capable to record both signals simultaneously in awake behaving monkeys doing an oculomotor task. **Methods** We used an ultrasound neuroimaging scanner (Iconeus, France). For ultrasensitive Doppler imaging, the scanning sequence consisted of 11 tilted planar ultrasonic waves with a pulse repetition frequency of 500 Hz and a linear ultrasonic probe (128 elements, 0.1 mm pitch, 15 MHz). Electrophysiology was performed using regular tungsten microelectrode with electrical signal recorded on a MAP system (Plexon). Electrophysiological signals were filtered using the basic

feature 0.5 to 135 Hz for LFPs and 40kHz for spike activity. Here we aim to investigate the relation between the Power Doppler signal, proportional to the local Cerebral Blood Volume (CBV) and neuronal firing using simultaneous fUS and electrophysiology recordings. **Results** First, the ultrasonic imaging of local tissue motion during electrode insertion enabled us to precisely locate the electrode tip with a 100 µm precision. After the positioning of the electrode in the supplementary eye field (SEF) region at 2mm depth in the prefrontal cortex, we made electrophysiological and fUS coupled recording. The SEF was chosen for its role in monitoring oculomotor movement during cognitive tasks. We compared multiple and single unit activity with corresponding fUS signal. We saw that neuronal activity always preceded hemodynamic activity. We also observed long term dissociations between CBV and neuron firing recorded within a close area. **Conclusion** The simultaneous recording of local electrophysiological signals and global functional ultrasound imaging data allows us to record distinct biological phenomena at the same time, but also to monitor the insertion and precise positioning of the electrophysiological probe in the brain, in real time. **References** Neurophysiological investigation of the basis of fMRI signal, NK Logothetis *et al.,* 2001, Nature, DOI : 10.1038/35084005 Functional ultrasound imaging of the brain reveals propagation of task-related brain activity in behaving primates, A. Title: Intermittent Stimulation of the Pudendal Sensory Nerve Alters Voiding Behavior in Conscious Unrestrained Wistar Rats

Authors: *C. L. LANGDALE[1], J. A. HOKANSON[1], D. DEGOSKI[1], P. MILLIKEN[5], W. M. GRILL[1,2,3,4];
[1]Biomed. Engin., [2]Electrical and Computer Engin., [3]Neurobio., [4]Neurosurg., Duke Univ., Durham, NC; [5]Galvani Bioelectronics, Stevenage, United Kingdom

Abstract: Overactive bladder (OAB), resulting in urgency, frequency, and incontinence, is a highly prevalent condition that leads to medical complications and decreased quality of life. Pudendal (Pud) nerve stimulation (STIM) has shown promising clinical results, but effective STIM parameters to reduce OAB symptoms remain unclear. Preclinical studies demonstrated

that the effects of pudendal sensory nerve (PudS) STIM on bladder capacity were both frequency and amplitude-dependent, but these studies were in anesthetized animals. Our goal was to quantify the effect of PudS STIM on voiding behavior in conscious unrestrained female Wistar rats. Food and water consumption, body weight, void frequency (VF), and void volume (VV) were recorded. Rats were habituated in metabolism cages for ~24 h/day, twice a week, and after habituation, the left PudS was implanted with a 300 μM bipolar cuff connected to a skull-mounted headcap. After recovery, animals were placed into metabolism cages three days a week (Pre-STIM: Mon, STIM: Wed, and Post-STIM: Thu). For STIM, rats were connected to an external stimulator, impedances recorded, and STIM threshold determined at 10 Hz (minimum amplitude that produced either a visual contraction of the pelvic region or any sign of awareness). The test amplitude was set just below this threshold, i.e., without contractions or awareness. PudS STIM was delivered at 10 Hz with one of three duty cycles (1/1, 3/1, or 1/2 h on/off) for 24 h once per week for several weeks. All three PudS STIM paradigms increased VV and decreased the VF over the 24 h period during STIM compared to Pre-STIM. The 1/1 h on/off STIM also increased VV on Post-STIM. All PudS STIM paradigms increased VV and decreased VF during STIM compared to Pre-STIM with both lights on and lights off. No change in normalized food consumption was observed across all duty cycles. The 3/1 h on/off STIM decreased normalized water consumption, whereas the 1/1 and 1/2 h on/off had no effect. Our results demonstrate, as reported in acute anesthetized studies, that PudS STIM is effective in changing the voiding behavior in conscious unrestrained animals. We observed increased VV and decreased VF using three different PudS STIM paradigms. Furthermore, with the 1/1 h on/off paradigm these effects persisted the following day, i.e., a carryover effect. Our results suggest that continuous STIM may not be necessary to reduce OAB symptoms and provide positive evidence that electrical STIM of peripheral nerves responsible for the coordination of lower urinary tract function may have utility in treating OAB.

Title: Sex Differences in Insular Gyrus activity during a Foot Cold Pressor

Authors: *B. KRAUSE-SORIO[1], K. E. MACEY[2], R. KUMAR[3], J. OGREN[2], R. HARPER[2], P. M. MACEY[4];
[1]Univ. of California Los Angeles, UCLA, CA; [2]UCLA, Los Angeles, CA; [3]Dept. of Anesthesiol., [4]UCLA Sch. of Nursing, Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Introduction: Cardiovascular disease (CD) is the leading cause of death with striking sex differences. Neural control of cardiovascular functioning may underlie sex differences. We found sex- and region-specific variation across the five distinct gyri of the insula, which hold distinct roles in central autonomic regulation, using fMRI during a Valsalva maneuver (predominantly sympathetic activation) and a handgrip challenge (mainly parasympathetic withdrawal). Men showed greater left-lateralized responses in anterior, middle and posterior gyri, while women displayed greater right-lateralized activation in anterior and posterior, but not middle gyri. In order to determine whether the effects are task-specific, we compared sex and regional insular activity during a cold pressor challenge, an autonomic challenge targeting sympathetic activation associated with vasoconstriction and pain.**Methods:** Twenty-two women (age; mean±std: 50±4 yrs) and 39 men (45±3 yrs) underwent fMRI scanning using a 3T Siemens Trio scanner. The BOLD response during the 1 min right-foot cold pressor challenge was compared to a preceding 2 min baseline and a subsequent 2 min recovery period. Regions of interest were left and right anterior short gyri (ASG), mid-short gyri (MSG), posterior short gyri (PSG), anterior long gyri (ALG), and the posterior long gyri (PLG, anterior-to-posterior order). Heart rate (HR), blood oxygen saturation, and BOLD signals were compared between gyri, hemispheres, anterior vs. posterior insula and sexes at 2 sec intervals.**Results:** Women had higher baseline HR than men but there was no difference in percent HR change during the challenge. The BOLD signal initially peaked in all gyri, returned towards baseline at 10-15sec and increased again. Right hemisphere gyri responded more strongly than left gyri. Anterior vs posterior responses were also right-lateralized, with greater sub-regional differentiation in men. Increased right vs left responses in the ASG were similar for women and men, but women showed higher increases than men in the middle gyri (MSG, PSG, ALG).**Conclusions:** These findings are in line with our previous results demonstrating that the anterior gyri of the insula, particularly in the right hemisphere, responded more strongly to sympathetic activation. Unlike the Valsalva and hand grip challenges, there were no sex differences in lateralization in the ASG, but men showed reduced right hemisphere responses compared to women in the mid gyri. Despite similar lateralization, a comparable stimulus elicited differences in anterior insular responses, suggesting this region may be involved in sex differences in cardiovascular symptoms.

Title: Cross-frequency dynamics of neural, cardiac and respiratory rhythms in the context of effortful cognition and breath focus meditation

Authors: *J. R. SORIANO, J. RODRIGUEZ-LARIOS, K. ALAERTS;
KU Leuven, Leuven, Belgium

Abstract: Background. Pairs of neural oscillators can only phase-synchronize when their peak frequencies form harmonic relationships (e.g., $f_2 = f_1/2$; alpha = 10 Hz; theta= 5 Hz; ratio alpha:theta = 2:1). It is hypothesized that transient shifts in peak frequencies of different neural oscillators form the principal mechanism by which cross-frequency coupling and decoupling (i.e., facilitating information integration and communication) is implemented in the brain. Brain oscillatory activity in the alpha and theta bands has been shown to undergo peak frequency shifts upon conditions of cognitive effort, breath focus meditation practice and rest. Thus, considering the growing evidence that an interplay between neural and other main physiological oscillations (e.g. cardiac, respiratory and gastric rhythms) also takes place in a state-dependent manner, a similar mechanism of cross-frequency relationships has been proposed to characterize brain-body interactions. **Methods.** In line with a systemic approach to study human oscillatory physiology, we here explored cross-frequency relationships between neural-cardiac (i.e., alpha and heart rate; HR), as well as neural-respiratory oscillators (i.e., alpha and respiration rate; RR). Electroencephalography, electrocardiography and respiration were recorded from 18 young adults (mean age 23.56 ; 11 women) during three 5-min conditions of (i) rest, (ii) breath focus meditation and (iii) a cognitively demanding arithmetic task. Then, transient frequency changes per oscillator and the ratio between frequencies of oscillator pairs were computed. **Results.** The transient incidence of alpha-HR and alpha-RR cross-frequency relationships at or around the harmonic (8:1 for alpha-HR, 32:1 for alpha-RR) was significantly higher during the arithmetic task compared to rest and breath focus meditation. On the contrary, the incidence of approximately non-harmonic relationships (multiples of the respective harmonic ratio multiplied by the irrational number golden mean, 1.618; i.e., ratios of 12.94:1 for alpha-HR, 51.78:1 for alpha-RR) was shown to be higher during breath focus meditation compared to both rest and arithmetic task. **Conclusion.** These findings extend insights into the physiological underpinnings of cognition considering the integration of dynamically interacting body subsystems. More specifically, the cross-frequency relationships predominant in each condition suggest that during effortful cognition there is a greater degree of coupling between neural and cardiac/respiratory

oscillators. Conversely, breath focus meditation seems to be characterized by decoupling between these oscillators.

Title: Relationship between autonomic responses and balance control during stationary standing balance tasks

Authors: *K. J. HALL[1], M. LAYLOR[1], K. VAN OOTEGHEM[1], P. POLASTRI[2], J. VARGHESE[1], W. MCILROY[1];
[1]Univ. of Waterloo, Waterloo, ON, Canada; [2]Sao Paulo State Univ., Bauru, Brazil

Abstract: A critical role for the autonomic nervous system (ANS) in the control of balance reactions has been proposed previously with evidence for potential involvement being inferred from the observation of phasic galvanic skin responses (GSR) evoked by external balance perturbations. The current study explored whether the coupling between ANS reactivity and balance reactions would be observed during spontaneously occurring instability while standing. It was hypothesized that time varying changes in GSR (ANS reactivity) would be associated with time varying changes in mediolateral center of pressure (ML-COP) (somatomotor reactivity). Nine individuals (5 females, 4 males; aged 19-37 years) were recruited. To induce varying balance demands during standing the study compared ML-COP and GSR data across different task conditions varying the availability of vision and width of the base of support. Subjects completed 3, 30 second trials for each of the following stance conditions: standard, narrow and tandem eyes closed, tandem eyes open, tandem eyes open with dome to shield visual input and restricted peripheral visual field. ANS activity was evaluated by measures of GSR recorded from Ag-AgCl electrodes on the middle phalanges of digits 2 and 4 on the left hand; balance measures include ML-COP excursion frequency and amplitude recorded from two force plates embedded in the floor underneath each foot. Subjects were instructed to stand as still as possible with arms crossed in front of their chest. When comparing mean task differences across subjects there was an expected increase in postural sway from tasks with wide stance and no sensory restrictions (least challenging) to those with narrow stance and no vision (most challenging). The correlation analysis revealed a significant positive relationship between ML-COP variability and GSR variability when comparing across tasks ($r=0.94$, $df=5$, $p<0.05$). In addition, correlations coincided within each subject and revealed a significant positive correlation in 7 participants ($r=0.47, 0.57, 0.62, 0.62, 0.81, 0.64, 0.69$ respectively, $df=19$, $p<0.05$) and no significant relationship in 2 participants ($r=0.36, 0.29$ respectively, $df=19$, $p>0.05$). The current study revealed a significant relationship between ML-COP and GSR during balance tasks, revealing the ANS reactivity associated with naturally occurring instability when standing still, which is

proportional to the degree of instability. Next steps will explore the temporal association between the time varying changes in COP and GSR to establish if ANS reactivity phase leads or lags the evoked motor reactions.

Title: Intact Parasympathetic Withdrawal During Handgrip Challenge Reflected by Insular Functional Organization And Heart Rate Variability In Obstructive Sleep Apnea

Authors: *A. PAL[1], J. A. OGREN[2], F. MARTINEZ[1], R. S. AYSOLA[3], R. KUMAR[4], L. A. HENDERSON[5], R. M. HARPER[2], P. M. MACEY[1];
[1]UCLA Sch. of Nursing, [2]Neurobio., [3]Div. of Pulmonary and Critical Care, [4]Dept. of Anesthesiol., Univ. of California at Los Angeles, Los Angeles, CA; [5]Univ. of Sydney, Sydney, Australia

Abstract: Study Objectives: Insular gyri regulating autonomic function is disrupted in obstructive sleep apnea (OSA), which may contribute to cardiovascular comorbidities. Distinct activity patterns in insular gyri emerge to autonomic challenges, including anterior and right-side dominance during sympathetic activation; yet, OSA patients show only modest changes to such organization to Valsalva. We assessed neural responses of insular gyri in OSA and healthy Control participants to a static handgrip (HG) pressor task that principally is accompanied by parasympathetic withdrawal. We also assessed the parasympathetic nervous system activity compared to normal resting values (PNS index) aspect of heart rate variability in a separate cohort to estimate parasympathetic withdrawal during HG in OSA vs Control. **Methods:** We measured insular gyral response patterns with blood oxygen level-dependent functional MRI (fMRI). We studied 48 newly-diagnosed OSA (age mean±std:46.5±9years; AHI±std:32.6±21.1events/hour; 36 male) and 63 healthy (47.2±8.8years; 40 male) participants. Subjects performed four 16s HGs (1min intervals, 80% subjective maximum strength) during scanning. fMRI time-trends from five insular gyri—anterior short (ASG); mid short (MSG); posterior short (PSG); anterior long (ALG); and posterior long (PLG)—were assessed with repeated-measures ANOVA (p<0.05). Outside the scanner, we collected ECG data from 34 newly-diagnosed OSA (51.5±13.9years; 21.0±15.3events/hour; 20male) and 37 healthy (44.1±13.8years; 12male) participants during three 30s HGs (90 s intervals, 80% maximum strength) to estimate the PNS index calculated by Kubios. HG compared to baseline PNS indices

were averaged for 3 HGs in each subject, followed by group comparisons between OSA and Controls using ANOVA. **Results:** Females showed greater right anterior dominance in the ASG, but no fMRI differences emerged between OSA and controls relative to the functional insular organization in response to HG. Males showed greater left anterior dominance of the ASG, but there were no differences between OSA and controls. HG compared to baseline PNS indices, reduced by 0.8 a.u. (Control) and 0.7 a.u. (OSA), but with no significant OSA vs. Control differences. **Conclusions:** PNS index changes consistent with parasympathetic withdrawal during HG did not differ in OSA vs. Controls. Insular gyral functional organization responses to HG in OSA and Controls did not diverge significantly, further supporting an interpretation that parasympathetic withdrawal markers in the insula are largely intact in OSA, despite earlier studies showing morphologic injury to the overall insular structure in OSA.

Title: Sex Differences in repeated restraint stress-induced hyperthermia in rats

Authors: *T. J. PHILIPPE, M. DORDEVIC, V. VIAU;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Experience with a controllable challenge can protect an organism from the negative consequences of stress. Thus, determining the mechanisms of adaptive responses has important implications for understanding stress resistance and vulnerability. In our model of stress habituation, male and female rats emerge from repeated restraint exposure to show comparable declines in glucocorticoid stress responsivity, but also marked differences in thermoregulatory responses to serotonin (5-HT) 1A receptor activation. Since this receptor also modulates stress-induced hyperthermia, at least under acute conditions, here we explored the extent to which core body temperature responses are deferentially modulated by repeated restraint stress in male and female rats. Core body temperature was continuously monitored (5 min intervals) in 90 day old rats bearing intraperitoneal telemetric temperature sensors (Anipill, BodyCAP), implanted 7 days before testing (n = 8/group) in stress naïve animals, and those exposed to 2h periods of restraint, repeated daily (9:00 to 11:00 AM) for 5 consecutive days. As a function of repeated stress exposure, males, but not females showed reliable reductions in restraint-induced hyperthermia. Furthermore, females continued to show anticipatory thermal responses for up to 72 h following the last restraint exposure. Taken together, these findings suggest sex differences in stress-metabolic adaptations, and for this to occur as a consequence of changes in 5-HT regulation of

sympathetic nervous system outflow in male and females. While these potential differences in 5-HT signaling may well serve homeostatic responses to controllable stress, they may also be relevant to sex disparities in mood disorders associated with chronic stress exposure.

Sch. of Med., Toyoake, Japan; [8]Akita Univ, Dept Neurophysiol., Akita, Japan

Abstract: Barrington's nucleus controls micturition behavior through the downstream projection to the spinal cord. In the Barrington's nucleus, two types of projection neurons, which were classified by the expression of *Crh* (Bar^{CRH}) and *Esr1* (Bar^{ESR1}), have suggested playing distinct roles on micturition behavior by manipulations of neural activity. The difference of their functional roles was explained by their projection targets, i,e, Bar^{CRH} preferentially projected to the L6-S1 intermediolateral (IML) region in the spinal cord, and Bar^{ESR1} projected to L6-S1 IML and dorsal commissure nucleus (DCN) region in the spinal cord. However, the synaptic connections from Bar to the spinal cord have not been fully elucidated. To understand the detailed mechanisms of synaptic integration in the spinal cord, we conducted *in vitro* slice patch-clamp recordings from spinal neurons, which are involved in the regulation of pelvic organ function. We examined the synaptic connectivity from Bar populations by using ChR2 assisted circuit mapping (CRACM) techniques. As a result, we revealed a direct glutamatergic synaptic connection from both types of Bar populations to DiI-labeled sacral pre-ganglionic neurons (S-PGN). Comparing the properties of opto-evoked excitatory post synaptic current (oeEPSC) to the S-PGN, Bar^{CRH} and Bar^{ESR1} send similar strong output to some populations of S-PGN. The stimulation of Bar^{ESR1} sometimes evoked modest intensity of oeEPSC, which might excite interneuron in the slice preparation. In addition, Bar^{ESR1} stimulation evoked opto-evoked inhibitory post synaptic current (oeIPSC) response to small portions of S-PGN. Optical stimulation of Bar^{CRH} and Bar^{ESR1} terminals elicited monosynaptic oeEPSC and polysynaptic

oeIPSC to the sacral DCN neurons, which might include interneurons projected toward either IML regions or ventral horn. Application of capsaicin or some neuropeptides (Substance P, somatostatin, gastrin-related-peptide, corticotrophin-releasing factor) modulate spontaneous post synaptic currents, but did not significantly alter oeEPSCs by Bar terminal stimulation.In current-clamp recordings, bath application of capsaicin increased opto-evoked responses to trains stimulations of Bar terminals. In conclusion, we provide the principles of synaptic connectivity from Bar to the spinal cord and suggest one part of the mechanisms of synaptic integration in the spinal cord.

Title: Circadian Influences on Chemotherapy Efficacy in a Mouse Model of Brain Metastases of Breast Cancer

Authors: ***W. H. WALKER**[1], J. R. BUMGARNER[1], S. A. SPROWLS[2], J. A. LIU[1], O. H. MELÉNDEZ-FERNÁNDEZ[1], J. C. WALTON[1], P. R. LOCKMAN[2], A. C. DEVRIES[3], R. J. NELSON[1];

Abstract: In general, chemotherapy is more effective in the treatment of peripheral tumors than brain metastases, likely reflecting the reduced ability of chemotherapy to cross the blood brain barrier (BBB) and/or blood tumor barrier (BTB) at an efficacious concentration. Recent studies in *Drosophila* have demonstrated circadian regulation of BBB permeability. Thus, we sought to determine whether BBB/BTB permeability to chemotherapeutic agents displays circadian regulation. We predicted that optimally timed chemotherapy would increase anti-tumor efficacy in a murine model of brain metastases of breast cancer (BMBC). First, female NU/NU mice received a 1oo µl intracardiac injection of the human brain seeking Her2+ breast carcinoma cell line, JIMT-1BR3-Luc ($1.75x10^5$ cells). Thirty days following tumor inoculation, we characterized daily alterations in ^{14}C-paclitaxel within BMBC following injections given at four time points across the day: (zeitgeber time (ZT) 0 (lights on), ZT5, ZT14 (lights off), ZT17). Peak and trough concentrations of ^{14}C-paclitaxel within BMBC occurred mid-dark phase and at

the beginning of the light phase, respectively. Next, we assessed the functional significance of increased ^{14}C-paclitaxel concentrations within BMBC by monitoring the onset of neurological symptoms and cell death within BMBC. Mice received a 1oo µl intracardiac injection of the cell line, JIMT-1BR3-Luc ($1.75x10^5$ cells). Following 14 days a tumor growth, mice were randomly assigned to treatment groups, ZT0 or ZT17, and received once a week injections (2 weeks total) of paclitaxel (13 mg/kg) corresponding to either the peak or trough of BBB/BTB permeability (determined in Exp.1). Mice that received chemotherapy injections during the dark phase demonstrated increased cell death within BMBC and delayed onset of neurological symptoms relative to mice that received injections during the light phase. Together, these data provide strong evidence that chrono-chemotherapy is a novel and potentially effective treatment strategy for BMBC, and emphasizes the importance of time of day when administering chemotherapy to patients.

Abstract: Study of the anticipatory activity to nebulized nicotine in female mice Strain C57BL / 6 Zenaida Rosas Ovando, Yumey Bonastre, Rossana C Zepeda, Mónica Flores, Óscar López, Thuluz Meza, Albertina Cortés, Tania Molina, Claudia Juárez PortillaAnticipatory activity allows to organisms to be prepared to future resources; it is characterized by increasing their locomotor activity from 1-2 h prior to a wide variety of high motivational value stimuli. It has been suggested that drugs of abuse can be synchronizers of circadian rhythms, as subjects show spontaneous locomotor activity 2 h prior drug arrival. In addition, intensity of effects as well as the potential to develop addiction depends on the sex of users. For instances, several reports have shown that women consume higher doses of certain drugs such as methamphetamine, cocaine and nicotine than men. Experimental female rats intake drugs faster, from the operant chamber, than male rats. Under these considerations, the goals of the present work were 1) to assess whether female mice show anticipatory activity to daily-nebulized

nicotine, and 2) to compare the intensity of the anticipatory activity to nicotine between female and male mice (previous data). Female C57/BL6 mice were divided in two groups, control group was nebulized with water and experimental group received nebulized nicotine at ZT4 during 20 minutes over 14 days. Animals were recorded 4 h prior to nebulization time and one h later for all experimental days. Videos were analyzed manually and behavior such as movement, grooming were identified considering the time in which they were performed. Results show that females anticipate 1 h prior nicotine availability. The anticipatory activity was significantly higher than anticipation of male mice. This latter result suggests that the ovary hormones could influence the increment in the intensity of anticipation from females.

Title: Examination of correlations between delta-, theta-, alpha-, beta-, and gamma-wave activity of the circadian clock and locomotor activity rhythms in the Madeira cockroach Rhyparobia maderae

Authors: *J. A. PLATH[1], J. Y. GESTRICH[3,1], P. ROJAS[2], M. BARTHOLMAI[1], A. MASSAH[1], C. LESEIGNEUR[1], M. J. A. PLATH[1], M. GARCIA[2], M. STENGL[1];

Abstract: During the daily sleep-wake rhythm typical oscillatory brain waves, field potentials of mostly unknown origin, occur in mammalian brains. Recent insect studies suggested that brain waves are an evolutionary conserved property not limited to mammalian brains. In the Madeira cockroach we investigated which brain waves are generated by the circadian clock network and postsynaptic brain neuropils suited to regulate sleep-wake cycles. The cockroach clock was allocated previously to the accessory medulla (AME), a small neuropil in the brain's optic lobe. It is innervated by ~240 neuropeptidergic clock neurons, receives sensory inputs and sends outputs to different central brain neuropils to regulate daily activity rhythms. In search for clock-contacted premotor areas suited to regulate sleep-wake cycles we performed backfills from central pattern generators in the thorax combined with immunocytochemical staining of neuropeptidergic clock outputs. To investigate circadian modulation of brain wave frequencies,

we performed long-term loose-patch recordings from the AME (n = 28). *In vivo* brain wave recordings from the AME were combined with simultaneous recordings from premotor areas and/or with electromyograms from the leg muscle in intact animals (n = 8). Also, action potentials and local field potentials from the AME-clock and leg electromyograms as motor outputs were monitored simultaneously (n = 3). Previous results indicated that leg muscle activity approximates locomotor activity, thus, can serve as motor output assay (n = 10). We aimed to characterize whether / how brain waves and action potential frequencies in the clock change over the day in correlation with activity rhythms in premotor areas and motor outputs. Multiscale activity (ms to s) showed distinct activity peaks at dawn (Zeitgeber time/ZT 23.5), midday (ZT 6.5), dusk (ZT 10.5), and midnight (ZT 18.5). Interestingly, midday, evening, and midnight peaks were dominated by mid-scale events (2 - 290 ms), while action-potential-scale (1 - 2 ms) and longer events (290 ms - 9 s) were present mostly during the morning peak. Preliminary results showed that delta and theta waves were mostly found at dusk and late day to evening during photic phase shifting. Alpha and beta frequencies dominated during midday and also gamma was stronger during the day than night. Preliminary correlations between changes in locomotor activity and changes in the activity of the AME were observed (n=3). Taken together, we found ZT-dependent multiscale circadian activity of the AME also manifesting in mammalian-type brain waves that appear to correlate with either sensory input or motor output of this insect circadian clock.

Title: The dual orexin receptor antagonist DORA-22 improves cage change-induced sleep alterations during the inactive phase of nocturnal rats

Authors: M. C. GAMBLE[1,2], F. KATSUKI[1,2,3], J. G. MCCOY[1,2,4], R. E. STRECKER[1,2,3], ***J. T. MCKENNA**[1,2,3];
[1]Boston VA Res. Institute, Inc., Boston, MA; [2]VA Boston Healthcare Syst., West Roxbury, MA; [3]Psychiatry, Harvard Med. Sch., West Roxbury, MA; [4]Stonehill Col., Easton, MA

Abstract: Dual orexinergic antagonists (DORAs) have been recently developed as a pharmacotherapy alternative to established hypnotics. It is unclear if DORAs improve insomnia-related sleep initiation and maintenance alterations during the rodent light/inactive period, which

is most analogous to when sleep disruption such as insomnia occurs in humans. Rats were first administered DORA-22 (Merck & Co., Inc.; 30mg/kg) or the GABA receptor-targeting hypnotic eszopiclone (10mg/kg), and then exposed to hourly clean cage changes, allowing behavioral evaluation of the propensity to sleep/sleepiness (hourly NREM sleep onset latency measures). Sleepiness was also measured following this insomnia model exposure using a rodent multiple sleep latencies protocol. A common complaint concerning hypnotic use is lingering hypersomnolence, which may impact performance, and this is a concern in pharmacotherapy of the elderly. Therefore, a second study was designed to determine a dose of DORA-22 which would initially promote sleep but exhibit minimal extended hypnotic efficacy. To determine this, animals were administered various doses of DORA-22 doses (1, 3, and 10mg/kg), then exposed to six hours of an insomnia model variant comprised of a single cage previously dirtied by a conspecific, followed by return to home cage for three hours of undisturbed recovery. In our first study, both DORA-22 and eszopiclone initially promoted sleep (hours 1 and 2), with DORA-22 exhibiting a more rapid hypnotic onset; and exhibited extended efficacy, evident six hours after administration. In our dose response second study, all DORA-22 doses initially promoted sleep; only the lowest dose (1mg/kg) did not exhibit extended hypnotic efficacy at the six-hour timepoint at the end of insomnia model exposure. In summary, we report that DORA-22 improved sleep measures when animals were exposed to mild stress-inducing stimuli (cage exposures), establishing a translatable model of hypnotic treatment in the light/inactive period, similar to when sleep disturbances occur in humans. Furthermore, a minimal dose of DORA-22 may initially promote sleep, yet exhibit few lingering (extended) effects that may impair next day mood and performance.

Title: Functional characterization of p90 ribosomal S6 kinase (RSK) signaling in the murine suprachiasmatic nucleus

Authors: *H. YOON[1], A. KALIDINDI[1], K. R. HOYT[2], K. OBRIETAN[1];
[1]The Ohio State Univ., Columbus, OH; [2]Pharmacol., Ohio State Univ., Columbus, OH

Abstract: The phasing of the master mammalian circadian clock, located in the suprachiasmatic nucleus (SCN) of the hypothalamus, is tightly regulated by the external light cycle. Within the

SCN, a key event in the light entrainment process appears to be the activation of the p44/42 mitogen-activated protein kinase (MAPK) cascade. Our previous work has shown that photic stimulation leads to activation of the MAPK pathway effector p90 ribosomal S6 kinase (RSK) in the SCN, thus raising the prospect that RSK signaling contributes to clock entrainment. Here, we tested this idea by employing an in vivo infusion approach to deliver the RSK inhibitor SL0101 [kaempferol 3-O-(3", 4''-di-O-acetyl-alpha-l-rhamnopyranoside)] to the SCN. Importantly, intraventricular infusion of SL0101 (25 mM) led to a potent suppression of light-evoked RSK activity in the SCN, and a marked attenuation of light evoked clock entrainment, as assessed using wheel running activity. In specific, in vehicle-infused C57/Bl6 mice, light exposure during the early subjective night led to a phase delay (~ -160 min) in activity onset. Contrary to this, disruption of RSK activity led to a significant relative decrease (~ - 110 min) in the phase-delaying effect of light, revealing that RSK signaling influences the magnitude of the light-evoked phase shift. Current phase-shifting experiments are focused on an examination of the contribution of RSK signaling to the late-night phase-advancing effects of light. Further, potential transcriptional and post-transcriptional mechanisms by which RSK signaling affects clock entrainment are currently being investigated. Finally, to examine whether RSK signaling affects the inherent timing properties of the master clock, cultures of SCN tissue from per1-Venus reporter mice were chronically treated (~ 4 days) with SL0101. We did not detect an effect of RSK inhibition on either the period or amplitude of the SCN, thus indicating that RSK signaling contributes to clock entrainment but does not influence the inherent pacemaker properties of the SCN.

Title: Cannabinoid receptor signaling supports sleep throughout development in males and females

Authors: *S. M. GAY[1], S. C. MARTIN[1], N. PAZHAYAM[1], M. YE[1], M. ARMSTRONG[2], N. REISDORPH[2], G. H. DIERING[3];
[1]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Univ. of Colorado, Aurora, CO; [3]Cell Biol. and Physiol., Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Sleep is an essential process that supports cognitive functions, such as learning and memory. The endocannabinoid (eCB) system has emerged as a key regulator of sleep stability and quality. Increasing evidence indicates that the eCB system is differentially regulated between males and females and during development. We present our characterization of the eCB system in sleep in developing and adult male and female mice. Synaptic cannabinoid receptor 1 (CB1) is activated by endogenous bioactive lipids anandamide (AEA) and 2-arachidonoylglycerol (2-

AG). Targeted mass spectrometry indicate that synaptic 2-AG is upregulated by sleep deprivation in juvenile mice, but not adults, whereas synaptic AEA increases during sleep in adults but not juveniles. These results suggest that eCBs may differentially impact sleep during development. To test this idea, we used a piezoelectric device to non-invasively measure wake and sleep behavior in mice following pharmacological manipulations of the eCB system. Juvenile (p21-p42), adolescent (p42-p56) and adult (p100) mice were injected with PF-3845, a selective FAAH inhibitor to increase AEA, MJN-110, a selective MAGL inhibitor to increase 2-AG levels, or AM-251, a CB1 inhibitor. MJN-110 or PF-3845 treatment increased sleep amount and stability in males at each age but had minimal effects in females. CB1 inhibitor AM-251 decreased sleep amount and stability in both males and females at each age. These results suggest that an eCB tone acting on CB1 supports sleep in developing and adult males and females, and that pharmacological enhancement of the eCB tone further promotes sleep in males only. Further studies are ongoing to determine the molecular basis of the sex-based differences. These results show a clear link between sleep behavior and endocannabinoid signaling which will be useful in designing therapeutic interventions targeting the eCB system.

Title: Kynurenic Acid Synthesis Inhibitor PF-04859989 Prevents Acute Kynurenine-induced Sleep Disturbances in Rats

Authors: *K. M. RENTSCHLER[1], A. M. BARATTA[2], H. NICHOLSON[1], J. A. MONG[3], A. POCIVAVSEK[1];
[1]Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [2]Ctr. for Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [3]Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Individuals who suffer from neurocognitive disorders, such as age-related dementias or schizophrenia, often suffer from sleep disturbances and comorbid parasomnias. Kynurenic acid (KYNA) is a tryptophan metabolite implicated in the pathophysiology of these disorders. Modest increases in KYNA, which acts as an antagonist at *N*-methyl-*D*-aspartate (NMDA) and α7 nicotinic acetylcholine (α7nACh) receptors, and an agonist at the aryl hydrocarbon (AhR) receptors, result in cognitive impairments and alterations in sleep-wake behavior (Pocivavsek et al. *Sleep* 2017). We presently sought to determine if pharmacological inhibition of the KYNA synthesizing enzyme, kynurenine aminotransferase II (KAT II), may serve as a potential avenue

to overcome sleep deficits. We explored the hypothesis that elevated KYNA adversely impacts sleep quality. Adult male and female Wistar rats (N = 9-11 per sex using a within animal treatment design) were implanted with telemetric devices to acquire electroencephalogram (EEG) and electromyogram (EMG) recordings and challenged with kynurenine, the direct precursor to KYNA. At the beginning of the light phase, rats received injections of either 1) vehicle, 2) kynurenine (100mg/kg; i.p.), 3) the systemically active KAT II inhibitor, PF-04859989 (30 mg/kg; s.c), or 4) PF-04859989 and kynurenine in combination. Analysis of vigilance state-related parameters categorized as wake, rapid eye movement (REM) and non-REM (NREM) were assessed for 24 h after treatment. The kynurenine challenge significantly reduced REM duration by 15% compared to vehicle treatment ($P<0.05$) during the light phase. PF-04859989 given prior to the acute kynurenine challenge elicited unchanged REM sleep duration compared to vehicle treatment or PF-04859989 treatment alone during the light phase in males. Interestingly, PF-04859989 increased NREM duration ($P < 0.05$) and decreased wake duration ($P < 0.05$) across 24 hours in both vehicle and kynurenine-treated trials, suggesting that the KAT II inhibitor may have slight sedative properties. Taken together, REM was restored when PF-04859989 was administered prior to the kynurenine challenge, suggesting that KAT II inhibition was sufficient to prevent the kynurenine-induced reduction in REM. Changes in vigilance state parameters elicited by the KAT II inhibitor may indicate mild somnolence. The present and future complementary experiments provide mechanistic value to understanding the role of KYNA in modulating sleep behavior and demonstrate KAT II inhibition as a potential therapeutic avenue for improving sleep disturbances associated with neurocognitive disorders.

Title: Sleep deprivation differentially modulates rat auditory cortex processing in a manner similar to NREM sleep

Authors: *A. MARMELSHTEIN, Y. NIR;
Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: <u>Background:</u>
Despite the prevalence of sleep deprivation (SD) in modern lifestyle, how SD affects brain activity and behavioral deficits remain poorly understood. It has been suggested that SD-associated deficits may stem from sleep-related neural processes that invade the waking brain.

However, which aspects of neural processing are involved, and whether they also affect early sensory regions, remain unclear.

Results:

We presented sounds (tones and click-trains at different rates) to male Wistar rats (n=7) undergoing 5 hours SD, followed by 5 hours sleep opportunity, and recorded EEG, EMG, as well as spiking activity in the auditory cortex. We found that SD affected particular aspects of auditory processing -- mainly modulating late components of the auditory response and population synchrony. Accordingly, spontaneous firing rate (FR) and onset response magnitude were relatively unaffected by sleep pressure (6±1.3% and 1.1±1.1% increase, respectively, when comparing last vs. first 1.5h of SD, n=193 units, mean±sem). In contrast, post-onset FR (40-100ms), entrainment to fast click trains (20-40 Hz) and population coupling (a measure of population synchrony) were strongly modulated by sleep pressure (-35±2%, -20±2% and 17±2%). Qualitatively similar effects were observed during NREM sleep, showing even stronger modulation of post-onset FR, clicks entrainment and population coupling, when compared to wakefulness (-62±2%, -57±2%, 33±2%). Interestingly, auditory processing during REM sleep was similar to that during wakefulness (≤10% change).

Conclusions:

Specific aspects of auditory cortical processing, including population synchrony, post-onset FR and adaptation to fast modulations in stimulus intensity, are strongly affected by sleep pressure. Such changes are qualitatively similar to those observed during NREM, but not REM sleep. This implies that a NREM-like synchronized cortical state may invade the waking brain and contribute to impaired neural processing during SD.

Aviv Sourasky Med. Ctr., Tel Aviv, Israel; [8]Dept. of Neurosurg., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Reduced responsiveness to the environment is a hallmark of sleep, yet it remains unclear how responses along cortical sensory pathways during different sleep stages compare to those during wakefulness. Previous non-invasive studies in humans and intracranial studies in animal models have yet to resolve where along the sensory hierarchy, in which signals, and what factors affect sensory responses during sleep. Here, we performed recording sessions in 13 drug-resistant epilepsy patients implanted with clinical depth electrodes. Upon informed consent, we recorded intracerebral EEG, LFPs, and neuronal spiking activity along with polysomnography while we intermittently presented a battery of simple (click-trains) and complex sounds (e.g. words, sentences, music) during wakefulness and sleep (8 full-nights and 6 naps). We found that auditory spiking responses (n=305 in 55 units) as well as LFP high gamma (80-200Hz) responses (n=556 in 74 microwires) were largely preserved during sleep. Sleep responses exhibited moderate amplitude attenuation (median attenuation = -30% and -0.22dB for spiking activity and gamma, respectively), yet remained tightly locked to soundwave envelopes (median correlation coefficient r=0.39 in wake and 0.37 in sleep). By contrast, LFP alpha-beta (10-30Hz) power decrease during auditory stimulation (n=252 in 57 microwires) were prevalent in wakefulness but significantly disrupted in sleep (median attenuation = -1.4 dB). The degree of NREM sleep attenuation was robustly correlated with response latency in each microwire ($r=-0.8$, $p<0.001$). In addition, stronger attenuation was observed in downstream regions than in A1 itself for units' responses, in late sustained responses than in early onset responses ($p<0.001$), and during intervals with high slow wave activity (median attenuation=-5%, $p<0.001$). During REM sleep, we observed entrainment of iEEG/LFP to 40Hz click-trains at wake-like levels, unlike its partial attenuation during NREM sleep (median attenuation = 15% and 30% for LFP and iEEG respectively). Altogether, robust auditory responses persist during sleep across the temporal lobe well beyond primary auditory cortex while LFP alpha-beta power decrease, possibly reflecting top-down processes, is deficient.

Title: The effects of hypoxia on the activity of hypoglossal motoneurons during non-REM and REM sleep

Authors: C. D. TOBIN[1,2], S. J. FUNG[1,2], *M. XI[1,2], M. H. CHASE[1,2,3];
[1]WebSciences Intl., Los Angeles, CA; [2]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [3]UCLA Sch. of Med., Los Angeles, CA

Abstract: We have developed an animal model of hypoxia in the chronically-instrumented, unanesthetized cat preparation during the course of experiments which were designed to explore neuromechanisms that were responsible for the suppression of hypoglossal motoneuron activity during REM sleep under normoxic and hypoxic conditions. In the present study, using this animal model with extracellular recording techniques, we examined the effects of hypoxia on the activity of hypoglossal motoneurons during spontaneously-occurring states of non-REM and REM sleep. Adult cats were prepared for monitoring behavioral states of sleep and wakefulness as well as extracellular recordings of hypoglossal nerve. During the experiment, the oxyhemoglobin saturation (SpO_2) level and heart rate were continuously monitored. Single episodes of hypoxia were induced, via a breathing mask positioned in front of the animal's nose and mouth, by a ventilatory system that controls "on" and "off" flows of nitrogen gas and air. The hypoglossal nerve activity was examined during naturally-occurring non-REM and REM sleep under normoxic and hypoxic conditions. Under normoxic conditions, there was a mean decrease of 12.5±2.2% (n=31) in the hypoglossal nerve activity during REM sleep compared to non-REM sleep. However, under hypoxic conditions (75% SpO_2), the nerve activity decreased by 21.0±2.5% (n=28) during REM versus non-REM sleep. The reduction in the hypoglossal nerve activity during REM sleep under hypoxic conditions was significantly greater than that under normoxic conditions (P= 0.012, unpaired t-test). In addition, there was a mean increase of 9.9±1.8% in the nerve activity during non-REM sleep under hypoxic conditions compared to normoxic conditions. The present results demonstrate that there is an increase in the activity of hypoglossal motoneurons during non-REM sleep under hypoxic conditions, and a significantly greater suppression in the activity of these motoneurons during REM sleep under hypoxic conditions compared to normoxic conditions. These data support our hypothesis that during REM sleep under hypoxic conditions (e.g., Obstructive Sleep Apnea), disfacilitation (withdrawal of excitatory drives present during non-REM sleep) and postsynaptic inhibition are responsible for the suppression of hypoglossal motoneuron activity and ensuing atonia of the genioglossal muscle.

Title: Daytime Sleep in Infants - A Marker of Brain Maturation?

Authors: *S. F. SCHOCH[1,2], J. L. CASTRO-MEIJA[3], D. S. NIELSEN[3], L. KRYCH[3], W. KOT[3], B. LENG[3], M. KOHLER[2], R. HUBER[4,5], G. ROGLER[2], L. BIEDERMANN[2], J.-C. WALSER[6], S. KURTH[2,7];

Zurich, Zurich, Switzerland; [5]Psychiatric Hosp. Univ. of Zurich, Zurich, Switzerland; [6]ETH Zurich, Zurich, Switzerland; [7]Univ. of Fribourg, Fribourg, Switzerland

Abstract: *Objective.* A close link has been proposed between infant sleep and developmental processes of brain and body physiology. Even though daytime sleep accounts for one-third of infants' overall sleep, it is often understudied due to difficulties with its accurate quantification. We aimed to characterize daytime sleep (duration, regularity) across infancy and tested whether it relates to nighttime sleep electroencephalography (EEG) power, behavioral development, and gut bacteria.
Methods. We measured sleep behavior (11 days with actigraphy and 24-h diary), behavioral development, and gut bacteria composition in a longitudinal population of 162 infants at ages 3, 6, and 12 months. In a subset of 32 infants age 6 months, nighttime sleep EEG was recorded (128 electrodes, EGI, recording duration for 2 hours, 500 Hz sampling). A principal component approach was used to generate sleep composites, including one, which encompasses several aspects of daytime sleep. We applied standard EEG processing (bandpass filter 0.5-50 Hz, down-sampling to 128 Hz, average referencing, sleep stage scoring, semi-automated artifact rejection, spectral analysis with Fast Fourier transform routine), and computed EEG power for slow wave activity (1-4.5 Hz). Behavioral development was quantified using parent-reports (Ages and Stages Questionnaire). We determined gut bacteria composition from stool samples using 16S rRNA gene sequencing and quantified 3 measures: alpha diversity, enterotype (classification into simplified profiles), and relative maturational status (random forest). Multilevel models were applied across all 3 time points and general linear models for each time point separately.
Results. Daytime sleep duration decreased by 40% across the first year of life. Daytime sleep was associated with behavior (sum score, $p = 0.03$), such that infants with less daytime sleep scored higher on behavioral development. This effect was most pronounced at 3 months of age. Infants with less daytime sleep had significantly higher gut bacterial diversity ($p = 0.03$), again, specifically prominent at 3 months. Less daytime sleep was associated with lower slow wave activity in temporal and parietal areas of the scalp during nighttime sleep ($p = 0.007$, cluster corrected).
Conclusions. Our results indicate that daytime sleep duration and regularity in infants is associated with markers of behavioral development and gut bacterial diversity. As slow wave activity signifies sleep pressure, we propose that infants with less daytime sleep have a more

mature neurophysiology and advanced ability to sustain prolonged wakefulness, resulting in lower sleep pressure at nighttime sleep.

Title: Closed-loop intracranial stimulation during sleep enhances cortico-hippocampal synchronization and memory consolidation in humans

Authors: *M. GEVA-SAGIV[1,2,4], E. A. MANKIN[2], D. ELIASHIV[3], S. EPSTEIN[5], N. CHERRY[2], G. KALENDER[2], N. TCHEMODANOV[2], Y. NIR[4,5], I. FRIED[2];

Abstract: A long line of research has established a role for sleep in memory consolidation, yet the specific mediating mechanisms remain unclear. At present, there is a formidable gap between animal studies — which use direct recordings and manipulations of neural circuits to link hippocampal-cortical synchronization to memory consolidation — and non-invasive human studies. Building upon rodent studies in which precisely timed electrical stimulation during sleep reinforced the endogenous coordination between hippocampal and neocortical activities, we developed a closed-loop system that monitored activity in the human medial temporal lobe (MTL) to trigger brief pulses of electrical stimulation in neocortical white matter. Upon informed consent, 14 pharmacoresistant epilepsy patients implanted with intracranial electrodes for clinical monitoring participated in intracranial stimulation and recording sessions during sleep. Closed-loop *sync-stimulation*, robustly locked to MTL slow-wave (SW) active phase, enhanced subsequent slow wave (N = 248 iEEG contacts, $P<10^{-30}$) and spindle activity ($P<10^{-29}$) across the brain, as well as their coupling ($P<10^{-9}$). These effects were not observed in a control group receiving mixed-phase stimulations (across all MTL slow-wave phases, N = 215 iEEG contacts,

p>0.5). Following *sync-stimulation*, neuronal units (N = 280) across multiple neocortical sites significantly synchronized their firing to MTL SW activity, evident by increased ($P<10^{-8}$) phase locking to MTL field potentials. We further examined the cognitive effects of this intervention in a subset of patients (N = 9) who learned paired associations between images in the evening and performed recognition tests immediately after learning and in the morning following sleep. Each patient participated in two night sessions (order counterbalanced) either with closed-loop stimulation during sleep or without. Six of seven participants in the *sync-stimulation* group exhibited improved memory accuracy following sleep-intervention relative to the no-stimulation nights. No improvement was observed in the participant group receiving mixed-phase stimulation. Importantly, memory accuracy improvement across all participants was tightly correlated (Tau=0.45, $P<10^{-19}$) with the extent of unit-firing synchronization to the MTL and with spindle-rate enhancement (R = 0.77, P = 0.013), but not to a change in interictal spikes activity (P = 0.15). Our results provide causal evidence in humans for a model in which cortico-hippocampal synchronization during sleep mediates memory consolidation.

Title: Prenatal kynurenine elevation elicits sex-dependent changes in sleep and arousal during adulthood: Implications for schizophrenia

Authors: *S. MILOSAVLJEVIC[1], K. M. RENTSCHLER[1], A. L. DITTY[1], N. T. J. WAGNER[1], C. J. WRIGHT[1], J. A. MONG[2], A. POCIVAVSEK[1];
[1]Dept. of Pharmacology, Physiol. and Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC; [2]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Dysregulation of the kynurenine pathway (KP) of tryptophan catabolism has been implicated in psychotic disorders including schizophrenia (SZ) and bipolar disorder. Kynurenic acid (KYNA) is a KP metabolite synthesized by kynurenine aminotransferases (KATs) from its biological precursor kynurenine, and acts as an endogenous antagonist of N-methyl-D-aspartate and α7-nicotinic acetylcholine receptors. KYNA has been linked to cognitive impairments in SZ and may also contribute to sleep disturbances in patients. To further understand the role of KYNA in SZ etiology, we employ the embryonic kynurenine (EKyn) model in rats and fed kynurenine (kyn; 100 mg/day) to pregnant Wistar dams from embryonic day (ED) 15 to ED 22

(control: ECon; kyn-treated: EKyn) to elevate KYNA in the fetal brain. The present study was designed to 1) define sleep-wake behavioral dysfunction during light and dark phases and 2) test the effectiveness of PF-04859989, a KAT II inhibitor, which reduces brain KYNA, in adult (postnatal day 56 - 85) offspring from ECon and EKyn litters. We assessed the impact of this developmental exposure by examining vigilance state parameters in adult male and female rats using electroencephalogram (EEG) and electromyogram (EMG) telemetry and determined sex differences in sleep and arousal in EKyn offspring. EKyn males exhibited reduced rapid eye movement (REM) sleep (-20%, $P<0.05$), while EKyn females displayed hyperarousal compared to controls, evidenced as 1.4-fold longer average duration of wake bouts ($P<0.01$) demonstrating consolidated wakefulness. To complement sleep-wake behavioral analysis, relative cage activity was significantly reduced in EKyn females (-42% during light phase, -18% during dark phase, $P<0.05$), but no differences were determined between EKyn males and controls ($P=0.36$). When adult ECon and EKyn rats were also assessed in the open field paradigm to determine general locomotor activity, anxiety, and willingness to explore a new arena, no major deficits were determined. Preliminary analysis of data obtained after acute PF-04859989 (30 mg/kg) treatment in EKyn offspring indicate a significant increase in REM duration, suggesting that an acute decrease in brain KYNA may restore deficiencies in REM sleep and mitigate sleep deficits. Taken together, our findings demonstrate striking sex-dependent sleep alterations in EKyn offspring, and we are continuing to investigate the interplay between sleep and KYNA in a translationally relevant model of neuropsychiatric illness.

Title: Dose-dependent effect of ethanol on sleep patterns in Drosophila melanogaster

Authors: *M. E. RAMIREZ ROMAN, G. AYALA-SANTIAGO, J. AGOSTO, A. GHEZZI; Univ. of Puerto Rico, Rio Piedras Campus, Rio Piedras, PR

Abstract: Alcohol consumption is known to affect many physiological processes necessary for the proper functioning of the organism. In the brain, alcohol binds to several molecular targets to produce an overall suppression of neuronal activity. This leads to a series of neuroadaptive mechanisms implemented to counterbalance ethanol-induced neuronal suppression and help the system restore homeostasis. These neuroadaptive changes have been associated with the development of alcohol tolerance, dependence and ultimately addiction. In addition, these

adaptations are also believed to be the root of a series of sleep disturbances, which often manifest during the development of alcoholism. As both, alcohol addiction and sleep regulation are under homeostatic control, we hypothesize that these processes share a common mechanism. Here, we use Drosophila melanogaster as a biological model to study alcohol-sleep responses. We compare two different methods of alcohol administration and examine the ethanol concentration that each fly had after the experiment in order to study the effect alcohol has on sleep. Our results suggest that ethanol influences sleep, but this effect varies according to the manner in which it is administered. For future studies, we believe that the integration of genetic analyses with physiological modulation of neural activity within specific sleep circuits has tremendous potential to uncover the functionally relevant molecular targets whose action contributes to the deleterious effect of alcohol on sleep.

Title: Basal forebrain parvalbumin neurons modulate cortical E/I balance, cortical responses to sensory stimuli, and vigilant attention

Authors: *F. L. SCHIFFINO, D. D. AGUILAR, F. KATSUKI, L. K. RADZIK, J. T. MCKENNA, R. E. BROWN, *R. E. STRECKER, J. M. MCNALLY;
VABHS and Harvard Med. Sch., West Roxbury, MA

Abstract: Recent work has shown that manipulation of a subpopulation of BF GABAergic neurons, those containing the calcium-binding protein parvalbumin (PV), allows exquisite control of cortical fast oscillations. Optogenetic excitation of BF-PV neurons in mice increases cortical fast oscillations, locomotion, wakefulness, and triggers arousals from sleep; BF-PV inhibition produces opposite effects. Here we investigated whether BF-PV neurons regulate more complex behaviors such as attention, learning, and the cortical processing of sensory stimuli. Brief (2s) continuous low power laser photoexcitation of BF-PV neurons (473nm@5mW) enhances cortical entrainment to repetitive presentations of 40Hz sensory stimuli; in contrast,

longer duration excitation (e.g., 2min) elevates broadband cortical gamma band activity (30-80Hz) and impairs the cortical entrainment to 40Hz sensory stimuli. Thus, brief and long durations of BF-PV excitation produce opposite effects. This suggests that appropriately timed activity of BF-PV neurons can enhance cortical responses to stimuli, while either inhibition or prolonged excitation of BF-PV neurons can impair cortical sensory responses. This strongly supports an inverted U-shaped dose response effect of BF-PV activity on cortical responsiveness and is consistent with models of the relationship between arousal and performance (i.e., Yerkes-Dodson law). These results also show how proper E/I balance is necessary for optimal cortical processing. Next, we used brief (1s) continuous laser excitation of BF-PV in a mouse vigilant attention task. Excitation of BF-PV neurons (1s,473nm@5mW) that preceded the signal by 0.5s improved vigilant attention as indicated by quicker reaction times. In contrast, both sleep deprivation (8h) and ArchT mediated inhibition of BF-PV neurons (1s,530nm@10mW) slowed reaction times. Importantly, brief BF-PV photoexcitation prior to the signal rescued deficits observed in sleep deprived mice. Finally, preliminary fiber photometric data show that continuous excitation of BF-PV increases population activity of pyramidal neurons in prelimbic cortex (CAMKII-GCaMP6f), suggesting altered E/I balance. Control experiments indicate that excitation of BF-PV neurons does not alter motivation (e.g., hunger) and is not rewarding, indicating that excitation of BF-PV neurons may enhance cognition with limited side effects and low addictive potential. The combined findings support the idea that BF-PV neurons briefly activate cortex in anticipation of, or in response to, meaningful stimuli; in turn this enhances cortical processing and facilitates attention-dependent performance.

Title: Sleep and Survival of Drosophila melanogaster SerT mutants

Authors: ***R. C. ARNOLD**[1], N. DALILI[1], M. M. SAMPSON[2], S. JOIS[3], A. KAISER[3], H. SCHOLZ[3], D. E. KRANTZ[4];
[1]Neurosci., Univ. of California Los Angeles, Los Angeles, CA; [2]Mol. Toxicology, UCLA, Los Angeles, CA; [3]Biol., Univ. of Cologne, Cologne, Germany; [4]Univ. California Los Angeles, Los Angeles, CA

Abstract: The annual prevalence of mental health illness in the United States is on the rise, with anxiety and depression holding the top two spots, at 19.1% and 7.2%, respectively. The serotonergic system, and more specifically the serotonin reuptake transporter (SerT), are the most common pharmacological targets of anxiety and depression treatments. To better understand the relevance of altered serotonin signaling due to changes in serotonin transporter function, we generated SerT mutants in *Drosophila melanogaster* SerT using imprecise excision mutagenesis. SerT mutant sleep behavior and survival were measured as anxiety and depression are often accompanied by sleep irregularities and abnormal eating patterns. SerT mutants showed an increase in night sleep bout duration and a decrease in sleep latency. We provide evidence that the level of SerT influences sleeping patterns, since changes in SerT level influence sleep differentially. These behaviors were partially rescued in heterozygous flies. Rescue experiments using UAS-SerT were performed to ensure that the phenotypic differences observed in behavior were truly due to the lack of SerT, which in sleep is regulated by a subset of serotonergic neurons. In the desiccation experiments, SerT mutants survived longer than the wildtype flies, which is consistent with a previously published SerT hypomorph. Understanding the function of SerT and the effects of increased extracellular serotonin contributes to our knowledge about current treatments for mental illness.

Title: Exposure to Dim Light at Night During Recovery from Cardiac Arrest Affects Behavior and Brain Vasculature

Authors: O. H. MELÉNDEZ-FERNÁNDEZ, S. M. BROADWAY, W. H. WALKER, II, J. A. LIU, J. R. BUMGARNER, N. ZHANG, *J. C. WALTON, A. C. DEVRIES, R. J. NELSON; Neurosci., West Virginia Univ., Morgantown, WV

Abstract: Electrical lighting and devices are now ubiquitous. Whereas these devices and ability to illuminate the night contributes to societal productivity, the negative impact of exposure to light at night (LAN) is becoming uncovered. Exposure to LAN disrupts of the endogenous circadian biological clock, and consequently, has many downstream effects. Mice exposed to dim LAN (dLAN) have decreased expression of vascular endothelial growth factor-A (VEGF), increased microglial expression, and reduced brain derived neurotrophic factor. Moreover, the development of major depressive disorder has been associated with varying VEGF

concentrations in serum and plasma, suggesting that vasculature is disrupted by LAN. These results suggest that LAN alters brain physiology and behaviors. In the present study, the effects of dLAN on mouse behavior, and neurovasculature after cardiac arrest (CA) were examined. We hypothesized that exposure to dLAN after CA would impair behavior and hippocampal vascularization in mice. Male and female Swiss Webster mice (8 wks of age; n=160) underwent a cardiac arrest/cardiopulmonary resuscitation (CA/CPR) or sham procedure, and were placed into either dark night housing [14 h light 125 lux):10 h dark (0 lux) n=40m/40f)] or dim white light at night conditions [14 h light (125 lux):10h dim light (5 lux) (n=40m/40f)] for one week. Following that week, all mice were returned to dark night conditions for 1 week. Behavioral testing and tissue collection were conducted at the end of this week. Anxiety-like behaviors were assessed using the elevated plus maze (EPM). Prior to euthanasia, mice were administered tomato lectin via a tail vein injection to visualize and quantify vasculature. Females that underwent CA and exposed to dLAN reduced anxiety-like behaviors in the EPM compared to their counterparts in dark nights. Further, females exposed to dLAN reduced vascularization in the CA2 and dentate gyrus regions of the hippocampus, which was exacerbated by CA. Males exposed to dLAN reduced their latency to enter open arms in the EPM compared to their counterparts, however they displayed no differences in total open arm entries. Males displayed vascular differences in the dentate gyrus in response to dLAN exposure, but not in response to CA. These data suggest that the effects of dLAN exposure after CA on behavior can be reversed by return to dark nights, however, vascular effects may not be reversed in that time frame. Supported by NIH grant NS092388.

Title: Electrophysiological Biomarkers of Sleep in Children with Duplications of 15q11.2-13.1 (Dup15q syndrome)

Authors: *V. SARAVANAPANDIAN[1], D. NADKARNI[2], S. JESTE[1];
[1]Psychiatry, UCLA, Los Angeles, CA; [2]Pediatric Neurol., Children's Hosp. Med. Ctr. of Akron, Akron, OH

Abstract: Duplications of 15q11.2-13.1 (Dup15q syndrome) are highly penetrant for autism, intellectual disability, delayed development and epilepsy. Several genes in the 15q region,

particularly UBE3A and a cluster of $GABA_A$ receptor genes, are critical for early brain development, including synaptic function and inhibitory neurotransmission. During wakefulness, children with Dup15q syndrome have increased beta oscillations (12-30 Hz), that likely reflect aberrant GABAergic neurotransmission. Healthy sleep physiology is necessary for robust cognitive development, and prior studies have shown that non-REM sleep rhythms are highly dependent on GABAergic neurotransmission. Yet, no studies to date have quantified NREM sleep physiology parameters in children with Dup15q syndrome. Therefore, in order to examine sleep physiology, we analyzed 7 hours of overnight sleep EEG recording from a cohort of children with Dup15q syndrome (n=15, mean age: 5.7 years) and age-matched neurotypical controls (n=12, mean age: 5.8 years). We computed beta power in sleep, spindle density and percentage of slow wave sleep (SWS), and compared these features between the two groups. Compared to typically developing, age-matched controls, children with Dup15q syndrome showed significantly elevated beta power in sleep (frontal: $p=0.001$, central: $p=0.01$ and occipital: $p=0.0009$ channels), reduced spindle density ($p<0.0001$) and reduced SWS (frontal: $p<0.0001$, central: $p=0.0003$ and occipital: $p=0.0005$ channels). These abnormal sleep features may thus serve as quantitative electrophysiological biomarkers of sleep in children with Dup15q syndrome. Insights from this study not only promotes a greater mechanistic understanding of the pathophysiology defining the syndrome but also lays the foundation for studies that investigate relationship between sleep and cognition. Abnormal sleep physiology may undermine cognitive development in Dup15q syndrome and may serve as a quantifiable and modifiable target for behavioral and pharmacological interventions.

Title: Deploying genetic diversity to explore the impact of diet induced obesity on AgRP neuronal activity

Authors: A. C. KORGAN, S. L. A. MARTIN, K. M. S. O'CONNELL;
The Jackson Lab., Bar Harbor, ME

Abstract: Neurons in the arcuate nucleus of the hypothalamus (ARH) that co-express the neuropeptides agouti-related peptide (AgRP) and neuropeptide Y (NPY) are essential for driving food intake. Consistent with their role in energy balance, their activity is tightly correlated with nutritional status: increased activity is associated with hunger while decreased activity is

associated with satiety. Further, a rapid response to food cues suggests that this response does not require ingestion and supports evidence for “top-down” synaptic modulation of AgRP neurons. Our lab has previously demonstrated that AgRP neuronal activity is sensitive to diet thus diet-dependent plasticity may be a causal factor in obesity. However, up to 70% of the variability in BMI is attributable to genetic factors, most of which remains unexplained. Notably, genes within BMI-associated loci in human GWAS are highly enriched for the brain and CNS, suggesting the susceptibility to obesity may be strongly influenced by GxE effects on neuronal function. However, this research has primarily been conducted using inbred mouse models that lack genetic diversity, and do not capture the considerable influence that genetic factors play in controlling obesity and bodyweight. Here, we utilize mouse strains resilient and susceptible to diet-induced obesity to explore the impact of high-fat diet (HFD) feeding on AgRP neuronal function. Genetically resilient mice (CAST/EiJ, PWK/PhJ, and WSB/EiJ) and susceptible (NZO/H1ltJ) mice of both sexes were assessed for feeding and anxiety-like behavior; we additionally assessed AgRP neuronal excitability and synaptic plasticity in identified NPY^{+} neurons using an F1 panel. Predictably, compared to B6 mice, genetically resilient mice consume less food while susceptible mice consume significantly more. This effect is sexually dimorphic as females in both the resilient and susceptible strains are less likely to gain weight on an obesogenic diet. AgRP neuronal activity mirrors diet-induced weight gain in most susceptible strains, with the exception of the particularly resilient WSB/EiJ. Synaptic plasticity onto AgRP neurons suggests that mechanisms that drive AgRP excitability in fasted B6 mice are similar to resilient and susceptible mice, while diet-induced excitability originates from a divergent etiology. Ongoing work will explore hypothalamic gene expression and the prevalence of inflammatory markers (GFAP and IBA1) in these mice. Overall, we hope these studies will identify genetic traits linked to weight gain and obesity, which might provide insight into the diversity of the human response to DIO.

Title: Effects of maternal hyperglycemia and snack intake on male and female offspring high-protein diet preference on infancy

Authors: ***G. V. SILVA**[1], M. G. MARTINS[1,2], A. G. CRUZ[1,2], G. P. OLIVEIRA[1,2], L. P. RODRIGUES[1], B. C. WOODSIDE[3], A. C. I. KISS[1,2];

Abstract: Changes on maternal metabolism and nutrition can increase offspring susceptibility to develop obesity and associated metabolic disorders. This risk is also related to offspring nutrition in postnatal life. Poor food choice has a significant impact on many non-communicable chronic diseases. There is growing evidence suggesting food choice has its origins early in life. In rats, brain circuits involved in feeding behavior control starts developing in the second half of pregnancy and continues until the first 4 weeks of postnatal life, thus making the offspring vulnerable to changes on maternal metabolism during pregnancy and lactation. However, the effects of the association between maternal hyperglycemia and inappropriate nutrition during pregnancy and lactation on offspring food preference have not been explored yet. Therefore, the present study aimed to evaluate the effects of maternal hyperglycemia associated with snack intake on male and female offspring high-protein diet (HPD) preference on infancy. To achieve this goal, pregnant Sprague-Dawley rats were divided into two groups: Control (n = 19) fed with standard chow and Snack (n=21) fed standard chow plus potato chips and 1,5% sucrose solution until lactational day 14. On pregnancy day 7, both experimental groups were then subdivided into normoglycemic dams and dams that were rendered hyperglycemic by streptozotocin administration (STZ, 35mg/kg, i.p.). Thus, four experimental groups were formed: Control (n =11), Control-Snack (n = 9), STZ, (n = 10), STZ-Snack, (n = 11). On postnatal day (PND) 30, one male and one female from each litter were housed on individual cages and fasted for 12 hours. Food preference was then evaluated by offering two different kinds of powdered diet: standard chow (22% protein) and a HPD (38.64% protein), which consisted in standard powdered chow enriched with casein (25%) and corn starch (13%) . Fasting animals were given access to both diets in the early dark phase of the cycle, and food intake was assessed 1, 12 and 36 hours later. Food preference was determined as the percentage of consumed HPD in relation to the total amount consumed of both diets (standard chow plus HPD). The results show that maternal hyperglycemia increased offspring HPD preference in the first hour, while maternal snack intake reduced it. No significant effects were observed at 12 and 36h, indicating that offspring appetitive response to HPD was altered, but not the consummatory response. In conclusion, maternal metabolism and snack intake independently changed offspring HPD preference, without further effects by their association.

Title: Peripheral and Ventral Hippocampal Long-chain Ceramides Correlate with Depressive-like Behaviors in Rats

Authors: *L. SAMBOLIN-ESCOBALES[1], L. TIRADO-CASTRO[1], W. FONSECA-FERRER[2], D. PACHECO CRUZ[3], K. SANTOS-AVILES[1], N. HAUGHEY[4], M. COLON-ROMERO[1], A. HERNANDEZ[1], G. CHOMPRE-GONZALEZ[3], J. PORTER[1];

Abstract: Previous studies suggest that high-fat diet (HFD), stress, and high concentrations of long-chain ceramides are linked to depression. However, it is unclear whether these factors interact to induce depressive-like behaviors. We hypothesized that combining a chronic HFD and short-term unpredictable stress (STU-stress) STU-stress would increase the concentration of long-chain ceramides in serum to increase depressive-like behavior. To test this hypothesis, adult male and female rats were exposed to 10 weeks of a HFD and four days of randomly applied stressors. Three days later, rats were subjected to sucrose grooming test (SGT) and forced swim test (FST) to assess anhedonia and depressive-like behavior. Female rats exposed to LFD or HFD showed an increased ratio of immobility to struggling only when combined with STU-stress, suggesting that stress rather than diet led to depressive-like behavior. Changes were not seen in males. At sacrifice, blood was collected to quantify ceramide concentration in serum by liquid chromatography-electrospray ionization tandem mass spectrometry. Male and female HFD exposed animals showed increased long-chain C18 and C20 ceramides and C20 ceramides were higher in females than males. This effect was amplified in animals exposed to the HFD and STU-stress. Since females exposed to HFD and STU-stress showed higher C20 ceramides levels and more depressive-like behavior, we tested whether direct infusion of C20 ceramides into the VH of rats is sufficient to increase depressive-like behavior. Male and female rats received seven infusions of C20 ceramides directly into the VH, one infusion every 48 hours. Twenty-four hours after each infusion, a sucrose preference test (SPT) was performed to assess anhedonia. Male and female rats that received C20 infusions showed less sucrose preference suggesting the development of anhedonia. In summary, our data suggest that a brief exposure to unpredictable stressor with either LFD or HFD increases peripheral C20 ceramides and depressive-like behavior only in female rats. However, local increases in C20 ceramides in the VH are sufficient to cause anhedonia in both sexes suggesting that diet and STU-stress may not have increased C20 ceramides in the brain of male rats sufficiently to induce depressive-like behaviors.

Title: Age-related alterations in white matter microstructures in those with gastrointestinal symptoms

Authors: *A. PIRWANI[1], Z. FANG[1], A. SMITH[1], G. NORTHOFF[2], N. ISMAIL[1];
[1]Sch. of Psychology, Univ. of Ottawa, Ottawa, ON, Canada; [2]Univ. of Ottawa Brain and Mind Res. Inst., Ottawa, ON, Canada

Abstract: Gastrointestinal symptoms (GIS) such as abdominal discomfort, bloating, diarrhea and constipation are commonly found in gastrointestinal disorders such as irritable bowel syndrome (IBS) and inflammatory bowel disease (IBD). The onset of these symptoms usually occurs in early life and remain consistent over time. These enduring symptoms have been associated with changes in brain structure in adults experiencing various gastrointestinal disorders. However, it is unclear whether these GIS-related structural alterations in the brain are limited to adults or could be present earlier in life as well. Therefore, we investigated GIS-related changes in white matter (WM) microstructure organization in pre-adolescent (8-10 years), adolescents (12-16 years) and young adults (17-20 years). We hypothesized that those who have experienced GIS will display altered WM compared to the controls. We also hypothesized that there would be age-specific differences in the WM, as age of onset and duration of GIS has been found to play a role in impacting structural alterations. We tested these hypotheses by using structural brain images provided by the Philadelphia Neurodevelopmental Cohort (PNC) database. We conducted diffusion tensor imaging (DTI) analysis in order to objectively analyze the fractional anisotropy (FA) across the whole brain and compare between participants with GIS (N=90) and their age and sex matched controls (N=97). Our results show that all participants who experienced GIS have an altered WM microstructure organization. Specifically, in comparison to the controls, pre-adolescents with GIS displayed increased fractional anisotropy (FA) in the anterior cingulum, the superior frontal gyrus, the middle frontal gyrus, the right hippocampal cingulum and the right anterior thalamic radiation. The adolescent GIS group showed decreased FA in the left middle temporal gyrus and the cerebellar areas such as the right cerebellum crus1 and the middle cerebellar peduncle, in comparison to their control counterparts. Finally, compared to controls, the young adult GIS group displayed increased FA in the cingulum from the anterior to the posterior division, the superior frontal gyrus, the anterior thalamic radiation, the bilateral superior and inferior longitudinal fasciculus, the internal and capsule. These altered regions are a part of the somatosensory and motor pathways which are involved in pain perception and indicate a dysfunction in the gut-brain axis. In conclusion, the structural differences found in the GIS participants, especially at different ages, support the need for further research into the neurophysiological impact they might have.

Title: Voiding and muscle contractility dysfunction in a rat model of detrusor underactivity

Authors: ***E. J. GONZALEZ**[1], M. R. ODOM[1], J. L. HANNAN[2], W. M. GRILL[1];
[1]Duke Univ., Durham, NC; [2]East Carolina Univ., Greenville, NC

Abstract: Detrusor underactivity (DUA) is an understudied health concern with inadequate clinical management. The limited availability of animal models that exhibit the pathophysiology of DUA impedes the development of new therapeutic approaches. The current studies characterized voiding function and contractility of bladder and urethral tissues in an obese prone (OP) rat model of DUA. Eight-week old female OP and obese resistant (OR) rats were fed a 60% fat diet from 9 weeks old to end of study. At 45-65 weeks old, rats were anesthetized with urethane (1.2 g/kg sc) for acute urodynamic studies. A catheter was inserted into the bladder dome to infuse saline and measure pressure. A bipolar paddle electrode was placed between the pubic symphysis and the EUS to record EMG signals. After testing of voiding function, rats were euthanized and full thickness longitudinal bladder strips and urethral rings (proximal and middle) were harvested and mounted in chambers (DMT, Denmark). Viability was assessed with potassium chloride (120mM). Both bladder strips and urethral rings underwent escalating concentration response curves to carbachol (10^{-8}M to 10^{-5}M). Urethral rings were then exposed to caffeine ($4*10^{-2}$M) for 10 min. Bladder strips also underwent electric field stimulation (EFS) with or without atropine (10^{-7}M) or alpha,beta-methylene ATP (10^{-6}M), whereas EFS in urethral rings was in the presence or absence of dantrolene (10^{-5}M). Voiding efficiency decreased by 31% in OP rats compared to OR rats (95% CI = -41, -22, $p < 0.0001$). EUS activity during filling increased by 4.6 μV (95% CI = 2.4, 6.8, $p = 0.0011$) and EUS bursting time decreased by 1.45 s (95% CI = -2.57, -0.317, $p = 0.0175$) in OP rats. In addition, pressure at volume threshold increased in OP rats by 6.8 cmH_2O (95% CI = 2.2, 11, $p = 0.0067$). Compared to OR rats, OP rats had decreased contraction strength on exposure to carbachol in the bladder ($p = 0.0002$) and proximal urethra ($p = 0.0004$), whereas OP rats had increased contraction strength in the middle urethra ($p = 0.002$). Following EFS, OP rats had increased contractility at 32 Hz in both the proximal ($p = 0.006$) and middle ($p = 0.047$) urethra. Contractility was also increased with caffeine in the middle urethra of OP rats ($p = 0.006$). These results suggest that impaired cholinergic-dependent contractions of the bladder may contribute to poor voiding function in OP

rats. In addition, the middle urethra of OP rats appears to compensate for poor bladder contractility by increasing its activity and responsiveness. This urethral compensation may indicate an attempt to stimulate the pudendo-vesical reflex to promote bladder activation.

Title: First encounters: establishment of the microbiota-gut-brain axis in mice

Authors: *N. M. RONCZKOWSKI[1], A. CASTILLO-RUIZ[1], B. CHASSAING[1,2,3,4], N. G. FORGER[1];
[1]Neurosci. Inst., [2]Ctr. for Inflammation, Immunity and Infection, Inst. for Biomed. Sci., Georgia State Univ., Atlanta, GA; [3]INSERM U1016, Paris, France; [4]Univ. de Paris, Paris, France

Abstract: At birth, the mammalian fetus exits a sterile womb and enters a world teeming with microbes. These microorganisms, primarily bacteria, colonize the gut, as well as other sites on the body, and influence immune function, behavior, and disease states. We recently reported significant differences between the brains of germ-free and conventionally colonized mice on the day of birth, but not one day earlier. This raises the questions that our current work aims to answer - when do microbes arrive in the gut, which species of bacteria are present during colonization, and what impact does this event have on the brain? We have established timed pregnancies in Swiss Webster mice, and collected the brains and colons of male and female offspring either one day before birth or after birth at 3h, 6h, 12h, 24h, postnatal day (P)3, and P7. Through quadruple-tagged fluorescent in situ hybridization and immunocytochemistry, and subsequent confocal imaging, we examined when bacteria begin to arrive in the colon and in what quantities. We have visualized bacteria in the colon as early as 3h after birth, with a stark increase in bacterial quantity between 24h and P3. Via qPCR and 16S rRNA gene sequencing we are examining which bacterial species are present and in what quantities at each time point. Finally, we used c-Fos immunohistochemistry to examine neural activation in brain regions which receive input from the vagus nerve, a primary route of gut-brain communication; these include the paraventricular nucleus of the hypothalamus, the nucleus of the solitary tract, and the arcuate nucleus of the hypothalamus. This work allows us to pinpoint exactly when the newborn gut is colonized by microbes, identify which bacterial species are present during colonization, and identify associated changes in brain activation in primary areas of interest.

Title: Ablation of Selenoproteins in Agrp Neurons Protects Against Diet-induced Obesity in a Sexually Dimorphic Manner

Authors: *D. TORRES[1], M. PITTS[1], L. SEALE[1], A. HASHIMOTO[1], K. AN[1], A. HANATO[1], K. HUI[2], S. REMIGIO[3], M. BERRY[1,4];
[1]Univ. of Hawai'i at Manoa Dept. of Cell and Mol. Biol., Honolulu, HI; [2]UCSD, San Diego, CA; [3]Mary Baldwin Univ., Staunton, VA; [4]Pacific Biosci. Res. Center, UH Manoa, Honolulu, HI

Abstract: The trace element selenium (Se) is known mainly for its antioxidant properties and is critical for proper brain function. The role of Se in regulating energy metabolism, and the sexually dimorphic nature of Se functions, however, are underappreciated, and warrant increased attention. Recent work in our lab has highlighted the importance of Se utilization in hypothalamic regulation of energy metabolism. Dietary Se is incorporated into selenoproteins in the form of the unique amino acid selenocysteine (Sec). The objective of this study was to assess the role of selenoproteins in Agouti-related peptide (Agrp)-positive neurons, an orexigenic sub-population of the hypothalamus. We generated mice with Agrp-Cre-driven deletion of selenocysteine tRNA (Trsp-Agrp KO mice), which is essential for Sec incorporation into selenoproteins, thus ablating selenoprotein synthesis in Agrp-positive neurons. The metabolic phenotype of Trsp-Agrp KO mice challenged with a high-fat diet was characterized via glucose tolerance test (i.p. injection) and the use of analytical chambers to measure food intake and respiratory metabolism. Prior to sacrifice, mice were challenged with leptin (i.p. injection) to assess neuronal leptin responsivity via immunohistochemistry and western blot. Brown adipose tissue (BAT) morphology and thermogenic protein expression were also analyzed. Female Trsp-Agrp KO mice displayed resistance to diet-induced obesity, which was accompanied by improved glucose tolerance and elevated energy expenditure levels without changes in food intake. Female Trsp-Agrp KO mice also had greater leptin sensitivity and showed signs of elevated BAT thermogenesis. Male Trsp-Agrp KO mice displayed no changes in metabolic phenotype. Loss of selenoproteins in Agrp-positive neurons of the hypothalamus promotes energy expenditure and reduces diet-induced obesity in a sexually dimorphic manner, leading to resistance to a high-fat diet in females.

Title: Eating response is rapidly elicited by $GABA_A$ or $GABA_B$ receptor stimulation in the lateral septum

Authors: *I. GABRIELLA[1], A. TSENG[2], K. SANCHEZ[3], H. SHAH[3], B. G. STANLEY[1]; [1]Psychology, [2]Neurosci., [3]UC, Riverside, Riverside, CA

Abstract: Over 40% of adults in the USA are obese and therefore identifying the neural substrates of overeating is a priority. Recent studies have highlighted the lateral septum as important in eating control mechanisms. The current study used central injections of GABA receptor agonists and antagonists to explore potential roles for $GABA_A$ and $GABA_B$ receptors within the lateral septum in the control of food intake. The study's hypotheses predicted that GABA receptors disinhibit pathways leading to feeding, therefore agonists of GABA $_A$ and $_B$ receptors would increase food intake, while antagonists would decrease food intake. We used 4 groups of satiated adult male Sprague-Dawley rats (n ≥11 subjects/group) chronically implanted with a guide cannula terminating in the lateral septum. Doses of drugs dissolved in the artificial CSF vehicle were injected through the guide cannula into the lateral septum in 0.3 µl volumes during the early portion of the light-phase. Ingestion of a palatable milk-based mash diet and water were measured 1, 2, 4 and 24 hours post injection. Each experiment had a within-subjects repeated measures design with all subjects tested in each condition in counterbalance order. Experiment 1 showed that injection of the $GABA_A$ receptor agonist, muscimol (doses: 0.1, 0.2, and 0.3 µg), into the lateral septum elicited intense, dose-dependent feeding responses (e.g. mean food intake 1 hour after the 0.3 µg dose was 6.7 g , SE = 1.8). Experiment 2 showed that pretreatment injections with the $GABA_A$ receptor antagonist, picrotoxin (doses: 0.05, 0.1, 0.2 µg), markedly reduced the muscimol-elicited feeding response, indicating mediation by $GABA_A$ receptors. Experiment 3 tested the $GABA_B$ receptor agonist, baclofen hydrochloride (doses: 0.45, 1.125, 2.25 µg), and found a similar dose-dependently elicited eating response (e.g. mean food intake 1 hour after the 2.25 µg dose was 6.9 g, SE = 1.4). Finally, experiment 4 showed that pretreatment injections with the $GABA_B$ receptor antagonist, 2-hydroxysaclofen (doses: 0.5, 1.25, 2.5 µg), substantially reduced baclofen-elicited eating, consistent with elicited feeding being mediated by $GABA_B$ receptors. In contrast, water intake was not significantly affected by any of the drugs 1 hr after injection, which provides support for GABA receptors being involved in eating but not drinking responses. These results, showing that activation of lateral septal

$GABA_A$ or $GABA_B$ receptors are capable of strongly stimulating eating behavior, suggest potential roles in feeding control neurocircuitry.

Title: Chemoarchitectural analysis of cocaine- and amphetamine-regulated transcript, alpha-melanocyte-stimulating hormone, and dopamine beta-hydroxylase: Systematized mapping within a standardized stereotaxic reference atlas.

Authors: *B. E. PINALES[1], K. J. GALVAN[2], E. J. PEREZ[2], P. A. PARADA[2], M. A. PEVETO[2], K. A. S. BURNETT[2], K. T. LORENZANA[2], A. M. KHAN[2];

Abstract: Cocaine- and amphetamine-regulated transcript (CART) and alpha-melanocyte-stimulating hormone (αMSH) are known for their appetite-inhibiting effects. Norepinephrine is a neuromodulator involved in autonomic function, synthesized by the enzyme dopamine beta-hydroxylase (DβH). These neural messengers are distributed within several regions of the mammalian brain, yet their anatomical arrangements have not been systematically reported within a standardized reference atlas at high-spatial resolution. *Our objective is to provide high-spatial resolution maps of CART, αMSH, and* DβH within a standardized atlas (*L.W. Swanson, Brain Maps 4.0, 2018), with a primary focus on their spatial arrangements and putative colocalization.* A Nissl stain (thionin) was used for cytoarchitectural analysis in coronal-plane sections of the adult male rat brain. This facilitated the atlas level assignment of adjacent sections, fluorescently tagged with CART, αMSH, and DβH antibodies, the patterns were then mapped onto digital atlas templates. We report co-spatial relationships between CART, αMSH, and DβH within atlas levels (23-30). The immunoreactive labels were observed in the paraventricular thalamic nucleus (PVT), central and medial amygdalar nucleus (MEA; CEA), lateral hypothalamic area (LHA), arcuate (ARH), paraventricular (PVH), periventricular- (pv), and dorsomedial hypothalamic (DMH) nuclei. Both anorexigenic markers are co-localized to a high degree, with a few single-label fibers evident. CART-immunoreactive cells were observed in the ARH, PVH, zona incerta (ZI), LHA, and supraoptic nucleus (SO); however, cells expressing CART and αMSH displayed moderate co-expression within the ARH. DβH-immunoreactive fibers were present within the same subregions as the anorexigens, but with

minimal co-localization (*e.g.*, PVH, pv, ARH, LHA, and PVT). The PVT showed a dense representation for each label; however, sparse expression was seen in dorsal or ventral regions where CART and DβH were separately expressed. Putative co-localization of the three markers was in the medial and lateral aspects of the nucleus. Robust staining of CART, αMSH, and DβH was also observed in hypothalamic regions (*e.g.*, ARH, PVH, and some subregions of the LHA). Fibers for each were moderately expressed within the CEA/MEA, with a greater distribution of DβH. The aforementioned mapping of co-spatial patterns among CART-, αMSH-, and DβH-ir fibers, may aid in precision targeting using tract tracers or virally-directed methods. Moreover, the spatial arrangement of these neuromodulators within a stereotaxic reference space can aid in their further study using functional techniques.

Title: Viral Tracing of Axonal Projections from Tyrosine Hydroxylase-expressing Neurons of the Zona Incerta

Authors: *B. BONO[1], K. NEGISHI[2], K. S. SCHUMACKER[1], D. P. SPENCER[1], M. PONCE[2], E. MEJIA[2], A. J. HEBERT[4], A. M. KHAN[3], M. J. CHEE[1];

Abstract: Hypothalamic zona incerta (ZI) tyrosine hydroxylase (TH) neurons produce dopamine and can also signal via GABA transmission. GABA ZI neurons drive motivated behaviors like feeding, hunting, and sleep via projections to the paraventricular thalamus (PVT), periaqueductal gray (PAG), and lateral hypothalamic area (LHA), respectively. However, it is not known if these behaviors require dopamine transmission. To determine the brain regions affected by dopaminergic transmission we identified the projection sites of ZI TH neurons. We used a *Th-cre* mouse line expressing Cre recombinase in TH neurons and validated the specificity of *Th-cre* expression in *Th-cre;L10-Egfp* neurons. Dual fluorescence *in situ* hybridization on *Th-cre;L10-Egfp* brain tissue showed that Cre-mediated expression of *Gfp* mRNA colocalized in all ZI *Th* mRNA cells. Interestingly, while all *Th-cre* neurons in the rostromedial ZI were TH-immunoreactive (TH-ir), less than 20% of *Th-cre* neurons in the lateral ZI were TH-ir. To visualize ZI TH projections, we injected two male *Th-cre* mice with a Cre-dependent adeno-associated virus encoding mCherry. In light of differential TH expression in the ZI, *Th-cre* mice

were given either a focused injection (25 nl) targeting the rostromedial TH-ir neurons or a larger volume (75 nl) to encompass the lateral ZI also. About 60% of TH-ir neurons from our focused injection were dsRed-ir, while in the larger injection only 24% were dsRed-ir. High resolution spatial maps revealed that both injection cases produced a similar pattern of dsRed-ir fibers, though the larger injection produced a greater density. In the cerebral hemispheres dsRed-ir fibers were found in the lateral septum and bed nucleus of the stria terminalis. Projections to the thalamus were directed towards the rostral PVT and the nucleus of reuniens. In the hypothalamus, dsRed-ir fibers were prominent in the LHA and anterior, dorsomedial, and posterior hypothalamic nuclei but absent in the suprachiasmatic, ventromedial hypothalamic, and premammillary nuclei. Caudally, the PAG contained dense dsRed-ir fibers which spread to the superior colliculus and parabrachial nucleus. In aggregate, we observed widespread projections from ZI *Th-cre* neurons that were independent of TH expression. The pattern of projections from ZI TH neurons suggest putative dopamine targets, which also overlap with known GABAergic ZI projections.

Title: Chronic central leptin infusion effects on food intake of male and female offspring of mild hyperglycemic rats

Authors: G. P. OLIVEIRA[1,2], A. G. CRUZ[1,2], G. V. SILVA[1], M. G. MARTINS[1,2], B. C. WOODSIDE[3], ***A. C. KISS**[1,2];

Physiol., Inst. of Biosciences, Univ. of São Paulo (USP), São Paulo, Brazil; [3]Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Maternal hyperglycemia during pregnancy and lactation can increase the susceptibility of the offspring to develop several metabolic disorders later in life, such as obesity and diabetes. There is growing evidence suggesting that the early programming of neuroendocrine systems could play a role in this scenario. Maternal severe diabetes is associated with central leptin resistance and lifelong disorganization of the hypothalamic pathways regulating energy expenditure and food intake. However, the effects of maternal mild hyperglycemia, which better

resembles human gestational diabetes, have not yet been investigated. In addition, most studies only explore the effects on male offspring, while females are often overlooked despite the growing evidence of sex differences on control of food intake. Therefore, the aim of the present study was to evaluate the chronic central leptin infusion effects on food intake of male and female offspring of mild hyperglycemic rats. In order to achieve this goal, pregnant Sprague-Dawley rats were divided into two experimental groups: Control (n=6) and STZ (n=6, 35 mg/kg i.p. on pregnancy day 7). Rats gave birth naturally and the litters were culled to 4 males and 4 females. On postnatal day 75 (PND 75), 2 male and 2 female offspring from each litter were used and each received a different treatment (saline or leptin). Thus, the experimental groups were formed according to the presence or absence of maternal hyperglycemia and treatment with saline or leptin, as follows: Control saline (n=6), Control leptin (n=6), STZ saline (n=6), STZ leptin (n=6). On PND 82, animals underwent surgery for cannula implantation the lateral cerebral ventricle (Alzet model 2001) which released saline 0,9% or leptin (1 microgram of leptin per day at a rate of 1 microliter/hour for 7 consecutive days). Body weight and food intake were daily monitored for 7 days before and 7 days after surgery. On PND 89, rats were killed and cannula placement was evaluated. All experimental procedures were approved by the local ethics committee (Protocol number 1134). The chronic central leptin infusion was able to decrease the food intake in offspring from all experimental groups. However, the leptin treatment affected Control and STZ offspring differently and there were also sex-related differences. In conclusion, maternal mild hyperglycemia impaired offspring sensibility to chronic central leptin infusion and males and females responded differently. More studies will be carried out to unravel the pathways involved on those changes.

Title: Cytoarchitecture-guided laser-capture microdissection of the arcuate hypothalamic nucleus: Developing a workflow for the standardized mapping of the sampled site in a reference atlas of the rat brain

Authors: *S. BALIVADA, K. NEGISHI, A. M. KHAN;
Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX

Abstract: Laser-capture microdissection (LCM) of brain regions, followed by their high-throughput analysis, are well-established methods to identify the molecular constituents of a region of interest (ROI). Accurate ROI identification and dissection are the keys to connect

molecular information to ROI functionality. However, current methods lack an estimation procedure for accurately mapping the spatial location of the ROI (Khan AM, 2018. *Adv. Neurobiol*. *21*, 101). Here, we approached this problem by developing a workflow that includes cytoarchitecture-guided LCM followed by standardized mapping of the ROI using a widely used open-access rat brain reference atlas (*Brain Maps 4.0 (BM4.0)*; Swanson LW, 2018. *J. Comp. Neurol*. *526*, 935). A fresh-frozen brain collected from an adult male Sprague Dawley rat was cryosectioned at 20 µm-thickness and serially mounted onto both glass and polyethylene-napthalate-membrane (PEN-M) slides. The sections on glass, stained with thionine, were used as "guide sections" on a Leica LMD7000 for LCM of serially adjacent PEN-M sections. First, guide sections were spatially calibrated to PEN-M sections using user-defined fiducials. The arcuate hypothalamic nucleus (ARH) target ROI was identified based on its cytoarchitectural features on the guide sections, and contours delineating the ARH were drawn. These contour drawings were transferred onto the PEN-M sections, and the ROI was microdissected from those sections. LCM samples were processed for RNA using a PicoPure™ RNA isolation kit (Thermo Fisher Scientific), and RNA quality was estimated using TapeStation (Agilent). Histological analysis of the PEN-M sections used for LCM revealed that the sampled ROI was bounded by the ventromedial hypothalamic nucleus, median eminence, and third ventricle; suggesting that the dissected sample contained the ARH. Nissl-based parcellation of the guide sections, together with plane-of-section analysis, helped to identify that the sampled ROI is associated with *BM4.0* atlas levels 27-29, and the contours were mapped onto digital *BM4.0* atlas templates accordingly. Analyzed RNA samples displayed an RNA integrity number greater than 7. These initial results suggest that our workflow can be used to 1. perform reliable LCM of an ROI based on the guide section's cytoarchitecture; and, 2. map the location of the ROI within the *BM4.0* rat brain atlas. Our plans are to develop this method further by quantifying microdissection accuracy using mapped contours and validating these findings for hypothalamic ROIs that require greater precision to microdissect, such as sub-regions of the lateral hypothalamic area.

Title: Decoding of thirst states in the mammalian brain

Authors: *A.-H. POOL[1], T. WANG[1], *J. NGAI[2], Y. OKA[1];
[1]Caltech, Pasadena, CA; [2]Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: The motivation to drink is triggered by two distinct thirst states. Increased internal osmolality induces osmotic thirst that drives animals to drink pure water. Conversely, loss of body fluid volume induces hypovolaemic thirst, in which animals drink both water and minerals to recover blood volume and electrolyte composition. Sensory nuclei in the Lamina terminalis (LT) including the subfornical organ (SFO) and organum vasculosum of lamina terminalis (OVLT) are critical for sensing both types of thirst-inducing stimuli. However, how different thirst modalities are encoded in the brain and how the thirst need state is decoded in higher order brain centers remains unknown. Here we employed single cell RNA-seq based stimulus-to-cell-type mapping to identify cellular substrates that detect the two kinds of physiological thirst states as well as thirst need signal decoding cellular populations in downstream hypothalamic nuclei. These studies revealed diverse types of excitatory and inhibitory neuron in each sensory LT nuclei SFO and OVLT. We show that unique combinations of these neuron types are activated under osmotic and hypovolaemic stresses. These results elucidate the cellular logic that underlies the detection of distinct thirst modalities. Furthermore, optogenetic gain of function in thirst-modality-specific cell types in the SFO and OVLT recapitulated water-specific and non-specific fluid appetite caused by the two distinct dipsogenic stimuli. Furthermore, we identified neural populations downstream of SFO and OVLT that orchestrate thirst motivation and endocrine responses in response to the thirst need state. Together, these results outline a robust and rapid strategy to map out cellular substrates for motivated behaviors and reveal that thirst is a multimodal physiological state that is mediated by specific neuron types in the mammalian brain.

Title: Gut-brain pathways that regulate hypothalamic hunger neurons to control feeding

Authors: *N. GOLDSTEIN[1], A. D. MCKNIGHT[1,2], J. R. E. CARTY[1], A. L. ALHADEFF[1,2], J. N. BETLEY[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Monell Chem. Senses Ctr., Philadelphia, PA

Abstract: Food intake is influenced by coordinated activity in neural circuits that integrate physiological needs. Proper feedback from the gastrointestinal (GI) tract communicating energy status is critical in maintaining homeostasis. While extensive work has identified gut-to-brain pathways that activate satiation centers in the brain, it remains unknown if the same pathways are used to disseminate nutrient status information to brain regions that promote food-seeking and consumption. To explore the gut-brain pathways that inhibit hunger circuits, we assessed neural activity in Agouti-related protein (AgRP)-expressing neurons of the arcuate nucleus of the hypothalamus. AgRP neurons are active during hunger, inhibited by food intake, and are necessary and sufficient for feeding. Importantly, AgRP neuron activity decreases rapidly during direct nutrient infusion in the GI tract, suggesting that the nutritive value of food detected in the gut regulates AgRP neuron activity. We find that the inhibition of AgRP neurons during direct infusion of food is calorie-dependent and individual macronutrients (i.e. fat, carbohydrate, protein) are each sufficient to inhibit AgRP neurons. Do different macronutrients signal to the brain via a common gut-brain pathway? We hypothesized that the vagus nerve, a major highway between the gut and the brain, is crucial for relaying information from the GI tract to AgRP neurons. To test this hypothesis, we engineered mice to express the genetically encoded calcium indicator GCaMP6s in AgRP neurons and monitored *in vivo* neural activity in mice that received a complete sub-diaphragmatic vagotomy. Vagotomy blocked the ability of intragastric fat to inhibit AgRP neuron activity. Additionally, we found that cholecystokinin (CCK), a satiation peptide which is sufficient to inhibit AgRP neurons, can no longer alter AgRP neuron activity following vagotomy. These results support a model whereby fat, through the release of CCK, stimulates vagal afferents to ultimately inhibit AgRP neurons. However, we found that a complete diet containing all macronutrients maintains the ability to inhibit AgRP neurons following vagotomy, suggesting that not all macronutrients signal to the brain exclusively via the vagus nerve. Ongoing experiments further explore the mechanisms through which distinct macronutrients relay energy status to the brain. Taken together, this work highlights multiple gut-brain pathways that facilitate the inhibition of hunger circuits during calorie consumption to regulate feeding behavior.

Title: Altered Neuronal Activity of the Organum Vasculosum of the Lamina Terminalis Contributes to Genetic Salt-Sensitive Hypertension

Authors: *S. D. STOCKER[1], M. M. WENNER[2], W. B. FARQUHAR[2], K. N. BROWNING[3]; [1]Univ. of PIttsburgh, Pittsburgh, PA; [2]Univ. of Delaware, Newark, DE; [3]Penn State Col. of Med., Hershey, PA

Abstract: The organum vasculosum of the lamina terminalis (OVLT) is located along the rostral wall of the third ventricle, lacks a complete blood brain barrier, and contains NaCl-sensitive neurons that regulate thirst, neuroendocrine function and arterial blood pressure (ABP). The present study assessed whether activation of OVLT neurons directly alters sympathetic nerve activity (SNA) and contributes to salt-sensitive hypertension. Male Sprague-Dawley rats (250-400 g) received an OVLT injection of rAAV9-CaMKIIa-hChR2(H134R)-mCherry (50nL, $1x10^{13}$ vg/mL, Addgene) and an optical ferrule (200um OD, Thor Labs). At 2 wks later, optogenetic excitation of OVLT neurons (5 ms pulse, 50% duty cycle, 9-12 mW) produced frequency-dependent increases in ABP (1Hz: 0±1; 5Hz: 3±1; 10Hz: 6±1; 20Hz: 9±2 mmHg; n=6, P<0.05). These pressor responses were unaffected by the vasopressin antagonist Manning Compound (10ug/kg, IV; 20Hz: 8±1 mmHg) but completely abolished by the ganglionic blocker chlorisondamine (5mg/kg, IV; 20Hz: 1±1 mmHg; P<0.05). Second, optogenetic activation of OVLT neurons (n=5) significantly increased the discharge of bulbospinal vasomotor neurons in the rostral ventrolateral medulla (Δ; 5Hz: 4±1, 10Hz: 7±2, 20Hz: 11±2Hz; P<0.05), lumbar SNA (5Hz: 113±4%; 10Hz: 120±7%; 20Hz: 129±10%; P<0.05) and renal SNA (5Hz: 108±2%; 10Hz: 114±3%; 20Hz: 134±5%; P<0.05). Third, chronic chemogenetic activation of OVLT neurons by rAAV9-hSYN-HA-hM3D(Gq)-IRES-mCherry (50nL, $1x10^{13}$ vg/mL, Addgene, n=5) and clozapine-N-oxide (3 mg/kg/day, 7 days) significantly increased fluid intake (Day 0: 52±8mL vs Day 7: 177±29mL, P<0.05) and ABP (Day 0: 89±3 vs Day 7: 103±3 mmHg, P<0.05). Ganglionic blockade decreased ABP more at Day 7 versus Day 0 (-53±4 vs -38±5 mmHg, P<0.05). Finally, Dahl-Salt-Sensitive and Dahl-salt-resistant rats were fed 0.1% or 4% NaCl diet for 3-5 wks. In vivo single-unit recordings of OVLT NaCl-sensitive neurons indicated a significantly higher discharge in Dahl-salt-sensitive rats fed 4% NaCl (4.2±1.3 Hz, n=8) versus Dahl-salt-sensitive fed 0.1% (1.9±0.4Hz, n=7) or Dahl-resistant rats fed 0.1% (1.7±0.6Hz, n=7) or 4% (1.8±1.7Hz, n=6). Inhibition of OVLT neurons by muscimol injection (5mM, 20nL) significantly decreased lumbar SNA and ABP in Dahl-salt-sensitive fed 4% NaCl (SNA: -22±4%, ABP: -12±2mmHg, n=6; Ps<0.05) but not Dahl-salt-sensitive fed 0.1% (SNA: -2±1%, ABP: -3±1mmHg, n=5) or Dahl-resistant rats fed 0.1% (SNA: -1±1%, ABP: -1±1mmHg, n=5) or 4% (SNA: -3±1%, ABP: -4±3mmHg, n=5). Altogether, these findings suggest activation of OVLT neurons increase SNA and ABP, and the elevated activity of OVLT neurons contribute to salt-sensitive hypertension.

Title: Mapping of brain-wide circuits that control food intake by comparing neural activity in different need-based states and feeding behaviors

Authors: *T. OUELLETTE[1], K. O'CONNELL[2];
[1]Tufts Univ., Boston, MA; [2]The Jackson Lab., Bar Harbor, ME

Abstract: Neurons expressing agouti-related peptide (AgRP) in the arcuate nucleus of the hypothalamus (ARH) are critical for regulating hunger and food-seeking behavior. AgRP neurons are highly active during periods of caloric depletion and are inhibited in satiated state. While the activity of AgRP neurons is well-known to be modulated by peripheral hormones such as leptin or ghrelin, recent advances in real-time imaging of neuronal activity in freely moving animals has revealed that AgRP neurons are rapidly inhibited by sensory detection of food (Betley et al., 2015; Chen et al., 2016; Garfield et al., 2016) and that this can be potentiated by the palatability of the presented food (Garfield et al., 2016), indicating that AgRP neurons are also potently modulated by presynaptic inputs from other regions of the brain. However, the origin and identity of these presynaptic neurons remains poorly characterized. In this study, we used an unbiased approach to fluorescently label neurons brain-wide that are activated in response to periods of high metabolic need using a transgenic mouse line (Ai14;Arc^{CreERT2}) to identify neurons that are active following a fast or during presentation of food. In these mice, the immediate early gene *Arc* (which is well-defined as a molecular marker of activated neurons) drives expression of Cre recombinase following administration of 4-hydroxy-tamoxifen (4-OHT), thereby permitting the permanent labeling of activated neurons using Cre-dependent expression of the reporter tdTomato. This approach allows us to identify novel brain regions involved in the CNS response to caloric depletion and food presentation.

Title: Chemogenetic activation of olfaction results in sex-specific modulation of energy homeostasis

Authors: *P. JOVANOVIC, Y. WANG, E. NOVINBAKHT, N. MORONES, C. E. RIERA; Ctr. for neural science and medicine, Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Olfactory inputs are important for hedonic evaluation of food, resulting in food choice and possible consumption. The hypothalamus is a well established center integrating internal hormonal signals originating from peripheral organs to adjust energy intake and expenditure. Whether external stimuli, such as olfactory information are processed within the hypothalamus to contribute to energy balance regulation remains unknown. Here, we employ chemogenetic manipulation of olfactory mitral cells to specifically interrogate alterations in hypothalamic activity and whole-body energy metabolism. Using mice genetically encoding the human M3 muscarinic DREADD receptor, we show that acute stimulation of Tbx-21-positive neurons caused by clozapine-n-oxide (CNO) led to a rapid rise in oxygen consumption, heat production, and an increase in brown adipose tissue temperature in females, with no observed changes in activity or food intake. Analysis of thermogenesis related gene expression in brown adipose tissue (BAT) suggests that these changes are due to an increase in creatine metabolism in BAT in females with no changes observed in males. Acute CNO delivery produced c-fos early gene activation in various regions in the brain, including main olfactory bulb, amygdala and several hypothalamic nuclei. In particular, cFos activation was visible in the female dorsomedial hypothalamus, a hypothalamic nucleus playing a role in feeding, thermoregulation and circadian regulation. Taken together, these results indicate that the mammalian brain has developed dedicated neurocircuits to integrate olfactory inputs in the control of energy balance, which present different characteristics in male and female rodents.

Radiology and Biomed. Imaging, [7]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [8]Dept. of Medicine,, Fleischer Inst. for Diabetes and Metabolism, Albert Einstein Col. of Med., Bronx, NY

Abstract: Objective: Nutritional signals that arise following the ingestion of nutrients play an important role in the central control of eating behavior. Animal studies have shown that in diet-induced obesity, these regulatory mechanisms are disturbed. To assess this in humans, we studied the effect of intra-gastric macronutrient infusions on neuronal activity using functional MRI.
Methods: In 28 lean and 30 obese humans, we compared the effects of intra-gastric infusions of glucose 50% (250ml, 500kcal), Intralipid® 20% (250ml, 500kcal) and water (250ml) on i) the BOLD signal of the hypothalamus, nucleus accumbens, caudate nucleus, putamen, amygdala and insula with a region-of-interest (ROI) and a explorative whole-brain voxel-wise analysis using functional MRI, and ii) striatal dopamine release using SPECT imaging. Neuroimaging was repeated in the obese group after a 3-month hypocaloric diet with a weight loss of 9.5 ± 2.8%.
Results: In the nucleus accumbens, the BOLD signal decreased after both the intra-gastric infusion of glucose and lipid in lean, but not in obese subjects. In the putamen, signal decreased after the intra-gastric glucose infusion in both lean and obese subjects, and after the intra-gastric lipid infusion in lean subjects only. In addition, a voxel-wise analysis identified several regions with a decrease in BOLD signal in lean subjects, with the most pronounced effects in the striatum and frontal pole after the intra-gastric glucose infusion and in the insula and frontal regions after the lipid infusion. This pattern of nutrient-induced decreases in BOLD signal was absent in the obese subjects. Intra-gastric glucose infusion induced striatal dopamine release in lean and obese subjects while intra-gastric lipid infusion induced dopamine release in the lean subjects only. The lack of response in neuronal activity in the obese subjects was not reversible after weight loss.
Conclusion: Using fMRI, we identified a lean response phenotype in brain neuronal activity and striatal dopamine release after intra-gastric infusion of macronutrients. In obese individuals, this neuronal response is attenuated and this is not reversed by a diet-induced weight loss of 10%. Lipid sensing in the dorsal striatum seems to be particularly reduced in obese humans. These findings imply a defect in the feedback of energy consumption to the brain in obese humans, in a taste and preference independent manner. This may contribute to the pathological eating behavior of obese humans and the frequent weight-regain after weight loss interventions.

Title: Water and Brain Function: Effects of Hydration Status on Transcranial Magnetic Stimulation

Authors: *S. S. CRITZER[1], T. J. BOSCH[1], K. A. FERCHO[2], L. A. BAUGH[1];
[1]Univ. of South Dakota, Vermillion, SD; [2]FAA Civil Aerospace Med. Inst., Oklahoma City, OK

Abstract: INTRODUCTION: Transcranial magnetic stimulation (TMS) is used to study, diagnose and treat neuropsychiatric conditions but can fail or produce variable results. TMS depends on volume conduction so should depend on brain volumes. Hydration can affect brain volumes but the effects on TMS are unknown. We aimed to characterize the effects of hydration on basic motor TMS in awake behaving humans.
METHODS: 30 participants (8M, 22F) were tested in dehydrated and rehydrated states. TMS was targeted to the left M1-HAND area for first dorsal interosseus muscle while TMS-evoked potentials (TEP) and motor evoked potentials (MEP) were recorded. Threshold, hotspot, recruitment curve, paired pulse, and cortical silent period measures were recorded. Control data were collected for age, gender, handedness, urine specific gravity, blood glucose, maximum voluntary contraction, sleep, stimulant-depressant use, and fluid intake patterns.
RESULTS: Rehydration decreased the motor threshold and shifted the motor hotspot. Significant effects on TMS measures occurred despite being re-localized and re-dosed to these new parameters. Rehydration increased short excitatory facilitation of the MEP and magnitude of specific TEP components in inhibitory paired pulse protocols, consistent with favored excitability.
DISCUSSION: Results reflect macroscopic and microscopic volume changes, including shifts in 3D positioning, decreased scalp-cortex distance bringing cortex closer to the stimulation and recording sites, astrocyte volume changes including swelling-induced glutamate release, increased excitability, and ease of activating circuits in the rehydrated brain. Paired pulse TMS showed evidence of altered neurotransmission events (glutamate/GABA-dependent) in the stimulated circuits. Differential effects of hydration were observed on the short timeframe of activity in motor circuits that produces the MEP versus the longer timeframe of activity across all stimulated circuits that produces EEG signals. Increased short excitatory facilitation reflects increased excitability and generation of larger action potential volleys reaching the muscle, whereas altered inhibitory TEP peaks reflect effects on slower electrical activity that reaches EEG electrodes.
CONCLUSIONS: Variables like osmolarity, astrocyte volume, and brain volumes can affect neurostimulation and recording. Controlling for hydration may reduce variability in research studies and improve success rates in neurostimulation treatments. Rehydration offers a mechanism to 1) macroscopically bring target cortical areas closer to the TMS coil and 2) microscopically favor excitability.

Title: Expression of orexin and melanin-concentrating hormone genes in tumor-bearing mice

Authors: *C. MORDEN, M. LICURSI, H. BRIGGS, M. HIRASAWA;
Div. of Biomed. Sci., Mem. Univ., St John's, NL, Canada

Abstract: Many cancer patients present with cancer anorexia/cachexia syndrome (CACS), characterized as a severe loss of appetite and body weight. This is a leading cause of patient mortality with limited interventions available. Thus, it is important to illuminate the underlying mechanisms of CACS. It is thought that peripheral tumours can influence the energy balance circuitry in the brain, however, this process remains poorly understood. Melanin concentrating hormone (MCH) and orexin neurons are orexigenic cells that comprise the hypothalamic energy balance circuitry. Thus, it was hypothesized that the presence of a tumor alters MCH and orexin expression which contributes to cancer anorexia/cachexia. To test this, 8-week old, male C57BL/6 mice were injected subcutaneously in the hind flank with vehicle or Lewis-Lung carcinoma (LLC) cells (high dose: $1x10^6$cells or low dose: $0.5x10^6$cells). Once some mice reached an established end point, the LLC groups were sacrificed along with time-matched controls. RT-qPCR was performed to analyze the expression of MCH and orexin mRNA in the hypothalamus.

High dose LLC injections resulted in tumour growth that reached established endpoints after 14 days. In these mice, white adipose tissue (WAT) mass was reduced, while food intake (FI) and lean muscle mass remained similar to vehicle controls. Additionally, body weight (BW) gain was significantly reduced compared to controls, however there was large variability within the group. Furthermore, MCH/orexin gene expression was positively correlated with BW change. Thus, tumor-bearing mice that gained little to no weight after injection expressed near-control levels of MCH/orexin mRNA. In contrast, LLC mice with BW gain comparable to controls had elevated MCH/orexin mRNA expression. Secondly, low dose LLC injections resulted in tumours that took up to 30 days to reach the endpoint. These mice had a reduction in BW gain, WAT and FI when compared to controls. MCH gene expression was not different from that of controls and was not correlated with BW change, FI or final tumor mass. On the other hand, orexin mRNA was significantly reduced and showed a positive correlation with FI, but it was not correlated with BW change or final tumour mass.

In conclusion, our study suggests that the expression of appetite-promoting MCH and orexin in tumor-bearing mice is correlated with anorexia and weight loss. Mice with upregulated MCH and orexin genes were able to maintain BW and FI comparable to controls, whereas those that

showed signs of anorexia and weight loss did not upregulate these genes. Thus, lack of counterregulatory response by these neuropeptides to the tumor load may contribute to CACS.

Title: Cart peptide mediates anorexia in zebrafish by modulating the activity of a specific telencephalic region

Authors: *A. MADUSKAR[1], D. BODAS[2], D. WAKHLOO[2], T. KANIGANTI[2], N. SUBHEDAR[2], A. GHOSE[2];
[1]Indian Inst. of Sci. Educ. and Res., Pune, India; [2]Indian Inst. of Sci. Educ. and Research, Pune, Pune, India

Abstract: Of the various neuromodulatory agents found in the central nervous system, the class of peptide modulators is of particular interest in the context of innate motivated behaviours, where they have been shown to modify synaptic gain and alter intrinsic properties of the neurons to initiate or extend stable behavioural states (e.g. sleep/arousal, fear and anxiety etc.). An important behaviour where peptides have been shown to exert modulatory control is in the regulation of feeding behaviour. Although much is known about the neuropeptides involved in regulating feeding and the anatomical networks they affect, the details of the exact molecular mechanisms employed still remain poorly understood. In this study, we used pharmacological intervention coupled with behavioural monitoring and neuronal activity imaging in adult zebrafish (Danio rerio) to better understand the molecular mechanisms involved in the initiation and maintenance of Cocaine-and Amphetamine-Regulated-Transcript (CART) -mediated anorexia. We generated activity maps of the adult zebrafish brain in varying energy states and also under the influence of CART peptide. These studies found a strong correlation between high levels of the neural activity marker, phosphorylated extracellular signal-regulated kinase (pERK) in a region of the dorsal telencephalon and an associated anorexic behavioural output. We found that active N-methyl-D-aspartate (NMDA) receptor signalling is necessary for CART peptides' action, as the increase in pERK levels and reduction in feeding drive were both disrupted by blocking NMDA receptor signalling. We then tested if protein kinase A (PKA) is involved in mediating this effect. Indeed, we found that PKA activity was required for CART-induced upregulation of pERK in the dorsal telencephalic region and suppression of feeding drive. Additionally, we recorded the activity of telencephalic neurons, in ex vivo whole brain preparations, to varying strengths of excitatory stimuli. Interestingly we found that the response in this region was sensitized under conditions of CART treatment or satiety. Indicating that CART action via PKA sensitizes NMDA receptors, possibly via post-translational modification

of receptor subunits, leading to ERK activation that maintains a neural representation of sated state.

Title: Coexpression and distribution of MCH, CART and NK3R in the mouse hypothalamus

Authors: ***P. A. MILLER**, M. J. CHEE;
Carleton Univ., Ottawa, ON, Canada

Abstract: Melanin concentrating hormone (MCH) neurons are important for energy balance and sleep regulation. These neurons are exclusively expressed in the hypothalamus, but their distribution within this region is widespread. Furthermore, MCH neurons also express additional chemical messengers and can be marked by their coexpression of cocaine- and amphetamine-regulated transcript (CART) or the neurokinin 3 receptor (NK3R). Recent transcriptomic studies indicated that a third of MCH neurons coexpress both CART and NK3R, but the relative distribution of these or other MCH neurons have not been mapped to the mouse brain. In order to capture the neurochemical and neuroanatomical heterogeneity of MCH neurons, we quantified the proportion of MCH neurons that coexpress CART and/or NK3R and mapped the distribution of these cells to mouse brain atlas templates from the *Allen Reference Atlas*. We identified MCH neurons by native EGFP fluorescence (EGFP-f) produced by *Mch-cre* neurons in *Mch-cre;L10-Egfp* mice, as over 96% (979/1016) of all MCH-immunoreactive (MCH-ir) neurons coexpressed EGFP-f, though some EGFP-f neurons (64/1043) were not MCH-ir. High resolution spatial maps revealed that EGFP-f neurons may be spread over the medial hypothalamus in the anterior and dorsomedial hypothalamic nuclei and the medial zona incerta. MCH neurons distributed lateral to the fornix were found in the lateral hypothalamic area and in the extremity of the zona incerta, surrounding the ventral tip of the globus pallidus. We also performed serial immunohistochemical stains on *Mch-cre;L10-Egfp* mouse brain tissue to label NK3R-ir neurons using tyramide signal amplification followed with standard immunohistochemical staining to label CART-ir neurons. About half (49%) of all neurons counted expressed EGFP-f only and were most commonly found in the lateral hypothalamus around the globus pallidus. In contrast, 47% of EGFP-f neurons coexpressed CART and were more common in the medial hypothalamus. Of these EGFP+CART cells, half of them also coexpressed NK3R, which appeared equally distributed throughout the medial and lateral hypothalamic regions. Less than 4% of EGFP-f neurons coexpressed NK3R but not CART. In aggregate, these results indicate robust neurochemical and neuroanatomical heterogeneity of MCH neurons, and this may facilitate gene- or stereotaxic-driven approaches to isolate distinct MCH neuron subpopulations.

Title: Electrophysiological characterization of putative subpopulations of melanin-concentrating hormone neurons

Authors: D. R. ADEKUNLE, L. FANG, K. KATO, *M. HIRASAWA;
Div. of Biomed. Sci., Mem. Univ., St. John's, NL, Canada

Abstract: The hypothalamus is home to a heterogeneous population of neurons that are crucial in maintaining physiological and behavioural homeostasis. Melanin-concentrating hormone (MCH) neurons are essential regulators of energy and glucose homeostasis, sleep-wake behaviours, motivation, learning and memory. As MCH neurons are involved in these diverse processes, it is likely that there are specific subpopulations that might serve these distinct functions. MCH neurons occupy different areas of the hypothalamus and zona incerta (ZI), which may send projections to different parts of the central nervous system. Furthermore, neurochemical subpopulations of MCH neurons have been described: MCH neurons that co-express cocaine and amphetamine regulated transcript (CART) and those that do not. Therefore, we hypothesized that MCH neurons in distinct anatomical areas or with differential CART expression represent functional subgroups with different electrophysiological properties. To test this, whole cell patch clamp recording was performed on acute mouse brain slices in three MCH neuron-rich brain areas: medial hypothalamus (MH), lateral hypothalamus (LH) and ZI. Following recording, a subset of cells was immunohistochemically identified as MCH+/CART+ or MCH+/CART- neurons. MCH neurons in the three areas assessed had no difference in intrinsic properties such as the resting membrane potential (RMP), action potential (AP) waveform and firing activity upon positive current injections. Furthermore, these neurons in the three anatomical areas showed no electrophysiological differences when held at a subthreshold potential. In contrast, MCH+/CART- neurons had more depolarized RMP and fired APs than MCH+/CART+ neurons, suggesting that MCH+/CART- neurons are more excitable. These results suggest that MCH neurons are not electrophysiologically homogeneous. These differences in intrinsic properties, in addition to their neurochemical property and connectivity, are likely to be critical in how MCH neuron subpopulations function within the network.

Title: An analysis and representation in an atlas reference space of synaptic interactions between alpha-melanocyte stimulating hormone-immunoreactive axonal fibers and neurons expressing hypocretin/orexin or melanin concentrating hormone: light and electron microscopic evidence

Authors: *A. TOCCOLI[1], L. SOTO ARZATE[1], V. I. NAVARRO[1], E. PERU[1], D. SOTELO[1], A. SZILVÁSY-SZABÓ[2], R. YVETTE MAGDOLNA[2], E. FARKAS[2], A. GUEVARA[1], J. GUERRA-RUIZ[1], K. NEGISHI[1], S. Med., Budapest, Hungary; [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: Alpha-melanocyte stimulating hormone (αMSH), melanin-concentrating hormone (MCH), and hypocretin/orexin (H/O) are three major neuropeptide systems involved in the hypothalamic control of feeding and the regulation of metabolic state. MCH and H/O are neuropeptides which can be found in various sub-regions of the lateral hypothalamic area (LHA) and are known orexigenic peptides. On the other hand, αMSH is an anorexigenic peptide which is primarily expressed in the arcuate hypothalamic nucleus (ARH). Due to the opposing behavioral effects that these neuropeptides exert, along with their differential localization within the hypothalamus, there has been an interest in the field to determine whether putative appositions between αMSH-immunoreactive (-ir) axonal fibers and H/O-ir and MCH-ir somata are formed, and if so, whether these can be discerned to form synaptic relations at the electron microscopic (EM) level. Previous reports of such appositions, however, did not offer descriptions of their precise spatial distributions. Here, we report, within a standardized spatial framework, the mesoscale distributions of putative appositions between αMSH-ir fibers and H/O-ir or MCH-ir somata within the adult male rat hypothalamus from levels 23-30 of a standardized rat brain atlas (Brain Maps 4.0; Swanson, 2018, J. Comp. Neurol.). With the use of double-label immunoperoxidase histochemical staining and atlas-based mapping, we found that the LHAs had the highest density of putative appositions between αMSH-ir fibers and MCH-ir somata, with the LHAjvd and LHAd also containing high densities. Similarly, we found that the LHAs had the highest density of putative appositions between αMSH-ir fibers and H/O-ir somata, with the LHAd also having a high density. EM data from select regions also provided evidence of synaptic relationships between αMSH-ir terminals and H/O-ir and MCH-ir somata. The maps presented here will help determine regions of high likelihood of possible interactions between αMSH and H/O or MCH, and will allow for further testing to determine whether there is a clear pattern or organization of the distributions of these neuropeptides.

Title: Prostaglandin E2 signalling in MCH neurons contributes to high-fat diet-induced obesity

Authors: *L. FANG[1], M. LICURSI[1], M. HIRASAWA[2];
[1]Div. of Biomed. Sci., Mem. Univ., St. John's, NL, Canada; [2]Div. of Biomed. Sci., Mem. Univ., St John's, NL, Canada

Abstract: Due to the increased availability of energy-dense, high-fat foods, the incidence of obesity and non-alcoholic fatty liver disease are on the rise without effective therapeutic options.High-fat diet (HFD) induces inflammation of the brain, including the hypothalamus where the energy balance circuitry exists. Interestingly, HFD-induced hypothalamic inflammation can drive further food intake and weight gain, causing a vicious feedforward cycle. However, the molecular mechanism by which inflammation promotes positive energy balance remains poorly understood. The lateral hypothalamus (LH) is a hypothalamic nucleus that has been shown to undergo inflammation after prolonged HFD consumption. Orexigenic melanin-concentrating hormone (MCH) neurons within the LH are known for their role in promoting weight gain, fat accrual, and hepatic lipid accumulation. Given the role of MCH neurons, we hypothesized that MCH neurons mediate the hyperphagia and weight gain induced by HFD-induced hypothalamic inflammation.To test this, male rats or mice were fed a standard chow or a HFD for at least 4 weeks up to 14 weeks. Animals were then sacrificed, and in-vitro patch clamp electrophysiology was performed.We found that HFD induced a robust depolarization of MCH neurons compared to chow-fed controls. We then asked what is causing this depolarization? Prostaglandin E_2 (PGE_2) is an inflammatory mediator that is downstream of various cytokines known to be elevated after HFD feeding. Indeed, we found that PGE_2 mimicked the HFD effect while inhibition of cyclooxygenase-2, a prostanoid-synthesizing enzyme, reversed it. Further, antagonizing the PGE_2 EP2 receptor (EP2R) subtype blocks the PGE_2- and HFD-induced depolarization of MCH neurons. These results suggest that HFD increases endogenous PGE_2, which activates EP2R to depolarize these neurons. To determine the functional role of EP2R, mice lacking this receptor in MCH neurons ($MCH^{EP2R\ KO}$) and their littermate controls were fed with HFD. Preliminary results indicate that $MCH^{EP2R\ KO}$ mice gain less weight and consume fewer calories than the controls. Further, $MCH^{EP2R\ KO}$ mice tend to have less adiposity without a

difference in lean muscle mass compared to controls. Also, $MCH^{EP2R\ KO}$ mice have smaller livers than controls, and appear to be protected from liver steatosis. Together, we found that MCH neurons are activated by PGE_2-EP2R signaling during HFD feeding. This mechanism may provide a link between HFD-induced inflammation and the development of obesity and associated metabolic syndrome.

Title: High spatial representation of the inputs and outputs of the lateral hypothalamic area dorsal region of the hypothalamus in the adult male rat using the common spatial framework of Brain Maps 4.0

Authors: *V. I. NAVARRO[1], K. NEGISHI[1], E. M. WALKER[1,2], A. M. KHAN[3];
[1]Biol. Sci., The Univ. of Texas at El Paso, El Paso, TX; [2]Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [3]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX

Abstract: The lateral hypothalamic area (LHA) was long considered to be one large monolithic structure spanning that vast majority of the hypothalamus. However, Swanson (2004; *Brain Maps 3.0*) proposed further provisional subdivisions of this larger structure which were initially based on careful reconsideration of cytoarchitecture. These provisional subdivisions, which are retained in Swanson (2018; *Brain Maps (BM) 4.0*), have since been further tested with the targeted use of tract-tracers to explore if connectional differences between subregions may offer support. These experiments, however, have thus far only covered select subdivisions of the LHA, leaving others untested. Here we explore the inputs and outputs of the lateral hypothalamic area dorsal region (LHAd) from *BM4.0* atlas levels 27-41 of the male rat in order to test whether it differs in connections from that of the lateral hypothalamic area juxtadorsal (LHAjd), lateral hypothalamic area juxtaparaventricular (LHAjp) and lateral hypothalamic area suprafornical (LHAs) regions which have previously been reported. We have employed the use of the tract-tracers cholera toxin B subunit (CTB) and *Phaseolus vulgaris*-leucoagglutinin (PHA-L) in order to visualize the inputs and outputs respectively of the LHAd. Inputs and outputs were represented with high-spatial resolution within the common spatial framework of *BM4.0* in order to bring these data into spatial registry with those that have previously been generated. Preliminary results suggest that connections of the LHAd include reciprocating inputs and outputs to regions such as the CEA, VMH, TU, RE, VTA, SUM, COM, MRNm and RR with the largest densities of these in VTA and SUM. The observed inputs to the VTA were compared

with, and were found to confirm, results from retrograde tracing studies of the VTA using the track-tracer, Fluorogold. Efferent projections from LHAd also include BLA, RE, PVT, PAG, PH, RM and RL while afferent inputs to LHAd also include LHAp, VISC, PAG, PH, SPFpm, NPC, CLl and the SUB of the hippocampus. Thus far, these preliminary results appeared to demonstrate some variations and overlap in the connectional profiles of the LHAd when compared to that of LHAjp, LHAjd and LHAs. These preliminary results offer some additional support to the hypothesis that the provisional cytoarchitectural subdivisions of the LHA have connectional differences.

Title: Mesoscale and microscale interactions of fibers immunoreactive for alpha-melanocyte stimulating hormone and hypocretin/orexin with somata immunoreactive for neuronal nitric oxide synthase: A representation in an atlas reference space of the adult male rat, with supporting ultrastructural evidence

Authors: *D. SOTELO[1], A. GUEVARA[1], E. PERU[1], V. I. NAVARRO[1], A. TOCCOLI[1], A. SZILVÁSY-SZABÓ[3], R. YVETTE MAGDOLNA[3], E. FARKAS[3], J. GUERRA-RUIZ[1], L. SOTO ARZATE[1], K. NEGISHI[1], S. BALIVADA[1], A. ARNAL[1], C. FEKETE[3], A. M. KHAN[2]; [1]Biol. Sci., [2]Dept. of Biol. Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX; [3]Dept. of Endocrine Neurobio., Inst. of Exptl. Med., Budapest, Hungary

Abstract: Hypocretin/orexin (H/O) and α-melanocyte-stimulating hormone (αMSH)-expressing neurons of the hypothalamus have been implicated as participants within feeding control circuits. Nitric oxide (NO) has been reported to modulate the effects of various feeding-related neuropeptides; however, this influence has not been characterized on anatomical grounds. To investigate the relationship between feeding-control circuits and NO-producing neuronal populations in the hypothalamus, the localization, distribution, and putative appositions of neuronal nitric oxide synthase (nNOS)-expressing neurons in relation to that of H/O- and αMSH-expressing neurons was examined. A combined diaminobenzidine/nickel-enhanced diaminobenzidine reaction was used to distinguish the neuronal populations in reactions involving paired combinations of antibodies against these neuropeptides. An adjacent tissue series was Nissl-stained to delineate cytoarchitectonic boundaries and assign levels according to *Brain Maps 4.0* (L.W. Swanson, 2018; *J Comp Neurol*.) αMSH-ir somata were restricted to the ARH and immediately adjacent regions. The highest αMSH-ir fiber density was within the DMHa and DMHv. H/O-ir somata in the LHAs, LHAd, and LHAjd comprised 67% of the total

average of H/O-ir somata per subject, with the densest population found within the LHAs. nNOS-ir somata were most prominent within the DMHv. H/O-ir fibers contacted nNOS-ir somata more than αMSH-ir fibers, with 18.8% of all nNOS-ir somata receiving putative appositions from H/O-ir fibers, while αMSH-ir fibers only formed putative appositions onto 15.8% of all nNOS-ir somata. These putative appositions were mainly found in regions where high colocalization of nNOS-ir somata with H/O- and αMSH-ir fibers was present. In addition to these quantitative data, we also generated high-spatial resolution representations of neuronal populations and mesoscale representations of putative appositions between key hypothalamic neuropeptides and nNOS-ir somata. These data sets allowed for the generation of high-spatial resolution aggregate density maps to visualize areas with high presence of these neuronal populations. The predictive power of these data maps has been demonstrated by the fact that we found, at the EM level, evidence of synapses between αMSH-ir fibers and nNOS-ir somata in the AHN and LHA. In sum, we have mapped interactions between feeding-related neuropeptides and nNOS-expressing neurons; these maps can aid functional investigations using techniques such as chemogenetics, optogenetics, or electrophysiology.

Title: Acute and lasting effects of setmelanotide, an MC4R agonist, on hypothalamic Pomc-deficient and high-fat-fed wildtype mice

Authors: *Z. THOMPSON[1], B. P. SHAH[2], A. S. GARFIELD[2], M. J. LOW[1];
[1]Univ. of Michigan, Ann Arbor, MI; [2]Rhythm Pharmaceuticals, Boston, MA

Abstract: Arc-*Pomc* knockout mice have a selective loss of pro-opiomelanocortin (*Pomc*) gene expression in the arcuate nucleus of the hypothalamus. Due to a lack of central endogenous melanocortin-4 receptor (MC4R) agonists these mice develop early onset obesity, and progressive insulin resistance. Setmelanotide is a melanocortin-4 receptor agonist, currently under FDA review for treatment of human POMC and LEPR deficiency obesity. Here we investigated the effects of early MC4R agonist intervention prior to obesity onset in this POMC-deficient mouse model. We tracked the impact of setmelanotide treatment in two groups of male mice: Arc-*Pomc* knockout mice, fed regular chow, and their wildtype counterparts, fed a 45%

high-fat diet. These two groups of mice were randomized into three cohorts: one treated with setmelanotide throughout the entire study, one treated with setmelanotide only for the first 4 weeks of the study and then switched to vehicle, and one cohort that received vehicle for the entire study. We serially measured body weight, food intake, body composition, glucose tolerance, insulin tolerance, and several measures of metabolism, including oxygen consumption, energy expenditure, and ambulatory activity. Among other results, at the end of the study (24 weeks of age), Arc-*Pomc* knockout mice in the chronic setmelanotide treatment group weighed significantly less and had improved glucose and insulin tolerance when compared to the vehicle group. Wildtype mice on high-fat diet, treated chronically with setmelanotide, also showed improved fasting insulin when compared to their vehicle group. However, despite the observation of beneficial effects of a single month's treatment prior to obesity onset, cessation of acute treatment resulted in a steady reversal of metabolic benefit and the return of these animals to a native phenotype. We conclude that the obesity syndrome caused by a loss of hypothalamic *Pomc* expression was completely blocked by setmelanotide treatment started before the onset of obesity and that continued treatment is required for continued metabolic benefit.

Title: Neuropeptidergic regulation of traumatic stress and metabolism via the locus coeruleus

Authors: *F. A. MOHAMED, S. ELEAZER, K. L. BLANKENSHIP, S. K. HART, P. RAJBHANDARI, A. K. RAJBHANDARI;
Psychiatry and Friedman Brain Inst., Icahn Sch. of Med., New York, NY

Abstract: Clinical observations have shown that patients with psychiatric disorders, like Post-Traumatic Stress Disorder (PTSD), may develop metabolic syndromes such as Type II Diabetes and obesity in their lifetime. Empirical evidence from both systems neuroscience and endocrinology have suggested a mechanistic link between psychological stress and metabolism.

Our laboratory has been focused on further characterizing the relationship between trauma-like stress and metabolism by investigating the role of the neuropeptide Pituitary Adenylate Cyclase-Activating Peptide (PACAP) and its receptor PAC1. PACAP and its receptor PAC1 have been known to be associated with PTSD and metabolic dysfunction. Previous findings in the laboratory have shown that PACAP innervates the brown adipose tissue (BAT), a metabolically active type of fat tissue that converts food substrates into heat energy. PACAP receptor PAC1 is also abundant in BAT. These two findings suggest a role for PACAP and PAC1 in BAT thermogenic regulation, a key aspect of energy metabolism. We also found that the locus coeruleus (LC), a major source of norepinephrine (NE) in the forebrain, is rich in PAC1 expression. LC can modulate aspects of traumatic stress and metabolism via the sympathetic pathway, which innervates the BAT and various brain areas. Our major hypothesis is that traumatic stress enhances metabolism on the short term for high energy demand, but in the long run can lead to decreased metabolism, thereby inducing metabolic syndromes. To answer our questions, we use mice (males and females aged between 3-4 months) with floxed PAC1 receptors and employ a range of techniques, including viral-mediated knockdown, the stress-enhanced fear learning (SEFL) behavioral assay for traumatic stress, immunohistochemistry, in situ hybridization, and qRT-PCR. Upon knockdown of PAC1 receptors in BAT, we found that expression of UCP1 (uncoupling protein 1), a critical BAT-specific mitochondrial protein involved in cellular respiration, increased. We have also observed that viral-mediated knockdown of PAC1 receptors in the LC led to enhanced fear expression in SEFL, decreased fat mass and enhanced expression of UCP1 acutely. After a chronic time-point, fear expression in SEFL was still enhanced, but fat mass increased. Taken together, our results indicate that PACAP/PAC1 is an important neuropeptidergic system in the sympathetic node that links the brain and the body to regulate traumatic stress and associated metabolic changes.

Title: Restriction of dietary fat, but not carbohydrate, dampens striatalresponse to food images

Authors: *I. GALLAGHER[1], V. L. DARCEY[1], J. A. AVERY[2], J. GUO[1], A. COURVILLE[1], K. SIMMONS[3], J. INGLEHOM[2], A. MARTIN[2], K. D. HALL[1];

Abstract: Weight loss interventions often target restriction of either dietary carbohydrate or fat. Here, we investigated selective isocaloric reduction of dietary carbohydrate versus fat on fMRI brain activity to visual food stimuli (Clinicaltrials.gov #NCT0084604). Fifteen weight-stable adults (age=35.3±7.7 years; m=7, f=8) with obesity (BMI=35.87±4.7 kg/m^2) consented to two 14-day inpatient admissions to the NIH Clinical Center for a controlled feeding study. Each stay began with 5 days on a baseline eucaloric diet (50% carbohydrate, 35% fat, 15% protein), followed by cutting 30% of daily calories solely by reducing either carbohydrate (RC diet) or fat (RF diet) while keeping other macronutrients at baseline. Subjects completed both diet conditions in randomized crossover fashion. After approximately 4 days on each condition (baseline, RC and RF), subjects completed evening fMRI scans, 4.5 hours after their last meal, including a task requiring them to rate the pleasantness of 144 food pictures, varying from highly processed, high calorie foods to uncooked fruits and vegetables. A reward-circuit mask (including bilateral OFC and striatum) was applied for small volume correction. Mean food pleasantness did not differ across condition. Additionally, weight loss was not significantly different after 4 days on each condition. Results of a repeated measures ANOVA (3dANOVA2; AFNI) revealed an overall effect of dietary condition on reward circuit response to all food stimuli in the left putamen (96 voxels; x -19, y 9, z 6) and right putamen (32 voxels; x 25, y 5, z 10) (F(5.49); p_{uncorr}=0.005, cluster extent > 20 voxels surviving multiple comparisons using 3dClustSim at alpha=0.05). Post-hoc analyses revealed while the RC condition did not alter reward circuit response to food pictures from baseline, the RF condition caused a reduction of activity to food images bilaterally in a region spanning the left dorsal putamen and caudate (142 voxels; x -19, y 9, z 6) and right caudate (115 voxels; x 23, y 3, z -2) compared to baseline; p_{uncorr}=0.005, surviving multiple comparisons using 3dClustSim at alpha=0.05. Our results suggest that selective reduction of energy intake from dietary fat dampens reward circuit response to food images in people with obesity whereas isocaloric carbohydrate restriction had no significant effect.

Abstract: Obesity is a worldwide threat for health and is associated with major metabolic complications such as type 2 diabetes. Obesity increases the risk for ischemic stroke but the fate of hemodynamics in obese organisms is not well known. To bring further insights on the impact of obesity on sensory-evoked regulation of cerebral microcirculation, we explore relative changes in Cerebral Blood Volume (CBV) in the barrel cortex of obese and age-matched control mice at early ages during whisker stimulation using functional Ultrasound (fUS) imaging.Experiments were performed on 40 male mice divided into 2 groups, according to the time spent on high fat diet (HFD). In the first group, the mice are 2 months old and had 3 weeks of HFD (3W group, n=22), in the second group the mice are 4 months old and had 2 months of HFD (2M group, n=18). The mice were weighed, their fat measured with echoMRI and underwent 2 different metabolic tests: an oral glucose tolerance test (OGTT) and an Insulin tolerance test (ITT). The imaging sessions are fully non-invasive. The animals were anesthetized and placed in a stereotaxic frame. Ultrasound imaging acquisitions were performed in a coronal plane at Bregma – 1.70 mm, through the intact skin and skull. We measured CBV changes in the barrel cortex in response to whisker stimulation (2Hz). The acquisition was composed of a one minute baseline followed by 5 successive trials. Each trial consisted in 30 seconds of stimulation and 60 seconds of recovery. For each mouse we computed relative changes in power Doppler compared to the initial baseline. Then we averaged the 5 trials for each mouse. We also computed the correlation between stimulation pattern and the CBV time signal in each pixel of the Doppler film. As expected, both groups showed a significant weight and fat mass gain due to HFD compared to controls. For the metabolic tests, the 3W group showed normal time course responses to OGTT and ITT whereas the 2M group showed hyperglycemia in a fasted state, glucose intolerance and insulin resistance which are typical of a pre-diabetic stage. The 2M group shows an altered vascular response compared to controls (control mice CBV is 40 % higher than HFD, $p < 0.01$). Surprisingly, the 3W group also shows the same alteration of the vascular response to stimulation (40 %, $p < 0.001$). In the mean correlation map of the 3W, we observe a clear difference of activation between the HFD mice and control mice who showed an intense and spatially defined activation in the barrel cortex during stimulation, whereas the 3W HFD mice showed a less pronounced activation.fUS imaging showed an early neurovascular alteration in obese mice before the pre-diabetic stage where the mice do not have metabolic issues.

Title: Divergent midline thalamic projections to hippocampus and amygdala regulate retrieval and renewal of conditioned fear

Authors: *K. VASUDEVAN, J. LIU, K. R. RAMANATHAN, S. MAREN;
Dept. of Psychological and Brain Sci. and Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: The expression of memories is strongly linked to the context in which learning occurs. This is particularly relevant to fear extinction because extinction retrieval is poor outside of the extinction context, resulting in fear 'renewal.' Recent work from our laboratory indicates a key role of the thalamic nucleus reuniens (RE) in acquisition and expression of fear extinction in rats. Here we explored whether projections from the RE to the hippocampus (HPC) or basolateral amygdala (BLA) are involved in context-dependent retrieval of extinction memories. Male Long-Evans rats were infused with retrograde AAVs expressing the inhibitory opsin ArchT (AAVretro-CaMKII-ArchT-GFP) (n=9-12 per group) or control virus (AAVretro-CaMKII-GFP) (n=9-10 per group) into the HPC or BLA. Optical fibers were implanted into the RE for delivery of continuous green light (532nm). Rats underwent 5 tone-shock pairings in a distinct context, and the next day were extinguished in a different context (45 CS-only trials). Over the next two days, rats received within-subjects counterbalanced extinction retrieval tests in which light was either on or off during CS-only trials. Freezing served as the index of conditioned fear and was recorded with an automatic, unbiased motion threshold system. Inactivating RE → HPC projections during extinction increased freezing when compared to light-off responding. In animals receiving BLA AAVs, we observed that opsin was concentrated in the midline centromedial nucleus (CM), dorsal to the RE. Because midline projections to the BLA have been implicated in conditioned fear, we next examined whether CM → BLA projections are involved in fear renewal. Presentation of the extinguished CS in a novel context caused renewal, which was attenuated by inhibition of CM neurons projecting to BLA. There were no light-dependent effects in GFP rats. These data suggest a role for CM → BLA projections in promoting fear expression in novel contexts, whereas RE → HPC projections mediate fear suppression during retrieval in the extinction context. In conclusion, we have identified two distinct thalamic pathways that differentially modulate extinction retrieval and fear renewal.

Title: Early life stress results in atypical defensive behaviors in mice

Authors: *C. R. CODY, A. KISNER, *A. M. POLTER;
George Washington Univ., Washingon D.C, DC

Abstract: Defensive behaviors are a crucial aspect of survival and conservation of species. The ability to correctly develop and execute defensive strategies in response to threats is a complex process. Adverse experiences during early life significantly enhance the risk for the development of emotional and threat-related pathologies. One paradigm used to study ELS in the mouse is the limited bedding and nesting (LBN) model, in which dams and pups are placed in a low resource cage for seven days. This leads to disrupted maternal care, and results in behavioral, anatomical, and physiological changes in the brains of pups. It remains unknown how these adaptations affect naturalistic defensive responses and contribute to the development of fear-related disorders, as well as how sex may contribute to these adaptations. In order to test the effects of ELS on defensive behaviors, we utilized a Looming Disk (LD) behavioral assay. In the mouse, looming stimuli mimic the approach of aerial predators, and evoke innate, species-specific defensive behaviors such as running and freezing. Our data indicates that ELS affects typical defensive responses seen in mice. We have identified a relationship between ELS and atypical defensive responses such as darting. We also see an increase in reaction time to a threatening stimulus, followed by a decrease in the length of time spent sheltering or freezing after the looming stimulus. The results of this work indicate that fragmented and atypical responses to threatening stimuli occur as a result of ELS. These deficits may be related to changes in the brain's serotonergic (5-HT) system. Future work will examine what anatomical and physiological effects ELS has on the 5-HT system, and how this contributes to the changes in defensive behavior that we observe.

Title: Ventral pallidum neurons dynamically signal relative threat

Authors: *M. MOADDAB, M. H. RAY, M. A. MCDANNALD;
Boston Col., Chestnut Hill, MA

Abstract: The ventral pallidum (VP) is anatomically poised to contribute to threat behavior. Recent studies report a VP population that scales firing increases to reward but decreases firing to aversive cues. Here, we tested the hypothesis that VP neurons signal relative threat through firing decreases. We recorded VP single-unit activity from male Long Evans rats (n = 14) undergoing fear discrimination consisting of cues predicting unique foot shock probabilities: danger (p = 1.00), uncertainty (p = 0.25) and safety (p = 0.00). Fear discrimination took place over a baseline of reward seeking. Rats' behavior and VP single-unit firing discriminated danger, uncertainty and safety cues. Cue-inhibited neuron-types (Low firing and Intermediate firing) dynamically signaled relative threat, decreasing firing according foot shock probability during early cue presentation, but disproportionately decreasing firing to uncertain threat as foot shock drew near. Low firing neurons increased firing to reward, consistent with a bi-directional signal for general value. Intermediate firing neurons were unresponsive to reward, revealing a specific signal for relative threat. Consistent with salience signaling, another population of VP neurons showing firing increases to cues, also increased firing to reward; cue firing reflected fear output, and relative threat that was disproportionate to foot shock probability. The results reinforce anatomy to reveal the VP as a neural source of a dynamic, relative threat signal.

Title: Prefrontal cortical control of emotional responding through projections to the brainstem noradrenaline system

Authors: *M. WATANABE[1], A. UEMATSU[1,2,3], J. P. JOHANSEN[1,4];
[1]Ctr. for Brain Sci., RIKEN, Wako-shi, Japan; [2]Grad. school of Sci., [3]Intl. Res. Ctr. for Neurointelligence, [4]Grad. school of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Trauma-related disorders including post-traumatic stress disorder (PTSD) are among the most common neuropsychiatric conditions in the world. Hyperarousal and an inability to extinguish emotional memories are characteristic symptoms of PTSD and dysregulation of the noradrenaline system has been implicated as a mechanism of PTSD pathology. The brainstem locus coeruleus (LC) is the major source of noradrenaline to the forebrain and plays important

roles in arousal, stress responses, cognition and emotional processing through its broad connectivity throughout the nervous system. Previously we demonstrated how distinct submodules within LC differentially regulate forebrain target sites in the amygdala and prefrontal cortex to control fear extinction learning. However, it is unclear how forebrain sites such as the prefrontal cortex regulate LC-noradrenaline function and whether prefrontal inputs to LC modulate emotional processing is not known.
Here we used viral optogenetic and anatomical tracing approaches in rats to elucidate the detailed prefrontal-to-LC anatomical connectivity and test whether prefrontal innervation of the LC regulates fear extinction learning. Using anterograde viral and retrograde tracing approaches, we found that the LC/pericoeruleus area receives projections from both dorsal and ventral subregions of the mPFC (dmPFC, vmPFC). Using transsynaptic rabies virus, we also found that dmPFC and vmPFC project to a mPFC-projecting subpopulation of LC, demonstrating reciprocal connectivity between these regions. We next examined whether the dmPFC and vmPFC synaptic inputs to the LC participate in extinction of auditory fear memories. To test this question, we injected archaerhopsin-T (ArchT) into either the dm- or vmPFC and inhibited axon terminals from these regions in the LC during fear extinction learning sessions. We found that inhibition of the dmPFC input to the LC enhanced extinction learning. By contrast, inhibition of the vmPFC to LC pathway impaired extinction learning. This demonstrates that distinct mPFC subregions bidirectionally regulate fear extinction learning through projections to the LC-noradrenaline system. These findings suggest that the mPFC provides top-down cognitive control of the LC noradrenergic system for flexible control of emotional processing.

Title: The associative nature of fear: Learned and inherent sources of danger

Authors: *S. CAREW[1], T. SEPAHVAND[1], C. CROSSLEY[1], A. GHOSH[1], S. EDWARDS[2], C. REINHARDT[1], Q. YUAN[1];
[1]BioMedical Sciences, Fac. of Med., [2]Psychology, Fac. of Sci., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Animals acquire knowledge about features that predict danger through classical conditioning, an important survival skill. In first order conditioning (FOC), rats are trained to associate a neutral stimulus with an inherent source of danger, such as a shock, causing fear of that conditioned stimulus (CS1). If the learned CS1 is later presented with a different 2nd neutral stimulus (CS2) in the absence of shock, the rat also becomes afraid of CS2. This is called second

order conditioning (SOC). The basolateral amygdala (BLA) encodes negative valence of FOC memories and has been implicated in SOC memories as well. However, whether other sensory areas are involved in SOC is not clear. We mapped the activation pattern of several brain regions following SOC to understand the circuitry involved in this type of learning.
Adult (3-6 months) Sprague Dawley rats of both sexes were trained to associate either an odor, tone, or context (CS1) with a shock then trained to associate another neutral cue from a different sensory modality (CS2) with CS1. cFos immunohistochemistry was employed to study activity upon reactivation of these memories across multiple brain regions including: layer II of the anterior and posterior piriform cortex (aPC/pPC), CA1 and CA3 of the dorsal and ventral hippocampus (dHipp/vHipp), the BLA, and the primary auditory cortex. In a subset of animals D-APV was infused in the BLA immediately following tone/odor SOC to block NMDARs.
Odor, context, and tone may be used interchangeably as conditioned stimuli to produce FOC and SOC in the rat. When odor is used as a CS1 in FOC or CS2 in SOC increased neural activity is seen in the BLA, pPC, and vHipp CA1. When context is used as CS1 and odor as CS2, the dHipp CA1 and vHipp CA3 are also activated. Preliminary data suggests that when tone is used as CS1 with odor as CS2, the auditory cortex is recruited instead. These results postulate there are common brain regions involved with the expression of SOC fear memories regardless of the sensory modalities of the CSs, and that ancillary regions are recruited depending on the identity of the CS1. D-APV infusion to the BLA immediately following tone/odor SOC resulted in impaired recall of the odor CS2 upon re-exposure, highlighting how NMDAR signaling in the BLA is crucial for the expression of SOC fear memory.
A traumatic event that elicits emotions which can be transferred to temporally-associated neutral stimuli has the capacity to produce aberrant negative thought patterns, potentially leading to issues with mental health. With ever increasing diagnoses of anxiety, understanding the circuitry and mechanism of second order conditioning is critical.

Title: Dopamine-dependent rewiring of the anterior insular cortex circuit retains explicit emotional memory

Authors: ***H. NAMKUNG**, S. LOCKHART, J. D. CHABOT, B. J. LEE, A. SAWA;
Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: We tend to preferentially remember emotionally salient events that are associated with the feelings of joy, sorrow, pleasure, or pain. These associative emotional memories serve as potent predictors of important events when re-encountering similar situations, therefore shaping adaptive responses for survival. Supported by recent human neuroimaging studies, the anterior insular cortex (AIC) is emerging as an important brain region in learning and memorizing emotionally salient events. Nevertheless, there has been no systematic study to elucidate a neural mechanism by which AIC plays a role in emotional learning and memory. By utilizing two complementary paradigms of fear conditioning [delay fear conditioning (DFC) and trace fear conditioning (TFC)] in conjunction with pharmacological intervention, electrophysiology, and optogenetics, we show a neuronal mechanism whereby AIC-centered neural circuits retain explicit emotional memory. Pharmacological inactivation of AIC impaired fear memory retention in TFC, but not in DFC, showing the necessity of AIC in retaining explicit fear memory. Given that potentiation of excitatory synaptic transmission represents a neurobiological substrate underlying associative learning and memory, we next measured miniature excitatory postsynaptic currents (mEPSCs) in layer V pyramidal neurons of AIC, the main output neurons of AIC. As a result, we found significant increase in both amplitude and frequency of mEPSCs. By employing retrograde tracing, we next searched for upstream brain regions that project glutamatergic axons to and therefore possibly form excitatory synaptic potentiation onto AIC neurons. Among them, we focused on the basal amygdala (BA) and dorsomedial prefrontal cortex (dmPFC) for further study because of their necessity in TFC. By using projection-specific optogenetic inhibition, we tested the necessity of BA-to-AIC and dmPFC-to-AIC pathways in explicit fear memory retention. As a result, we found that silencing either BA-to-AIC (strong effect) or dmPFC-to-AIC (modest effect) pathway during TFC abolishes explicit fear memory retention. Given that dopamine (DA) modulates synaptic plasticity in response to emotionally salient events, we next hypothesized that DA gates potentiation of BA-to-AIC and/or dmPFC-to-AIC synapses, which underlies explicit fear memory retention. Blocking DA signaling in AIC using D1R-type receptor antagonists abolished explicit fear memory retention. Taken altogether, the present study shows a potential mechanism by which DA-gated potentiation of BA-to-AIC and/or dmPFC-to-AIC synapses retains explicit emotional memory.

Title: Optogenetic inhibtion of basolateral amygdala principal neurons attenuates the retrieval of both recent and remote cued fear memories in rats

Authors: *J. LIU, S. MAREN;
Texas A&M Univ., College Station, TX

Abstract: After initial encoding in the brain, memory undergoes reorganization with the passage of time. It has been demonstrated that different brain circuits underlie the retrieval of recent and remote fear memories in animal models. Despite extensive evidence implicating the basolateral amygdala (BLA) in fear memory, there are controversial results concerning the involvement of the BLA in the retrieval of remote fear memory. In this study, we show that optogenetic inhibition of BLA principal neurons reduces retrieval of both recent and remote fear memory in rats. To inhibit neuronal activity in the BLA, we expressed the red-shift microbial rhodopsin JAWS (AAV8-CaMKII-JAWS-GFP) or a control GFP (AAV8-CaMKII-GFP) in male rats. In the first experiment, rats underwent auditory fear conditioning during which a conditioned stimulus (CS; 2 kHz tone) was paired with a footshock (n = 5-6/group). Cued fear memory was measured 1 day (recent memory) and 7 days (remote) after conditioning in a neutral context. In the second experiment, male and female rats (n = 7-8/group)were conditioned using a within-subject procedure in which one conditioned stimulus (CS1; 8 kHz tone) was paired with footshock 14 days (remote memory) prior to testing, and a second CS (CS2; 2 kHz tone) was conditioned 1 day prior to testing (recent memory) in a distinct context. Retrieval testing to each CS was conducted in four counterbalanced tests (i.e., there were two tests for each CS, one with light on and the other with light off) and freezing behavior served as the index of conditional fear. In both experiments, we found that optogenetic inhibition of the BLA (red light, 635 nm, continuous illumination starting 10 sec before the first CS test trial) significantly attenuated freezing behavior to both the remotely and recently conditioned CS; rats expressing the control virus did not exhibit memory deficits. We did not observe any difference between male and female rats in the second experiment. Consistent with previous lesion studies, the present study indicates that the BLA is essential for the retrieval of both recent and remote cued fear memory.

Sci. and Border Biomed. Res. Ctr., Univ. of Texas at El Paso, El Paso, TX; [5]Dept. of Psychology, Univ. At Albany, SUNY, Albany, NY

Abstract: Prior studies indicate that the capacity to acquire and retain contextual fear memories undergoes a protracted maturation that spans key developmental periods from infancy, juvenility, adolescence to adulthood. However, the status of context fear conditioning (CFC) neural circuits at these stages of development remains poorly characterized. Determining the ontogenetic organization of basolateral amygdalar (BLA) nucleus afferents - including those originating from the hippocampus and medial prefrontal cortex - may provide a window into the functional contributions of these projections. The BLA, comprised of anterior and posterior subregions, extends ~3.3 mm rostrocaudally. We iontophoretically infused the retrograde tracer, Fluorogold, into rostral and caudal portions of the BLA of 44 male rats at postnatal days (PND) 16, 21, 32 and 87. Following four days to allow for retrograde transport, brains from perfused rats were sectioned to identify retrogradely labeled Fluorogold neurons in the anterior cingulate dorsal area dorsal part (ACAd), prelimbic (PL) and infralimbic (ILA) areas of the medial prefrontal cortex, and the ventral part of Field CA1 (CA1v) of the hippocampal region. Fluorogold injections in rostral (*AP* -2.0 to -2.7 mm from ß) and caudal (*AP* -3.25 to -3.90 mm from ß) portions of the BLA resulted in retrograde labeling of neurons in all regions and ages examined. Our results revealed that the PL undergoes significant growth from juvenility to adulthood that largely results from injections within the rostral portion of the BLA. In contrast, the ILA underwent significant pruning from juvenility to adulthood, that resulted from ipsilateral injections within rostral BLA. The ACAd underwent significant pruning from juvenility to adulthood irrespective of the BLA injection site. The CA1v underwent significant growth from juvenility to adulthood that was also irrespective of BLA injection site. Control experiments involving injection of the anterograde tracer, *Phaseolus vulgaris* leucoagglutinin (PHA-L), into the PL confirmed the existence of monosynaptic projections from the PL to the BLAa and BLAp. These results provide insight into developmental differences in the connectivity patterns of key limbic circuits during development, which may account for the differential activation patterns we have previously reported for these animals in these regions.

Title: Time alone following initial acquisition is sufficient to make signaled active avoidance dependent on the retrosplenial cortex

Authors: *M. R. KREITLOW[1], L. KEPPLER[2], J. M. MOSCARELLO[1];
[1]Psychological and Brain Sci., Texas A&M Univ., College Station, TX; [2]UT Hlth. San Antonio, San Antonio, TX

Abstract: Signaled active avoidance (SAA) behavior involves a multistage learning process supported by a shifting neural substrate. While recent work has begun to explore the circuitry by which the avoidance response is initially acquired and expressed, less is known about the mechanisms underlying the long-term maintenance of the response. In particular, it is unknown whether these mechanisms are brought online by continued training following acquisition, or whether time alone is sufficient to recruit them, suggesting a role for a systems consolidation-like process. Because it plays a known role in the long-term maintenance of aversive memory, we hypothesized that the retrosplenial cortex (RSC) is necessary for the expression of avoidance after substantial training. In an initial experiment, rats received intra-retrosplenial infusions of an AAV containing the gene construct for either the inhibitory hM4Di DREADD or GFP on a CamKII promoter to ensure expression in pyramidal neurons. Following recovery, subjects received training in an SAA paradigm in which they learned to shuttle across a divided chamber during a tone in order to avoid a foot shock. To compare the effects of retrosplenial inactivation across different phases of SAA maintenance, four days of initial acquisition were followed by two sessions of SAA preceded by CNO or vehicle in a counterbalanced order. Subjects then underwent two additional days of SAA training without drug treatment prior to two final sessions that were again preceded by counterbalanced administration of CNO or vehicle. While CNO inactivation of the retrosplenial cortex had no effect on the avoidance response following the initial four days of training, a robust decrement was observed at the latter time point, after subjects had undergone at least eight daily sessions of SAA. Then, in a subsequent experiment, we set out to determine if RSC is recruited by the passage of time or by continued training following initial acquisition. Rats expressing hM4Di in RSC pyramidal neurons received four days of SAA training followed either by two test sessions identical to those described above or by four days of time off in the homecage prior to two test sessions. CNO inactivation of RSC following the time off period caused a significant decrement in the avoidance response, while inactivation immediately following the initial four days of training had no effect. Thus, our data confirm that RSC plays a role in the long-term maintenance of the avoidance response, and that RSC is recruited to SAA by a systems consolidation mechanism and not by continued training following initial acquisition of the response.

Title: Chemogenetic inhibition of basolateral amygdala neurons projecting to the infralimbic cortex rescues stress-induced impairment in fear extinction in male, but not female, rats

Authors: *A. N. BINETTE[1,2], O. W. MILES[1], K. R. RAMANATHAN[1,2], S. MAREN[1,2]; [1]Psychological and Brain Sci., Texas A&M Univ., College Staion, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Stress exposure prior to extinction learning results in an impairment in long-term extinction memory. For example, extinction training conducted shortly after fear conditioning results in diminished extinction retention, known as the 'immediate extinction deficit' (IED). Underlying this impairment is perturbed neural activity in a variety of extinction-relevant circuits. In particular, footshock stress causes a lasting increase in firing rate in the basolateral amygdala (BLA) and a decrease in firing rate in the infralimbic (IL) cortex, a region critical for extinction learning and retention. We hypothesize that BLA projections to the medial prefrontal cortex underlie suppression of IL neuronal activity and mediate the IED . To examine this, we infused male and female rats (n = 8 per group) with a retrograde CAV expressing Cre recombinase (CAV2-Cre) into the IL and a Cre-dependent AAV expressing an inhibitory designer receptor exclusively activated by designer drugs (DREAADs) into the BLA (AAV-DIO-CaMKII-hM4di-mCherry). After recovery from surgery, animals received a systemic injection of either clozapine-N-oxide (CNO; 5 mg/kg, i.p.) or vehicle immediately prior to a standard 5-trial auditory fear conditioning procedure; this was followed after 15-min by a 45-trial extinction session. Animals were then tested for extinction retention 48 hours later. CNO administration did not affect freezing behavior during the conditioning or extinction sessions. During retention testing, however, male, but not female, rats treated with CNO displayed significantly lower levels of freezing compared to rats treated with the vehicle. These results suggest that silencing IL projectors in the BLA rescues the IED in male rats. This is consistent with our hypothesis that stress-induced BLA activation dampens IL activity to impair extinction.

Title: Prefrontal projections to the basolateral amygdala mediate safety learning

Authors: *E. KORZUS, J. PASTORE, T. W. BAILEY, J. MAYER, J. H. SPEIGEL, III; Psychology, Univ. of California Riverside, Riverside, CA

Abstract: This research focuses on developing a basic understanding of the circuit-level mechanisms governing behavior. While the prelimbic (PL) and infralimbic (IL) subdivisions of the medial prefrontal cortex (mPFC) are recognized for their excitatory and inhibitory effects on the fear circuit, respectively, the mechanisms driving fear discrimination remains unclear. Our previous research demonstrated that fear discrimination learning is mediated by prefrontal mechanisms. We showed that differential fear conditioning sparks neuronal ensembles associated with the inhibition of generalized fear in both the prelimbic and infralimbic cortices. In addition, real-time recordings from large neuronal population acquired from PL using head-mounted miniature microscopes across learning on a fear discrimination task revealed distinct PL neuronal assemblies, which show safety learning-triggered quantitative changes. Current research evaluated the role of PL projections to the basolateral amygdala (BLA) in differential fear conditioning. Considerable evidence indicates that coactivator of transcription and histone acetyltransferase cAMP response element binding protein (CREB) binding protein (CBP) is critically required for normal neural function and long-term memory consolidation. CBPΔHAT mutant has no intrinsic acetyltransferase activity due to its inability to interact with a donor of acetyl group, acetyl-CoA but retains all protein-protein interaction domains. When expressed acutely in adult excitatory neurons, CBPΔHAT functions as a specific blocker of long-term memory consolidation without disrupting information acquisition or short-term memory (Korzus et al. 2004). Our current data showed that expression of the selective inhibitor of long-term memory consolidation CBPΔHAT via a viral vector in PL neurons projecting to BLA results in severe deficits in differential fear conditioning but not in fear conditioning. We found decreased levels of histone acetylation and decreased induced-levels of activity marker cfos protein expression in neurons expressing CBPΔHAT. However, induced-levels of CREB phosphorylation were spared in the CBPΔHAT mutant mice indicating that upstream signals triggering the induced gene expression program remain intact in neurons expressing CBPΔHAT. Thus, CBPΔHAT mutant protein interferes with the epigenetic regulation of gene expression via negative modulation of histone acetylation resulting in circuit and behavioral deficits. Fear is known to be difficult to control and understanding the neural mechanisms that underlie the appropriate balancing of fear responses has clinical implications.

Title: Dissociation between the nucleus accumbens subregions in associative fear processing

Authors: *S. DUTTA[1], J. BEAVER[2], A. M. JASNOW[3];
[1]Biomed. Sci., [2]Psychological Sci., Kent State Univ., Kent, OH; [3]Dept. of Pharmacology, Physiol. & Neurosci., Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: The nucleus accumbens (NAcc), consisting of core (NAcC) and shell (NAcS) sub-regions, has primarily been studied as a locus mediating the effects of drug reward and addiction. However, there is ample evidence that this region is also involved in regulating aversive behavior, but the neurobiology is poorly understood. In our studies, we sought to elucidate the precise functions of the two sub-regions in regulating cued fear expression and extinction. We first examined expression of Arc as an indicator of neuronal activity during associative fear processing. Groups of mice were exposed to several control conditions and normal cued fear training, and then tested for fear expression or extinction. Arc expression was restricted to the NAcC during fear expression, whereas it was restricted to the NAcS during fear extinction. Next, mice were stereotaxically implanted with cannulae directed at either the NAcC or NAcS. We infused lidocaine into the NAcC or NAcS 5 mins prior to a fear expression test which also served as extinction training. Fear expression was not influenced by lidocaine infusions into the NAcS, however, extinction memory was disrupted during an extinction retention test. These data indicate that the NAcS is important for the consolidation of fear extinction. In contrast, mice with local infusions of lidocaine into the NAcC showed attenuated fear expression that was not due to their ability to freeze, suggesting that the core sub-region is involved in fear memory recall. To understand the unique roles of the NAcS and NAcC in fear processing, mice were infused with AIDA, an mGluR1 antagonist within the NAcS or NAcC prior to extinction training. Inactivating mGluR1s within the NAcS resulted in disrupted extinction memory but had no effect on fear expression or within-session extinction. There was no effect on fear processing when mGluR1s were blocked in the NAcC. These data suggest that mGluR1 signaling within the NAcS is critical for the consolidation of extinction, but not for expression or extinction learning itself. We next infused a MEK inhibitor into the NAcS post-extinction, which disrupted extinction retention. These data indicate that mGluR1 through ERK signaling specifically within the NAcS is critically important for the consolidation of extinction memory. These findings suggest that the NAc may be considered a critical region involved in regulating both fear recall and extinction memory depending on the subregion. It's dual role in appetitive and aversive regulation likely underlies the high co-morbidity between anxiety disorders and substance use disorders.

Title: Oxytocin selectively excites interneurons and inhibits output neurons of the bed nucleus of the stria terminalis (BNST)

Authors: *W. FRANCESCONI[1], F. BERTON[2], V. OLIVERA-PASILIO[1], J. DABROWSKA[1]; [1]Rosalind Franklin Univ. of Med. and Scien, North Chicago, IL; [2]Rosalind Franklin Univ. of Med. and Scien, Chicago, IL

Abstract: ***Abstract*** The dorsolateral bed nucleus of the stria terminalis ($BNST_{DL}$) has high expression of oxytocin (OT) receptors (OTR), which were shown to modulate fear and anxiety. The $BNST_{DL}$ contains GABA-ergic neurons classified based on intrinsic membrane properties into three major types. Using *in vitro* patch-clamp recordings in male rats, we demonstrate that OT selectively excites Type I neurons in an OTR-dependent manner as revealed by a significant depolarization of the resting membrane potential (from -62.39 ± 0.84 mV to -57.94 ± 1.39 mV, $P = 0.0013$, paired *t*-test), increased input resistance (from 170.98 ± 8.6 MΩ to 233.64 ± 18.6 MΩ, $P = 0.0085$), reduced rheobase (from 21.96 ± 2.29 pA to 17.32 ± 2.26 pA, $P = 0.0023$), reduced fast (from 8.63 ± 0.89 mV to 7.47 ± 0.77 mV, $P = 0.0062$) and medium spike afterhyperpolarization (from 10.69 ± 0.61 mV to 8.45 ± 0.72 mV, $P = 0.0001$), reduced threshold and latency to a first spike
(from - 38.38 ± 0.68 mV to -39.75 ± 0.88 mV, $P = 0.0346$), as well as a left shift in the spike frequency/current relationship. OT also increased spontaneous firing rate of Type I neurons recorded in a cell-attached mode (from 0.88 ± 0.66 Hz to 2.19 ± 0.93 Hz, $P = 0.0242$). As Type I neurons are putative $BNST_{DL}$ interneurons, we next recorded inhibitory synaptic transmission in all three types of neurons. We demonstrate that OT increases the frequency (from 1.03 ± 0.20 Hz to 2.64 ± 0.47 Hz, $P = 0.0033$), but not amplitude ($P = 0.9205$) of spontaneous inhibitory post-synaptic currents (sIPSCs) selectively in Type II neurons, an effect abolished by the presence of an OTR antagonist or tetrodotoxin. In addition, OT reduced spontaneous firing rate in Type II neurons (from 1.85 ± 0.74 Hz to 1.15 ± 0.69 Hz, $P = 0.0525$), without changing the amplitude of evoked IPSCs (eIPSCs, $P = 0.2459$, paired *t*-test) in these neurons. These results suggest an indirect effect of OT in Type II neurons, which is mediated via OT-induced increase in firing of Type I interneurons. In contrast, In Type III neurons, OT reduced the amplitude but not frequency, of both sIPSCs ($P = 0.0314$) and eIPSCs ($P = 0.0105$), suggesting a direct postsynaptic inhibitory effect. As Type II and Type III neurons were shown projection neurons of the $BNST_{DL}$, these results present a model of fine-tuned modulation of intrinsic $BNST_{DL}$ neurocircuitry by OT, which selectively excites Type I interneurons and inhibits Type II and Type III output neurons, via an indirect and direct mechanism, respectively.

Title: The role of the nucleus reuniens in coordinating prefrontal-hippocampal synchrony during the expression of fear and extinction memories.

Authors: *M. TOTTY, K. RAMANATHAN, S. MAREN;
Psychological and Brain Sci. and Inst. for Neurosci., TAMU, College Station, TX

Abstract: The nucleus reuniens of the thalamus (RE) is a small midline structure interconnecting the medial prefrontal cortex (mPFC) and hippocampus (HPC) that has been proposed to coordinate mPFC-HPC interactions. One mechanism by which the RE may facilitate mPFC-HPC communication is by the coordination of neural oscillations. Recent work has revealed that the expression of fear and extinction memories results in distinct 4 and 8 Hz network oscillations in the amygdala and mPFC. Additionally, RE inactivation impairs extinction retrieval and also mPFC-HPC synchrony during working memory tasks. We thus hypothesize that the RE may participate in these network oscillations and facilitate mPFC-HPC communication during fear and extinction memory retrieval. Using auditory fear conditioning and extinction, we show in male rats that the RE displays distinct 4 and 8 Hz oscillations that correlate with freezing behavior (n=4). In an additional experiment, we show the mPFC and HPC display similar 4 and 8 Hz oscillations (n=7), and pharmacological inactivation of the RE impairs 8 Hz mPFC-HPC coherence and results in a shift in spectral power towards the freezing-related 4 Hz oscillation (n=4). These data extend our current understanding of fear and extinction network dynamics.

Title: Subthreshold fear conditioning produces a rapidly developing neural mechanism that primes subsequent learning

Authors: *K. E. COLE[1], J. LEE[2], R. G. PARSONS[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Michigan State Univ., East Lansing, MI

Abstract: Learning results in various forms of neuronal plasticity that provide a lasting representation of past events, and understanding the mechanisms supporting lasting memories has been a primary pursuit of the neurobiological study of memory. However, learning also alters the capacity for future learning, an observation that likely reflects its adaptive significance. In the laboratory we can study this essential property of memory by assessing how prior experience

alters the capacity for subsequent learning. Previous studies have indicated that while a single weak fear conditioning trial is insufficient to support long-term memory, it can facilitate future learning such that another trial delivered within a protracted time window results in a robust memory. Here, we sought to determine whether or not manipulating neural activity in the basolateral amygdala (BLA) using designer receptors exclusively activated by designer drugs (DREADDs) during or after the initial learning trial would affect the ability of the initial trial to facilitate subsequent learning. Our results show that inhibiting the BLA prior to the first trial prevented the ability of that trial to facilitate learning when a second trial was presented the next day. Inhibition of the BLA immediately after the first trial using DREADDs was not effective, nor was pharmacological inhibition of protein kinase A or the mitogen activated protein kinase. These findings indicate that the neural mechanisms that permit an initial subthreshold fear conditioning trial to alter later learning develop rapidly and do not appear to require a typical post-learning consolidation period.

Title: A sensorimotor neural circuit for transforming aversive experiences into emotional memories

Authors: *L.-F. YEH[1], Y. KASUGA[1,2], Y. ISHIZU[1], J. P. JOHANSEN[1,2];
[1]RIKEN Ctr. for Brain Sci., Wako-shi, Japan; [2]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., Univ. of Tokyo, Tokyo, Japan

Abstract: Innately aversive experiences induce immediate escape and autonomic reactions, accompanied by persistent emotional memories. A common view is that external sensory properties of aversive experiences instruct memory formation; while competing views suggest that the bodily reactions to unpleasant events engage an emotional state that produces associative memories. The neural mechanisms that transduce aversive events into emotional states which regulate learning and behavior are unclear. Here we identify a brainstem-cuneiform (CnF) circuit which conveys both aversive external-sensory and aversive internal-motor information to the lateral and basal amygdala (LA/B), a brain region which stores emotional memory, to set an aversive sensorimotor state which instructs associative fear memory and enhances defensive behaviors. Using viral tracing and synaptic connectivity approaches, we found that glutamatergic CnF neurons project to and make synaptic connections with LA/B neurons. Rabies tracing studies revealed that this ascending CnF-to-LA/B receives monosynaptic inputs from spinal cord and brain regions which participate in aversive-sensory and aversive-motor functions. Notably,

LA/B neurons encode an aversive sensorimotor state during innately aversive experiences and both the sensory and motor components of this state representation are conveyed through the CnF-to-LA/B pathway. Finally, optogenetic perturbation experiments showed that during aversive events the CnF-LA/B pathway instructs aversive emotional memory formation and modulate the intensity of ongoing escape behaviors. Our findings reveal a brainstem circuit that enables aversive sensorimotor state encoding in amygdala networks and functions to produce emotional memories and enhance defensive behavioral reactions. This mechanism may explain the individual scaling of emotional memory strength by the magnitude of bodily reactions to trauma.

Title: The neural circuitry of conditioned nausea in rats

Authors: *A. BERNANKE[1], N. HERNANDEZ[1], S. ZIMMERMAN[1], J. MURPHY[1], *S. SETTE[1], Z. REAVIS[1], C. M. KUHN[2];
[1]Duke Univ. Med. Ctr., Durham, NC; [2]Dept of Pharmacol. and Cancer Biol., Duke Univ. Hosp., Durham, NC

Abstract: Chemotherapy-induced nausea and vomiting is one of the most troubling and difficult to manage side effects in cancer patients. Twenty-five to fifty % of patients undergoing chemotherapy will develop anticipatory nausea and vomiting (ANV), in which symptoms occur in anticipation of treatment. ANV is triggered by environmental cues and shows little response to traditional antiemetic therapy, suggesting that unique neural pathways mediate this response. ANV decreases quality of life and can lead to early cessation of treatment. Understanding the underlying neural mechanisms of this disorder is critical to the development of novel therapeutic interventions. The purpose of the present study was to identify brain areas activated during ANV. We used a rat model of ANV, by pairing a novel context with the emetic drug lithium chloride (LiCl) to produce conditioned nausea behaviors in the LiCl-paired environment alone. Male and female rats were treated with NaCl or LiCl (96 mg/kg) on alternate days for 4 treatments (day 1,3,5,7). On Day 9, they were placed in the context and we measured gaping, an analogue of human vomiting. To identify brain regions associated with acute LiCl and ANV, we measured c-fos activation by immunochemical staining. Behavioral results were analyzed by 2-way ANOVA (sex x treatment) and c-fos activation by 3-way repeated measure ANOVA of cell numbers containing c-fos expression (sex x treatment x area as repeated measure). Both male and female rats exhibited gaping behavior on test day, but males exhibited more gaping behavior than females ($p < 0.0244$)
Acute LiCl and ANV activated different brain areas differentially ($F = 11.4$, $p < 0.0001$ for area

x treatment). Acute LiCl activated multiple brain regions including the supraoptic nucleus of the hypothalamus, central nucleus of the amygdala (CeA), nucleus of the solitary tract (NTS) and area postrema (AP), that were not activated during ANV. ANV activated c-fos expression in the frontal cortex and insula of males, and the VTA of both sexes, indicating areas unique to the conditioned response. These data suggest that therapies such as ondansetron which target the area postrema are not effective in ANV because it is not a site activated during ANV response. Further studies aimed at characterizing the cell types that are activated in the conditioned nausea response will help identify novel therapeutic targets for the treatment of this condition, improving both quality of life and outcomes for patients undergoing chemotherapy.

Abstract: Background: Although electroconvulsive therapy (ECT) has been successfully used for decades in the treatment of severe psychiatric disorders, little is known about the underlying brain mechanisms. One of the major risks of ECT that significantly limits its use is an overall memory impairment. Nevertheless, the mechanisms of ECT-dependent memory impairments are not well understood. Here, using a rat model of fear conditioning, we characterize the effects of electroshocks on functional connectivity of brain regions that may underly fear memories.
Methods: All experiments were conducted using Sprague-Dawley rats. On two consecutive days before fear conditioning, subjects were habituated for 10 minutes in the conditioning chamber. On the day of fear conditioning, subjects learned to associate a neutral sound (1-5kHz, 50-80 dB; the conditioned stimulus [CS]) with an electric foot shock (1-s, 0.5-mA; the unconditioned stimulus) delivered through a grid floor. 24 hours after fear conditioning, subjects were returned to the conditioning chamber and exposed to the CS tone a single time to reactivate the fear

memory. Immediately after fear memory reactivation, subjects received either an electroconvulsive shock under anesthesia ($n = 4$) or a sham procedure ($n = 4$). 24 hours later, all subjects were returned to the conditioning chamber and exposed to the CS tone 5 times; subjects were then perfused, and the brain was collected. c-Fos, an immediate early gene commonly used as a measurement of neural activity, was quantified in regions of interest. **Results**: We present preliminary data on the functional connectivity of regions of interest based on c-Fos expression analyzed using graph theory from animals that received an electroshock or a sham procedure: correlation matrices, network visualizations, participation coefficients, and measurements of centrality (i.e., betweenness and degree centrality).

Title: Hypnotic suggestions provide evidence for a causal role of affect sharing in driving observational fear learning

Authors: *A. MÜLLNER-HUBER[1], L. ANTON-BOICUK[1], E. PRONIZIUS[1], L. LENGERSDORFF[1], A. OLSSON[2], C. LAMM[1];
[1]Univ. of Vienna, Vienna, Austria; [2]Karolinska Institutet, Stockholm, Sweden

Abstract: In humans and other social species, fears of and knowledge about what is dangerous and should be avoided are often learned through observing others in distressing situations rather than through one's own experiences, termed observational fear learning. Our aim was to assess the causal role of affect sharing - an important aspect of empathy that describes the ability to partially re-experience what and how another person is feeling - in observational fear learning. N=39 healthy students screened for above-average hypnotic suggestibility (30 female, 9 male, age range 18-24 years) completed an observational Pavlovian fear conditioning paradigm, consisting of a learning stage followed by a test stage. In the learning stage, the participant watched videos of another person - the demonstrator - responding with distress when receiving electric shocks (unconditioned stimulus) paired with a predictive color cue (conditioned stimulus; CS+; a second color served as CS-). In the test stage, an increased skin conductance response (SCR) to the CS+ compared to the CS- in the absence of the demonstrator indexed observational fear learning. Each participant completed this paradigm under two different hypnotic suggestions, which were administered before each learning stage to induce high or low affect sharing with the demonstrator, following a counterbalanced within-subject design. Each suggestion was revoked (so-called "cancellation") after the learning stage to bring the participants back to their habitual level of affect sharing before the start of the test stage. In the

learning stage, high affect sharing resulted in stronger unconditioned skin conductance responses, increased eye gaze toward the demonstrator's face, and higher self-reported unpleasantness while witnessing the demonstrator's distress. In the test stage, participants showed a stronger conditioned fear response (SCR) when they had learned under high, compared to low, affect sharing. These findings demonstrate that affect sharing is causally involved in driving observational fear learning, and thus advance our understanding of the role of empathy in social learning.

Title: More Than Reduplication: Dissociable Electrophysiological markers of First and Higher Order Conditioning

Authors: ***P. DHAMIJA**[1,2], A. WONG[1,2], A. GILBOA[1,2];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Res., Rotman Reserarch Inst. Baycrest, Toronto, ON, Canada

Abstract: Background: Compared to the vast literature exploring the neurobiology of first order conditioning (FOC), relatively little attention is devoted to high order conditioning (HOC), partly because of the misconception that both rely on equivalent stimulus-stimulus associative neural mechanisms. Recent rodent research has demonstrated dissociable FOC and HOC neural substrates, with the hippocampus being required for HOC associations formation and maintenance. In this study, we aimed to determine if this held true for humans with two predictions: (1) The electrophysiological responses of FOC and HOC are spatially and temporally distinct and (2) The hippocampus is involved in higher order associations. Methods: Middle aged adults (40 - 65 years, n = 14) underwent aversive auditory FOC using an aversive burst of white noise as the unconditioned stimuli (US+/US-) and subsequent HOC. Four initially neutral tones were used for FOC (CS+/CS-) and subsequent HOC (HO+/HO-) stimuli. Behavioural and neural responses were indexed by pupil dilation and electroencephalogram responses respectively.Results: Pupillometry demonstrated robust acquisition of FOC and HOC as demonstrated by enlarged pupil size to CS+/HO+ compared to CS-/HO-. Interestingly, while responses to CS+ were extinguished during testing, HO+ responses were maintained suggesting post-learning independence. Evoked response potentials for both CS and HO tones revealed typical cortical auditory components including a clear P1, N2 and P3 at roughly 50 ms, 150 ms, and 250 ms respectively. When comparing CS+ and CS- stimuli, there was a significantly greater

P3b peaking bilaterally over frontoparietal electrodes in response to CS+ tones. By contrast, HO+ was significantly larger as early as the N2 component over central-parietal electrodes as well as greater modulation of P3 over occipitoparietal and N3 over frontal electrodes,. Using source estimation algorithms, medial prefrontal and insula were identified as the source for the significant P3b component in response to CS+, whereas the hippocampus was identified as a major source of neuronal activity for the significant N2 component in response to SO+. Discussion: This experiment demonstrates that first order and higher order conditioning associations have both dissociable patterns of electrophysiological response and sources of activity. Furthermore, it suggests that HOC does not rely on stimulus-stimulus associative neural mechanisms and might instead rely on higher order hippocampally supported associative neural mechanisms potentially involving stimulus-value expectation associations.

Title: The Relationship between Individual Variation in Fear Extinction and Activation of Infralimbic Cortex Afferents

Authors: *A. S. RUSSO, K. COLE, R. G. PARSONS;
Stony Brook Univ., Stony Brook, NY

Abstract: Pavlovian fear conditioning occurs when an individual learns to associate an aversive, unconditioned stimulus (US) with a neutral, conditioned stimulus (CS) such that the individual expresses a conditioned fear response (CR) when presented with the CS alone. Extinction is the diminished expression of the CR in response to the CS as a result of multiple presentations of the CS alone. Because it is known that patients diagnosed with posttraumatic stress disorder (PTSD) display poor ability to extinguish conditioned fear, it is of interest to understand which brain circuits are activated during successful extinction, and what goes wrong when extinction is not successful. Previous work has implicated activation of the infralimbic cortex (IL) as important during extinction, yet knowledge about the activity of this brain area in subpopulations of subjects that vary in their ability to extinguish fear responses is lacking. Results from earlier work have shown that there is elevated activation of mitogen-activated protein kinase (MAPK), a protein important for fear and extinction learning, in the IL of rats which display good extinction compared to rats which display poor extinction. However, the cause of IL-hypoactivation in poor-extinguishers remains elusive. It is possible that deficient activation of cells which send projections to the IL is responsible for the lack of IL activity seen in poor-extinguishing

individuals. Using a projection-targeted activity mapping approach, we assessed activation of cells in a range of brain areas which send projections to the IL in rats which display good and poor extinction recall following an extinction recall session and control rats which had either been exposed to a fear recall session or remained in their home cages. AAV-CAG-GFP (Addgene) works as an effective retrograde tracer, producing robust and consistent labeling in areas such as the ventral hippocampus (vHPC), basolateral amygdala (BLA), paraventricular thalamus (PVT), claustrum (CLA), and prelimbic cortex (PL) after being infused in the IL. Furthermore, preliminary results suggest that rats which undergo extinction recall show more activation of cells in the vHPC and PVT compared to control groups. Further analysis will determine whether rats displaying individual differences in extinction recall differ in activation of IL-projecting cells from the aforementioned brain areas. Ultimately, completion of this project may implicate areas which could be targeted for pharmacological treatment of PTSD and help us understand what makes some individuals particularly susceptible to PTSD.

Abstract: Drug abuse is one of the foremost public health problems of our time. Cocaine is a widely abused drug worldwide, and produces a variety of behaviors, including psychomotor stimulation, reward, craving, and relapse. The mechanisms that underlie cocaine-induced disorders are unresolved and effective treatments are lacking. Here we report the discovery that an autophagy-related protein Becn2 is a novel regulator of cocaine reward behaviors. Global or dopamine (DA) neuron-specific mutations in Becn2 protect mice from cocaine-stimulated locomotion and reward behaviors, as well as cocaine-induced DA accumulation and signaling, due to an increase in presynaptic dopamine receptor 2 (D2R) in DA neurons, an autoreceptor that inhibits DA release. DA neuron-specific re-expression of wild-type Becn2, or D2R antagonism,

in the global Becn2 mutant mice rescues their cocaine-induced behaviors. We further found that Becn2 regulates D2R trafficking, degradation, and cocaine-induced behaviors via interacting with a D2R-bound adaptor protein GASP1. In addition, we found that inactivating Becn2 by upstream autophagy inhibitors stabilizes striatal presynaptic D2R, reduces DA release, and prevents the physiological and behavioral responsiveness to cocaine in normal mice. Thus, we demonstrate that the autophagy protein Becn2 is essential for cocaine psychomotor stimulation and reward through the regulation of DA signaling, and targeting Becn2 by upstream autophagy inhibitors is a potential strategy for preventing cocaine-induced behaviors.

Title: A Role for VTA glutamate and GABA co-releasing neurons in consummatory reward

Authors: *D. MCGOVERN[1], E. PREVOST[1], A. PHILLIPS[2], D. H. ROOT[1];
[1]Psychology and Neurosci., Univ. of Colorado Boulder, Boulder, CO; [2]Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Within the last 10 years a unique population of neurons that express the cellular machinery to vesicularly package and release both glutamate and GABA has been identified within the brain's reward center, the ventral tegmental area (VTA). The contribution of these co-releasing neurons to motivated behavior is unclear. These experiments utilized a genetically modified mouse line that expresses **cre** recombinase in neurons with the vesicular glutamate transporter (VGLUT2) and **flp** recombinase in neurons with the vesicular GABA transporter (VGaT). Infusing intersectional viral constructs to record and manipulate **cre and flp** positive neurons allowed for selective monitoring and perturbation of exclusively glutamate and GABA co-releasing neurons within the VTA. Population level changes in intracellular calcium were recorded using a **cre and flp** dependent GCamP6m and fiber photometry to determine the neuronal response to reward by glutamate/GABA co-expressing neurons. Neuronal activity was measured from these neurons when mice consumed various rewarding solutions (fat, sucrose, and saccharine).
Results indicate that although mice display a distinct behavioral preference for fat, neuronal activity is greater for sweeter solutions (sucrose and saccharin) and neuronal activity was blunted by prior feeding. To determine the role of this activity in reward, we injected either a **cre and flp**

dependent inhibitory opsin (iC++) or excitatory channelrhodopsin2 in the VTA to optogenetically silence or excite glutamate/GABA co-expressing neurons during reward consumption. Glutamate/GABA silencing reduced consumption for certain solutions. Optogenetic activation of these neurons selectively increased preference for sweet solutions. Together, these results suggest that VTA glutamate/GABA neurons significantly impact consummatory reward behavior.

Title: The medial orbitofrontal cortex controls value-based action through neurotrophin systems and interactions with the ventral hippocampus

Authors: *E. P. WOON, S. L. GOURLEY;
Pediatrics, Neurosci. Program, Emory Univ., Atlanta, GA

Abstract: Value-based decision making, referring to selecting actions based on the value of prospective outcomes, relies on the medial orbitofrontal cortex (MO), yet molecular mechanisms are unclear. One candidate is the Brain-derived Neurotrophic Factor receptor, tyrosine/tropomyosin receptor kinase B (TrkB). Here, we trained mice to respond for 2 distinct food outcomes. We next reduced the value of one outcome using conditioned taste aversion (CTA), then characterized decision-making strategies. We administered a TrkB antagonist during new memory encoding (during the CTA procedure) or during a period of memory retrieval (the choice test). Inhibiting TrkB during the encoding, but not retrieval, of new memories regarding food value impaired the ability of mice to preferentially respond for high-value foods. Overexpression of an inactive isoform of TrkB, *Trkb.t1*, selectively in the MO had the same consequences, particularly when outcomes were unobservable and had to be envisioned. What inputs to the MO might be needed for value memory encoding? We found that ventral hippocampal (vHC)→MO projections are necessary for value memory encoding, serving to transfer value information across contexts (*i.e.*, from the CTA context to the testing context). Overall, these patterns suggest that neurotrophin activity in the MO is necessary for value-based action, as are inputs from the vHC to the MO. Future experiments will determine whether functional vHC MO interactions require TrkB presence.

Title: Mitochondria-related nuclear gene expression in reward-related brain regions and blood mitochondrial copy number after high fat diet in male and female C57BL/6 mice

Authors: *C. A. CALARCO[1], S. M. KEPPETIPOLA[1], M. LOBO[2];
[2]Anat. and Neurobio., [1]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Rates of obesity have been steadily on the rise nationally, garnering public health concern. Both diet composition and overall weight impact many aspects of reward related behavior, and obesity is frequently comorbid with both altered reward processing and depression. Diet-induced obesity is associated with several cellular and molecular changes, including altered cellular metabolism and mitochondrial function, impacting neuronal and circuit function. Mitochondrial function in the context of diet-induced obesity has been extensively studied in muscle tissue, pancreas, and other body systems, but less work has been done characterizing the impact of high fat diet (HFD) on mitochondria in the brain, specifically in reward-related brain regions. Mitochondrial function has been shown to play an important role in both cellular activity and structural plasticity. Further, altered mitochondrial function can be sufficient to alter behavior. Here we examine how varying lengths of HFD exposure impact mitochondria-related nuclear gene expression in both male and female C57BL/6 mice and how peripheral changes in blood mitochondria correlate with brain-region-specific gene expression.
Male and female mice were group housed and exposed to HFD (45% calories from fat) or standard lab chow for 24hr, 1wk, 1mo or 3mo. Body weight and food intake were measured, and both brain tissue punches and trunk blood were collected on the final day of exposure. We used quantitative real time PCR (qPCR) to investigate the expression of several nuclear genes involved in mitochondrial function in the nucleus accumbens, dorsal striatum, lateral hypothalamus, and ventral tegmental area. HFD increased body weight in male and female mice at the 24hr and 3mo time points. Weight was also significantly increased in male mice at 1mo. Altered gene expression was observed for all the genes examined, although the patterns of increased or decreased gene expression at different time points in different brain regions were unique between sexes. Interestingly, in both sexes, more genes were significantly altered at the earlier time points (24hr and 1wk) than the later time points (1mo, 3mo), indicating rapid changes that normalize over time. DNA was extracted from whole blood and the relative expression of mitochondrial to nuclear DNA, measured via qPCR, was used as a proxy for mitochondrial copy number. These findings represent an initial probe into mitochondrial molecular mediators in reward-related brain regions after HFD and further studies are needed to

probe how these changes in gene expression correspond to behavioral and cellular changes associated with HFD.

Title: Rhoa overexpression in nucleus accumbens d1-msns lowers motivation for sucrose in male mice and enhances sucrose seeking in female mice.

Authors: *S. L. COLE, M. E. FOX, R. CHANDRA, M. K. LOBO;
Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: RhoA is a GTPase involved in the regulation cytoskeletal, neuronal morphology, and dendritic arborization. Previous research from our lab has demonstrated that enhanced RhoA in nucleus accumbens D1-dopamine receptor expressing medium spiny neurons (D1-MSNs) leads to enhanced dendritic atrophy in promotes depressive-like behaviors. However, whether RhoA impairs or enhances natural reward seeking behavior has been left unexplored. Here, we infused male and female C57BL/6J mice with a retrograde virus expressing Cre recombinase into the ventral tegmental area (VTA) and a Cre-dependent viral vector in NAc to overexpress RhoA or control EYFP in NAc D1-MSNs, and examined whether RhoA regulation impacts operant responding for sucrose pellets. To parse whether enhanced RhoA expression NAc-VTA projecting MSNs/D1-MSNs affects reward learning or motivation, we utilized multiple schedules of reinforcement in both food restricted and *ad lib* fed conditions. Mice were able to choose between 1) a nose poke port producing a light cue or 2) a second nose poke port producing a light cue and sucrose delivery into a food cup. In food restricted conditions (up to 85% of baseline bodyweight), RhoA overexpression produced no alterations in acquisition of sucrose operant behavior and consumption at either FR1 or FR3 schedules of reinforcement , progressive ratio responding or in seeking for sucrose pellets under extinction conditions. However, in *ad lib* fed mice, trending results suggest that at an FR3 schedule of reinforcement, males with enhanced RhoA show lower responding relative to EYFP controls and females with enhanced RhoA show a slight enhancement in responding. Interestingly, RhoA overexpression decreased operant responding during progressive ratio testing in males, but not females. Finally, in seeking tests, where operant responding produces light cues but no sucrose delivery, RhoA overexpression decreased persistent seeking for sucrose reward in males. Conversely, female mice with RhoA overexpression in D1-MSNs showed an enhancement in responding vs female EYFP controls. Thus, enhanced motivation for sucrose in a food restricted state prevents

behavioral effects of enhanced RhoA. Collectively, these preliminary data suggest that RhoA plays a role in motivation for sucrose reward in a sex-dependent manner.

Title: Differences Between Adolescent and Young Adult Rats In Development Of Habitual Control Over Behavior And Immediate Early Gene Expression In Dorsal Striatum

Authors: G. HAWS[1], C. RICE[1], J. AGUILAR[2], T. MOORE[2], ***K. A. KEEFE**[1];
[1]Col. of Pharm., Univ. of Utah, Salt Lake City, UT; [2]Juan Diego Catholic High Sch., Draper, UT

Abstract: Addiction is thought to reflect habitual control over drug-related behaviors driven by neuroplastic changes in dorsolateral striatum (DLS). Earlier age of initial drug use correlates with propensity for addiction, suggesting that plastic processes in DLS may differ as a function of age. We examined development of habitual control over appetitive instrumental behavior in adolescent vs. young adult rats and, also, expression of *Arc* and *zif268* in DLS and dorsomedial striatum (DMS). Adolescent (post-natal day (PND) 28; n=8) and young adult (~PND105; n=8), male Long-Evans rats were trained to lever press for food reward on random-interval schedules of reinforcement. Upon completion of training, they were tested for goal-directed vs. habitual control over the instrumental behavior using a sensory-specific devaluation procedure. Rats were then sacrificed immediately after extinction testing under devalued conditions, and the brains processed for *Arc* and *Zif268* mRNA expression via RNAScope. Imaging and data analysis were conducted with the experimenters blinded to the treatment group of the animals. All rats acquired lever press responding over the days of training ($p=0.0005$), with PND105 rats pressing more across days of training than PND28 rats ($p=0.05$). Similarly, both ages showed decreased behavior under the devalued test condition ($p=0.01$). PND28 rats pressed significantly more under both valued and devalued conditions than did PND105 rats ($p<0.04$). The ratio of responding under the devalued condition to that under the valued condition, also was significantly higher in PND28 (0.9 ± 0.3) vs. PND105 rats (0.3 ± 0.1; $p<0.03$). There were no differences between the two ages in the number of cells expressing *zif268* mRNA expression in DMS ($p=0.4$) or DLS ($p=0.1$). However, there were significantly greater numbers of *Arc* mRNA-positive cells in DLS ($p<0.04$) and DMS ($p<0.005$) of PND28 vs. PND105 rats ($p<0.04$). Further, the number of cells with *Arc* mRNA expression in DLS was significantly correlated with lever pressing under the devalued condition immediately prior to sacrifice ($r^2=0.33$,

p<0.02), whereas the number of *Arc*-positive cells in DMS (p=0.2) and the number of *Zif268*-positive cells in DMS (p=0.7) and DLS (p=0.7) were not. These data suggest that adolescent rats transition to habitual control over instrumental behavior more readily than do young adult rats. Further, given that correlations between *Arc*mRNA expression in a brain region and behavioral performance reflect task-relevant encoding processes occurring in that brain region, the data suggest that *Arc*-mediated plasticity may contribute to formation of habitual control over behavior.

Title: Fentanyl induces divergent behavioral effects in female and male rats but reduces inflammatory markers uniformly

Authors: S. KALLAKURI[1], A. GAULDEN[2], N. BURSON[1], N. SADIK[1], I. GHOSH[1], S. KHAN[1], S. BRUMMELTE[1], *S. A. PERRINE[1];
[1]Wayne State Univ. Sch. of Med., Detroit, MI; [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: The synthetic opioid fentanyl has received considerable public attention due to its role in the opioid epidemic and overdose deaths; however, the effects of fentanyl on addiction-related behaviors is not well understood, particularly between sexes. Furthermore, many naturally occurring and semi-synthetic opioids have been shown to possess pro-inflammatory effects which are thought to contribute to the rewarding effects of opioids, but the inflammatory effects of fentanyl are unknown. Thus, the purpose of this study is to assess the sex effects and inflammatory changes following fentanyl administration in male and female rats. Adult female and male Sprague-Dawley rats were subjected to acute or repeated fentanyl hydrochloride administration. Locomotor activity (LMA) and behavioral sensitization in an open field (OF) paradigm and contextual-reward behavior in a conditioned place preference (CPP) paradigm were assessed. In the OF paradigm, animals were given a single (acute) or repeated (once daily for 8 days) fentanyl (20 µg/kg; subcutaneous) injections. On days 1 and 8 of the experiment, LMA in the OF field arena was measured. Brain regions encompassing the mesolimbic circuit were probed for the inflammatory marker (interleukin 6, IL-6) analysis by western blot. In the CPP paradigm, animals were subjected to either 4 or 16 µg/kg fentanyl injections to assess context-associated reward. In the OF paradigm, females, but not males, showed elevated LMA in response to acute and repeated fentanyl exposure (20 µg /kg). In contrast, males showed greater behavioral sensitization only after one week of daily fentanyl administration. Furthermore,

fentanyl administration was shown to lead to decreased inflammatory cytokine (IL-6) levels in regions of the mesolimbic circuit (prefrontal cortex, infralimbic cortex, and nucleus accumbens) in both sexes. In the CPP paradigm, both sexes preferred the contextual cues associated with fentanyl; however, females preferred the 16 μg /kg fentanyl dose, while males preferred both 4 and 16 μg /kg doses. Our results suggest that males and females exhibit divergent behaviors to fentanyl. Females were more acutely responsive albeit lacking a robust behavioral sensitization to daily or alternating fentanyl administration. Males showed more contextual preference than females for a low dose of fentanyl in the CPP paradigm. The uniform decrease in inflammatory load across sexes suggests that the locomotor activating and contextual-rewarding of fentanyl are not dependent on IL-6 based inflammatory response.

Title: Role of vasopressin signaling in the ventral pallidum in the sex-specific regulation of social play behavior in juvenile male and female rats

Authors: *J. D. A. LEE, C. J. REPPUCCI, S. M. BOWDEN, E. D. M. HUEZ, R. BREDEWOLD, A. H. VEENEMA;
Michigan State Univ., East Lansing, MI

Abstract: Social play is predominantly displayed by juveniles of many mammalian species, including rats and humans, and engagement in social play helps develop social competence throughout life. Children diagnosed with autism spectrum disorder, a sex-biased neurodevelopmental disorder, show decreased involvement in social play, thus emphasizing the need to better understand the neural mechanisms underlying social play in both sexes. We recently showed that vasopressin (AVP) acting in the lateral septum (LS) regulates social play behavior in juvenile rats and that AVP acting in the ventral pallidum (VP) regulates sociosexual motivation in adult rats, with AVP modulating both behaviors in a sex-specific manner. However, whether AVP signaling in the VP has a role in the sex-specific regulation of juvenile social behaviors, like social play, is unknown. Here, we hypothesized that, similar to the LS, AVP in the VP regulates social play in a sex-specific manner. First, in order to examine the organization of the AVP system in the VP in juvenile rats, we examined AVP-immunoreactive (-ir) fiber density and AVP 1a receptor (V1aR) binding density across the anterior to posterior extent of the VP. We found a robust sex difference in AVP-ir fiber and V1aR binding density in

the VP, with denser AVP-ir fibers and denser V1aR binding in juvenile males compared to females. Next, we wanted to determine the effects of pharmacological manipulation of AVP signaling in the VP on social play behavior. Using a specific V1aR antagonist, we found that V1aR blockade in the VP increased social play duration in juvenile male rats but decreased social play duration in juvenile female rats compared to subjects of the same sex who received vehicle infusions. The opposite effect was found when administering synthetic AVP into the VP, with decreased social play duration in juvenile males and increased social play duration in juvenile females compared to subjects of the same sex who received vehicle infusions. These findings demonstrate that, similar to the LS, AVP signaling in the VP inhibits social play in males while it facilitates social play in females. Finally, to start addressing the underlying sex-specific mechanisms, we are currently determining whether social play exposure alters the activation of V1aR-expressing VP neurons in sex-specific ways. Together, these findings start to elucidate the involvement of AVP signaling across a network of brain regions in the sex-specific regulation of social play behavior in juvenile rats.

Title: Establishing the link between spontaneous eye blink rate and striatal dopamine synthesis capacity

Authors: R. VAN DEN BOSCH[1], J. MAATTA[1], L. BARREIRO FERNANDEZ[2], L. HOFMANS[1], D. PAPADOPETRAKI[1], ***R. COOLS**[1];
[1]Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [2]Centralised and Point of Care Solutions, Roche Intl. Diagnostics Intl., Rotkreuz, Switzerland

Abstract: Spontaneous eye blink rate (sEBR) has been described in the literature as an index of dopamine transmission in the striatum (Jongkees et al 2016). Work with nonhuman primates has shown that sEBR predicts dopamine levels (Taylor et al., 1999) and dopamine D2 receptor availability (Groman et al., 2014) and work with human volunteers has demonstrated a link with (dopamine drug effects on) reinforcement learning (Slagter et al., 2015). However, there is no direct evidence for a link between dopamine levels and spontaneous EBR in humans. One aim of the present large pharmacological PET study with 100 young healthy volunteers was to establish this link. Specifically, we investigated whether individual differences in sEBR, quantified using electrooculography at rest, can be predicted from striatal dopamine synthesis capacity, measured with [^{18}F]-FDOPA PET. Preliminary analyses suggest a positive association between sEBR

(blinks per minute) and individual variation in ventral striatal dopamine synthesis capacity (see Figure), but additional analyses are required to substantiate this observation. We will additionally explore whether sEBR also predicts individual differences in common dopamine drug effects on reinforcement learning task and associated neural signals in frontostriatal circuitry, measured on separate sessions in the context of this same study. *References:* Groman at al. Title: Striatal dopamine synthesis capacity predicts methylphenidate effect on striatal and prefrontal reward and punishment learning

Authors: *R. VAN DEN BOSCH[1], B. LAMBREGTS[1], J. MÄÄTTÄ[1], L. HOFMANS[1], D. PAPADOPETRAKI[1], A. WESTBROOK[2], R.-J. VERKES[1], J. BOOIJ[3], R. COOLS[1]; [1]Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [2]Brown Univ., Providence, RI; [3]Amsterdam Univ. Med. Ctr., Amsterdam, Netherlands

Abstract: The psychostimulant methylphenidate is widely used by both patients and healthy people for its enhancing effects on a range of cognitive functions. However, the neural locus of its actions on cognition remains unclear. The effects may reflect direct action on dopamine and noradrenaline transmission in the prefrontal cortex, or modulation of dopamine in the striatum. We tested the hypothesis that methylphenidate acts on the striatum to influence the gating of prefrontal cortical representations in proportion to their association with reward vs punishment. We used fMRI to assess the neural locus of methylphenidate's effects on a reversal-learning task, as a function of variation in striatal dopamine synthesis capacity, measured with [18F]DOPA PET, across 88 healthy participants. Participants predicted whether a stimulus was associated with a reward or punishment outcome, and updated predictions when an unexpected reward/punishment outcome signaled a reversal of contingencies. Outcomes were not contingent on the response, but only signaled the currently relevant stimulus-outcome mapping. We compared methylphenidate's effects with those of the selective dopamine D2/3-receptor antagonist sulpiride to address neurochemical selectivity to dopamine.
Both methylphenidate and sulpiride boosted reward vs punishment-based reversal accuracy to a greater degree in participants with higher striatal dopamine synthesis capacity. Consistent with this behavioral effect, the higher synthesis participants showed greater methylphenidate-induced increases in lateral orbitofrontal BOLD signal, specifically to unexpected rewards vs punishments. Trial-level orbitofrontal BOLD estimates predicted the striatal dopamine-dependent effect of methylphenidate on reversal accuracy. Methylphenidate also increased valence-nonspecific prediction error signals in the striatum and stimulus-specific visual association cortex, but this effect was greater in participants with lower dopamine synthesis. These results reveal a double dissociation: methylphenidate boosted reward vs punishment prediction learning (signals) while attenuating valence-nonspecific striatal prediction error signals to a greater degree in higher-dopamine participants. We hypothesize that these orbitofrontal and striatal effects reflect modulation of a model-based, task-appropriate outcome prediction strategy and a model-free, task-inappropriate winstay-loseshift strategy, respectively. These results concur with the working hypothesis that drugs like methylphenidate counteract biased competition between distinct frontal and striatal learning strategies.

Title: Input specific enhancements in excitatory transmission in the nucleus accumbens core following junk-food diet consumption

Authors: T. L. FETTERLY[1], C. R. FERRARIO[1,2];
[1]Dept. of Pharmacol., [2]Psychology Dept., Univ. of Michigan, Ann Arbor, MI

Abstract: Alterations in brain reward circuits, including the Nucleus Accumbens (NAc), contribute to over-eating and craving that drives the development and persistence of obesity in humans. In rats, cue-triggered food-seeking is enhanced in obesity-prone rats and this behavior is mediated by calcium-permeable AMPA receptors (CP-AMPARs) in the NAc. AMPA-type glutamate receptors provide the main source of excitation to the NAc, a small portion of which are CP-AMPARs under basal conditions. Interestingly, when placed on a sugary, fatty junk-food diet, a rapid and persistent increase in both NAc CP-AMPAR synaptic transmission and surface expression is observed in male obesity-prone, but not obesity-resistant rats. While increases in CP-AMPAR surface expression are observed following consumption of the junk-food diet, increases in synaptic transmission only emerge following a 24-hour deprivation period in which junk-food is removed and replaced with standard chow. While this demonstrates junk-food induced enhancement in glutamatergic transmission in the NAc, it does not provide any information about the specific inputs affected. The NAc receives glutamatergic input from a wide variety of brain regions, including direct connections from the medial prefrontal cortex (mPFC) and basolateral amygdala (BLA). Whether junk-food induced increases in CP-AMPAR transmission are input specific is unknown. To differentiate these inputs, we used whole-cell patch clamp recordings in combination with a viral optogenetic strategy to selectively record responses in either mPFC-to-NAc or BLA-to-NAc inputs. Following stereotaxic injection of pAAV-CamKII-Chronos-GFP into either the mPFC or BLA, we prepare ex vivo brain slices containing the NAc and then record optically-evoked AMPAR currents in medium spiny neurons using whole-cell patch-clamp electrophysiology. The contribution of CP-AMPARs to overall AMPAR transmission was determined using naspm (200 μM), a CP-AMPAR selective antagonist. We found that eating junk-food (10 days) enhanced CP-AMPAR transmission in mPFC-to-NAc inputs, whereas preliminary results in BLA-to-NAc inputs show no change in CP-AMPARs. Thus, initial results suggest that junk-food induced enhancements in CP-AMPARs occur preferentially at mPFC inputs. Therefore, junk-food consumption may alter mPFC function, but not BLA function, in a manner that may promote CP-AMPAR insertion. Others have shown alterations in the mPFC following high-fat diet consumption, including both changes

in perineuronal nets and spine density, suggesting that changes in NAc transmission may be downstream of these effects.

Abstract: The flashing lights and sounds of modern casinos are alluring and may contribute to theaddictive nature of gambling. Such cues can profoundly influence the noradrenaline (NA)system, suggesting a viable therapeutic target for gambling disorder (GD). While there issubstantial evidence to support the involvement of NA in the impulsive symptoms of GD, itsfunction in mediating the “pro-addictive” impact of cues is less understood. We wished toinvestigate the role of NA in our rodent assay of risky decision making and impulsivity, the cuedrat gambling task (crGT). Given the pronounced sex differences in addiction disorders and themonoaminergic regulation of behaviour, we also prioritised evaluating noradrenergic drugs inboth sexes. Female and male rats were trained to stability on the crGT and then givenintraperitoneal injections of the noradrenaline reuptake inhibitor atomoxetine, the α2A receptoragonist guanfacine, the beta receptor antagonist propranolol, and the α2 receptor antagonistyohimbine. Atomoxetine dose-dependently improved decision making score irrespective of sexor risk-preference. Guanfacine selectively enhanced decision making in risk-preferring malesand optimal-performing females. Propranolol and yohimbine had no effect on decision making.Atomoxetine and guanfacine reduced premature responses, while yohimbine bi-phasicallyaffected this index of motor impulsivity. These results support the hypothesis that NA is animportant neuromodulator of the cue-induced deficits in decision making observed in laboratory-based gambling paradigms, and suggest that NAergic drugs like atomoxetine and guanfacinemay be useful in treating GD.

Title: Effects of Junk-Food Diet on NAc Glutamatergic Transmission and Intrinsic Excitability in Feamles

Authors: *A. M. NIETO[1], A. M. FRANCE[1], H. PAPACOSTAS QUINTANILLA[1], Y. ALONSO-CARABALLO[3], C. R. FERRARIO[1,2];
[1]Dept. of Pharmacol., [2]Psychology Dept., Univ. of Michigan, Ann Arbor, MI; [3]McLean Hosp., Harvard Med. Sch., Bellmont, MA

Abstract: The nucleus accumbens (NAc) plays critical roles in motivated behaviors, including food-seeking in response to Pavlovian cues. Eating diets high in fats and sugars (i.e., junk-food) produces alterations in NAc function in males and enhances cue-triggered approach. However, few studies have examined the effects of junk-foods on NAc function in females. Activity of medium spiny neurons (MSN), the major output neurons of the NAc, is influenced by excitatory glutamatergic transmission and by intrinsic properties of MSNs that govern their firing. The goal of the studies presented here was to examine the effects of junk-food on NAc excitatory transmission and MSN intrinsic excitability in females. Obesity-prone female rats were given a junk-food diet (10 days) followed by a return to ad lib standard chow for either 24-72 hours (short junk food deprivation) or 14-16 days (long junk-food deprivation) to examine persistence of effects. Controls remained on standard chow throughout. Whole-cell patch clamp recordings from ex vivo brain slices were used to measure effects of junk-food on intrinsic excitability and AMPA receptor-mediated transmission. The estrus cycle was monitored throughout and slices were prepared when females were in the metestrus/diestrus phase of the cycle because this is when food intake and cue-triggered motivation for food are highest. Junk-food consumption followed by a short deprivation period did not alter MSN intrinsic excitability compared to chow fed rats. However, this did increase the amplitude of spontaneous excitatory post-synaptic current (sEPSC) in these same cells. In addition, preliminary data suggest that this effect is not found after long junk-food deprivation. These effects are in striking contrast to effects in males given the same junk-food diet exposure, where junk-food reduces MSN excitability, and increases AMPAR transmission, with both effects persisting throughout prolonged junk-food deprivation. Thus, females appear to be protected from the long-lasting effects of junk-food consumption compared to males. Future studies will investigate the effect of junk-food on D1- and D2-type MSNs as well as how sex hormones may influence the effects of junk-food on NAc plasticity in females.

Title: Effects of intra-NAc insulin on motivation for food

Authors: *J. E. FINNELL[1], C. R. FERRARIO[1,2];
[1]Pharmacol., [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Insulin receptors are expressed throughout the adult brain, and insulin from the periphery has widespread distribution in the central nervous system. In humans and rodents, actions of insulin in the brain decrease food intake. In addition to these behavioral effects, recent studies have shown that insulin can affect dopamine and glutamate transmission within the nucleus acumbens (NAc). The NAc plays critical roles in food-seeking and feeding, behaviors that are mediated by both dopamine and glutamate. However, the effect of insulin on cue-triggered food-seeking (i.e., "craving" that drives the development of obesity) or motivation for food mediated by the NAc were unknown. Therefore, the current study examined the effects of intra-NAc insulin on motivation for food and cue-triggered food-seeking in adult male Sprague Dawley rats by assessing break point using a progressive ratio schedule and Pavlovian conditioned approach, respectively. Direct infusion of 60 uM insulin (0.5 uL/min) into the NAc did not affect conditioned approach behavior compared to vehicle infusion (ACSF). In contrast, intra-NAc insulin significantly reduced break point compared to vehicle infusion. In addition, home cage food intake was measured for 1 hour following testing for cue-induced food seeking and break point. On both testing days, insulin reduced home cage food intake, suggesting that the absence of effects on conditioned approach are not due to ineffective infusion in these rats. Taken together, these data show that insulin within the NAc does not alter the incentive-motivational properties of a food cue, but instead reduces the motivation to obtain food and food intake. This indicates a dissociation between the regulation of the motivation to consume food vs food seeking by insulin. This not only has implications for the regulation of food-seeking and eating, but may also be important in the dysregulation of feeding that accompanies obesity. Finally, ongoing studies to determine the role of insulin receptors and insulin like growth factor receptors (which can also be activated by insulin) will shed light on the specific mechanisms mediating these effects of intra-NAc insulin on motivation for food.

Title: Striatal dopamine mediates relative contributions of reinforcement learning and working memory during task learning

Authors: *A. WESTBROOK[1,2], R. VAN DEN BOSCH[2], J. MÄÄTTÄ[2], D. PAPADOPETRAKI[2], L. HOFMANS[2], R.-J. VERKES[3], M. FRANK[1,4], R. COOLS[2,3];
[1]Brown Univ., Providence, RI; [2]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands; [3]Psychiatry, Radboud Univ. Med. Ctr., Nijmegen, Netherlands; [4]Carney Inst. for Brain Sci., Providence, RI

Abstract: Learning a new task involves slow, incremental reinforcement learning and fast, flexible, albeit capacity-limited working memory. In simpler learning tasks, working memory plays a bigger role: maintaining recent information and supporting predictions. In more complex tasks - especially those exceeding working memory capacity - people rely relatively more on reinforcement learning. Striatal dopamine has been implicated in both working memory and reinforcement learning processes, raising the prospect that striatal dopamine might mediate the relative contributions of each to task learning.
To test this hypothesis, 100 healthy young adult humans were recruited to perform the Reinforcement Learning Working Memory task (RLWM; Collins and Frank, 2012 Eur J Neurosci; 2018 PNAS), after taking either the dopamine reuptake inhibitor methylphenidate, the D2-antagonist sulpiride, or placebo. We further used [18F]-fluorodopa PET imaging to quantify participants' dopamine synthesis capacity. As expected, we find that participants relied relatively more on reinforcement learning for more demanding task levels, and relatively more on working memory on less demanding levels.
We also find that striatal dopamine influenced both the efficacy and relative contributions of these learning mechanisms. Specifically, both higher dopamine synthesis capacity, and methylphenidate versus placebo sped learning, while sulpiride slowed learning. The specific pattern of correct and incorrect responses suggests that these effects reflect modulation of distinct strategies. Methylphenidate boosted the efficacy of reinforcement learning, while sulpiride attenuated the efficacy of working memory Furthermore, individuals with higher dopamine synthesis capacity had more stable working memory contents over time and relied on working memory to a greater extent, while relying less on reinforcement learning. In addition, we found that while participants treated more demanding task levels as more effort-costly, methylphenidate blunted this effect, consistent with our prior work showing that methylphenidate can boost cognitive motivation by making people less sensitive to effort costs.

These findings demonstrate that striatal dopamine alters the relative reliance on working memory or reinforcement learning for task learning. Future pharmacological-imaging work is required to isolate the neural locus of the dissociable effects of dopamine synthesis capacity, methylphenidate, and sulpiride.

Title: Investigating the effects of ropinirole on risk preference in female rats

Authors: *H. BRODIE, B. RUSSELL, C. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Ropinirole is a D2/3 receptor agonist drug commonly prescribed to Parkinson's disease (PD) patients to alleviate motor symptoms. However, a significant minority of patients who take this drug go on to develop gambling disorder or other impulse control disorders (ICDs). Previous research using rodent models of gambling has indicated that chronic ropinirole treatment increases risky decision making and risk preference regardless of baseline preference for risk. This research has largely been focused on males, as the incidence of PD and ICDs are higher in males. The effects of chronic ropinirole administration on risky decision making in females has yet to be established. Accordingly, the object of the present experiment was to determine whether chronic ropinirole administration increases risk preference in female rats during acquisition of the rat gambling task (rGT). A cohort of 48 female Long-Evans rats (4 months old) were trained on the cued version of the rGT which is a rodent adaptation of the Iowa Gambling task commonly used in humans. In both tasks, optimal behaviour is achieved by preferentially selecting the two low-risk, low-reward options over the high risk, high reward options. In the rGT, selection of the low-risk, low-reward options results in fewer time-out penalties and more sugar-pellet rewards earned overall. The presence of reward-paired audiovisual cues in the cued version of the task reliably increases the number of risk-preferring rats. Ropinirole was delivered via osmotic mini pump at 0(saline), 2.5 or 5mg/kg per day (n=16 per group). Mini pumps were surgically implanted prior to training on the rGT and allowed for slow, continuous release of drug over a period of 28 days. Following two weeks of drug administration, results do not show the expected increase in risky decision making previously observed in male rats. Results from this experiment offer further insight into the role of

dopaminergic transmission in decision making involving risk and uncertainty and provide evidence for potential sex differences in the effects of ropinirole on risky decision making.

Abstract: Title: Childhood Adversity Diminishes Confidence in Value-Based Decisions
Authors: TS Mullins, DF Aragon, J Romero, K Rogge-Obando, E Eversole, VD Costa, & J Hogeveen
Abstract: Human development benefits from a highly stable reinforcement environment. Individuals exposed to a significant number of adverse childhood experiences (ACEs) are likely to come from households with highly unstable reward environments, which is likely to have a deleterious impact on the development of confidence during value-based decision making. While it is well established that ACEs drive elevated risk for psychopathology in adulthood, the mechanisms driving this risk remain unclear. Here, we test the hypothesis that adults with prior exposure to ACEs have decreased confidence in value-based decisions, and we investigated value-based decision confidence N=38 adult participants with varying exposure to ACEs (range: 0-10 on the ACEs Checklist) completed a reinforcement learning task. Individuals also rated the confidence associated with each decision prior to feedback. Optimal task performance was modeled as a Partially Observable Markov Decision Process (POMDP), which generated trial-by-trial estimates of the immediate expected value (IEV) associated with each choice option. Typically, we expect increases in IEV (a more rewarding stimulus) to be accompanied by increases in confidence in the choice. We evaluated the potential moderating effect of ACEs on the relationship between decision confidence and IEV. Across the sample, there was a significant association between trialwise confidence and IEV. Specifically, participants were more confident when making the choice option had a higher predicted IEV. Critically, ACEs moderated this association: individuals who experienced two or more ACEs in childhood had a reduced association between confidence and IEV relative to individuals with minimal exposure to ACEs during childhood, despite having intact IEV learning. These results provide evidence for

a potential cognitive mechanisms underlying impaired reward-guided decision making in individuals with high exposure to ACEs. Individuals with higher ACEs may not feel confident in learned reward probabilities, likely due to experienced instabilities in the early reward environment. This disruption may persist when reward probabilities are more predictable, which may increase vulnerability to developing psychopathology related to reward-based decision making.

Title: Individual differences in the impulsive action on two timing-related operant behaviors are correlated in rats

Authors: *Y.-H. YANG[1], S.-F. CHEN[1], N.-S. YEN[1,2], R.-M. LIAO[1,2,3];
[1]Psychology, [2]Res. Ctr. for Mind, Brain, and Learning, [3]Neurosci., Natl. Cheng-Chi Univ., Taipei, Taiwan

Abstract: Operant behavior performed on a differential reinforcement of low-rate-response (DRL) task has been used to characterize impulsive action and further to probe the trait impulsivity involved in this domain of impulsive behavior. Like DRL behavior, the operant behavior maintained on a fixed-interval (FI) schedule requires a timing process in the reinforcement contingency. However, behavioral inhibition is required in the performance of DRL behavior, whereas it is not in the FI behavior. To date, little is known whether there is inter-individual variability in FI behavior as compared to DRL behavior. In the present study, a cohort of rats (n=34) were first trained on a FI 30 sec (FI 30-s) schedule for 21 days. With the measure of post-reinforcement pause (PRP), the subjects were classified into three groups as high- (n=9), intermediate- (n=16), and low- (n=9) impulsivity by quartile. Subsequently, these rats were subjected to acquire a DRL 10-s and then a DRL 20-s task (each for 5 days), which measurement of the response efficiency was used to delineate the individual difference in this task. The results showed individual differences existed in FI 30-s behavior as revealed by significant differences between three groups in the 6th to 10th 3-sec bins of the inter-response-time distribution curve within a 30 sec interval. Moreover, the mean PRP was significantly lower in the high-impulsive group than the low-impulsive one. The DRL data were separately analyzed and confirmed the individual differences manifested in either DRL 10-s or DRL 20-s task by showing the significant between-group difference on the response efficiency. Namely, a lower efficiency ratio appeared in the high-impulsive group and vice versa for the low-impulsive group. Correlational

analysis was further conducted to determine the behavioral traits that might be associated with the FI and DRL tasks. Surprisingly, there was a significant positive correlation between the PRP of FI 30-s and the response efficiency of DRL 10-s, and so to the DRL 20-s task. In summary, the trait impulsivity observed in the FI and DRL tasks may be attributed to the behavioral component of timing similarly involved in these two tasks.

Title: Early-life risperidone increases preference for small, immediate rewards in adulthood.

Authors: S. A. STEFFEN, T. DOWNNEN, K. DOLEZAL, K. THOMPSON, N. NAIL, J. R. YATES, *M. E. BARDGETT;
Psychological Sci., Northern Kentucky Univ., Highland Heights, KY

Abstract: Antipsychotic drugs are given to children to alleviate various psychiatric disorders even though there is little research on their impact on brain development and behavior. This study determined if early-life administration of risperidone, the most widely prescribed antipsychotic drug in children, led to changes in impulsive behavior, as assessed through delay discounting, during adulthood. Long-Evans rats were administered vehicle or risperidone (3.0 mg/kg, sc) daily for a four-week period beginning on postnatal day 14 (n = 14 rats per drug, 7 females and 7 males). Four weeks later, rats were acclimated and trained in operant chambers and thereafter blindly assessed in a delay discounting task for five weeks. Rats received one pellet immediately if they chose one lever or four pellets after delays of 5, 10, 20, or 40 seconds if they chose the other lever. Delays increased across blocks of trials within each daily session. During the second week of testing, there was a significant difference between the rats that received risperidone and the rats that received the vehicle treatment. Rats that received risperidone were more likely to choose the small immediate reward during the 40 second delay trials. There were no sex differences in choice behavior in the task. These results indicate that risperidone administration during development can lead to more impulsive behavior during adulthood. Such outcomes raise concerns about the long-term effects of risperidone administration on disorders linked with poor impulse control such as substance abuse.

Title: Parallel and serial dopamine circuit control of conditioned behavior during Pavlovian learning

Authors: *L. ENGEL[1], A. WOLFF[1], S. SINHA[2], V. COLLINS[1], B. SAUNDERS[1];
[1]Neurosci., Univ. of Minnesota, Minneapolis, MN; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Environmental cues, through Pavlovian learning, become conditioned stimuli that guide animals toward the acquisition of rewards (for example, food) by invigorating and directing seeking behavior. We have previously shown that brief optogenetic excitation of dopamine neurons, in temporal association with visual sensory cues, can instantiate those cues as conditioned stimuli that evoke conditioned movements. It remains unclear 1) how dopamine-neuron mediated, cue-evoked behavior is signaled by dopamine release downstream in striatal subregions and 2) how subregional signals evolve across stages of learning. Here, we made use of a genetically encoded dopamine biosensor (dLight) to monitor dopamine signaling simultaneously in multiple striatal regions with fiber photometry, while tracking detailed movement features, during optogenetic Pavlovian cue conditioning of VTA or SNc dopamine neurons. Our results demonstrate a serial pattern of cue-evoked dopamine signaling across ventral to dorsal striatal subregions that correlates with different features of cue-evoked behavior. Cues paired with optogenetic activation of VTA dopamine neurons evoked dopamine release in the nucleus accumbens core relatively early in training, when behavioral responses were slower and directed toward the cue. This pattern evolved as conditioning progressed. Late in training, cue-evoked signals emerged in the dorsolateral striatum, as movement patterns became more vigorous and not directed at the cue. Cues paired with optogenetic activation of SNc dopamine neurons did not reliably evoke dopamine release in the dorsolateral striatum, even though those cues spurred vigorous movements. Together our studies show dissociable, parallel functions for ventral and dorsal striatal dopamine signaling in guiding versus invigorating behaviors. Further, they suggest that large-scale coordination of signaling across ventral-to-dorsal striatal dopamine networks emerges during Pavlovian learning to coordinate behavioral diversity.

Title: Hierarchical regulation of mesolimbic dopamine and striatal encoding of reward-paired cues governs behavioral flexibility

Authors: *K. M. FRASER[1], V. COLLINS[2], F. PAT[1], P. JANAK[1], B. T. SAUNDERS[2]; [1]Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: The ability to resolve uncertainty surrounding reward-associated cues is essential for the proper organization and generation of reward-seeking. Dopamine neurons are reported to be sensitive to the likelihood of reinforcement yet how dopamine neurons, dopamine release, and the activity of their striatal targets are related to the coding and resolution of uncertainty is unclear. Here we make use of pharmacology, *in vivo* electrophysiology, calcium imaging, and optogenetics to determine the contributions of the mesolimbic dopamine system to the hierarchical organization of reward-seeking. Long-evans rats were trained to discriminate when a conditioned stimulus would be followed by sucrose reward by exploiting the prior and non-overlapping presentation of a separate discrete stimulus, an occasion setter. Only when the occasion setter's presentation preceded the conditioned stimulus did the conditioned stimulus predict sucrose delivery. We found that either reversible inactivation or dopamine antagonism within the nucleus accumbens prevented rats from properly estimating when the conditioned stimulus would be rewarded. Optogenetic inhibition of dopamine neurons in TH-Cre transgenic rats during either the conditioned stimulus or the occasion setter prevented rats from utilizing the occasion setting cue to increase their reward-seeking when appropriate. We recorded single neurons within the nucleus accumbens (n=235) and observed that the magnitude of conditioned-stimulus evoked inhibitions were greater when the conditioned stimulus would be followed by reward, than when it would not. Moreover, we observed a population of neurons in the nucleus accumbens that dynamically altered their firing to the conditioned stimulus, being excited when this cue was not predictive and inhibited when it would predict reward. We monitored dopamine release in the nucleus accumbens making use of fiber photometry and the fluorescent dopamine sensor dLight 1.3b. Dopamine release tracked the presentation of the occasion setter and dynamically scaled when the conditioned stimulus would or would not predict reward predicated on the prior presence or absence of the occasion setting cue. Together these results reveal a mechanism for dopamine neurons and the effects of dopamine release in the nucleus accumbens to dynamically control striatal encoding of ambiguous reward-predictive cues and appropriately generate reward-seeking.

Title: Mesoaccumbal glutamate/dopamine projections require glutamate release to promote positive reinforcement

Authors: ***S. M. WARLOW**[1], V. ZELL[1], A. C. HUNKER[2], L. S. ZWEIFEL[2], T. S. HNASKO[1]; [1]Neurosciences, Univ. of California San Diego, La Jolla, CA; [2]Pharmacol., Univ. of Washington, Seattle, WA

Abstract: Ventral tegmental area (VTA) projections to the Nucleus Accumbens medial shell (NAc) drive reward-related motivation and positive reinforcement. Although primarily composed of dopamine neurons, a subset of mesoaccumbal dopamine projections also express the type 2 vesicular glutamate transporter (VGLUT2) and release glutamate at NAc terminals. Optogenetic stimulation of VGLUT2-expressing VTA neurons promotes positive reinforcement, showing characteristics distinct from typical dopamine-mediated reinforcement such as preference for shorter bursts of stimulation rather than longer ones. Further, concomitant dopamine release by VGLUT2-expressing neurons is not required for positive reinforcement, suggesting glutamate release is primarily responsible for this distinct signature of positive reinforcement. Here we asked whether glutamate release by VTA glutamate neurons, including those that co-release dopamine (or GABA), is necessary for promoting positive reinforcement. We expressed Cre-dependent Channelrhodopsin (ChR2) in VTA of male and female VGLUT2-Cre mice, in combination with either a Cre-dependent CRISPR/Cas9 AAV designed to induce indel mutations in *Slc17a6* (VGLUT2) or a control AAV. We found that disruption of VTA VGLUT2 effectively eliminated optogenetically triggered excitatory postsynaptic currents in NAc. Furthermore, disruption of glutamate release from VTA neurons abolished optogenetic self-stimulation in both nose-poke self-stimulation and real-time place tasks. Operant reward seeking for natural food rewards was left intact, suggesting disruption of VTA glutamate does not interfere with basic reward learning. Our results suggest that VTA glutamate neurons mediate positive reinforcement, which contributes to a more complex understanding of mesoaccumbal circuitry involved in addiction and other motivational disorders.

Title: Orexin (hypocretin) input to ventral tegmental area modulates palatable food-seeking behavior in female rats with a history of obesity and binge-like eating

Authors: *J. B. MEHR, S. LIU, K. FERNANDOPULLE, S. O'CONNOR, H. E. BOWREY, N. T. BELLO, G. ASTON-JONES, M. H. JAMES;
Rutgers Univ., New Brunswick, NJ

Abstract: Introduction: Binge eating disorder (BED) is characterized by recurrent episodes of palatable food consumption with a concomitant perceived loss of control, and often presents comorbidly with obesity. Studies using animal models of addiction implicate projections of hypothalamic orexin (hypocretin) cells to ventral tegmental area (VTA) in regulating reward behavior; this signaling is hypothesized to be primarily mediated via actions at orexin-1 receptor (Ox1R). Here, we assessed the role of this orexin-VTA pathway, as well as VTA Ox1R signaling, in pathological food-seeking behaviors using a rat model of BED. **Methods**: Lean (chow, ad libitum) and obese (high fat diet; HFD; 45% fat, ad libitum) female Long-Evans rats were given access to sweetened fat (vegetable shortening/10% sucrose) for 30 minutes twice a week over 4 weeks. Rats were next tested for motivation for palatable food (sucrose pellets) on a behavioral economics assay. In Group 1 (n=32; 16/group), brain tissue was collected and processed for orexin immunoreactivity in VTA. In Group 2, rats received intra-VTA microinjections of a retrograde AAV containing either an orexin shRNA (n=9) or a control scrambled shRNA (n=8), before being exposed to the binge paradigm and tested for food motivation as above. In Group 3 (n=24), Ox1R was knocked down in one hemisphere of VTA, and TH neurons were silenced in the other. Rats were then exposed to the binge paradigm and tested for food motivation as above. **Results**: Obese, but not lean rats exhibited enhanced motivation for sucrose post-binge. This was associated with a corresponding increase in orexin terminal density in VTA in these rats. Rats that received intra-VTA orexin shRNA failed to escalate their binge intake and did not exhibit a post-binge increase in food demand. Contralateral knockdown of Ox1R and silencing of DA neurons in VTA blocked the enhancement of food motivation following binge; this was not observed in rats that received unilateral injections of either virus. **Conclusions**: These data indicate that orexin signaling in VTA, specifically at Ox1R, contributes to enhanced food-seeking behavior in obese rats with past binge experience. Together, these data highlight the orexin system as a potential therapeutic target for BED.

Title: Optogenetic Stimulation of Lateral Hypothalamic Orexin/Dynorphin Inputs to the Ventral Tegmental Area Potentiates Mesolimbic Dopamine and Promotes Reward-related Behaviours

Authors: *C. S. THOMAS[1], M. RANA[2], A. MOHAMMADKHANI[3], M. QIAO[2], S. L. BORGLAND[3];
[1]Dept. of Psychology, [3]Physiol. Pharmacol., [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: Reward-related processes are key to species survival. These processes rely heavily on mesolimbic dopamine (DA) neurotransmission to direct motivated behaviours to acquire rewards. One important neuromodulatory source to the ventral tegmental area (VTA) dopamine neurons is the lateral hypothalamic neuropeptide orexin-containing (Ox) neurons. Ox in the VTA is necessary for numerous reward-related processes including conditioned behaviours. Further, exogenous application of Ox increases the firing rate of VTA DA neurons projecting to the nucleus accumbens, a key node in the brain's reward circuitry. However, the impact of endogenous Ox on mesolimbic DA neurotransmission and reward related behaviours are not known. Furthermore, Ox is co-released with the inhibitory neuropeptide dynorphin (Dyn; $LH_{Ox/Dyn}$). The contributions of endogenous $LH_{ox/dyn}$ to modulation of mesolimbic DA and motivated behaviour is not fully understood. As such, we infused male and female Ox-cre mice with cre-dependent channelrhodopsin or control (mCherry) virus. Next, we implanted optical fibres targeting the VTA. We found that optical stimulation of $LH_{Ox/Dyn}$ in the VTA in one half of a 2-chamber box produced real-time and conditioned place preference. This effect was attenuated by antagonism of Ox receptor 1 (OxR1). We next assessed the involvement of optical stimulation of $LH_{Ox/Dyn}$ in the VTA in a Pavlovian food conditioning task. We found that stimulation of $LH_{Ox/Dyn}$ terminals in the VTA increased cue-directed motivated behaviour but did not produce conditioned reinforcement. Finally, we used anaesthetized fast-scan cyclic voltammetry combined with optical stimulation of $LH_{Ox/Dyn}$ in the VTA to show that Ox release in the VTA potentiates electrically evoked mesolimbic DA. This effect was attenuated by antagonism of OxR1. Together these findings demonstrate a robust role for Ox in the VTA in modulating mesolimbic DA neurotransmission and in sculpting various reward-related behaviours. These findings provide significant support for examining the role of $LH_{Ox/Dyn}$ in states of aberrant motivation, such as addiction.

Title: Projection target defined effects of endogenous orexin and dynorphin co release on activity of ventral tegmental area dopamine neurons

Authors: A. MOHAMMADKHANI, M. QIAO, *S. L. BORGLAND;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Dopamine neurons in the ventral tegmental area (VTA) respond to motivationally relevant cues and are key targets of addictive drugs; circuit-specific signaling of these neurons drives different aspects of motivated behavior. Orexins (ox; also known as hypocretin) and dynorphin (dyn) are co-expressed lateral hypothalamic (LH) neuropeptides that project to VTA. While LHox promotes drug-seeking behavior, dynorphin inhibits drug-seeking behavior. Furthermore, these peptides have opposing effects on the firing activity of VTA dopamine neurons. Previous work in our lab demonstrated that exogenously application of ox and dyn, modulate non-overlapping VTA dopaminergic projections. Specifically, exogenous application of orexin potentiates firing of dopaminergic neurons that project to the nucleus accumbens (DA-NAc), but not the basolateral amygdala (DA-BLA), whereas dynorphin inhibits firing in subpopulations of dopamine neurons in both projections. However, it is unknown if dynorphin inhibition of these circuits in opposition to LHox is driven by the LHox/dyn input, rather than other sources. This study sought to determine the effects of endogenous LHox/dyn release on DA-BLA and DA-NAc VTA neurons in mice. We expressed channel rhodopsin2 selectively in LHox/dyn neurons and photostimulated terminals in the VTA while recording VTA neuronal firing using combination of circuit tracing and patch clamp electrophysiology. VTA dopamine neurons were labeled with biocytin during recordings and posthoc imaged for tyrosine hydroxylase expression. We showed a diverse response of LHox/dyn photostimulation on dopamine neuronal firing rate. Photostimulation of LHox/dyn inputs in the VTA inhibited firing of the majority of DA-BLA neurons. However, photostimulation of LHox/dyn inputs in the VTA both increased and reduced firing of dopamine neurons that project to either the lateral or medial nucleus accumbens shell (DA-lAcbSh, DA-mAchSh). SB334687, an ox1 receptor inhibitor or NorBNI, a kappa receptor inhibitor reversed the potentiation or inhibition of firing, respectively. Furthermore, these effects on firing were not driven by synaptic glutamate or GABA release. Our findings provide evidence that LHox/dyn corelease may tune the output of the VTA by simultaneously inhibiting and activating different VTA projection neurons that are distinct in their electrophysiological properties and contribute to different aspects of reward seeking.

Title: Hippocampal neurogenesispromotes effortful responding but does not regulate effort-based choice

Authors: ***D. R. SEIB**, O. PRINCZ-LEBEL, E. CHAHLEY, S. B. FLORESCO, J. S. SNYDER; Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: One brain region that has been implicated in the pathology of depression is the hippocampus. Interestingly, in humans, it is the brain region that is capable of generating new neurons throughout life. To date, little work has thoroughly examined how a reduction in new neurons modulates the hippocampal network during behavior and which of the complex behavioral traits of depression are caused by reductions in neurogenesis. One of the hallmarks of depression is a lack of motivation and energy to pursue goals. When patients are given a choice, they are more likely to choose rewards that require less effort to obtain, even if they are less valuable. In addition to discounting effortful rewards, patients also work less to obtain rewards.To determine the role of hippocampal neurogenesis in reward choices based on effort, we ran neurogenesis-deficient rats in an effort-discounting operant task. We tested transgenic rats (hGFAP-TK), in which drug-treatment can deplete actively dividing neural progenitors in a time- and region-specific manner and consequently stop the production of new neurons. Rats were faced with a choice between a low reward (2 sugar pellets) that was associated with a low effort (1 lever press), and a high reward (4 sugar pellets) that was associated with a higher effort (2, 5, 10 or 20 lever presses across blocks). As the amount of required effort increased, WT and TK rats chose the high reward less often, with no difference between genotypes. However, upon making a choice, TK rats lever-pressed at a slower rate than WT rats. Other behavioral measures were comparable between WT and TK rats suggesting similar levels of activity and motivation to perform the task. Moreover, untreated WT and TK rats did not differ in effort discounting or lever pressing behavior. In summary, while we found that neurogenesis did not regulate effort-based choice, it did contribute to effortful responding. Once a choice had been made, TK rats lever-pressed at a lower rate to obtain the rewards. This implicates neurogenesis in aspects of response vigor, and fits with recent findings that TK rats also obtain fewer rewards and press at a lower rate in a progressive ratio paradigm.

Title: Ventral CA3 and CA1 projections to the lateral septum differentially regulate approach-avoidance conflict resolution

Authors: ***D. C. M. YEATES**, D. LEAVITT, S. SUJANTHAN, A. C. H. LEE, R. ITO; Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: The ventral hippocampus is thought to be one of the primary regulators of approach-avoidance conflict resolution in rodents. Previous work has shown that the ventral CA3 (vCA3) subfield mediates the avoidance of stimuli that simultaneously predict both positive and negative outcomes, while the ventral CA1 (vCA1) directs approach towards motivationally conflicting stimuli and suppresses approach towards motivationally neutral stimuli. The caudodorsal lateral septum (LScd) and rostral lateral septum (LSr) are primary targets of extrinsic vCA3 and vCA1 projections respectively, and we posited that these distinct pathways may mediate the previously reported divergent control of approach-avoidance conflict resolution. We therefore transfected the glutamatergic cells of either the vCA3 or vCA1 in male Long-Evans rats with the inhibitory DREADD AAV8-CAMKII-hM4Di-mCherry and cannulated over the LS for direct drug (Clozapine-N-Oxide) delivery. Control animals received the same manipulations with EGFP-tagged AAV8 infused into the hippocampal subfields. Animals were trained to associate distinct visuo-tactile cues with either sucrose reward, aversive footshock, or no outcome (neutral) in a Y-maze. Following successful acquisition, animals underwent a "conflict test", in which they chose between exploring an arm with combined appetitive-aversive cues and a neutral cued arm. Chemogenetic inhibition of the vCA3-LScd pathway potentiated approach towards the conflict stimulus alone, while inhibition of the vCA1-LSr pathway potentiated approach towards both conflict and neutral stimuli compared to controls. The same manipulation in both groups had no effect on preference for the appetitive or aversive cues individually. Furthermore neither pathway was found to affect animals' ability to detect novel stimuli, change the amount of food consumed in a familiar environment, or increase locomotion alone, suggesting that the pathways that regulate the Y-maze task are specifically engaged during motivational conflict. These findings are consistent with the idea that the vCA3-LScd circuit facilities avoidance during cued approach-avoidance conflict, while the vCA1-LSr pathway is important for suppressing non-specific approach responses during the same situations.

Title: Crf neurons in a paraventricular thalamic circuit regulate food-approach vs. threat-avoidance conflict

Authors: ***X. O. ZHANG**[1], D. S. ENGELKE[1], J. J. O'MALLEY[1], J. A. FERNANDEZ-LEON[1], S. LI[2], G. J. KIROUAC[2], M. BEIERLEIN[1], F. H. DO MONTE[1];

Abstract: Balancing food-seeking with threat-avoidance behaviors is crucial for animals to survive, but which neural circuits regulate this motivational conflict remain largely unknown. To answer this question, we designed an ethologically relevant "approach-food vs. avoid-predator threat" conflict test in which rats need to overcome their fear of predator odor to reach food. Animals were initially trained to press a lever for sucrose in the presence of an audiovisual cue. During the conflict test, cat saliva was positioned in the food area adjacent to the lever. Rats exhibited robust defensive behaviors and a clear suppression in food-seeking responses in the presence of the predator odor. Using *in situ* hybridization, immunohistochemistry and *in vivo* single-unit recordings from photoidentified cell-types, we identified a subpopulation of neurons in the anterior portion of the paraventricular thalamic nucleus (aPVT) which express the stress neuropeptide corticotrophin-releasing factor (CRF) and are preferentially recruited during conflict. Chemogenetic inactivation of $aPVT^{CRF}$ neurons during conflict reduced defensive responses and restored food-seeking behavior, but had no effect when the predator odor or the food-seeking tasks were carried out independently. Using both anterograde and retrograde viral tracing methods, we characterized the anatomical connectivity between $aPVT^{CRF}$ neurons and brain regions that are implicated in the regulation of food seeking and defensive responses. We observed that $aPVT^{CRF}$ neurons project densely to the nucleus accumbens (NAc), and optogenetic activation of the $aPVT^{CRF}$-NAc pathway recapitulated the predator odor-induced food-seeking suppression and avoidance responses by mediating target-dependent synaptic transmission in the NAc. In addition, we identified the ventromedial hypothalamus (VMH) as a critical input to $aPVT^{CRF}$ neurons, and demonstrated that aPVT-projecting VMH neurons are

activated by predator odor and necessary for the expression of defensive responses during conflict. Together, our findings describe a subpopulation of neurons in a hypothalamic-thalamostriatal circuit that suppresses reward-seeking behavior under the competing demands of avoiding threats.

Title: Cerebellar modulation of nucleus accumbens activity

Authors: *A. F. D'AMBRA[1], S. JUNG[1], S. GANESAN[1], E. G. ANTZOULATOS[1,2], D. FIORAVANTE[1,2];

Abstract: The cerebellum (CB) utilizes input integration and feedforward processing to perform complex computations. This complexity has not been elucidated for CB non-motor functions, including cognitive and emotional processing as well as reward-driven behavior and learning. We propose that the role of the CB in limbic processes is derived in part from functional connectivity with the nucleus accumbens (NAc). Here we paired in vivo electrophysiological recordings of NAc spiking activity with microstimulation of the CB nuclei to provide the first evidence of a functional CB-NAc connection. Our data suggest that CB stimulation has both excitatory and inhibitory effects on NAc spiking activity, but differentially influences the two NAc subregions, the medial shell (NAc_{Med}) and core (NAc_{core}). CB stimulation evoked inhibitory responses more often than excitatory ones in the NAc_{Med} ($p<0.0001$). The NAc_{Core}, on the other hand, showed significantly greater probability of excitatory responses than Nac_{Med} ($p<0.05$). We also found latency differences between response types, and between NAc subregions. Excitatory responses displayed significantly shorter onset latencies than inhibitory ones ($p<0.05$) and responses in the NAc_{Core} appeared more quickly than responses in the NAc_{Med} ($p<0.05$). After confirming the localized nature of our stimulation, we investigated the presence of any

topographical organization of this connection. We found no evidence of localized clusters in the CB nuclei that would elicit the same response type in the NAc, nor any CB response clustering in NAc. Finally, we investigated the circuitry underlying CB-NAc connectivity using anatomical tracing. We identified two regions to be involved in the disynaptic CB-NAc connection: the ventral tegmental area and the intralaminar nuclei of the thalamus, both of which contain cells that receive input from the CB and project to the NAc. The results of these experiments expound upon the involvement of the CB in higher-order functions such as motivation, reward learning, and emotional processing.

Title: Nurr1 deficiency shortens free running period, enhances photo-entrainment, and disrupts circadian cycling of the dopamine neuron phenotype

Authors: *H. PARTINGTON, J. M. NUTTER, S. BARKER, J. EELLS;
Brody Sch. of Med., Greenville, NC

Abstract: Neurological and neuropsychiatric disorders , including addiction, schizophrenia, and Parkinson's disease, involve dysfunction in midbrain dopamine (DA) neurotransmission and severity of disease symptoms and progression are associated with disrupted circadian rhythms. The nuclear transcription factor Nurr1, essential for DA neuron (DAN) development, survival, and maintenance, is also known to interact with circadian rhythm regulating clock gene proteins. Inthe Nurr1-null heterozygous (+/-) mice, a Nurr1 deficient model which reproduces some of the alterations in DA function found in schizophrenia and Parkinson's disease, we measured, using wheel-running activity, the free running period (tau) and photoperiod entrainment. Because Nurr1 has are role in regulating the dopamine phenotype, we also measured the circadian fluctuations in the number of DANs using tyrosine hydroxylase immunofluorescence. In Nurr1 +/- mice, tau was significantly shorter and entrainment to a 6h earlier shift in the dark cycle was faster. The Nurr1 wild-type (+/+) mice cycled DAN numbers across time, with a significantly greater number (~2-fold increase) of DANs at zeitgeber time (ZT) 0 than ZT12. The +/- mice, however, did not cycle the dopamine phenotype, as no differences in DAN numbers were observed between ZT0 and ZT12. Additionally, the +/- mice had significantly fewer DANs at ZT0 but not at ZT12 as compared to +/+ mice. Based these data, circadian fluctuations in DA transmission requires normal Nurr1 function. A better understanding is needed of the mechanisms regulating dopamine neurotransmission across the circadian cycle and how this is altered in circadian rhythm and DA neurotransmission associated disorders.

Title: Accumbal cholinergic interneurons are critical in the influence of cues over risk taking

Authors: *A. C. LI[1], T. J. HYNES[2], K. HRELJA[2], L. CALDERHEAD[2], C. S. CHERNOFF[2], C. A. WINSTANLEY[1];
[1]Psychology, [2]Neurosci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Many theories of gambling disorder posit a critical role of cues. The audiovisual cues in casinos are thought to promote riskier play, and this phenomenon can be modeled using the rat gambling task. Rats are given a choice between large, unlikely rewards (risky) and smaller, more certain ones (optimal). When casino-like cues are introduced, more rats choose the risky options. We theorize that the phasic dopamine release evoked by these cues cause compensatory changes in the dopamine system to promote risk taking. Cholinergic interneurons in the nucleus accumbens core (NAc) are critical titrators of NAc dopamine release. Cholinergic interneurons are tonically active and maintain steady levels of NAc dopamine. When motivationally relevant cues are presented, cholinergic interneurons pause, and thus the tonic stream of dopamine stops, giving way to the influence of the cue-evoked phasic dopamine we theorize to potentiate risk taking. Little is known of how cholinergic interneurons act in the NAc to affect dopamine release and orchestrate behaviour, but due to their critical role in regulating dopamine release, they are a potential treatment target for addictive disorders. We therefore asked the question as to whether NAc cholinergic interneurons could be targeted to manipulate gambling-like behaviour, hypothesizing that reducing accumbal CIN signaling should increase the influence of reward cues, thereby increasing risk taking over time. Their excitation should promote an optimal strategy. To test this, we used DREADDs in combination with ChAT-cre transgenic rats to gain bidirectional chemogenetic control over the NAc cholinergic interneurons in female and male rats. We then administered clozapine-N-oxide prior to each daily training session, to either inhibit or enhance NAc cholinergic interneuron activity. In rats that underwent inhibition, a longitudinal increase in risk taking was observed, while excitation resulted in a reduction. Interestingly, the inhibition effect was observed only in females and the excitation effect only in males -- this may be due to baseline differences in dopamine neurobiology across the sexes. These results support our hypothesis, suggesting that NAc cholinergic interneurons may be leveraged in the treatment disorders, and furthermore point to biological sex as an important consideration.

Title: Electrophysiological characterization of medium spiny neurons in the nucleus accumbens of sign- and goal-trackers, a model of individual variation in incentive learning

Authors: *C. E. MARÍA-RÍOS[1], G. G. MURPHY[2], J. D. MORROW[3];
[1]Neurosci. Grad. Program, [2]Mol. & Integrative Physiol., [3]Psychiatry, Univ. of Michigan, Ann Arbor, MI

Abstract: Pavlovian conditioned approach behavior in rats can be used to identify individual differences in sensitivity to reward cues, which is an identified risk factor for addiction. "Sign-tracker" rats (ST) will approach and interact with a reward cue, indicating that the cue itself acquires incentive value for them. In contrast, "goal-tracker" rats (GT) direct their behavior away from the cue and towards the site of impending food reward, indicating that they are using the cue solely as a predictor of the reward. As expected, ST are more susceptible to cue-induced 'relapse' of drugs of abuse when compared to GT. ST and GT exhibit different cue- and reward-evoked patterns of activity in the nucleus accumbens (NAc) during Pavlovian learning, but it is not known how these patterns arise or contribute to the ST/GT phenotype. Using whole-cell patch-clamp recordings, we explored whether differences in the intrinsic neuronal properties and in baseline excitatory inputs of NAc medium spiny neurons (MSNs) within the shell and core subregions contribute to the ST/GT phenotype. Consistent with previous literature, we found regional differences between the core and shell sub-regions. Cells in the shell exhibited lower cell capacitance and higher input resistance when compared to those in the core. We found no significant differences between ST and GT in either passive or active MSNs excitability properties. In addition, we found no significant differences in mEPSCs amplitude or frequency between ST and GT. Our findings suggest that the ST/GT phenotype does not correlate with intrinsic excitability properties of MSNs in the NAc, nor with their overall baseline excitatory synaptic properties. This suggests that the distinct activity profiles of ST and GT may result from circuit-level differences in input from other regions to the NAc. Continued work in this area will shed light on the neurobiological basis of increased susceptibility to cue-driven psychopathologies.

Title: Contributions of the mesolimbic dopamine pathway in reversal learning

Authors: *B. ARNOLD, S. MONROE, E. SNEDDON, A. RADKE;
Miami Univ., Oxford, OH

Abstract: Cognitive flexibility, which can be measured with reversal learning, is the ability of an individual to alter behavior in response to the changing of environmental conditions. Past studies

have found that dopamine (DA) is released in the nucleus accumbens (NAc) during reversal learning (Radke et al., 2019, Klanker et al., 2017). The present study sought to examine the effects of manipulating DA release in the NAc on reversal learning using Designer Receptors Exclusively Activated by Designer Drugs (DREADD). AAVrg-hSyn-DIO-hM3Dq-mCherry (Addgene) was injected into the NAc of male and female DAT-Cre mice. Mice first learned to master a basic task of discriminating between an active vs. inactive nose poke in an operant box while responding for a food reward. Once the criterion for discrimination was met, the active and inactive nose-poke holes were switched (i.e., reversal). Mice were administered the ligand clozapine-n-oxide (CNO, 1.0 mg/kg) 15 min before the first reversal session, exciting DA neurons projecting to the NAc. There were no differences between Cre- (=control) and Cre+ (=experimental) mice in correct or incorrect responses following administration of CNO during the first reversal. Following this session, the animals were trained to criterion (defined by a consistent 85% correct response rate), and the correct and incorrect nose pokes were reversed again. In this second reversal, the Cre+ animals that expressed the DREADD receptor showed a significantly greater number of incorrect responses on the side that was not reinforced (i.e., errors) compared to the Cre- animals that did not express the DREADD receptor. In a second experiment, mice with partial genetic deletion of the dopamine transporter (DAT-KO mice) were tested in the reversal learning paradigm. We hypothesized that increased DA concentrations in heterozygous DAT-KO mice would affect reversal learning in a manner similar to chemogenetic activation of DA neurons. Preliminary data suggest that DAT gene deletion does not significantly affect reversal learning. These data clarify the important role that dopamine in the NAc plays in reward learning and behavioral flexibility.

Title: Optogenetic inhibition of the rat perirhinal cortex disrupts object-based approach-avoidance conflict processing

Authors: *S. S. DHAWAN, A. C. H. LEE, R. ITO;
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Extant research has implicated the ventral hippocampus (vHPC) in the detection and resolution of learned approach-avoidance conflict (AAC), whereby rats are simultaneously presented with stimuli previously associated with competing motivational valences. Emerging findings from our group have implicated the human perirhinal cortex (PRC), a brain region crucial in representing item/object information, in the resolution of AAC when discrete ‘object’,

rather than contextual 'scene' stimuli were used. Currently, learned AAC paradigms in rats have only used contextual 'visuo-tactile' panels spanning a Y-maze arm as stimuli, and thus the present study sought to examine to role of the rat PRC in object-based AAC. Adult male Long-Evans rats surgically received bilateral infusions of either the inhibitory opsin ArchT (AAV1-CaMKIIa-ArchT-GFP) or control GFP (AAV8-CaMKIIa-GFP) followed by optic fiber implantation, and were then trained to associate 3 sets of object-pairs (2 feature-unique objects) with either reward, punishment, or no outcome in a novel, object-based AAC task. Rats traversed a narrow runway apparatus to allow incidental exploration of two objects, towards a goal compartment in which animals received the outcomes associated with the object pair (sucrose, shock or no outcome). Upon successful object-outcome learning, rats completed 2 'conflict tests' (with and without optogenetic inhibition of the PRC) in which the object-pairs contained one appetitive and one aversive object, and one 'neutral' test. PRC inhibition throughout the conflict test session, but not neutral test session, resulted in a robust increase in the time spent in the goal box, compared with laser-off sessions, and with laser-on GFP-control animals. Subsequent control experiments determined that the increase in 'approach' behaviour in ArchT animals was not driven by impairments in object memory or novelty processing. Rats also completed the vHPC-dependent cued AAC Y-maze task, upon which it was found that PRC inhibition did not impact conflict behaviour. These findings indicate that normally, the rat PRC promotes avoidance behaviour for AAC decisions represented by object-cues, akin to the role of the vCA3 of the HPC in contextual AAC decisions. Thus, AAC is a process that may be mediated by heterogeneous brain regions based on the type of stimulus representation.

Title: Prefrontal corticostriatal cells drive food restriction evoked running and receive fewer inhibitory contacts than neighboring pyramidal cells projecting elsewhere

Authors: *A. N. SANTIAGO[1], E. MAKOWICZ[3,1], M. DU[4], C. J. AOKI[2];
[1]Ctr. for Neural Sci., [2]Ctr. Neural Sci., New York Univ., New York, NY; [3]Biol., Hunter, New York, NY; [4]NYU Shanghai, Shandong, China

Abstract: Food restriction (FR) evokes running, which may promote adaptive foraging in times of food scarcity, but can become lethal if energy expenditure exceeds caloric availability. Here, we demonstrate that chemogenetic activation of either the general medial prefrontal cortex (mPFC) pyramidal cell population, or the subpopulation projecting to dorsal striatum (DS) drives running specifically during hours preceding limited food availability, and not during *ad libitum* food availability. Conversely, suppression of mPFC pyramidal cells generally, or targeting mPFC-to-DS cells, reduced wheel running specifically during FR and not during *ad libitum* food access. Post-mortem c-Fos analysis and electron microscopy of mPFC layer 5 revealed distinguishing characteristics of mPFC-to-DS cells, when compared to neighboring non-DS projecting pyramidal cells: 1) greater recruitment of GABAergic activity and 2) less axo-somatic GABAergic innervation. Together, these attributes position the mPFC-to-DS subset of pyramidal cells to dominate mPFC excitatory outflow, particularly during FR, revealing a specific and causal role for mPFC-to-DS control of the decision to run during food scarcity. Individual differences in GABAergic activity correlate with running response to further support this interpretation. FR enhancement of PFC-to-DS activity may influence neural circuits both in studies using FR to motivate animal behavior and in human conditions hallmarked by FR.

Title: Neuroanatomical evidence supporting the role of the ventrolateral prefrontal cortex in the salience network

Authors: ***L. R. TRAMBAIOLLI**[1], S. HABER[2];
[1]McLean Hosp. - Harvard Med. Sch., Belmont, MA; [2]Univ. of Rochester, Rochester, NY

Abstract: Introduction: Salience detection is the attentional process of identifying elements that stand out from neighbor events. Human neuroimaging studies report the existence of a salience network cortically anchored by the dorsal anterior cingulate cortex (dACC) and the fronto-insular cortex (FIC). One open question is the involvement of the ventrolateral prefrontal cortex (vlPFC) in this network. Due to the spatial limitation of neuroimaging technologies, portions of the vlPFC are often labeled as part of the FIC. However, this question can be addressed using the precision of neuroanatomic tracing methods to evaluate vlPFC connections in NHP. This study was designed to quantify the afferent connections from the dACC and FIC to the vlPFC to determine whether there is a sublocation within the vlPFC specifically related to the salience network. **Method:** We injected retrograde tracers in the right vlPFC of macaque monkeys: five injections in area 47/12, two in area 45, and one in area 44. For each injection, we quantified cells in 22 areas of the frontal cortex and six areas of the insular cortex. The connectivity strength between each cortical area and the vlPFC sublocation was measured as a

ratio between the number of cells in this area by the total number of labeled cells. To ensure that our results are different from chance, we performed 10^6 permutations of random labeling of cells in each injection. Then, we statistically compared the real labeling with the distribution of random labels.**Results:** All connectivity charts presented significant differences from the chance level ($p<0.01$). The two injections in the caudal portion of area 47/12 stood apart from the rest of the vlPFC with respect to inputs from the two salience detection nodes (FIC and dACC). After identifying the cluster of cells in these nodes, we placed two new tracer injections in the cluster location. Using anterograde tracing, we found both clusters projecting axon terminals to a similar location in caudal area 47/12, equivalent to our original injection sites.**Discussion:** Here, we identified a specific location within the vlPFC, specifically in caudal area 47/12, which is structurally linked to the central nodes of the salience network. The involvement of the vlPFC in this network has not been clear due to methodological issues from resting-state fMRI, such as echoplanar distortions. Thus, this is the first study to formally identify a portion of the vlPFC that is connected to the salience network. The next step of our research will be to translate these findings to functional imaging in NHP and humans.

Title: Does amyloid-β plaque accumulation correlate with cognitive effort costs? An exploratory study

Authors: *D. PAPADOPETRAKI[1], A. WESTBROOK[2], J. THOMAS[3], L. J. MENTINK[3], C. B. HOLROYD [4], J. CLAASSEN[3], R. COOLS[1];

Abstract: Sustained attention in a cognitively demanding task is known to incur performance decrements and sensations of fatigue. These cognitive effort costs bias people to avoid mentally demanding tasks, even at the expense of potential rewards. The precise nature of the costs remains elusive, with proposed theories including resource depletion, motivational, as well as metabolic accounts. A promising metabolic proposal is the waste-disposal hypothesis (Holroyd, 2015), which holds that control is treated as costly because it results in the accumulation of

amyloid beta (Aß) in the interstitial fluid (ISF) as a by-product of cortical noradrenaline signaling. By this account, the rate of Aß accumulation underlies the phenomenology of cognitive fatigue, which is then remedied by Aß clearance during sleep. The waste disposal hypothesis predicts that long term sleep deprivation results in detrimental Aß accumulation and enhanced effort costs.

We investigated the relationship between brain Aß levels measured with ^{18}F-flutemetamol PET-CT and cognitive motivation in a population experiencing chronic sleep disruption (maritime pilots, N=19) (Thomas et al., 2020). ^{18}F-flutemetamol is a validated Aß tracer that binds to Aß plaques, comparable to ^{11}C-Pittsburgh compound B. To assess cognitive motivation, we administered a classic working memory task, the N-back task, and a subsequent cognitive effort discounting task to quantify the subjective value assigned to executing the effortful tasks. Our preliminary results do not provide evidence for a relationship between Aß levels and the value of cognitive effort.

We do observe a trend towards a positive link between response latency during N-back task performance and Aß concentration in the temporal cortex. Further analyses and future PET-CT or biomarker studies with larger sample sizes are required to definitively test the waste disposal hypothesis.

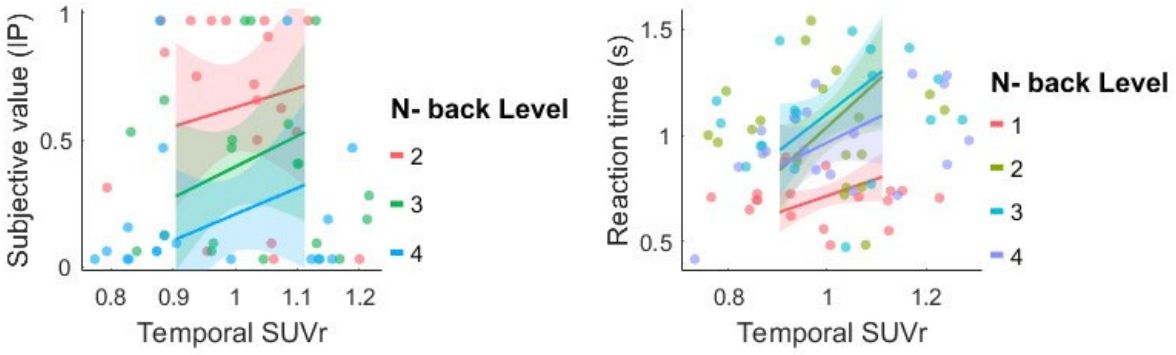

Figure 1. Left: No significant correlation between SUVr (standard uptake value ratio) and subjective value. Right: Relationship between latency during the N-back task and temporal SUVr.

Title: A within-subject experiments assess the effect of Loving Kindness Meditation (LKM) A pilot EEG study

Authors: *G. WONG[1], S. RUI[1], J. GAO[2];
[2]Ctr. of Buddhist Studies, [1]The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Background The need for social connection is a fundamental human motive. It has become much explicit that the feeling of social connection can confer mental and physical health benefits. However, in many different cultures, societal changes are leading to the growth of social distrust and alienation. As LKM characterizes a soft and slow affection, it may be associated with a slow-wave generation in the brain. Neuroimaging studies have demonstrated that LKM practice induces neural activation in the prefrontal cortex (PFC), anterior cingulate cortices (ACC), and insula. LKM may also affect subcortical brain activities and autonomic nervous system which additionally affect cardiac activities. Advance in neuroscience techniques makes it possible for its application to be used in LKM practice, for example, to give neurofeedback or to measure its progress. However, the effect of LKM training on brain modulation, especially empathy neuro-marker is still unknow. The purpose of this study aims to investigate the effect of Loving Kindness Meditation (LKM) on empathy modulation and to identify potential EEG neuro-marker. **Method:** In this study, a 46-year-old male meditation novice participant was recruited for this single-subject EEG experiment. There were consecutive 10-session LKM training under the instruction of a teacher with more than 20 years' experience of meditation. 128-chanel resting EEG signals were collected during each training session. The data were processed by EEGlab based on Matlab. Spectrum analysis was carried out to calculate the EEG power in different power bands (delta 1-4Hz, Theta 4-8 Hz, alpha 8-12 Hz, Beta 12-24 Hz, Gamma 24-40Hz). Self-reports of Loving Kindness Compassion Scale was also collected at the beginning and end of the 10-session training. **Result:** Investigation has been partially done on the change of EEG related to LKM training, and the alpha wave is supposed to be the LKM neuro-marker in the resting EEG. A significant difference in EEG alpha wave is noticed between the first 5-session and the last 5-session training ($p < 0.05$), while delta wave difference is marginal. Additionally, the Self-report of Loving Kindness Compassion Scale has improved. **Conclusion:** This study shows the long-term modulation effect of LKM training on alpha wave, which potentially could be an LKM neuromarker. Nevertheless, more training data and connectivity analysis may be needed to identify the neuromarker. The result of this study not only establishes a starting point to investigate the effect of LKM, from the perspective of neurological mechanism; but also provides a neural marker of LKM training for future neurofeedback training.

Title: A role for cerebral cortex in the suppression of innate defensive behavior

Authors: *S. NATALE, M. MASFERRER, S. DEIVASIGAMANI, C. GROSS;
European Mol. Biol. Lab., Monterotondo, Italy

Abstract: The cerebral cortex is involved in the control of cognition and the processing of learned information and it appears to have a role in the adaptation of behavior in response to unpredictable circumstances. In addition, the cortex may have a role in the regulation of innate responses since rodents, cats or primates with surgical removal or accidental destruction of cortical regions show excessive irritability, aggression and rage elicited by threatening stimuli. However, it remains unclear whether cortex has an acute role in suppressing innate threat responses because the imprecision and chronic nature of these lesions leaves open the possibility that compensatory processes may underlie some of these phenotypes. In the present study we used pharmacogenetic inhibition to precisely, rapidly and reversibly suppress cortical pyramidal neuron function and examine its contribution to defensive behaviors elicited by a variety of innately aversive stimuli. Inhibition of cortex caused an increase of defensive responses elicited by an aggressive conspecific, a novel prey, and a physically stressful stimulus. These findings are consistent with a role of cortex in the acute inhibition of innate defensive behaviors.

Title: Sex differences in activation of reward-related brain circuitry during juvenile rat social play

Authors: *S. E. ASHTON[1], J. W. VANRYZIN[2], M. M. MCCARTHY[2];
[1]Program in Neurosci., [2]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Rough-and-tumble play is a highly rewarding social behavior conserved across mammalian species, including humans, and involves dopaminergic (DA) cells in the ventral tegmental area (VTA) that project to the nucleus accumbens (NAc). Juvenile males engage in more frequent and intense play than females, but contrary to expectation we have previously shown that engaging in play resulted in greater neuronal activation in the NAc of juvenile female rats compared to males, as measured by immediate early gene expression (Egr1). We hypothesize that, despite playing less, juvenile females experience greater motivation to acquire play. Therefore, we predicted that play specifically activates DA receptor-expressing cells in the

NAc and likewise DAergic cells in the VTA of females. To test this, we phenotyped play-active cells in these regions using RNAscope. There was no sex difference in the total number of Egr1+ cells in the VTA, however we found that 67% of Egr1+ cells colocalized with tyrosine hydroxylase (TH), a marker of DA cells, in females compared to only 52% in males. In NAc, we found a greater number of Egr1+ cells across the core and shell subregions in females compared to males, and further found that all Egr1+ cells in both sexes expressed either one or both DA receptors D1 (Drd1a) and D2 (Drd2). In the core specifically, 54.7% of D1+ cells and 61.2% of D2+ cells coexpressed Egr1 in females compared to 39.9% and 37.2% in males. These findings demonstrate that play activates a greater proportion of putative DAergic cells in the female VTA, which is mirrored by increased activation of DA receptor-expressing cells in the NAc. To directly test the motivation to engage in play behavior, we adapted the operant social preference task (Borland et al., Journal of Neuroscience Methods 2017) for juvenile rats. In this task, animals must push through a transparent, perforated one-way swinging door in order to physically interact with a sex- and age-matched play partner. We found that both males and females readily acquire this task, making an average of nearly 30 entries per 3 minute session when housed in isolation. When the weight of the door is progressively increased after each successful entry, juveniles will push through a weight of up to 200g (~200% body weight) to access a playmate. We found no sex differences in any measure of this task, suggesting a different mechanism controls the appetitive versus consummatory components of juvenile social behavior. Future directions will examine DA transmission in NAc during the social motivation task and play behavior.

Title: Effect of access duration on operant responding for social interaction with a peer in male and female rats

Authors: *J. J. CHOW, J. M. CHABOT, M. VENNIRO, Y. SHAHAM;
IRP/NIDA/NIH, Baltimore, MD

Abstract: Background: We recently developed an operant model of social reward and choice where rats lever-press for access to social interaction with a peer. We reported that rats strongly prefer the social reward over opioid and psychostimulant drugs. Here we further characterized the operant social reward by determining the effect of access duration on operant responding for social interaction under fixed and progressive ratio reinforcement schedules. **Methods:** We

trained male and female rats (n=16; 8 females) to lever press for social interaction (60 s access for 1-h/day; 10 days, fixed ratio 1 to 5 schedule). Next, we assessed operant responding at various access durations (3.75 to 240 s, 1-h/day; 2 days per duration). Next, we examined the effect of duration of social interaction (15, 30, and 60 s; 3 days per duration) on progressive ratio responding. **Results:** Operant responding was higher for 3.75 to 60 s of social interaction than for 120 and 240 s. A demand analysis of the data showed that unrestrained consumption (Q_0) was 2194 and the rate of decline in consumption (a) was 4.375e-5. Progressive ratio responding was similar for 15, 30, and 60 s of social interaction. Operant responding for social reward was similar in males and females. **Conclusions:** Results indicate that rats will decrease operant responding for longer durations of social interaction and confirm our previous results that social interaction with a peer serves as an operant reward to rats.

Title: Maternal immune activation leads to sex specific effects on social-decision making and insular cortex CRF function

Authors: *N. S. RIEGER, J. P. CHRISTIANSON;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Prenatal infection increases risk for neuropsychiatric disorders such as autism in offspring. In the rodent maternal immune activation (MIA) paradigm, prenatal administration of the viral mimic Polyionsinic:polycytidylic acid (PolyI:C) allows for investigation of developmental consequences of gestational sickness on offspring social behavior and neural circuit function. MIA alters cortical development, stress response, and leads to altered sociability, therefore, we hypothesized that MIA would lead to changes in social decision-making in a rat social affective preference (SAP) task. In this task, test rats are exposed to both a stressed (via 2 mild foot shocks) and naive to stress same-sex conspecific and the amount of time they spend investigating these conspecifics is recorded. Under control conditions both male and female test rats show a preference for stressed juveniles but avoid stressed adult conspecifics. We found that, following 0.5 mg/kg PolyI:C dose on E12, male adult offspring (P50) had altered social decision making compared to control rats, showing no preference for either stressed juveniles or naive adults. Female adult MIA offspring, however, maintained their preference for stressed juveniles but lost their preference for naive adults. These results indicate that males show a global change in SAP based social decision-making while females show a more subtle

change in social decision making that is age and MIA dependent. Behavior in the SAP test depends upon insular cortex corticotropin-releasing factor (CRF) and is related to an increased synaptic efficacy in control males but not females. As such, we followed up this experiment by testing for changes in field excitatory postsynaptic potentials (fEPSP) using a perforated multiple electrode array. Bath application of CRF (300 nM) led to sex-specific changes in synaptic efficacy such that male MIA offspring were not affected by CRF while female MIA offspring exhibited greater sensitivity to CRF compared to sham littermates. Taken together, these results show that prenatal PolyI:C affects male and female offspring social decision making differently and this may be due, at least in part, to a loss of insular sensitivity to CRF in males and a gain of insular sensitivity to CRF in females.

Title: Vasopressin in the bed nucleus of the stria terminalis regulates social behavior in male and female mice

Authors: *N. RIGNEY, G. J. DE VRIES, A. PETRULIS;
Georgia State Univ., Atlanta, GA

Abstract: The neuropeptide arginine-vasopressin (AVP) has long been implicated in the regulation of social behavior and communication, but the source of AVP release relevant for behavior has not been precisely determined. Ablations of the sexually dimorphic (greater in males than females) AVP-expressing cells within the bed nucleus of the stria terminalis (BNST) result in sex-different effects on social behavior. However, it is unknown if vasopressin itself, or other neuroactive substances present in these cells, is responsible for sex-dependent effects on social and communicative behaviors. To test the role of AVP specifically, we used a shRNA viral construct (or scrambled control virus) to effectively knockdown AVP gene expression within the BNST of wild-type male and female mice and evaluate any subsequent changes in anxiety-like behaviors (elevated plus maze) or social behaviors (social investigation, ultrasonic vocalizations, scent marking, copulation, aggression). Knockdown of BNST AVP in males strongly reduced investigation of male competitors as well as aggressive signaling (tail rattling), while not altering attack initiation. In females, BNST AVP knockdown reduced female sex behavior. These results point to differential involvement of BNST AVP in social behavior in the two sexes, which may contribute to sex differences of social communication disorders.

Title: Anterior cingulate cortex activity correlates with approach behavior induced by repeated playback of 50-kHz ultrasonic vocalizations and the impact of social factors in rats

Authors: *A. BERZ[1,2], C. PASQUINI DE SOUZA[3], M. BRUNTSCH[1], M. K. SCHAFER[4,2], S. STEINMÜLLER[1], M. WÖHR[5,1,2], R. K. SCHWARTING[1];

Abstract: Rats, which are highly social animals, use several routes of communication including vocal ones. Most of these are ultrasonic vocalizations (USV), which are known to serve situation-dependent socio-affective signals. In appetitive situations, for example juvenile play, 50-kHz USV occur, which are thought to reflect the sender's positive affective state and which support contact among conspecifics. Playback studies have shown that 50-kHz USV leads to a pronounced approach, especially in juvenile recipients. In contrast, a reduced approach to such playback is observed when the same playback is repeated days after the first one. Since the reasons for this memory-dependent habituation phenomenon are largely unknown, we asked whether it is due to the fact that playback is usually not followed by a social consequence. We tested three groups of male, juvenile Wistar rats, which, immediately after the first playback session, were exposed either to an empty cage, an unfamiliar male conspecific or returned back to their housing group cage. Unexpectedly, all three groups showed similar levels of habituation in the playback retest. After this retest, their brains were analyzed using c-fos immunohistochemistry focusing on the cingulate cortex, since it is involved in the processing of 50-kHz USV and behavioral responses to them. In parallel to the behavioral results, we found no group differences in the number of c-fos positive cells, but when considering individual levels irrespective of group assignment, we found a strong positive correlation between approach scores in the retest and cell numbers in the left cingulate cortex. These results do not support the hypothesis that habituation to repeated 50-kHz USV playback is due to the lack of social consequences after the first playback but indicate that the cingulate cortex is involved in the residual approach in the retest.

Title: An amygdalo-cortical circuit for cortical integration of multisensory social cues

Authors: *A. C. NOWLAN[1], A. CORONA[1], C. C. KELAHAN[2], S. D. SHEA[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Regeneron, White Plains, NY

Abstract: Many species, including mice, communicate using multisensory signals to coordinate social behaviors that are essential for survival (e.g. maternal care of offspring). Pup retrieval behavior requires caregivers to successfully detect both ultrasonic distress vocalizations and pup odors to retrieve isolated pups back to the nest. The onset of retrieval behavior coincides with dramatic changes in the auditory cortex of both mothers and 'surrogates' (virgin females cohoused with a mother and her pups). Interestingly, the presentation of volatile pup odors modifies the response profiles of auditory cortical (AC) neurons in caregiving mothers and surrogates, but not in naïve virgins. Currently, there is no known direct anatomical conduit between the olfactory periphery and AC that would allow this modulation to occur. Here we show that there is a projection from the basal amygdala (BA) to the AC that influences AC encoding of pup-related stimuli and may improve pup retrieval behavior. First, using fiber photometry to record population activity, we show that these amygdala-cortical projection neurons are sensitive to odors, including pup odor, and that they are primarily active while the surrogate searches for the isolated pup. Second, we find that optogenetic activation of the circuit during the presentation of auditory stimuli evokes complex changes to AC neuronal activity. Specifically, we found that optogenetic activation of the circuit preferentially suppressed auditory responses in naive females, but enhanced auditory responses in surrogates. Based on the amygdala's known role in valence processing, we hypothesize that the BA->AC circuit may attribute additional emotional salience to the representation of pup stimuli within the AC. Together these data suggest a bottom-up mechanism by which olfactory cues shape cortical auditory representations via the BA to drive appropriate social behavior.

Title: Sex differences in rat insular cortex CRF and endocannabinoid systems provide a sex-specific mechanism for social affective behavior.

Authors: *A. J. NG, N. RIEGER, J. CHRISTIANSON;
Boston Col., Chestnut Hill, MA

Abstract: Stress is an important determinant of social behavior, and corticotropin releasing factor (CRF) initiates the central response to stressors, including responses to observing stress in others. CRF fibers and receptors are found within the neural circuits underlying social decision-making and, as such, provide a link between stress and social systems. We investigated CRF in the insular cortex (IC), a region involved in approach/avoidance decisions with stressed others. In acute IC slices from adult rats, application of CRF (50 to 300nM) increases field excitatory postsynaptic potentials (fEPSP) in males, but not females. The CRF enhancement of excitatory transmission depends on CRFR1 and $GABA_A$ which led us to hypothesize that CRF may modulate presynaptic inhibition via endocannabinoid signalling. Pretreatment of slices with CB1 receptor antagonist (AM251, 2μM) prevented the CRF-induced increased fEPSP in males. Behaviorally, insular CRF increased social interaction in male rats but not when co-administered with AM251. Similarly, AM251 prevented approach or avoidance, respectively, of stressed adult (PN50) and juvenile (PN30) conspecifics, suggesting that the insular cortex is a site of CRF modulation of neural activity via CB1. Because these synaptic and behavioral effects were only observed in males, we investiaged sex-differences in insular CRFR1 and CB1 receptor expression with RNAScope *in situ* hybridization. Males expressed significantly more CRFR1 and CB1 mRNA and more co-expression in insular glutamateric (vglut1) cells compared to females, providing a basis for the physiological and behavioral sex differences at the level of gene expression. These results identify novel roles for CRF and endocannabinoids in regulating cortical circuit function and further delineate the neurobiology of social decision-making.

Title: Semantic segmentation for analysis of social preference in rats.

Authors: *N. B. WORLEY[1], A. J. NG[2], N. RIEGER[1], J. P. CHRISTIANSON[2];
[2]Psychology, [1]Boston Col., Chestnut Hill, MA

Abstract: Automated analysis of animal behavior using machine learning holds the promise of reducing experimenter effort and bias while improving temporal precision. Markerless pose estimation uses a model trained through supervised machine learning to identify key points on an animal (such as body parts or joints) frame by frame in a video. A ball and stick model created from these points is then used to perform behavioral analysis. This method alone may be insufficient when investigating social behavior where multiple moving conspecifics must be identified. To resolve this issue, we combined pose estimation with another supervised machine learning based tool known as semantic segmentation, which can identify the moving targets location at the individual pixel level. Example targets are labeled to form binary masks of the target, in this case a rat in a social interaction test, and the background. Using videos of a rat social preference test, we applied pose estimation to identify the location of the focal test rat's head and its orientation relative to targets isolated in plastic chambers at either end of the arena. To determine the location of the targets, we trained a semantic segmentation model, and quantified model performance (intersection over union) under several conditions. We systematically varied the model architecture (e.g. pretrained backbone, size and number of transposed convolutional filters) and training specifications (e.g. size of test set, batch size, data augmentation). The resulting masks were used to identify the minimum distance between the test and target rats. This machine learning method successfully reproduced hand-scored results. Additionally, this method rivals hand-scoring in terms of experimenter effort, reduces experimenter bias, and increases temporal accuracy which will facilitate time-series analysis with tools such as fiber photometry and electrophysiology.

Title: Waving through the window: an operant model of social reward in female mice

Authors: M. F. GARCIA, B. T. HOPE, Y. SHAHAM, M. VENNIRO, *L. A. RAMSEY;
NIDA IRP, Baltimore, MD

Abstract: Background: Maladaptive social behavior is a cardinal feature of neuropsychiatric disorders. Rodent models of social behavior classically rely on unconditioned measures of social preference such as time spent in contact with a social partner. We recently developed an operant self-administration and choice model in which rats lever-press for social interaction (Venniro et

al. Nat Neurosci 2018). Here we introduce a mouse version of this model.
Methods: We compared adult female C57/Bl6J to adolescent and adult female CD1 mice using custom-made social self-administration chambers. We first trained the mice to self-administer palatable food pellets (8 days – 1-h/d). Then, we trained them to lever-press for access to a female social partner (23 days – 1 h/d – fixed ratio 1 to 6 reinforcement schedule). We then tested their motivation to seek social interaction using a progressive ratio schedule (3 d). Finally, we investigated preference for food versus social interaction using a discrete trial choice procedure.
Results: The female mice of both strains showed reliable food self-administration. In contrast, only CD1 mice learned to lever-press for access to a social partner, whereas C57 mice did not. The CD1 mice continued to lever-press when the response requirements were increased under both fixed-ratio and progressive-ratio schedules. They also preferred social interaction over palatable food. We observed no differences between adult and adolescent CD1 mice.
Conclusions: Our new mouse social administration and choice model opens up new avenues for research on neurobiological substrates of social reward learning using multiple genetic tools that are only available in mice.

Title: Relationship between hostile sexism and gender-biased bullying mediated by nucleus accumbens volume

Authors: E. HAMEL[1], *H. SUZUKI[2];
[1]Dept. of Child, Youth and Family Studies, [2]Dept. of Educational Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Bullying is widespread in American schools. Social-group dimensions are often factors involved in bullying, with sexism showing the strongest association with bullying. Yet, no study has comprehensively investigated whether sexism is associated with altered brain structure and escalated gender-biased bullying. This study examined the relationships among sexism and bullying behavior with individual brain structure accounting for variation. We focused on the volume of the nucleus accumbens (NAc) as a mediator due to its role in social aspects of reward processing and involvement in aggression. We hypothesized that the relationship between sexism and gender-biased bullying existed indirectly, mediated by NAc

volume. Young adult participants (N=47) underwent T1-weighted Magnetic Resonance Imaging (MRI) scan (MP-RAGE, voxel volume = 1.0 x 1.0 x 1.0 mm^3) on a 3T Siemens Skyra scanner, with 32ch brain array coil. Then, participants were asked to report their history of bullying girls and boys respectively during schools. Gender-biased bullying was computed by dividing the number of girls who participants bullied by that of boys who participants bullied. Participants also completed the Ambivalent Sexism Inventory (ASI) to assess hostile and benevolent sexism. FreeSurfer was applied to MP-RAGE to measure the estimated intracranial volume (eTIV) and the bilateral NAc volumes. Then, we first tested correlations among hostile/benevolent sexism, NAc volumes, and gender-biased bullying in those with/without a history of bullying. Based on our correlations, we further tested the model where NAc volume mediated in the relationship between sexism and gender-biased bullying, with the bootstrapping method.Results revealed that hostile sexism, right NAc volume, and gender-biased bullying were associated with each other in those with a history of bullying (all p's<0.05). Furthermore, increased hostile sexism was associated with reduced right NAc volume (t=-2.50, p<0.05), which in turn increased gender-biased bullying (t=-2.46, p<0.05); when right NAc volume was controlled for, the relationship between hostile sexism and gender-biased bullying (t=2.79, p<0.05) turned to nonsignificant (t=1.47, p=0.16). In contrast, benevolent sexism or left NAc volume was not related to gender-biased bullying. These findings suggest that bullies with strong hostile sexism tend to have smaller right NAc volume. When their right NAc volume is reduced, they subsequently target female victims more than male victims. The role of the NAc in the context of sexism and bully needs to be further investigated.

Title: Social investigation of stressed juveniles is mediated by basolateral amygdala projections to the insular cortex

Authors: *A. DJERDJAJ, N. B. WORLEY, A. J. NG, N. S. RIEGER, J. P. CHRISTIANSON; Psychology, Boston Col., Chestnut Hill, MA

Abstract: Social vocalizations, chemosignals, and behavioral expressions of one's internal affective state shape the selection of social behavior responses made by others who detect these cues. A network of interconnected brain structures called the social decision making network (SDMN) integrates these stimuli and network output yields social behaviors that are appropriate for a given interaction. Deficits in SDMN connectivity underlie several psychiatric disorders

such as schizophrenia and autism so further understanding the function of the SDMN may grant us new insight into aberrant social behaviors. The basolateral amygdala (BLA) and the insular cortex (IC) are reciprocally connected and each contribute to social and emotional behaviors. We explored the involvement of BLA projections to the IC in a social affective preference (SAP) test in which a test rat is presented with 2 juvenile conspecifics (PN30), 1 naïve to treatment and 1 stressed via 2 footshocks. Test rats prefer interaction with the stressed juvenile in this paradigm. Chemogenetic inactivation of the BLA via bilateral transduction of AAV-hSyn-hM4D(Gi)-mCherry followed by systemic administration of clozapine-N-oxide (3mg/kg) prior to SAP tests prevented test rat preference for the stressed juvenile. Further, inhibition of IC-projecting BLA neurons via CNO injection (1μM) directly into the IC also prevented preference for the stressed juvenile. Additionally, DeepLabCut, a machine learning algorithm that can be implemented for markerless pose estimation, was used in conjunction with semantic segmentation to obtain unbiased behavioral data detailing the amount of time each rat spent investigating each conspecific. Ongoing investigations include transsynaptic tracing to determine BLA-IC projection patterns and in vivo Ca2+ imaging of BLA neuronal activity during encounters with stressed conspecifics to observe neural signatures of this social behavior. The current results identify a new tract by which social emotional information is processed within the SDMN.

Title: Mapping the neural correlates of approach and avoidance in adolescent social anxiety: An fMRI analysis of brain response during peer observation

Authors: *J. BEZEK, A. SMITH, Q. DO, M. YETTER, E. CARDINALE, D. PINE;
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Introduction: Adolescence is a sensitive developmental period defined by ongoing prefrontal maturation and an increased focus on peer interactions. However, this emphasis is often marked by enhanced fear of negative evaluation and greater risk for developing social anxiety. The conflict between social motivation to engage and fear of judgement reveals a complex interaction between approach and avoidance behaviors. However, most previous work in pediatric anxiety has focused on the avoidance system. The present study expanded this work by investigating the neural mechanisms underlying both approach and avoidance motivations in an evaluative social context.

Methods: Adolescents aged 8-17 (N=52; Age: M=14.26, SD=2.46) with a range of anxiety symptoms completed the BIS/BAS questionnaire to assess avoidance and approach tendencies, respectively (Carver & White, 1994). Errors during a cognitive control task (Eriksen Flanker), defined as indicating the incorrect direction of the center arrow, were measured during functional magnetic resonance imaging. The task was adapted such that participants believed they were being observed by an age- and sex-matched peer for half of the task and alone for the other half. Whole-brain analyses used BIS and BAS scores as continuous, between-subjects variables, while social context (peer, alone) and trial type (error, correct) were within-subject variables. All analyses controlled for age.
Results: Preliminary analyses revealed that high approach and avoidance scores were associated with distinct prefrontal activation patterns. Adolescents with higher approach scores showed decreased ventromedial prefrontal cortex (vmPFC) activity during peer observation relative to when they were alone ($r=-.41$, $p<.005$, $k=63$). Higher avoidance scores were associated with decreased medial frontal gyrus (mPFC) activation when youths committed an error in front of a peer relative to alone ($r=-.44$, $p<.005$, $k=80$).
Discussion: The current analysis revealed that youths with higher approach motivations demonstrated less prefrontal activation in regions typically associated with self-referential thought (i.e., vmPFC) when observed by peers. Alternatively, youths with stronger avoidance tendencies showed less mPFC recruitment, a region essential to engaging cognitive control, during peer-observed errors. This work suggests there are unique prefrontal profiles underlying distinct social motivations during this sensitive neurodevelopmental period. Dissecting these neural mechanisms is an important step toward informing interventions against maladaptive approach and/or avoidance behaviors in adolescence.

Title: Mapping the time course of brain activation in affective picture processing

Authors: *L. CUI, K. BO, A. KEIL, M. DING;
Univ. Florida, Gainesville, FL

Abstract: Viewing emotionally engaging scenes activates a large-scale brain network consisting of both cortical and subcortical regions. Mapping the time course of activation of these regions is a key step toward developing a theoretical account of affective scene processing. For aversive scene content, past work has suggested rapid processing along the subcortical pathway, superior

colliculus->pulvinar->amygdala, the function of which is to provide the context for the more deliberate processing along cortical visual pathway. Less is known about the neural processing of pictures displaying neutral and pleasant content. We recorded simultaneous EEG and fMRI data from 20 participants viewing pleasant (20), unpleasant (20) and neutral (20) pictures from the International Affective Picture System (IAPS). Following data preprocessing, representational dissimilarity matrices (RDMs) were obtained from fMRI in pulvinar, amygdala, early visual cortex, ventral visual cortex, and dorsal visual cortex for each of the three picture categories, as well as from EEG at each time point. RDMs from EEG at each time point were correlated with that from fMRI in each ROI. From the correlation functions peak latencies were estimated, the peak latency data suggested the following sequence of activation: (1) for unpleasant pictures: pulvinar->amygdala->early visual cortex->ventral/dorsal visual cortex, (2) for neutral pictures: pulvinar->amygdala/early visual cortex->ventral/dorsal visual cortex, and (3) for pleasant pictures: amygdala->pulvinar->early/ventral visual cortex->dorsal visual cortex. These results shed new light on affective scene processing and demonstrate that combining simultaneous EEG-fMRI with multivariate methods can yield spatial-temporal dynamics not possible with each method alone.

Abstract: The perception of opportunities and threats in complex scenes represents one of the main functions of the human visual system. The underlying neurophysiological basis is often studied by having observers view pictures varying in affective content. It is shown that viewing emotionally engaging, compared to neutral, pictures (1) heightens blood flow in limbic, frontoparietal, and anterior visual structures, and (2) enhances late positive event-related potential (LPP). The role of retinotopic visual cortex in this process has, however, been contentious, with competing theories predicting the presence versus absence of emotion-specific signals in retinotopic visual areas. Recording simultaneous EEG-fMRI while observers viewed

pleasant, unpleasant, and neutral affective pictures, and applying multivariate pattern analysis, we found: (1) unpleasant-versus-neutral and pleasant-versus-neutral decoding accuracy, were well above chance level in all retinotopic visual areas, (2) decoding accuracy in ventral visual cortex (VVC), but not in early or dorsal visual cortex, was correlated with LPP, and (3) effective connectivity from amygdala to VVC predicted unpleasant-versus-neutral decoding accuracy, while that from ventral frontal cortex to VVC predicted pleasant-versus-neutral decoding accuracy. These results suggest that affective scenes evoked valence-specific neural representations in retinotopic visual cortex and that these representations were influenced by reentry signals from anterior brain regions.

Abstract: Distracted by affective pictures: Neural mechanisms revealed by multivariate pattern analysis
Ke Bo[1], Changhao Xiong[1], Nathan M. Petro [2], Andreas Keil[3], Mingzhou Ding[11]J Crayton Pruitt Family Department of Biomedical Engineering, University of Florida[2]Department of Psychology, University of Nebraska at Lincoln[3]Department of Psychology and the NIMH Center for Emotion and Attention, University of Florida
Affective pictures are highly potent distractors. In this study we examined the impact of picture valence on task-relevant visual processing and the underlying neural mechanisms. Simultaneous EEG-fMRI were recorded while participants detected instances of coherent motion in a random dot kinematogram (RDK) overlayed on IAPS pictures (pleasant=erotic couples, neutral=workplace people, and unpleasant=bodily mutilations). Applying support vector machines to BOLD responses in ventral visual cortex (VVC) and MT cortex we found the following results. First, decoding accuracy of both pleasant-vs-neutral and unpleasant-vs-neutral distractors was above chance level in both VVC and MT cortex, at 62.6% and 59.4% for VVC , 71.2% and 64.5% for MT, respectively. Second, in early period of VVC (3-5 TR after stimulus onset) across subjects, decoding accuracy of unpleasant-vs-neutral distractors was negatively correlated with the correctly identified instances of coherent motion ($p=0.01$), namely, the higher the decoding accuracy the lower behavior performance; decoding accuracy of pleasant-vs-neutral distractors, however, was not associated with behavioral performance. Third, in MT we found

similar effect (p =0.019) on unpleasant-vs-neutral distractors with VVC in late period (6-8 TR after stimulus onset) yet pleasant-vs-neutral distractors did not show such effect. In summary, these results demonstrated that (1) although pleasant distractors were better represented than unpleasant distractors in these two ROIs, it was the unpleasant distractors that had a stronger adverse influence on behavior and (2) Unpleasant distractor represents on VVC and MT to adversely impacted behavior of ongoing task in sequence.

Title: Deep Brain Stimulation of the Anterior Nucleus of Thalamus Neutralizes the Effects of Emotions on Attention.

Authors: ***H. N. SONG**[1], Y. RAH[2], S. A. LEE[2];
[1]Dept. of Bio & Brain Engin., [2]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Deep brain stimulation (DBS) is an established treatment method for medication resistant epilepsy patients. The anterior nucleus of thalamus (ANT), a component of the Papez circuit, is one of main target regions for DBS treatment of epilepsy. However, there are reports that one of the adverse side effects of such treatment is abnormal emotional response. According to previous studies, the ANT-DBS may affect the interaction between attention and emotion. Taken together, this study focused on how the ANT-DBS changes the effects of emotions on attention. Five refractory epilepsy patients participated in this study, and one of them was rejected due to impairment of cognitive ability. For experimental conditions, three types of emotional pictures (neutral, positive, and negative) were selected from International Affective Picture System (IAPS). There were three DBS conditions (no-stim, left, and right), and the intensity of stimulation was 1.5V with 90usec of pulse width and 130Hz of frequency. In every trial, the picture was briefly presented (75ms) and masked by another neutral picture non-overlapping (225ms). Then, a cued flanker task was immediately presented in which patients had to press a button indicating the correct direction of a target arrow. Subjects were instructed to focus on the flanker task and to respond as quickly as possible. We found that, without DBS, patients tended to react more slowly when they were primed by negative emotion, replicating findings from previous studies that showed that emotional stimuli, in particular negative emotions, interfere with attention. With DBS, however, this effect was neutralized in that

reaction times following emotional pictures were significantly faster than that without DBS and identical to the neutral pictures condition. In contrast, DBS did not affect performance in the neural condition. ANT-DBS may have interrupted the processing of emotion and, consequently, its interference on attention. This effect of DBS was observed in every subject.

Title: The representations of realistic events are grounded in semantic and emotional brain regions.

Authors: *M. RIBERTO[1,2], R. PAZ[1], G. POBRIC[2], D. TALMI[3];
[1]Neurobiology, Weizmann Inst. of Sci., Rehovot, Israel; [2]The Univ. of Manchester, Manchester, United Kingdom; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Background. Human beings render events meaningful by categorising and attributing an affective value to them. Investigating the neural correlates of high-level representations of realistic events is of paramount importance for the research on semantic and social cognition, as well as mood and anxiety disorders. Different questions are still unsolved in this field. Which regions are involved in the representation of realistic events? Does this depends on the aspects (visual, semantic, and emotional) of the stimuli participants focus on during experimental paradigms? We know that different regions encode and integrate the relevant information about each stimulus, but it is not known whether its emotional value is encoded separately.**Methods.** We selected 72 complex pictures from freely-available sources, which depicted 4 separate categories of realistic events. Two were neutral (people doing laundry, people on the phone) and 2 negative emotional (poverty scenes, car accidents). The categories differed in valence and arousal, and were balanced for visual properties. During a functional Magnetic Resonance Imaging (fMRI) scan, participants (n=29) performed a visual complexity rating of the pictures. After the scan, they arranged these pictures in a bidimensional space according to the similarity among them (multi-arrangements, MA, task). We used searchlight Representation Similarity Analysis (RSA) to unveil which brain region represented the participants' similarity space. The brain activation-patterns matrix was obtained by moving a 3x3x3 spherical cluster throughout the brain and at each location a correlational distance (1-correlation) among t values is assigned to the centre voxel of the sphere. This was then correlated with the behavioural similarity matrix. Inference was performed at each voxel by performing a signed rank test across subjects (p_{FDR} <0.05). **Results.** In the behavioural experiment, we found higher dissimilarity between categories, than within category (p_{FWE}<0.001), and lower dissimilarity within the 'car accidents' category compared to the other within category conditions (p_{FWE}<0.05). The behavioural data significantly correlated with the neural patterns in the Inferior Temporal Cortex (ITC) (right:

x=48, y=-58, z=-10; Z=5.28; left: x=-48, y=-46, z=-22; Z=5.32) and in the Precuneus (right: x=9, y=-58, z=-10; Z=4.86; left: x=-6, y=-58, z=29; Z=4.86).**Conclusions.** The ITC is involved in the semantic representations of realistic events and the Precuneus in the representation of their affective dimension. This is separately encoded, despite of the aspects participants focused on during the task.

Title: Individual negativity bias is associated with biased neural processing weighing negative information in the salience network

Authors: *G. KIM, T. KIM, S.-H. LEE;
Korea Advanced Inst. of Sci. and Technol. (KAIST), Daejeon, Korea, Republic of

Abstract: The recognition of emotions through facial expressions is essential for our interpersonal communication. Negativity bias in facial emotion recognition, a tendency to interpret ambiguous facial expressions more negatively than they actually are, can therefore lead to difficulties in our social interactions. The negativity bias is thought to be caused by over-weighted negative information over positive or neutral information during the process of information integration. However, this possibility has not yet been clearly determined. Given that the salience network (SN) is considered to play a key role in the multiple information integration to evaluate subjective saliency, here we investigated whether individual negativity bias in face emotional recognition is mediated by the SN information processing. Using functional magnetic resonance imaging and neural pattern analyses for facial emotions, we found that the degree of individual negativity bias depends on how much weighted negative information is integrated into the neural representation of the SN. This tendency was not observed for positivity bias, and was not detected in other networks such as the higher visual network or default mode network. These findings suggest that individual negativity bias is critically associated with the biased information integration weighing negative information in the SN.

Title: Emotion regulation training induces wide-spread changes in functional activation and connectivity

Authors: *O. L. COOK, J. KANE, K. HUNT, B. DEPUE;
Univ. of Louisville, Louisville, KY

Abstract: Emotion Regulation Training Induces Wide-Spread Changes in Functional Activation and Connectivity Cook, O., Kane, J., Hunt, K., Naaz, F. & Depue, B.University of Louisville
"Brain Training" programs are becoming more ubiquitous in mainstream society. However, there are relatively few studies exploring whether specific task related training leads to functional plasticity in the brain. Furthermore, no studies exist, to our knowledge, that explore training an individual's ability to down-regulate emotion reactivity. Importantly, understanding which neural regions show changes across training highlights important brain mechanisms involved in emotion regulation processes; processes which are critical to efficient daily functioning. We explored this question using fMRI before and after emotion regulation training. Eighteen undergraduate students were recruited in a 5-day training study. Participants were scanned on day 1 and day 5. The emotion regulation task and training consisted of a standard emotion regulation paradigm, in which participants were asked to down-regulate their physiological response to negatively valanced IAPS pictures. A subjective emotion ratings task was performed before (baseline) and approximately 30 minutes later (ER-rating) required participants to interrogate their subjective emotional feeling toward IAPS pictures. Behaviorally, a significant decrease in subjective negative emotion ratings occurred on day 5 compared to day 1 ($p<.03$; M=2.1/2.6). Functional analyses revealed decreased activation in the dorsal medial prefrontal cortex (dmPFC), right inferior and middle frontal gyri (rIFG/rMFG), and both ventral and dorsal amygdalae on day 5 compared to day 1. Conversely, increased activation was seen in the orbitofrontal cortex (OFC) on day 5 compared to day 1. Using the above regions in functional connectivity analyses, revealed that while functional activation decreased, increased functional connectivity was observed in the rMFG-OFC and OFC-amygdalae.

Title: Gray matter volumetric correlates of impulsivity in children: an adolescent brain cognition development project

Authors: C. LI, S. ZHORNITSKY, J. S. IDE, ***C.-S. R. LI**;
Yale Univ., New Haven, CT

Abstract: Previous research has investigated the cerebral volumetric correlates of impulsivity, largely in moderate-sized samples, and the findings varied extensively across studies. Here, we followed published routines and performed voxel-based morphometry analysis of a data set (n=11,542; 5,491 girls, 9-10 years) curated from the Adolescent Brain Cognition Development project. Of the sample, 648 and 2,697 were identified as monozygotic twins and dizygotic twins/siblings, respectively. In linear regression with each of the subscores of the UPPS-P, we aimed to identify volumetric correlates of negative urgency, positive urgency, sensation seeking, lack of planning and lack of perseverance in girls and boys combined as well as separately. The results showed both sex- shared and specific correlates, involving a wide array of cortical and subcortical regions, for negative urgency, positive urgency, sensation seeking, and lack of planning. In contrast, lack of perseverance was distinctly associated with lower volumes of bilateral putamen across all subjects, with a steeper loss of volumes in boys than in girls as confirmed by a slope test. Further, genetic modeling showed that whereas negative urgency, positive urgency, sensation seeking, and lack of planning subscores were more amenable to unique environmental influences (h^2 ~0.25, e^2~0.74), lack of perseveration showed a strong heritability (h^2 ~0.79, e^2~0.47) in both girls and boys. The volumetric correlates showed strong heritability (h^2 ~0.70) for all five subscores. These findings highlight the neural markers of a critical personality trait and suggest a unique role of putamen volume in determining lack of perseverance. The findings may inform future studies in investigating the inter-relationship between genetics, cortical and subcortical volumes, and clinical manifestations, including those that specifically implicate putamen GMV deficits.

Title: Is your pain my pain? Effects of localized placebo analgesia on empathy for everyday painful situations

Authors: *H. HARTMANN, F. RIVA, M. RÜTGEN, C. LAMM;
Dept. of Cognition, Emotion, and Methods in Psychology, Univ. of Vienna, Vienna, Austria

Abstract: Empathy for pain involves the affective-motivational and the sensory-discriminative pain processing network. The shared representations account of empathy postulates that sharing another person's pain recruits similar underlying brain functions that are also engaged during first-hand pain processing. Previous research underlines this, reporting reduced empathy for pain when reducing first-hand pain by means of placebo analgesia. Critically, causal experimental evidence for shared representations has so far only been shown in brain areas related to affective pain processing, while the specific contribution of one's own somatosensory system to empathic responding remains controversial. The experimental paradigms used in previous studies did not direct attention towards a specific body part in pain and relied on inferring the other's pain via abstract cues, which could explain the absence of effects. In this study, we thus aimed to test more specifically whether a localized causal manipulation of first-hand pain affects somatosensory processing during empathy for everyday painful situations in a body part-specific manner. This study was preregistered prior to data collection (https://osf.io/uwzb5) and the main analyses are thus confirmatory, but we also include exploratory analyses. Forty-five participants (right-handed, 23 females, age: M/SD = 23.8/2.7 years) underwent a localized placebo analgesia induction targeted at the right hand (with the left hand acting as a control) and completed an empathy for pain task in the MRI scanner where they observed pictures of either right or left hands in pain and rated the pain intensity of the person in the picture as well as their own unpleasantness. Contrary to our predictions, we did not find evidence for a location-specific modulation of empathy for pain as a result of the placebo induction, in neither behavioral nor neural measures. However, exploratory data analysis revealed a general downregulatory effect of the placebo on empathy for pain, and increased brain activity in bilateral anterior insula when viewing other's hands in pain that corresponded one's placebo hand. Hence, somatosensory sharing during empathy does not appear to be modulated by placebo analgesia in a location-specific manner. These results refine our knowledge regarding the mechanisms underlying empathy for pain.

Title: Neural mechanisms and predictors of response to electroconvulsive therapy: a transdiagnostic approach

Authors: *M. WATSON[1,2], C. TIZZARD[2,1], A. GEBARA[1], L. MCMURRAY[3], S. GUIMOND[1,4,6], S. TREMBLAY[1,2,5];
[1]The Royal's Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [2]Neurosci., Carleton Univ., Ottawa, ON, Canada; [3]The Royal Ottawa Mental Hlth. Ctr., Ottawa, ON, Canada; [4]Psychologie, Univ. du Québec en Outaouais, Gatineau, ON, Canada; [5]Psychoéducation et psychologie, Univ. du Québec en Outaouais, Gatineau, QC, Canada; [6]Psychiatry, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background. Electroconvulsive therapy (ECT) is an effective treatment for many mental health disorders. Unfortunately, there are often cognitive side effects associated with ECT and not all patients will show clinical response. Developing a neurobiological predictor of outcome to identify which patients will benefit from ECT is essential to avoid unnecessary impairments for those who do not respond. In addition, the neural mechanisms of ECT are not well understood and research into the cognitive symptoms is inconsistent. **Objectives.** Using an open-label naturalistic approach, this exploratory study aims to identify neural mechanisms and neurobiological predictors of cognitive and clinical outcome, as well as monitor the effects of ECT on cognition. **Methods.** We will recruit 60 males and females, 18 to 65 years old, over two years with diverse mental health disorders (i.e. depression, psychosis) receiving ECT treatment. Using a Magpro X100 device (Magventure, Denmark), transcranial magnetic stimulation (TMS) will be applied to the left primary motor cortex to non-invasively explore how excitatory and inhibitory brain mechanisms are linked to clinical and cognitive outcome. We will use a standard TMS procedure: 1) single pulse TMS, 2) short interval intracortical inhibition, 3) long interval intracortical inhibition and 4) intracortical facilitation. For each of the four measures, 20 pulses will be sent every 5-7 seconds while electromyography signals are recorded on the left first dorsal interosseous muscle, reflecting corticospinal excitability. TMS recordings will be conducted pre- and post-ECT which will be correlated with clinical and cognitive outcome. We will use a novel cognitive screening tool, i.e. the ElectroConvulsive Therapy Cognitive Assessment (ECCA), which is a quick assessment of cognitive domains (orientation, attention, verbal delayed recall, factual knowledge, and autobiographical memory) commonly affected by ECT. ECCA will be administered before ECT and at two time points after. Repeated measures analysis of variance, correlational analyses and logistic regression models will be conducted for each subgroup diagnosis, ECT parameters, and biological sex. Due to COVID-19, our study is currently only collecting clinical and cognitive data remotely, and we do not have enough data at this time to report results. **Conclusion.** We are hopeful when research restrictions are lifted, this study will determine neural mechanisms of ECT, neurobiological predictors of clinical and cognitive outcome, and further validate the efficacy of the ECCA. This research is crucial to help guide clinicians and patients in their decision to receive ECT.

Title: Profiling extracellular vesicles in the anterior cingulate cortex of individuals with Major Depressive Disorder

Authors: ***P. IBRAHIM**[1], J.-F. THÉROUX[2], Z. AOUABED[2], C. NAGY[1], G. TURECKI[1]; [1]McGill Univ., Montreal, QC, Canada; [2]Douglas Hosp. Res. Ctr., Verdun, QC, Canada

Abstract: Major Depressive Disorder (MDD) is one of the leading causes of disability worldwide, affecting 20% of the population. MDD also confers a 20-fold higher risk of suicide. Environmental factors are thought to play a role in disease development, resulting in biological changes mediated by epigenetic mechanisms. MicroRNA's (miRNA) are well known epigenetic regulators that are disrupted in the depressed brain, and they are packaged into extracellular vesicles (EVs). EVs have emerged as means of intercellular communication, a process that is also disrupted in MDD. They are thought to transfer miRNA, as well as other bioactive molecules such as proteins, between cells. This can alter gene expression in recipient cells. Different cell types in the brain have been shown to release EVs, so it is possible that EVs might play a role in the pathogenesis of central nervous system disorders, including MDD. Therefore, we hypothesize that EV cargo from the anterior cingulate cortex, a brain region highly implicated in MDD, will have a disease specific profile that could mediate disease development in MDD subjects compared to healthy controls (HC). We aim to isolate EVs from human post-mortem anterior cingulate cortex, profile the miRNA and protein cargo, and compare it between MDD subjects and HC. EVs were isolated from post-mortem human brain tissue from the anterior cingulate cortex of 43 MDD subjects and 43 HC using size exclusion chromatography. The quality was assessed by western blots and transmission electron microscopy (TEM). RNA was extracted and a small-RNA library was constructed and sequenced using the Illumina Platform. Proteins were also extracted and profiled using LC-MS/MS. Differential expression analysis was then performed. Western blots showed little to no contamination with cellular debris, along with enrichment of the exosomal marker CD9. TEM images showed the typical cup-shaped morphology with sizes mostly between 30 and 200 nm. Preliminary differential analyses revealed that both the miRNA and proteomic profiles of the EVs are dysregulated in MDD. In conclusion, high quality EV extractions can be obtained from post-mortem brain tissue using our method. This will be the first study to profile brain-derived EV miRNA and protein in the context of depression. Future studies will be needed to determine the effect of the

dysregulated EV cargo in MDD. This could provide novel mechanistic insights into the pathophysiology of MDD and will serve as a starting point to examine the potential role of EVs in MDD pathology, which could be a starting point for the development of targeted therapeutic strategies as well as prevention measures.

Title: Activity based anorexia results in oxidative stress in adolescent female rats: Systemic and central evidence.

Authors: *M. M. HURLEY[1], K. MURLANOVA[2], S. C. O'BRIEN[1], L. K. MACIAS[1], M. TAREKEGNE[1], A. N. NAWARI[1], H. BHASIN[1], A. I. SABIR[1], K. L. K. TAMASHIRO[1], M. V. PLETNIKOV[2], T. H. MORAN[1];

[2]Dept. of Physiol. & Biophysics, Univ. of Buffalo, Buffalo, NY

Abstract: Anorexia Nervosa (AN) is a devastating eating disorder characterized by excessive exercise, starvation and weight loss. Our lab utilizes the activity based anorexia (ABA) rodent paradigm to study the behavioral and neural consequences of AN. The ABA paradigm combines time limited feeding with unlimited running wheel access, which results in voluntary hyperactivity, voluntary starvation and ultimately rapid weight loss. Previous studies have found that patients with AN have significant deficits in glutathione, one of the body's primary antioxidants, and patients with the lowest BMI also had the lowest glutathione levels, suggesting there may be a link between oxidative state and severity of AN. To determine whether alterations in oxidative state also occur in response to ABA, we examined plasma glutathione and cysteine, a precursor for glutathione, levels in ABA adolescent female rats (n=6/timepoint) sacrificed at maximum weight loss or 10 days weight recovered. These values were compared to levels in age-matched sedentary (ad lib chow + locked wheel; n=6/timepoint) controls. We found that ABA animals at max weight loss, but not weight recovered, have significant deficits in both cysteine ($p=0.0467$; $t=2.269$; $df=10$) and glutathione ($p=0.0478$; $t=2.255$; $df=10$). We then probed the medial prefrontal cortex (mPFC) for mitochondrial fission and found that ABA animals sacrificed at maximum weight loss, but not when weight recovered, have increased mitochondrial fission compared to sedentary control ($p=0.0056$; $t=3.509$; $df=10$), again suggesting increased oxidative stress. We conducted a follow up study to assess the impact of the

ABA paradigm on mPFC parvalbumin interneuron density as oxidative stress could lead to the permanent impairment of these cells. In brief, a separate cohort of animals (8 sedentary; 10 ABA) were perfused for double immunohistochemistry analysis of mPFC parvalbumin (PV) and 8-Oxo-2'-deoxyguanosine (8-oxo-dG), a single cell marker for DNA-oxidation. Raters counted the total number of PV positive cells in a 10x image and then quantified corrected total cell florescence of 8-oxo-dG in 20 of the PV positive cells. We found that ABA animals have significantly fewer PV cells ($p=0.0013$; $t=3.889$; $df=16$) than sedentary controls and, on average, the PV cells in the ABA animals had significantly greater 8-oxo-dG compared to levels in PV cells from sedentary controls ($p=0.0018$; $t=3.732$; $df=16$). Taken together, these data demonstrate that ABA produces significant peripheral and central signs of oxidative stress resulting in PFC neuronal loss.

Title: Characterizing gene-environment interactions in a preclinical model of psychiatric disease

Authors: ***S. Y. YI**[1], B. R. BARNETT[1], J.-P. J. YU[2];
[1]Neurosci. Training Program, [2]Radiology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Psychiatric disease remains one of the leading causes of disability worldwide, yet it is still unclear how these diseases develop. Both genetics and environmental factors are thought to play a significant role in the development of psychiatric illness and understanding how these factors might interact can help elucidate the underlying mechanisms of disease. In order to examine the gene-environment interaction that might occur in psychiatric disease, we paired the *Disc1 svΔ2* pre-clinical rat model of psychiatric disease with exposure to chronic early-life stress (CES), in the form of a limited bedding paradigm, and evaluated their individual and combinatory effects on behavior and brain microstructure. *Disc1 svΔ2* animals and wild-type controls were maintained in either cages with ample bedding or cages with limited bedding during postnatal days 2-9. A behavioral battery, including the open-field test, Y-maze, and elevated-plus maze, was conducted between P180-P190, and brains were imaged *ex-vivo* for subsequent DTI and multi-compartment diffusion weighted imaging studies. Both the *Disc1* mutation and CES individually resulted in hypoactivity and heightened anxiety in both male and female animals. However, *Disc1 svΔ2* animals also demonstrated global, sex-specific changes in white and gray matter microstructure, whereas CES preferentially affected female brains. *Disc1*

svΔ2 and CES combined was associated with hyperactivity and more severe anxiety in comparison to animals that received either genetic or environmental insult alone, and female *Disc1 svΔ2* brains were also more strongly impacted by CES. Our results suggest a significant interaction between the *Disc1 svΔ2* mutation and chronic early-life stress, and the ability of advanced multi-compartment diffusion weighted neuroimaging methodologies to dissect sex-specific gene-environment interactions in psychiatric illness.

Title: Anxiogenic effects of progesterone withdrawal and GABA/benzodiazepine receptor binding: Wistar Kyoto rats as a suitable experimental subject to study Premenstrual Dysphoric Disorder.

Authors: *D. ISLAS-PRECIADO[1], C. LOPEZ-RUBALCAVA[2], I. SOLLOZO-DUPONT[3], G. UGALDE-FUENTES[4], E. GONZÁLEZ-TRUJANO[4], E. M. ESTRADA-CAMARENA[5];
[1]Inst. Nacional De Psiquiatría, Mexico City, Mexico; [2]CINVESTAV-IPN, Mexico DF, Mexico; [3]CINVESTAV-IPN, Mexico City, Mexico; [4]Inst. Nacional de Psiquiatría, Mexico City, Mexico; [5]Inst. Nacional de Psiquiatria, Mexico City, Mexico

Abstract: Anxiety is one of the most common emotional symptoms of Premenstrual Dysphoric Disorder (PMDD). This might be related to an abrupt drop of progesterone towards the late luteal phase of the menstrual cycle and to abnormalities in the hypothalamus-pituitary-adrenal (HPA) axis, which may lead to impairments in $GABA_A$/benzodiazepine receptors. PMDD is considered a chronic stress-related disorder, hence stress susceptibility could play an important role in developing symptomatology. Thus, it is crucial to have an animal model that represents the stress vulnerability observed in PMDD women. Therefore, we evaluated the response of a stress-vulnerable strain, the Wistar-Kyoto rats (WKY), to the Progesterone withdrawal (PW) challenge in some core aspects of the PMDD: anxiety symptoms, HPA axis activity and $GABA_A$ receptor sensitivity. All experiments were performed using Wistar rats (W) as a control strain. Thus, female WKY and W rats were ovariectomized and administered with 1.5 mg/kg of progesterone for five days, and on day sixth, were tested in the anxiety-like burying behavior test (BBT). After BBT completion, animals were euthanized and trunk blood was collected to measure corticosterone levels. Brains were extracted to measure $GABA_A$/Benzodiazepine binding. An independent group was administered with different doses of Diazepam to explore the $GABA_A$/Benzodiazepine sensitivity. Results showed that PW induced anxiety-like behaviors in both strains and is exacerbated in WKY rats along with corticosterone concentrations. Differential strain-dependent [3H]-Flunitrazepam binding pattern was observed, as PW increased the [3H]-Flunitrazepam binding in the DG and central amygdala only in WKY rats, suggesting a

greater sensitivity to PW in the stress-vulnerable strain. WKY rats showed higher sensitivity to Diazepam but induced an anxiogenic-like response only in PW rats, which may parallel the observed in PMDD women. Our findings suggest that WKY rats could be a suitable experimental subject to explore the neurobiology of PMDD.

Title: Associations between impulsivity and nutrient intake in a longitudinal birth cohort study

Authors: *D. MATROV[1], T. KURRIKOFF[2], I. VILLA[3], K. SAKALA[3], A. PULVER[1], T. VEIDEBAUM[4], R. SHIMMO[1], J. HARRO[2];

Abstract: Introduction: Impulsivity has been associated with obesity, unhealthy food choices, and snacking. The neurobiological substrates that cause various types of impulsive behavior are dependent on metabolic pathways in CNS, therefore a more in depth study of gut-brain-behavior axis is warranted.
Methods: Two cohorts of schoolchildren from Estonian Children Personality Behavior and Health Study (ECPBHS) were followed into adulthood. In the current study, the results from the first cohort measured in 3 waves at ages of 15, 18, and 25 years were included. The second cohort was measured at ages of 18, 25, and 33. The available sample from the first cohort consisted of 550 subjects and 1377 observations. The second cohort included 613 subjects and 1509 observations. The impulsivity was measured with Adaptive and Maladaptive Impulsivity Scale (AMIS). AMIS is a Likert-type self-assessment questionnaire that measures functional (adaptive) and dysfunctional (maladaptive) categories of impulsivity. Additionally, averaged daily dietary intake was derived from 24 h to 72 h (the reported period varied at different measurement waves) self-reported eating diaries. The dietary intake was categorized into various macro and micronutrients using Micro-Nutrica and NutriData software. Several additional covariates such as aerobic fitness and BMI were included in the dataset. Because some observations within waves were missing (the missingness varied between 0.58% and 33%), a

multiple imputation of 100 plausible values was performed. Adaptive and maladaptive impulsivity scores were predicted from dietary data and covariates using linear mixed models. The 100 multiply imputed datasets were used for modeling and the final model coefficients were aggregated using Rubin's rules.
Results: Maladaptive impulsivity score was associated with a larger number of predictors. Negative associations included aerobic fitness, fish and vegetable consumption, while alcohol was positively associated. Among micronutrients, zinc was negatively associated in both sexes and sodium showed positive association only among females. Adaptive impulsivity score was positively associated with zinc and vitamin B6 intakes, while cereal products showed negative associations. Both types of impulsivity score declined with age and differed between sexes.
Conclusion: Maladaptive impulsivity was associated with unhealthy eating habits, while adaptive impulsivity was only associated with the reduced intake of cereal products. Several micronutrients that have been previously associated with ADHD symptomatology are also involved in the expression of impulsive behavior among young adults.

Title: Sex differences on the effects of consuming a high-fat diet in binge and/or ad libitum schedules on anxiety-like behaviour and the locomotor effects of acute and repeated cocaine exposure in adult male and female mice

Authors: *T. KENNEY, L. SEABROOK, M. SOBEY, S. BORGLAND;
Dept. of Physiol. and Pharmacology, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Binge eating disorder (BED) can be characterized by a loss of control in food intake leading to rapid consumption of large quantities of highly palatable food. While binge eating disorder is the most common type of eating disorder the neurobiology is poorly understood. Furthermore, even though BED prevalence is higher in women than men, pre-clinical studies of BED has overwhelmingly been focused on male subjects. The current study aimed to evaluate sex differences in the effects of binge consumption of high-fat diet (HFD) on anxiety-like traits in the open field and elevated plus-maze. Because the mesolimbic dopaminergic system is critically involved in both BED and substance use disorder, we also examined the effect of binge eating (BE) on cocaine-induced locomotion over 5 days. Adult male and female mice were given ad libitum access to chow, HFD, or chow plus three times per week for 4 weeks, mice had 1-

hour access to unlimited HFD (BE). Daily food and body weight were recorded before and after BE protocol. Limited access to a high-fat diet induces BE in both male and female mice, although only the HFD group gained weight. BE female mice showed increased anxiogenic behaviour on the elevated plus-maze compared to males. Furthermore, female BE and HFD mice had greater cocaine-induced locomotor activity than male BE or HFD mice. These results indicate that there are sex differences in anxiety-like behaviour and responses to cocaine in BE mice and imply that treatment of comorbidities associated with BE should have a sex-specific focus.

Title: Regional differences in various risk factors for postpartum depression: Applying mixed models to the PRAMS dataset

Authors: *J. PLUCHINO, R. DELLA VALLE, J. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: 10-15% of new mothers will experience depression symptoms of varying severity in the weeks following childbirth, known as postpartum depression. Susceptibility for postpartum depression has been linked to a variety of variables directly associated with socioeconomic, physical, psychological, and environmental factors. The purpose of this study was to assess the various risk factors for postpartum depression severity using a large dataset that included variables associated with previous mental health status, social factors, societal factors, health care access, as well as other state-wide or region-specific variables. We obtained the most recent (2016-2017) dataset from the Pregnancy Risk Assessment Monitoring System (PRAMS), which is a dataset compiled by the Centers for Disease Control (CDC) that collects state-specific, population-based data on maternal attitudes and experiences before, during, and shortly after pregnancy. A hierarchical linear model was used to analyze the data across various levels, with a symptom severity scale (0-8) as the dependent variable. Of the 21 predictor variables included in the final model, 9 were statistically significant predictors of symptom severity. Statistically significant predictors of postpartum depression symptom severity included previous depression diagnosis and depression symptoms during term, baby residing with mother, unintentional pregnancy, education, Women Infants Children (WIC) enrollment, and marital status. In contrast to these other factors, a postpartum follow up appointment significantly decreased symptom severity. Age revealed an inverted curve related to postpartum symptom severity. There was minimal discrepancy of symptom severity scores among the 39 participating states. Postpartum

depression symptom severity was associated most notably with previous depression diagnosis and previous symptom severity, but also important social and education factors that contribute to the support and well-being of the mother and child. Postpartum depression is more common than society is aware and these findings may aid in future studies that continue to investigate the causal relationship between specified variables and symptom severity.

Title: Specialized projections of the primate subgenual cingulate area 25 to the amygdala

Authors: *M. P. JOYCE, H. BARBAS;
Boston Univ., Boston, MA

Abstract: Communication between the primate prefrontal cortex and the amygdala is essential for the balance between cognition and emotion and the emergence of flexible behavior. Previous studies have shown that projections from medial prefrontal area 32 most densely innervate the basolateral nucleus of the amygdala. The posterior orbitofrontal cortex (pOFC, which includes area 13, the proisocortex, and the periallocortex) most densely innervates the inhibitory intercalated masses of the amygdala. The subgenual cingulate area 25 (A25) has unique contributions to mood and emotion states among prefrontal areas. A25 is positioned at the intersection of the medial prefrontal and the orbitofrontal cortex, and a comprehensive understanding of its innervation patterns in the amygdala remains unclear. Here we studied axonal termination patterns from five A25 sites in the amygdala, ranging from anterior to posterior, medial and orbital sectors of A25. Our results reveal that medial A25 innervates the basomedial and basolateral nuclei, while more orbital A25 shifts toward heavier innervation of the intercalated masses. These data suggest that in the context of amygdalar projections, A25 is a transitional area between the medial prefrontal and orbitofrontal systems. Our data also suggest that posterior medial A25 has a unique relationship with the amygdala among prefrontal areas, with denser projections extending more ventrally in the amygdala than projections from other sectors of A25. We also examined the postsynaptic inhibitory neurons targeted by medial and orbital A25 terminations across the basomedial, basolateral, and lateral nuclei of the amygdala. Preliminary data obtained using multiple labeling techniques for neuronal tracers and calcium binding proteins parvalbumin, calbindin, and calretinin suggest that A25 has a bias toward interacting with calretinin neurons in all basal nuclei of the amygdala. Terminations on calretinin

neurons, which are thought to be disinhibitory of nearby pyramidal neurons, may allow for the amplification of excitatory inputs.

Title: Medial prefrontal cortical projections are altered by a single acute fear experience: Evidence for biological mechanisms of anxiety and substance abuse disorders

Authors: ***E. L. BEARER**[1], T. W. USELMAN[1], C. S. MEDINA[2], R. E. JACOBS[3]; [1]Pathology, UNM Sch. of Med., Albuquerque, NM; [2]Univ. of Texa El Paso, El Paso, TX; [3]Zilkha Neurogenetic Inst., USC Keck Sch. of Med., Los Angeles, CA

Abstract: Pyramidal neurons from medial prefrontal cortex (mPFC) project into striatum, thalamus, hypothalamus, and went as far as dorsal raphe nucleus (midbrain) and locus coeruleus (pons). Neural activity in mPFC is reciprocally modulated by monoamine systems arising in these distant brain regions: noradrenergic, dopaminergic and serotonergic. By deregulating these systems genetically, we previously reported that functional projections from mPFC are similarly regulated by these monoaminergic systems using brain-wide tracing based on manganese-enhanced magentic resonance imaging (MEMRI) followed by statistical parametric mapping (SPM). Here we report that a single experience of acute threat alters mPFC projections in wild type mice, and this change correlates with multiple subtle behavioral effects. Mice with or without acute threat (30m exposure to predator odor (2,3,5-Trimethyl-3-thiazoline, TMT) were group housed in environmentally controlled facility for 3 weeks and then underwent MEMRI tract-tracing. Behavior was video recorded before odor, during odor and before tract tracing. $MnCl_2$ (3-5nL of 0.6M in buffered saline) prepared with 0.5 mg/ml 3k rhodamine dextran-amine was injected into right mPFC and location confirmed by post-injection MRI: x = 0.59 ± 0.13 (R of midline), y = +0.72 ± 0.49mm (bregma), z = -1.04±0.36 mm (deep) (n= 24). Longitudinal images were collected at 6h and 24h after injection. Between imaging sessions animals were returned to their home cages. At conclusion of imaging, animals were sacrificed and perfusion-fixed brains processed for microscopy. Voxel-wise SPM comparisons between time points revealed progression of M(II) accumulation distally. Application of our new in vivo atlas allowed automated digital measurements of Mn(II) signal, revealing dramatic anatomical differences in projections between animals experiencing acute threat and those without which corresponded to subtle behavioral effects. Computational analysis of threat-exposed projections

with non-threat exposed mice carrying genetic disruptions of monoaminergic transporters suggested that fear-induced mPFC projections were most similar to altered projections induced by deletion of norepinephrine transporter (NET), which increases the amount of noradrenaline in the synaptic cleft. Acute threat further impacted mPFC projections in mice lacking the serotonergic transporter (SERT). Thus acute threat produces long-term changes in the reward circuitry of the limbic system, which may explain how life-threatening experiences pose a risk for long-term anxiety and substance use disorders. Supported by NIH RO1 MH096093 (ELB) and DA018184 (REJ).

Title: Distinct interneuron ensembles in the cingulate cortex encode interactions with anxiogenic and social stimuli

Authors: *L. KRETSGE[1], C. JOHNSON[1], W. YEN[1], R. LIU[2], A. O'CONNOR[2], T. NGUYEN[2], E. CHO[2], T. JINADASA[2], E. FUCHS[2], E. SPEVACK[2], B. ESCUDE[2], B. SRIRAM[2], A. CRUZ-MARTIN[2];
[1]Biol., [2]Boston Univ., Boston, MA

Abstract: Studies in humans and rodents indicate that the anterior cingulate cortex (ACC) is involved in both social behavior and anxiety, but it remains unclear how ACC neural activity encodes information across these diverse functions. Local ACC microcircuits are composed of excitatory and inhibitory neurons. One subclass of inhibitory interneuron, which is positive for vasoactive intestinal peptide (VIP), can modulate local activity by inhibiting other inhibitory cells, thereby driving excitatory cell activity. Previous work shows that cortical VIP cells exhibit diverse molecular, morphological, and electrophysiological properties, but little is known about their functional heterogeneity. Recent studies provided some insight into ACC function by monitoring the activity of excitatory neurons or of this region as a whole. These studies were limited by techniques without cellular resolution, so they could not address whether ACC cells all activate similarly or if distinct subgroups activate to different kinds of stimuli. To our knowledge, no existing studies have monitored VIP interneurons in the ACC (VIPACC) in vivo with cellular resolution. To determine whether VIPACC are functionally heterogeneous, we monitored their activity during behavioral tasks. We injected AAV9-flex-GCaMP6f into the

ACC of VIP-IRES-Cre mice to express this fluorescent calcium indicator in VIPACC. We then implanted gradient-index lenses and miniaturized microendoscopes into the ACC to image VIPACC calcium dynamics. Animals performed anxiety-related and social tasks while neural activity was recorded. Our data demonstrate that overall VIPACC activity did not change as animals navigated different stimuli in any of the tasks. Despite the lack of population level changes, we identified distinct subgroups of VIPACC that preferentially activated to anxiogenic or anxiolytic zones or to social or non-social stimuli. In each task, selective cells could predict the animal's behavior. When neurons were monitored across anxiety-related and social tasks, we determined that most VIPACC were neutral or selective for only one of these stimuli. In summary, our data show that VIPACC are functionally heterogeneous and non-overlapping subgroups of VIPACC activate preferentially to different types of stimuli.

Title: Novel cerebello-amygdala connections provide missing link between cerebellum and limbic system

Authors: S. JUNG[1], ***K. VLASOV**[1], A. PARIGI[1], M. FERNANDEZ-FRENTZEL[1], M. ANGUIANO[1], E. G. ANTZOULATOS[1,2], D. FIORAVANTE[1,2];
[1]Ctr. for Neurosci., [2]Dept. of Neurobiology, Physiol. and Behavior, Univ. of California Davis, Davis, CA

Abstract: The role of the cerebellum (CB) in executive functions, including emotional processing, is well established but lacks mechanistic understanding (Schmahmann et al., 2019). The major limitation has been lack of knowledge of the anatomical and functional connectivity that supports CB regulation of emotion. Early electrophysiological experiments in animals have hinted to the amygdala, a central structure of the limbic system, as a recipient of CB signals (Snider & Maiti, 1976), which raises the interesting but untested possibility of a CB-amygdala circuit as a mediator of CB limbic function (Otsuka et al., 2016; Strata, 2015). To explore this

hypothesis, we investigated the anatomical and functional characteristics of connections between the CB and amygdala in the mouse brain. We first used anterograde and retrograde viral tracing in CB and basolateral amygdala (BLA), respectively, and found significant overlap between these labeled populations in two major nodes: the intralaminar thalamus (Th) (part of the higher order thalamic nuclei) and the ventral tegmental area (VTA). Using confocal imaging, we discovered putative synaptic contacts between CB fibers and BLA-projecting neurons in both nodes. We provided support for the synaptic nature of these connections using anterograde transsynaptic viral techniques, and we examined monosynaptic connections between CB and the thalamic node using slice electrophysiology combined with optogenetics and pharmacology. These experiments revealed functional connections between CB and neurons in the intralaminar and medial dorsal thalamus, which were monosynaptic and primarily excitatory—indicating fast, robust transmission of information from the CB through this node. Using immunohistochemistry and high resolution imaging, we found that the axons of CB-Th projectors in the BLA colocalized with pre- and postsynaptic markers, indicating putative glutamatergic synaptic contacts. Additionally, we found CB-Th projections in the nucleus accumbens (Nac) as well as cingulate and prelimbic cortices. We are currently performing similar experiments for the VTA. We have also launched functional manipulations of CB-Th and CB-VTA projections to investigate the conditions under which these two different pathways might be recruited, and the kind of information they might convey to influence affective processing and behavior. These studies will advance our understanding for how the CB can modulate complex non-motor functions and play a major role in neuropsychiatric and neurodevelopmental disorders (Fatemi et al., 2012; Parker et al., 2014).

Title: Automated Emotion Classification of Free-Moving Mice from Video

Authors: *A. TELFER[1], F. SHERRATT[2], O. VAN KAICK[2], A. ABIZAID[2];
[2]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada

Abstract: Studies involving emotion often use animal models and currently rely on manual labelling by researchers. This human-driven labelling approach leads to a number of challenges such as: long analysis times, imprecise results, observer drift, and varying correlation between observers. These problems impact reproducibility, and have contributed to our lack of understanding of fundamental mechanical questions such as how emotions arise from neuronal

circuits. Recent success of machine learning models across similar problems show that it can help to mitigate these challenges while meeting or exceeding human accuracy.
We developed a classifier pipeline that takes in videos and produces an emotion label. The pipeline extracts body part positions from each frame using a pose estimator and feeds them into an Artificial Neural Network (ANN) classifier built using stacked Long Short Term Memory (LSTM) layers. The data was collected by treating nine rats with Lypopolysaccharide (LPS) injections (10mg/kg). First, rats were recorded for 10 minutes under control conditions with no manipulation and no observed symptoms of stress or malaise. A week later, rats were injected with LPS and filmed for 10 minutes two hours post injection.
The method developed correctly labelled 7 out of 8 test videos. The test videos had varying environments and used rats that were different from the training videos, providing evidence of a degree of robustness in the model. Future work will involve growing the training and test sets in order to improve performance and evaluation, as well as exploring new features and model architectures.

Title: Individual differences in social play behaviour in rats: behavioural microstructure and communication

Authors: C. J. BURKE[1], S. M. PELLIS[1], L. J. VANDERSCHUREN[2], *M. ACHTERBERG[2]; [1]Dept. of Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Dept. Population Hlth. Sci., Utrecht University, Fac. of Vet. Med., Utrecht, Netherlands

Abstract: Social play behaviour is rewarding and important for the development of brain and behaviour. Disruptions of social play behaviour in rats have been associated with social and cognitive deficits. How natural variation in social play contributes to development of brain and behaviour remains unclear. It is common knowledge that there are differences in the amount of play behaviour between strain and sexes. Furthermore, even within a strain and within a sex, individuals differ in how much they play. Findings that show that individual differences in play lead to a different response to neural manipulations suggests that individual differences in playfulness may also be a valuable avenue for studying the neuro-behavioural mechanisms that regulate play. To this end, male Lister hooded rats were characterized as high, medium and low players (HP, MP and LP) based on the sum rank score of the amount of play they initiated and received across three days with an unfamiliar partner. Once animals were categorized in player-types, microstructural analyses of play were conducted to assess differences in the way animals play. To investigate differences in communication during play, ultrasonic vocalizations (USVs) were recorded. Our data shows that the player-types differ significantly in the amount of play

they initiate but less in the amount they receive. Furthermore, the microstructure of play differs between HP and LP as well as the communication during play. These results give insight into how individual animals behave and communicate during social play. Future research may indicate whether individual differences in play also lead to differences in the brain.

Title: Data-driven analysis of PET images reveals a pattern of in vivo kappa opioid receptor availability related to symptom severity in patients with Major Depressive Disorder

Authors: *K. SMART[1], M. A. OQUENDO[2], J. J. MANN[3], A. T. HILLMER[1], R. E. CARSON[1], J. M. MILLER[3];
[1]Yale Sch. of Med., New Haven, CT; [2]Dept. of Psychiatry, Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA; [3]Div. of Mol. Imaging and Neuropathology, New York State Psychiatric Inst., New York City, NY

Abstract: Preclinical studies have identified a central role of kappa opioid receptors (KORs) in stress response and depression-related behaviors. However, evidence in humans is limited. This work aimed to explore cross-regional patterns of variation in *in vivo* KOR availability in patients with major depressive disorder (MDD) in order to identify opioidergic networks that may be relevant to depression pathophysiology and treatment. A secondary analysis was performed of data acquired using positron emission tomography (PET) with the KOR radiotracer [^{11}C]GR103545 in 11 unmedicated, currently depressed individuals with MDD (32.6 ± 6.5 years, 5 women) and 13 matched healthy volunteers (34.8 ± 10 years, 6 women)[1]. Independent component analysis was performed at the region of interest (ROI) level to identify spatial patterns of coherent variance in KOR availability (tracer volume of distribution, V_T) across all subjects. Analyses were then repeated at the voxel level using whole brain images to better characterize spatial patterns. Expression of each component was compared between groups and relationships to symptoms were explored using the 17-item Hamilton Depression Rating Scale (HAMD). Three components of variation in KOR availability across ROIs were identified, spatially characterized by [^{11}C]GR103545 V_T contributions in (1) bilateral frontal lobe; (2) occipital and parietal cortices, right hippocampus, and putamen; and (3) right anterior cingulate, right superior frontal gyrus and insula. In MDD patients, component 3 was negatively associated

with symptom severity on the HAMD (r=-0.85, p=0.0021 uncorrected). Results were consistent in voxel-wise component analyses, with an ACC/insula component negatively correlated with HAMD score (r=-0.59, p=0.070). There were no group-wise differences in expression of any component between patients and controls. In MDD patients and controls, data-driven analyses identified independent patterns of variation in KOR availability across brain regions which could represent distinct signaling networks. KOR signaling in cortical regions relevant to depression, particularly the right anterior cingulate, may contribute to MDD pathophysiology.

Title: MEG gamma-band dysregulation and clinical outcomes demonstrate reduced emotional reactivity during mood induction in a depressed sample

Authors: *G. E. ANDERSON, C. R. BURTON, C. FARMER, J. R. GILBERT, E. D. BALLARD, C. A. ZARATE, Jr.;
Section on the Neurobio. and Treatment of Mood Disorders, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Individuals with depression may have cognitive biases that are activated by negative mood. This cognitive and emotional reactivity can be measured with mood induction paradigms, such as watching emotional movies. Here, we extend this research by collecting magnetoencephalography (MEG) during a mood induction paradigm in order to measure brain network-level differences in gamma power, a proxy measure of excitation-inhibition balance, between healthy control participants (HCs) and those with a mood disorder diagnosis (MDs). In this paradigm, a sample of MDs (n = 33) and HCs (n = 14) viewed emotional movie clips while undergoing MEG scanning. Two clips were used to induce positive mood, and two clips were used to induce negative mood (Negative 1 and 2; Negative 1 included a depiction of suicidal thoughts and behaviors). At baseline and after each clip, participants completed the Positive and Negative Affect Scale (PANAS) to rate mood and the Suicide Implicit Association Task (s-IAT) to asses *self-life/self-death* associations (after negative clips only). We hypothesized that HCs would experience a larger increase in positive affect after positive clips than MDs, while MDs would experience a larger increase in negative affect after negative clips than HCs coupled with stronger *self-death* associations. We also expected large-scale functional brain network gamma

power dysregulation in MDs, as evidenced by group-by-clip valence interactions. We used mixed effects models to compare group-level changes in mood ratings and *self-life/self-death* associations at baseline and following each clip and to test for gamma power group-by-valence interactions. Compared with baseline, HCs reported decreases in positive affect score following both positive clips and increases in negative affect following both negative clips. In contrast, MDs only reported a decrease in negative affect following Negative 2 and an increase in negative affect following Negative 1, along with no changes following both positive clips. On the s-IAT, both groups moved away from *self-life* associations following negative clips. Dysregulated gamma power was found in regions of the central executive network including dorsolateral prefrontal cortex, the salience network including insular cortex and amygdala, and the default mode network including inferior temporal cortex. Taken together, these preliminary findings suggest there is less emotional reactivity in MDs following emotional movie clips than HCs coupled with dysregulated gamma power in large-scale functional brain networks. Future work will examine the relationship between clinical presentation and brain network dysfunction.

Title: Modulation of cognitive control network in treatment-resistant depression with deep brain stimulation

Authors: *A. ALLAWALA[1], J. ADKINSON[3], K. BIJANKI[3], S. VARTANY[2], S. MATHEW[4], W. GOODMAN[4], N. POURATIAN[5], S. SHETH[3], D. BORTON[1];
[2]Neurosci., [1]Brown Univ., Providence, RI; [3]Neurosurg., [4]Menninger Dept. of Psychiatry and Behavioral Sci., Baylor Col. of Med., Houston, TX; [5]Neurosurg., UCLA, Los Angeles, CA

Abstract: Major Depressive Disorder is a common psychiatric illness affecting at least 4.4% of the global population, where a third of this population is treatment-resistant. Deficits in cognitive control, i.e., focal attention to relevant stimuli as well as inhibition of irrelevant material are thought to explain the inflexible behavior in depression. However, the underlying neurophysiological network state for control in depression and how this is modulated by DBS is unknown. The goal of this study is two-fold. First, to identify neural biomarkers involved in modulating control in depression. Second, to identify changes in neural biomarkers and cognitive control behavior driven by application of DBS.

Here, we report the outcome from a conflict task performed in our first human subject with Treatment-Resistant Depression (TRD) in an in-patient hospital setting with continuous psychiatric and intracranial monitoring, as part of a larger clinical trial study. The subject was implanted bilaterally with DBS electrodes in the ventral capsule/ventral striatum and subcallosal cingulate, as well as depth electrodes (stereo-EEG) spanning the prefrontal cortex (PFC), anterior cingulate cortex (ACC), orbitofrontal cortex and the amygdala for electrophysiology recordings collected across multiple days. The task was performed pre-, post-, and during DBS. In the task, a cloud of colored moving dots moving leftward or rightward is presented on a computer screen. The subject was asked to indicate the color of the dots (relevant feature) by pressing a button with their left or right index finger while ignoring the motion direction (irrelevant feature). Motion direction could either be congruent or incongruent with the required response side. Accuracy on the task improved from an average of 47% before DBS to 89% with DBS on and this effect was sustained after DBS was turned off the next day with 90% accuracy. Cognitive control is thought to be characterized by activity in theta band (4-7 Hz). Pre-DBS we found theta power to be greatest during high conflict and post-DBS there was an overall increase in theta power across all conflict conditions, especially in dorsolateral PFC and dorsal ACC compared to pre-DBS task states, suggesting that theta power may be a possible neural mechanism underlying cognitive control in depression. We will also present results from a second participant in the study, in addition to functional connectivity analysis to better understand the mechanistic account of control deficits, and how they are improved via DBS. Understanding these mechanisms would allow for optimized DBS treatment centered around electrophysiology for future closed-loop applications.

Title: Regional grey matter volume predicts clinical improvements in a clinical trial of Tai Chi in geriatric depression

Authors: *M. M. MILILLO, B. KRAUSE-SORIO, L. KILPATRICK, P. SIDDARTH, L. ERCOLI, K. NARR, H. LAVRETSKY;
UCLA, Los Angeles, CA

Abstract: Background: Geriatric depression (GD) is associated with significant medical comorbidity, cognitive impairment, and suboptimal treatment response compared to depression in younger adults. More efficacious treatment to improve mood, cognition and quality of life in

GD are urgently needed. Mind-body interventions like Tai Chi are a promising adjunct treatment to antidepressants, as they may improve stress and body awareness in GD. We tested the effect of twelve weeks of weekly Tai Chi lessons on clinical symptoms, resilience and neuroplasticity.
Methods: Forty-nine older adults over 60 (38 women, 11 men) diagnosed with major depressive disorder undergoing concurrent antidepressant treatment were randomized to either Tai Chi training (N=26) or health education control (N=23). We administered the Hamilton Depression Rating Scale (HAMD), Montgomery-Asberg Depression Rating Scale (MADRS), Hamilton Anxiety Scale (HAMA), Apathy Evaluation Scale (AES) and the Connor-Davidson Resilience Scales (CDRISC). General linear models were used to test whether the groups differed in demographics and symptoms at baseline and repeated-measures analyses of covariance tested the interactions between time point and group for symptom scores including age and sex as covariates. T1-weighted imaging was performed using a 3T Siemens Prisma scanner. Processing, reconstruction and fully corrected voxel-wise whole-brain general linear models on grey matter volume (GMV) were performed using Freesurfer version 6.0.
Results: The groups did not differ in demographics or clinical scores at baseline (*ps*>.05) and there were no group differences in symptom change from baseline to follow-up (*ps*>.11). Further, there were no differences in GMV change over the twelve weeks between groups. Across both groups, higher baseline GMV was associated with lower anxiety and apathy, but higher resilience in widespread regions. Furthermore, separate clusters demonstrated that while higher baseline GMV in the Tai Chi group was associated with less improvement in anxiety, the control group showed the opposite effect. This pattern was similar for depressive symptoms (MADRS) in a cluster in the right precuneus.
Discussion: While we did not observe neuroplastic changes in the cortex of patients with GD undergoing Tai Chi training vs. health education control, we found correlations between clinical variables and GMV at baseline, as well as indications that higher GMV in some regions may yield unfavorable outcomes for those participating in Tai Chi compared to control interventions.

Title: A Comparative Analysis of Evoked Potential Referencing Methods in Schizophrenia and Bipolar I Disorder

Authors: *M. ALHAMODY[1], S. ARORA[2], W. E. BUNNEY[3], J. V. PATTERSON[3];
[1]USC, Los Angeles, CA; [2]Univ. of California, Irvine, Irvine, CA; [3]Dept. of Psychiatry and Human Behavior, Univ. of California Irvine Sch. of Med., Irvine, CA

Abstract: The choice of reference location is a critical issue in recording evoked potentials (EPs) that has been debated often. EPs are brain responses to specific stimuli derived from the EEG that can be influenced by reference choice. In this study, we compared the effects of two different reference locations, linked mastoids (LM) and common average reference (CAR) on P50 sensory gating. Sensory gating is a process by which the brain filters out irrelevant or redundant stimuli in order to focus on the relevant information, and can be studied by comparing amplitudes of the positive EP around 50 ms post-stimulus to the first and second clicks using paired-click paradigm. LM is a unipolar reference obtained by averaging the left and right mastoids, while CAR is the average of the activity of all electrodes on the scalp. The subject groups included patients with bipolar I disorder with or without psychosis (n=45), schizoaffective disorder (n=39), paranoid schizophrenia (n=29), and controls (n=39), also evaluated by gender. A 64-channel EEG cap recorded EEGs while participants listened passively to 90 paired clicks (S1 and S2) 500 ms apart with pairs separated by a 10-second interval. A specialized software program (Cortech Solutions) was used to correct eye blinks and motor movements. The brain responses for each participant were averaged separately for S1 and S2 P50. These averages were measured from the pre-stimulus baseline to the maximum amplitude peak within the P50 window (40-80ms) using an automated peak-picking software feature. Missed peaks were measured by hand. The sensory gating ratio (S2/S1) and difference (S1-S2) were also calculated. Analysis of variance was used to compare these measures for each group with reference (CAR or LM) as a repeated factor in the design. The findings demonstrated that different locations influenced results for both click and gender. A gender by reference interaction was found showing that males and females produced different results at LM with males having a larger S1-S2 difference than females. Significant gender by reference and click by reference interactions also were found. Females had a larger P50 amplitude for LM than CAR and amplitude at LM for males was smaller than for females. Amplitude for CAR was smaller than LM for S1 but not for S2. For S1-S2 CAR a significant main effect of reference showed that S1-S2 for CAR was significantly smaller than for LM for all groups. Based on these findings, it was concluded that choice of reference location can affect interpretation of the results of a study, and comparison with previous studies may either require replication using the same reference or re-referencing to compare both reference locations.

Title: Predicting Dimensional Symptoms of Psychopathology from Task-Based fMRI using Support Vector Regression

Authors: *K. GARCIA[1], Z. ANDERSON[2], I. K. CHAT[4], K. S. F. DAMME[3], K. YOUNG[5], S. Y. BOOKHEIMER[6], R. ZINBARG[3], M. CRASKE[7], R. NUSSLOCK[2];

Abstract: Extensive research in psychiatry has highlighted the potential utility of machine learning (ML) automation for disease diagnosis. For many years, studies aimed at uncovering biomarkers for traditional DSM diagnostic categories of mood disorders, such as Major Depressive Disorder, have presented challenges for many researchers. Machine learning models have been successfully applied in the context of disease diagnosis and prediction for treatment prognosis, using both structural and functional neuroimaging data. Due to its computational complexity, which does not depend on input space dimensionality, Support Vector Regression (SVR) provides a supplementary approach for studying whole-brain data, providing a data-driven perspective with sensitivity to relatively small effect sizes and increased reliability offered by multivariate analytic techniques. However, few studies have examined the relationship between brain activation features from task-based functional Magnetic Resonance Imaging (fMRI) data and symptom dimensions of anxiety and depression. In this study, we develop a novel application of feature-based type of supervised machine learning, SVR, approach to detect potential biomarkers in fMRI data and dimensional symptoms of anxiety and depression on 209 subjects enrolled in the study for risk for anxiety and depression. We trained the SVR classifier on fMRI data collected during the well-established Monetary Incentive Delay (MID) task, which is a widely used task to measure neural activity in response to reward and loss in healthy and clinical populations. The MID datasets were preprocessed into multi-dimensional feature space using a 264 regions of interest (ROI) mask, and the model was fit using ten fold cross validation on all 264 dimensions in order to identify patterns of activation associated with dimensional symptoms of depression and anxiety. We demonstrate MID task-fMRI data is not an accurate predictor of dimensional clinical symptoms. The results predicted dimensional symptoms with R2 values ranging from -0.269 to -0.658 indicating poor model fit compared to a horizontal line fit denoting a null effect. The poor model fit of linear models reported in this study suggests that a non-reliable linear relationship between reward-related neural activation and dimensional clinical symptoms related to the experience of depression and anxiety. Future analysis will explore additional non-linear modeling methods and clustering to further explore the relationship between reward-related brain activation and dimensional symptoms.

Title: Transcriptional Profiles of Treatment Resistant Depression in Mouse Models

Authors: *A. TORRES BERRIO[1], E. M. PARISE[1], M. ESTILL[1], T. M. GYLES[1], F. J. MARTÍNEZ-RIVERA[1], C. J. BROWNE[1], A. GODINO[2], L. SHEN[1], E. J. NESTLER[1]; [1]Neurosci., [2]Nash Family Dept. of Neurosci., Nash Family Dept. of Neurosci. and Friedman Brain Inst., Icahn School of Medicine at Mount Sinai, NY

Abstract: Major Depressive Disorder (MDD) is the most prevalent psychiatric disorder worldwide, representing a high level of global economic burden. Fluoxetine (FLX) has been widely used to treat MDD, nonetheless, a majority of patients do not achieve full remission. Further, a subset of those afflicted is considered non-responsive to any orally-available treatments, which is termed treatment-resistant depression (TRD). More recently, Ketamine (KET) has been shown to induce a rapid antidepressant response in ~50% of TRD patients, providing a novel therapeutic approach. However, the molecular mechanisms underlying TRD and subsequent response vs. non-response to KET are poorly understood. This study was aimed at characterizing the transcriptional profile of successful vs. unsuccessful response to KET in mice that failed to respond to an initial course of FLX as a model of treatment resistance. We exposed adult male mice to chronic social defeat stress (CSDS), a validated mouse model of depression that differentiates between resilient and susceptible populations based on the social interaction test (SIT). Mice classified as susceptible underwent antidepressant treatment with FLX in their drinking water for 28 days or received water during the same period (water-treated). After FLX treatment, we identified a subset of mice (~35%) that continued to show reduced social interaction despite treatment (non-responders). FLX non-responders and water-treated mice were subsequently given a single injection of KET and assessed in the SIT 24h later. Transcriptome-wide changes in the prefrontal cortex (PFC) and nucleus accumbens (NAc) 48h after KET administration were profiled by RNA-sequencing. We found that ~50% of FLX-non-responder mice exhibited an antidepressant response to a single KET injection, a significantly greater response than that seen in susceptible mice treated with water (0%). We further identified a subset of treatment resistant mice who failed to respond to consecutive FLX and KET treatment. Pattern analysis of the differentially expressed genes in the PFC and NAc revealed transcriptional profiles associated with the antidepressant-like actions of FLX and of KET as well as a series of genes that were unique to treatment resistance to both drugs. We developed a novel paradigm of treatment resistance in mice that allows to identify potential mechanisms underlying TRD. The KET response rate in FLX-non-responders is similar to that seen in TRD

patients, lending further validity to our model. Moreover, our findings suggest that prior unsuccessful antidepressant treatment induces a "priming effect" that increases the likelihood of successful response to KET.

Title: Binding and electophysiological profiling of LCGA-17 - a novel peptide with stress-protective properties

Authors: *A. V. MALYSHEV[1], E. V. VASILEVA[2], I. A. SUKHANOVA[1], I. I. DORONIN[1], V. V. PAVSHINTCEV[1], N. A. MITKIN[1], V. R. GEDZUN[1], A. R. KUCHUMOV[1], G. I. KOVALEV[2], Y. A. ZOLOTAREV[3], G. A. BABKIN[1];
[1]Lactocore, Inc., Plymouth, MI; [2]FSBI "Zakusov Inst. of Pharmacology", Moscow, Russian Federation; [3]Inst. of Mol. Genet. of Natl. Res. Ctr. "Kurchatov Institute", Moscow, Russian Federation

Abstract: Background. Major depressive disorder (MDD) remains a substantial clinical burden worldwide with an unmet need for treatment**.** A dysregulation of excitatory/inhibitory (E/I) balance within CNS might have an implication in the pathogenesis of MDD. LCGA-17 is a novel peptide with prominent stress-protective effects in zebrafish and rodent models. This peptide was designed using a proprietary software suite "Peptimize". The aim of the study was to validate specific targets of LCGA-17. **Methods.** Competitive radioligand binding assays in rat cerebral cortex preparations were carried out using tritium labeled [^{3}H]-LCGA-17 peptide. The half-maximal inhibitory concentration (IC_{50}) for the binding of [^{3}H]-LCGA-17 was determined by adding test compounds (ligands of different sites of GABA and VGCC as well as dopamine (DA), serotonin (5-HT), acetylcholine (Ach), glutamate (Glu), glycine (GlyRA1), cannabinoid (CB1), and TRPM3 receptors) to the incubation medium at final concentrations of 10^{-10}-10^{-4} . Electrophysiological profiling of LCGA-17 was carried out using automated patch-clamp recordings (SyncroPatch 384i platform, "SB drug discovery"). Six concentrations (0.04, 0.4, 4, 25, 40, 400 μM) of the peptide were applied against the seven GABAA cell lines (α(1-6)β2γ2 and α4β3δ) in NAM and PAM modulation modes. The peptide effects on evoked currents of VGCC ($Ca_{V1.2}$) were tested at the same dose range.**Results.** Specific binding sites of the [^{3}H]-LCGA-17 in rat cortex membranes were found with IC_{50}=2*10^{-6} M. Gabapentin (inhibitor of α2δ subunit-containing VGCCs), and Pregnenolone sulfate (GABAAR NAM-site ligand) displaced [^{3}H]-LCGA-17 with IC_{50} ~3.8*10^{-6} M and 36*10^{-6} M respectively. We also found that Diazepam (GABAAR BZD-site ligand), Baclofen, and Phenibut (both are GABABR and α2δ subunit

VGCC ligands) demonstrated a competition with [^{3}H]-LCGA-17. There was no cross-reactivity found with DA, 5-HT, Ach, Glu, GlyRA1, CB1, and TRPM3 receptors. The electrophysiological assessment showed that LCGA-17 produced a concentration-dependent inhibition of the $Ca_{V1.2}$ channels in a similar manner to Gabapentin. Also, LCGA-17 showed an inhibitory effect on α(2,3)β2γ2, α4β3δ GABAARs. **Conclusion.** The results propose LCGA-17 as a functionally active ligand of the GABAAR NAM site and the α2δ VGCC subunit. Both targets are in tight inter-regulation and are involved in maintaining E/I balance within CNS. GABAAR and VGCC are clinically relevant in neuropsychiatric disorders, and their engagement by LCGA-17 may underlie its anxiolytic and antidepressant effects in vivo.

Abstract: Introduction: Depression is the leading cause of disability worldwide, with no reliable biomarkers for diagnosis or treatment responsiveness. With novel therapeutics such as ketamine, recent research has shifted away from the traditional monoaminergic hypothesis to focus on glutamatergic signaling and the mammalian target of rapamycin, shown to be essential for fast-acting antidepressant effects in the central nervous system. Reelin, an extracellular matrix glycoprotein downregulated in depression appears to activate similar molecular pathways at the synapse after exogenous administration. While there are parallels between ketamine and reelin in the brain, peripheral mechanisms play a large role in depressive pathophysiology and are often overlooked. Inflammatory events after chronic stress cause an upregulation of proinflammatory cytokines and alterations in peripheral cells such as lymphocytes. Our lab has shown that serotonin transporter (SERT) clustering on lymphocytes react to chronic stress, depression, and traditional antidepressants in both humans and animal models, providing a potential biomarker of treatment responsiveness. However, there is no data for the impact of

novel fast-acting therapeutics on these important peripheral measures.
Methods: Lymphocytes from male Long Evans rats were extracted through a Percoll gradient and incubated with 1mM of corticosterone (CORT) or a vehicle, which parallels the changes we observe in patients with depression. After the initial treatment, cells were incubated with varying concentrations of reelin (0.5nM - 5nM) and ketamine (10nM - 250nM), then rinsed and fixed. The lymphocytes were then stained with an anti-SERT antibody to determine changes in the size and number of protein clusters.
Results: CORT increased the size of protein clusters in comparison to vehicle ($p<0.05$). All concentrations of reelin decreased the size of the SERT clusters, but this was only significant at the highest concentration (5nM, $p<0.05$). Ketamine had no effect on the size of SERT clustering. No changes in number were observed across any of the groups.
Conclusions: The impact of reelin on SERT clustering that was not mimicked by ketamine indicates that they may have divergent mechanisms in the periphery, The effect of reelin paralleled what we have seen previously in patients who have responded to varying antidepressants, and supports reelin as a potential therapeutic. In a translational sense, these results could be greatly applicable to the clinic. Analyzing blood samples in this method is simple and inexpensive and could allow for the individualization of treatment as a putative biomarker of therapeutic efficacy.

Title: Neuron-glia interactions in the regulation of stress and depressive disorders

Authors: *R. U. CHOTTEKALAPANDA[1], V. YAO[2], A. ALY[1], S. KALIK[1], J. GRESACK[1], W. WANG[1], A. SCHAEFER[3], O. TROYANSKAYA[4], P. GREENGARD[1];

Abstract: An estimated 264 million people globally suffer from psychiatric disorders and are treated by antidepressant drugs that were developed three decades ago. Selective serotonin reuptake inhibitor (SSRI) drugs are still the most widely prescribed antidepressants in the world, thought to influence mood by increasing levels of the neurotransmitter serotonin in the brain's synapses. They are effective in only two-thirds of patients and require weeks to alleviate symptoms. Mood dysregulation is a hallmark of stress- and depressive-disorders caused by

structural and functional impairments within critical neuronal networks. The lack of understanding of the precise biological mechanisms of remodeling and regeneration of these networks, as well as the molecular basis for weeks-long lag in response times, are major obstacles in antidepressant research. To gain insight into the mode of action of SSRIs, we analyzed the dynamics of fluoxetine (Prozac) in the prefrontal cortex, an important region in the cortico-limbic mood circuit. We identified the activation of sequential-signaling pathways that included growth-factor signaling and the stimulation of AP-1 transcription complex, which in turn modulated plasticity-inducing effector molecules that lead to improved mood. Blocking AP-1 formation in the first week of treatment attenuated the behavioral response, demonstrating time- and sequence-dependent activation of signaling pathways. Profiling AP-1 target genes revealed neuronal remodeling and plasticity-inducing effector molecules, many with known links to depression and antidepressant responses. To determine the identity of the cell types contributing to the antidepressant response and how signaling pathways integrated within these cell types, we performed single-cell RNA-sequencing in the mouse cortex subjected to chronic social-isolation stress and fluoxetine treatment. Remarkably, we found that the onset of the fluoxetine response required neuron-glia interactions and indicated that the glia shapes the neuronal properties that progressively drive recovery processes to improve mood. In addition, I developed a cellular model system and recapitulated the precise timeline of the antidepressant response, providing a powerful tool to study the delayed onset, with strong translational potential for rodent and human studies. These studies provide strong evidence for the crucial role of neuron-glia interactions within the cortico-limbic mood-circuit during mood dysregulation and recovery.

Title: Effects of E. Coli Derived Psilocybin in Rats are enhanced by Norbaeocystin

Authors: N. ANAS[1], ***J. HINEGARDNER-HENDRICKS**[2], P. HAMILTON[2], K. MCCLOY[2], J. A. JONES[3], M. S. MCMURRAY[2];
[1]Biol., [2]Psychology, [3]Chemical, Paper and Biomed. Engin., Miami Univ., Oxford, OH

Abstract: Preliminary clinical research has shown that Psilocybin has potential therapeutic utility for the treatment of depression, anxiety, PTSD, and substance use disorders. However, our basic understanding of the drug and its possible clinical mechanisms are lacking. Additionally, it

is unclear if related tryptamines, such as baeocystin and norbaeocystin, could have similar or better efficacy, but with different side-effect profiles. Given their similar chemical structure and possible pharmacological targets, these substances may also interact with psilocybin to enhance or alter its efficacy (e.g. entourage effect). To address this topic, our lab examined the behavioral effects of psilocybin and norbaeocystin, individually and in combination. Psilocybin and norbaeocystin were synthesized using genetically modified E. coli, and verified for purity using mass spectroscopy. Varying doses of filtered E. coli broth containing each compound were then gavaged directly into male rat subjects, and head twitch responses and locomotion assessed. Head twitch responses were exhibited following the administration of both substances individually and were found to be dose-dependent. Additionally, the number of head twitches produced by low-dose psilocybin was enhanced when combined with low dose norbaeocystin, beyond simple additive levels, suggesting a pharmacological interaction may be occurring. Locomotor results showed similar trends but also exhibited a marked reduction of locomotion following high dose psilocybin. Combined, our data demonstrate the pharmacological efficacy of E. coli-derived psilocybin, and suggest that other tryptamines may supplement/augment its effectiveness, and should be considered for therapeutic testing alone and in combination with psilocybin. Additionally, our results demonstrate the relative safety of directly gavaging filtered E. coli broth containing these compounds. Future studies will assess the therapeutic potential of both compounds, as well as determine their mechanism of interaction.

Title: Behavioral and activity changes in response to ketamine in depressed subjects

Authors: *C. PUNTURIERI, W. C. DUNCAN, Jr, D. GREENSTEIN, J. W. EVANS, C. A. ZARATE, Jr.;
Natl. Inst. of Hlth. (NIH), Bethesda, MD

Abstract: Standard measures of antidepressant response, e.g., rating scales, which play an invaluable role in assessing treatment efficacy, may benefit from supplementation by real-time behavioral measurement using techniques such as actigraphy. Wrist activity monitors can be used to inexpensively and noninvasively assess 24-hour patterns of motor activity. Prior work has indicated that ketamine produces rapid antidepressant effects in individuals with depression and that actigraphy data may be of use in assessing this response. In order to better understand the relationship between treatment, symptomatology, and biological rhythms, we examined

associations between one behavioral measure, the Montgomery-Åsberg Depression Rating Scale (MADRS), and several nonparametric actigraphic variables within a randomized crossover study of ketamine.Thirty depressed subjects (18 female, mean age:36.5 years+-10.7) wore an Actiwatch (AW64; Philips, Amsterdam, the Netherlands) for one day before and two days after two intravenous infusions of either 0.5mg/kg ketamine or placebo over a 40-minute period. Infusions took place two weeks apart. Subject ratings on the MADRS at baseline and following infusions were used to quantify antidepressant response to ketamine. Five nonparametric variables were calculated by day using pyActigraphy, an open-source Python actigraphy analysis package: the most ten-hour active period (M10), the least five-hour active period (L5), the relative amplitude (RA), the intradaily variability (IV), and the interdaily stability (IS).We ran five linear mixed effects models examining the relationship between actigraphy metrics and fixed effects of age, gender, and the interaction between day (in relation to infusion), drug (placebo or ketamine), and MADRS score. We found an effect of drug by day ($t(183)=2.80$,$p=0.006$) and MADRS by drug by day ($t(183)=-2.74$,$p=0.007$) on the IS. No other variables appeared to be associated with day, drug condition, or treatment response.Preliminary work suggests that ketamine may impact motor activity patterns of depressed inpatients. However, there is a need to identify the most suitable metrics to best characterize these patterns in a short-term, inpatient setting. Factors such as restricted activity patterns may inadvertently obscure findings. Therefore, while these results suggest associations between ketamine administration and the IS, future work will need to replicate these findings, as well as explore alternative calculation techniques and other metrics of interest.

Title: Assessment of orotic acid as a superior carrier for lithium in the management of mania

Authors: *A. G. PACHOLKO, L. K. BEKAR;
Anatomy, physiology and pharmacology, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Lithium carbonate (Li_2CO_3) is a mainstay treatment option for the control of mania. However, Li_2CO_3 is not without its faults, specifically a narrow therapeutic index and common thyroid and renal complications. Lithium orotate (LiOr) is an alternative compound that is suggested to have uptake properties that would allow for markedly reduced dosages in treatment regimens, which would theoretically mitigate toxicity concerns and improve patient compliance. As a first step in exploring LiOr as a replacement for traditional lithium compounds in therapy, we established dose response curves for a range of LiOr and lithium chloride (LiCl) concentrations (0, 1.5, 2.5, 5, 10 and 15 mg/kg, normalized to elemental lithium) following a single injection (single injection protocol; SI) in male wild-type mice using an amphetamine-induced hyperlocomotion (AIH) model (3 mg/kg *d*-amphetamine). AIH is mania-mimetic and is sensitive to dose-dependent blockade by lithium. Lithium was injected intraperitoneally (IP) 30 minutes prior to IP administration of *d*-amphetamine. Animals were recorded for 120 minutes in an open field and scored for total locomotion. Next, to assess whether daily administration would further reduce the dose necessary for attenuation of AIH, mice were injected once daily over a span of 7 days (repeated injection protocol; RI) with LiOr at concentrations of 0, 1.5, 2 and 2.5 mg/kg, and with LiCl at concentrations of 5 and 10 mg/kg. The AIH protocol was performed on the 7^{th} day. The maximal effects of *d*-amphetamine on locomotor activity for SI were observed within the 5-35- and 70-120-minute time bins post-injection. LiOr, but not LiCl, elicited a complete blockade of AIH between minutes 5-35 at concentrations of 10 mg/kg and 15 mg/kg. For minutes 70-120, a partial attenuation of AIH was maintained by LiCl doses of 10 mg/kg or greater, while a complete blockade was induced by LiOr at concentrations of 5 mg/kg and beyond. Following RI, LiOr elicited a complete block at all concentrations of 1.5 mg/kg or greater within the 75-120-minute time bin, while LiCl remained effective only at doses of 10 mg/kg or above, with the strength of blockade unchanged (~40%). Neither compound attenuated AIH during the first window of peak hyperlocomotion. In conclusion, LiOr demonstrates superior efficacy to LiCl in the attenuation of mania-mimetic AIH, as evidenced by reduced dosage requirements and an enhanced strength of blockade at equivalent concentrations. Further, the reduced dosage requirements following RI for LiOr, but not LiCl, may suggest that the orotic acid carrier facilitates enhanced accumulation of lithium within the CNS over time relative to LiCl.

(NYSPI), New York, NY; [7]Dept. of Psychiatry, Columbia Univ. Irving Med. Ctr. (CUIMC), New York, NY

Abstract: Major depressive disorder (MDD) is the leading cause of global disability, yet current pharmacological approaches to treating MDD are both slow and not universally effective. In recent years, the drug (R,S)-ketamine has been promoted as a fast-acting, efficacious antidepressant. (R,S)-ketamine acts within an hour of administration and has single-dose effects that can last for weeks, but also has psychotropic and other unwanted side effects. Therefore, there is a need for alternative drugs that retain (R,S)-ketamine's potent antidepressant effect without its psychotropic side effects. (R,S)-ketamine is also active when administered in a prophylactic manner, prior to stress: both (R,S)-ketamine and its active metabolite (2R,6R)-hydroxynorketamine ((2R,6R)-HNK) can prevent the onset of depressive-like symptoms following exposure to stress. Despite its efficacy, (R,S)-ketamine's mechanism of action is still not clear, as multiple receptors, brain regions, and pathways have been indicated. As such, there is a need for more research into how (R,S)-ketamine exerts both its antidepressant and prophylactic effects. Recently, the hyperpolarization-activated cyclic-nucleotide gated channel 1 (HCN1) has been shown to be necessary for (R,S)-ketamine's antidepressant effect, and downregulation of HCN1 in the hippocampus (HPC) has been shown to be sufficient to induce an antidepressant effect. Thus, we were interested in how levels of HCN1 might mediate both the antidepressant and prophylactic effects of (R,S)-ketamine. We found that an antidepressant administration of (R,S)-ketamine, but not (2R,6R)-HNK, prevented a stress-induced increase in dorsal and ventral HPC HCN1 expression following behavioral stress in male, but not female, mice (7-8 week old 129S6/SvEvTac mice: Taconic, Hudson NY). Conversely, prophylactic administration of (R,S)-ketamine decreased dorsal HPC HCN1 expression prior to stress in male mice, while in female mice, prophylactic administration of both (R,S)-ketamine and (2R,6R)-HNK prevented a stress-induced decrease in dHPC HCN1 expression following behavioral stress. These results suggest that (R,S)-ketamine and (2R,6R)-HNK have sex- and time-specific effects on the expression of HCN1, and that (R,S)-ketamine may exert its prophylactic effect through downregulation of HCN1 prior to stress exposure. Further investigation will be necessary to establish a causal relation between (R,S)-ketamine, HCN1 expression, and antidepressant and prophylactic effects.

Title: The putative antidepressant pyro-glutamyl-glutamyl-prolineamide (EEP), an analog of Thyrotropin Releasing Hormone, decreased Bdnf mRNA in animals showing a positive response in the forced swim test.

Authors: T. W. BASTIAN[1], *R. L. LLOYD[2], D. LEFF[3];
[1]Pediatrics, Univ. of Minnesota, Minneapolis, MN; [2]Psychology, Univ. of Minnesota, Duluth, MN; [3]Scool of Med., Univ. of Minnesota, Minnesota, MN

Abstract: Thyrotropin releasing hormone (TRH) has been demonstrated to demonstrates rapid efficacy in treating major depression. However, this treatment must be given intrathecally, and the duration of effect is foreshortened due to? degradation byalpha aminopeptidase degradation. Thus, the mode of administration and duration of action makes TRH untenable as a therapeutic agent. Pyroglutamyl-glutamyl-proleneamide (EEP), a naturally occurring analogue, has been demonstrated to have a positive effect in the forced swim test (FST) with peritoneal, subcutaneous, and nasal administration. Interestingly, electroconvulsive seizures have been found to increase both TRH and EEP in brain tissue. Furthermore, both escitalopram and ketamine increase TRH and TRH-like peptides in limbic tissue, including EEP itself. Peripherally, both valproate and corticosterone increase TRH. In addition to its putative antidepressant effects, EEP has been found to have anxiolytic effects, as assessed by the elevated plus maze test. Virtually all antidepressant treatments (reuptake blockers, ECT, ketamine) enhance BDNF (Brain-derived neurotrophic factor) protein. Serum BDNF protein? has been reported to be elevated in patients undergoing psychotherapy, but only in those demonstrating a positive response. BDNF has been found to stimulates dendritic arborization, synaptogenesis, neuronal neogenesis in the hippocampus of adult rats, and enhanced enhances both the survival of new neurons, and activation of “silent neurons”. In turn, the hippocampus shows atrophy in those with major depression, which reverses upon treatment. We assessed the effect of EEP up\\on BDNF expression by measuring the mRNA amount abundance of several *BDNF Bdnf* isoforms mRNA in the hippocampus of EEP treated Wistar ratsanimals (3 injections of 0.5mg/kg EEP vs. saline) compared to vehicle treated controls (all animals ~42 days old upon arrival). While semi-chronic treatment with EEP enhanced swim time in the FST ($p=0.03$, 1-tail), there was a significant **decrease** in total *BDNF Bdnf* mRNA in treated animals ($p=0.017$, 2-tail), with the percent of variance accounted for being 28%. The expression levels of individual *Bdnf*

mRNA isoforms were not altered by EEP treatment. The outcome of this experiment was highly unexpected. The dose and rout of administration has given us a much stronger response in the FST in the past, and we anticipated that this behavioral effect would be associated with an increase in messenger RNA coding for BDNF.Add a summary/implications type sentence?

Title: An α5-containing benzodiazepine site on the $GABA_AR$ is required for the fast antidepressant-like actions of MRK-016 on stress-induced anhedonia and weakened synaptic function

Authors: *T. TROPPOLI[1], P. ZANOS[2], P. GEORGIOU[2], U. RUDOLPH[3], T. D. GOULD[4], S. M. THOMPSON[1];
[1]Physiol., [2]Psychiatry, Univ. of Maryland Baltimore, Baltimore, MD; [3]Dept. of Comparative Biosci., Univ. of Illinois at Urbana-Champaign, Urbana, IL; [4]Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Major depressive disorder (MDD) is a common psychological disorder characterized by chronic low mood, anhedonia and is comorbid with suicidal ideation. Traditional serotonergic antidepressants have a delayed onset of action, requiring 6-8 weeks of chronic dosing and up to half of MDD patients will remain refractory to treatment. Ketamine has shown promise as a rapid acting antidepressant by promoting surges in glutamatergic activity, but its broad antagonism of NMDARs throughout the brain causes side effects that limit its clinical use. We showed previously that negative allosteric modulators of α5-containing $GABA_A$ receptors (GABA-NAMs) have a rapid and persistent anti-anhedonic action in chronically stressed mice and selectively promote excitatory activity within reward regions of the brain with high endogenous $GABA_A$ α5 expression. Chronic multimodal stress was used to induce anhedonia in 8-week old male C57BL/6J mice as assessed through sucrose and female urine preference tests. Treatment with 3mg/kg of the GABA-NAM MRK-016 rapidly reversed stress-induced deficits in hedonic TA-CA1 synaptic strength as assessed via AMPA:NMDA ratios. Pretreatment with 20mg/kg of the benzodiazepine antagonist flumazenil was sufficient to prevent both behavioral and synaptic effects of MRK-016, suggesting that MRK-016's antidepressant-like effects are mediated through the benzodiazepine site of the $GABA_AR$. *In vitro*, MRK-016 has similar affinities for α1, α2, α3 and α5-containing $GABA_ARs$, though it produces the greatest inhibition of GABA responses at α5-containing receptors. We predicted that global genetic deletion of the α5 subunit *in vivo* would be sufficient to block the rapid antidepressant-like effects of MRK-016.

Cohorts of 8-week old, male C57BL/6J α5 KO mice and WT littermate controls were chronically stressed to induce an anhedonic phenotype. Treatment with 3mg/kg MRK-016 was sufficient to restore deficits in hedonic behavior and TA-CA1 synaptic strength in wildtype, but not α5 KO mice. The long-term behavioral and synaptic effects of ketamine and other rapid antidepressant interventions are believed to follow a transient period of high-frequency network activity to strengthen synapses in a use-dependent manner. We demonstrate that WT, but not α5 KO animals generate increases in high-frequency qEEG gamma power in response to 3mg/kg MRK-016. Both strains of animals, however, demonstrated increased gamma-power following 10mg/kg ketamine. We conclude the rapid-acting antidepressant-like activity of MRK-016 is mediated at an α5-containing benzodiazepine site of the $GABA_AR$ and that drugs of this class have potential in treating human depression.

Title: Effect of agomelatine on the CPF 5-HT2C receptor in a rat model of major depression

Authors: *D. JUÁREZ SERRANO[1,2], I. CESAR ARTEAGA[1,2], C. GARCIA-OLVERA[1,3], P. AGUILAR-ALONSO[1,2];
[1]Lab. de Investigaciones Quimico Clinicas, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Biochemistry-Molecular Biol., Posgrado en Ciencias Químicas, BUAP, Puebla, Mexico; [3]Facultad de Ciencias Químicas, BUAP, Puebla, Mexico

Abstract: Major depressive disorder (MDD) is a disease that affects people of all ages, showing a higher incidence in the female sex. The monoamine theory proposes that a decrease in the concentration of serotonin is the primary cause of this disorder, also affecting the levels of dopamine and norepinephrine. Among the different antidepressant drugs, selective serotonin reuptake inhibitors (SSRIs) stand out, including fluoxetine, which increases serotonin levels in the inter synaptic space, however, they have been described adverse effects with this drug, therefore, the investigation of new drugs for the treatment of this disorder is required, one of them is agomelatine, which is an antagonist of $5HT_{2C}$ receptors and an agonist of melatoninergic receptors, has shown the restoration of dopamine and norepinephrine levels within a few hours after their administration but not of serotonin, so further research is required on this drug. The aim of this work is to evaluate the effect of agomelatine on the $5\text{-}HT_{2C}$ receptor of prefrontal cortex (CPF) in a model of major depression in rats. 120 male rats of the Wistar strain weighing between 250-300g, 6 animals were randomly assigned to the following 5 groups: Sham (Sham surgery), OBX (bulbectomy) OPBX-V (Bulbectomy and vehicle), OBX-F (bulbectomy and fluoxetine) and OBX-A (bulbectomy and agomelatine). The depression model included bilateral

rat bulbectomy surgery (OBX) which was characterized by the olfactory discrimination test, the open field test and the Light/dark test, and the forced swim test. The administration of drugs was carried out daily for periods of 0, 7, 14, 21 days. The agomelatine dose was 40 mg/Kg and 10 mg/Kg for fluoxetine, both had 1% carboxymethylcellulose as vehicle during the aforementioned periods. Once the treatment was finished, the samples were kept at -80ºC. Subsequently, the quantification of serotonin in the supernatant was performed using the Serotonin ELISA kit ADI-900-175. The results of the behavioral tests showed an improvement in the motor behavior of the animals after the treatment. In addition, an increase in the concentration of serotonin in the prefrontal cortex occurs after prolonged treatment with agomelatine. In conclusion, both antidepressants reduced the hyperactivity of the animals with OBX after the different periods, as well as the regulation of neurotransmitters, which together suggest agomelatine as a good drug for the treatment of MDD.

Title: Brain stimulation rewarding experience ameliorates depression-associated cognitive deficits by modulation of astroglial plasticity

Authors: *S. CHAKRABORTY, S. J. TRIPATHI, B. S. SHANKARANARAYANA RAO; Dept. of Neurophysiol., Natl. Inst. of Mental Hlth. and Neuro Sci. (NIMHANS), Bengaluru, India

Abstract: Major depressive disorder (MDD) is a multifactorial disease and often co-exist with profound cognitive impairment and anxiety. One of the key features of MDD is anhedonia, which indicates altered reward circuitry. Recent studies have demonstrated that impaired reward processing or negative bias could precipitate anxiety and cognitive decline. Interestingly, reward-related behaviors and depression-induced dysfunctions are crucially regulated by astroglial cells. Moreover, brain stimulation of rewarding brain areas also modulates the astroglial expression and functions in the prefrontal cortex (PFC), which is a pivotal region for modulation of reward, memory and emotions. However, it is unknown whether brain stimulation rewarding experience could ameliorate depression-associated anxiety, cognitive deficits and accompanying aberrant astroglial plasticity in the PFC. Accordingly, we induced depressive-like behaviors in adult male Wistar rats by neonatal administration of clomipramine from postnatal days 8-21. Then, rats were subjected to intracranial self-stimulation (ICSS) of the medial forebrain bundle (MFB) at the level of the lateral hypothalamus (LH) for 14 days. Rats from control and ICSS groups were

subjected to assessment of depressive-, anxiety-like behaviors, and rewarded alternation task in T-maze. Following behavioral assessments, rats were sacrificed, and $GFAP^+$ astroglial cells were localized using immunohistochemistry. Astroglial expression was quantified using an optical fractionator, and their processes were reconstructed using Neurolucida in the prelimbic and anterior cingulate subregions of PFC. We demonstrated that neonatal clomipramine administration causes depressive-, anxiety-like behaviors, and precipitated cognitive deficits in adulthood. Depression-induced anxiety and cognitive deficits were associated with astroglial cell loss and arbors in the PFC. Interestingly, ICSS of LH-MFB restored affective symptoms and cognitive deficits in depressed rats. The beneficial effects of ICSS treatment were associated with improved astroglial plasticity in the PFC. Our results indicate that brain stimulation rewarding experience could restore astroglial dysfunctions in the PFC leading to amelioration of anxiety and cognitive deficits in depression. We speculate that brain stimulation rewarding experience might be a potential therapeutic tool for the management of depression-induced astroglial dysfunctions in the PFC.

Title: Eukaryotic initiation factor 4E-binding proteins mediate depressive behaviours in mice exposed to chronic variable stress.

Authors: *E. ARSENAULT, A. DANESHMEND, M. ZHANG, M. PARKHILL, E. MATTA-CAMACHO, S. SIMARD, N. SALMASO, A. AGUILAR-VALLES;
Dept. of Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Major depressive disorder (MDD) is one of the most common mental illnesses worldwide and chronic stress has been correlated with an elevated risk of developing depression. Ketamine, an N-methyl-D-aspartate receptor antagonist, has been demonstrated to rapidly reduce depressive symptoms in individuals with treatment-resistant MDD. Previously, we demonstrated that ketamine exerts antidepressant-like behavioural effects through regulation of negative regulators of protein synthesis termed eukaryotic initiation factor 4E binding proteins (4E-BPs) in naive mice. However, it is unclear whether this mechanism extends to depressogenic conditions, such as chronic variable stress (CVS). Therefore, we tested how male mice lacking 4E-BP1 and 4E-BP2 (Eif4ebp1/2 double knock out [DKO]) responded to CVS and ketamine. CVS consisted of 2 different stressors per day, for 5 weeks. Stressors included cage tilting, 15-minute restraint, wet bedding, no bedding, forced swimming, exposure to odour-induced variation, and altered light/dark cycle. Twenty-four hours after the last stressor, wildtype and Eif4ebp1/2 DKO mice received either a saline (IP, 10 ml/kg of body weight) or ketamine (IP, 10

mg/kg) injection, and were observed one hour later during a splash test. We found that in wildtype mice, CVS reduced grooming time in the splash test. In contrast, Eif4ebp1/2 DKO mice presented increased grooming in the splash test at baseline and this behaviour was not significantly changed by CVS or ketamine. Our results suggest that 4E-BPs are central in determining the response to ketamine and may be critical mediators of chronic stress.

Abstract: Major depressive disorder, the leading cause of disability worldwide, strikes women twice as often as men, yet the molecular mechanisms contributing to this sex difference are poorly understood. There is an urgent need for novel sex-specific molecular targets, which can aid the development of new diagnostics and therapeutics for depression. We recently reported that lncRNAs, a class of regulatory transcripts, are robustly regulated in a sex-specific manner in postmortem brain tissue from depressed subjects compared to controls (Issler et al., *Neuron* 2020). Utilizing advanced bioinformatic tools, we identified sex-specific lncRNAs linked to depression risk. Here we highlight one such target, which is upregulated in multiple brain regions in depressed females only; therefore, we named it FEDORA (FEmale DepressiOn lncRnA). FEDORA is primarily expressed in oligodendrocytes as well as in neurons. Our analysis suggests that it has a potential role in regulating oligodendrocyte function, as its expression levels in female brains correlate with multiple genes that have been implicated in myelination. To test if FEDORA has a sex-specific causal role in depression, we utilized a cell type-specific viral approach to express it in the prefrontal cortex (PFC) of mice of both sexes. We found that

expressing FEDORA exclusively in neurons promoted anxiety- and depression-like behaviors in females only, which mirrored the human sex-specific phenotype. These behavioral changes were associated with transcriptional changes that resemble the sex-specific transcriptional signature of human depression and were associated with changes in neuronal electrophysiological properties. Expression of FEDORA in oligodendrocytes again had a female-specific effect on motivational behavior, which was associated with changes in myelin thickness and gene expression. Finally, we found that circulating FEDORA levels are elevated in depressed women only and that these levels are normalized following antidepressant treatment. Together, these findings support our hypothesis that lncRNAs play key roles in depression and contribute to the sex-differences in this disorder, and may lead to the identification of novel targets for treatment and diagnosis.

Title: Prefrontal-limbic circuitry in the children of Superstorm Sandy: a preliminary MRI study

Authors: *J. BUTHMANN[1,2], T. WU[2,1], A. SHEREEN[3], Y. NOMURA[2,1];
[1]CUNY Grad. Ctr., New York, NY; [2]CUNY Queens Col., Flushing, NY; [3]Neurosci. Initiative, Advanced Sci. Res. Ctr. at the Grad. Ctr., New York, NY

Abstract: Rising rates of childhood psychopathology mandate investigation into the antecedents of symptom onset. Growing evidence shows prenatal maternal stress experienced in utero is a strong contributor to offspring neurodevelopmental deficits, including emotion dysregulation, a core feature of many types of psychopathology. Evaluation of the prefrontal-limbic circuit, thought to underlie emotion regulation processes, has begun to illuminate aberrations linked to prenatal maternal stress and the offspring's emotion dysregulation. Functional differences in this circuit associated with prenatal maternal stress, particularly in early childhood, remain understudied. We present preliminary MRI data from a small pilot study of <20 5-7 year old children who were prenatally exposed to maternal stress related to a natural disaster, Superstorm Sandy, comparing with children who were not prenatally exposed to the storm. Gray matter volume was assessed via structural MRI scan and brain activity was assessed using an emotional face viewing task during functional MRI (fMRI) scan. Among children prenatally exposed to

maternal stress related to the storm, we found marginally or significantly increased gray matter volume in the bilateral hippocampi and amygdalae as well as decreased gray matter volume in the left lateral orbitofrontal cortex and right parahippocampal gyrus. Further, prenatal exposure was associated with significantly increased bilateral amygdalae activation while viewing fearful or angry facial expressions compared with children who were not prenatally exposed to the storm. Male and female children were included, and sex effects are explored. This represents the first attempt to document prefrontal-limbic differences in prepubertal children on the basis of prenatal natural disaster exposure in boys and girls. These findings suggest structural and functional differences in the prefrontal-limbic circuit on the basis of prenatal stress exposure, which may contribute to risk for psychiatric symptomatology. Our sample size was hindered by the COVID-19 pandemic and current findings need to be interpreted as preliminary. However, our future plan to resume the investigation will target confirming the implication of prenatal stress exposure on the prefrontal-limbic circuit. Gaining insight into the repercussions of the increasing frequency and intensity of natural disasters on the next generation of children will have important public health implications.

Title: Gary matter volume correlates of attentional bias to threat in high anxious individuals

Authors: *J. M. CARLSON, L. FANG;
Northern Michigan Univ., Marquette, MI

Abstract: The preferential allocation of attentional resources to threatening stimuli is referred to as an attentional bias to threat. This attentional bias to threat is adaptive as it prepares individuals to face potential danger. Yet, exaggerated attentional bias to threat is associated with elevated levels of anxiety and can be maladaptive. The relationship between individual differences in brain structure and attentional bias to threat has been understudied. Limited evidence from a single study suggests that greater gray matter volume in the anterior cingulate cortex is linked to attentional bias to threat (Carlson et al., 2012). Yet, no studies have explored this relationship in high anxiety individuals. To address this, 111 right-handed high trait anxious adults (female = 75) between 18 and 38 (M = 21.90, SD = 4.71) years of age participated in the study. Participants performed a dot-probe task of attentional bias to threat using fearful and neutral faces. Gray matter volume was acquired from whole brain structural T_1-weighted MRI scans. A voxel based morphometry (VBM) regression analysis was used to assess the association between attentional bias to threat and regional gray matter volume. Small volume correction of an *a priori* region of

interest identified a significant positive correlation between gray matter volume and attentional bias in the anterior cingulate cortex (t = 4.02, k = 90, xyz = -9, 35, 20). This association was observed in a number of other regions including middle frontal gyrus, striatum, right posterior parietal cortex, cerebellum, and other distributed regions. No negative correlations between attentional bias to threat and gray matter volume were found. Lastly, exploratory analyses provide initial evidence that distinct sub-regions of the right posterior parietal cortex may contribute to attentional bias in a sex-specific manner: (1) greater gray matter volume in females compared to males: t = 4.53, k = 232, xyz = 44, -41, 42 and (2) greater gray matter volume in males compared to females: t = 3.57, k = 70, xyz = 51, -44, 30. In short, we extend previous findings in unselected samples that elevated attentional bias to threat is linked to greater gray matter volume in the anterior cingulate cortex. Our results illuminate how differences in gray matter volume morphology relate to attentional bias to threat in individuals with high trait anxiety. This knowledge could inform neurocognitive models of anxiety-related attentional bias to threat and targets of neuroplasticity in anxiety interventions such as attention bias modification.

Title: Assessing COVID-related stress on mental health and decision-making

Authors: *C. M. RAIO, A. MELLIS, A. VINA-ALBARRACIN, P. GLIMCHER;
Neurosci. Inst., New York Univ. Grossman Sch. of Med., New York, NY

Abstract: The COVID-19 pandemic is an unprecedented and pervasive stressor that poses a direct threat to individuals' health and survival and can also have downstream effects on mental health and decision-making. Understanding the effects of COVID-related health challenges and stress will be critical for informing interventions throughout the pandemic. To comprehensively assess these effects, we conducted a large-scale, mobile (smartphone) app-based, longitudinal study to track how COVID-related stressors affects psychological health (stress levels, depression) and economic decision-making (risk and ambiguity preferences, impulsivity). Each day, participants spent 5-10 minutes completing gamified decision-making tasks and survey instruments on their smartphones. To measure COVID-related stress, we developed the *COVID Stress Assessment* (CSA), a weekly self-report survey that identifies general and domain-specific

stressors as well as how unpredictable, uncontrollable and overwhelming each are perceived to be. Depression was measured using the *PHQ-8*. To measure risk and ambiguity aversion, participants made a series of binary choices between a certain gain and a lottery option with winning probabilities that were explicitly stated (risk) or partially hidden (ambiguity). We measured impulsivity using a delay discounting task. Initial trajectories of subjective stress responses and how they related to mental/physical health and decision-making were assessed in our current sample (n=171; 82% female; mean age = 42.77, SD=14.32). Overall, higher perceived controllability, predictability, and coping all predicted lower global stress levels as measured by the *CSA,* suggesting they serve as protective factors that buffer perceived stress. These protective factors were (on average) negatively correlated with depression levels (*PHQ-8*; Spearman's rho= -0.39, $p<.05$). In terms of physical health, these protective factors were negatively related to the stressfulness of COVID infections that participants experienced (subset reporting positive COVID infection: n=35; Spearman's rho = -0.68, p = 0.0034). While no effect of stress was observed on risk and ambiguity preferences, we found that our protective factors were related to lower impulsivity choice as measured through our delay discounting task (rho= -0.49, $p<.05$). Our results provide an initial assessment of subjective stress responses, as well as stress resilience factors, during the COVID-19 pandemic and set the stage for future analyses tracking how real-world stress predicts changes in physical/mental health and choice behavior.

Title: Empathy and its relationship with peer victimization in school

Authors: *R. BENÁ DE ARAUJO, R. P. MONTEIRO;
Dept. of Psychology, Federal Univ. of Mato Grosso, Cuiabá, Brazil

Abstract: Introduction: Empathy has been a topic of special attention between all kinds of scientists, in special in these days when societies across the world strive to fight racism, homophobia, sexism and many other types of prejudice. Empathy is frequently defined as a phenomenon comprising cognitive, emotional and behavioral aspects. Its cognitive compound relates to the ability of inferring someone's feelings and emotional state while emotional empathy is described by feelings of compassion and sympathy that guide towards a genuine motivation to help someone in need. The behavioral aspects of empathy are those related to the way the feelings are expressed through verbal and non-verbal behavior. Evolutionarily speaking, empathy is a form of prosocial behavior, especially important for social animals, that helps their members to maintain a social cohesion and the survival of their kins. On the other hand, we have bullying behavior as an aggressive type of interaction that occurs mainly among kids and

teenagers. According to the United Nation Children's Fund (2007), around 30% of children are targets of peers' physical and emotional aggression and many studies suggest that peer victimization, as a form of early life stress, impact the onset of psychopathologies later on in life. But despite all the deleterious effects of peer victimization in a child's life, could such sort of early stress give rise to positive emotions in adults? **Objectives:** This is an exploratory, cross-sectional, descriptive study in which self-reported peer victimization during school life was correlated with general score of empathy in adulthood. **Methods:** 236 brazilian human subjects (M_{age} = 28.61; SD_{age} = 13.04; 78.8% women and 21.2% men; 69.1% single; 41.5% middle class; 47.9% incomplete higher education) answered the Olweus Victim Questionnaire (OVQ) and the Basic Empathy Scale in Adults (BES-A). The items of the OVQ were adapted to evaluate past experiences. All ethical precepts for research with humans based on the Declaration of Helsinki were respected, including the Informed Consent, and data was collected from an aggregated database without the possibility of individual identification. **Results:** A statistically significant association was found between the variables peer victimization and empathy (r = 0,477; p < 0,01). **Conclusions:** This research showed that peer victimization in school is positively related to more empathetic adults, reinforcing pre-existing literature that shows a link between early stressful events and development of more empathetic people. Therefore, it contributes to the existing literature and shines a light towards the dynamics of positive emotions like empathy.

Title: The role of the kappa opioid system in stress-induced anxiety-like behaviors in females

Authors: *A. KHURANA[1], C. BOUARAB[1], A. M. POLTER[2];
[1]The George Washington Univ., Washington, DC; [2]Dept. of Pharmacol. and Physiol., George Washington Univ., Washington, DC

Abstract: Women are twice as likely as men to be diagnosed with a mood or anxiety disorder. Given that stress plays a significant role in the development of these disorders, sex differences in the response to stress are likely to be a critical factor in the enhanced vulnerability of females to these pathologies. Across both human populations and animal models, males and females exhibit divergent responses to stress at all levels, from molecular signatures to behavioral adaptations. Sub-chronic variable stress (SCVS) is a model of depression and anxiety in which female mice

develop anhedonia and anxiety-like behaviors but males do not.
Dysregulation of the mesolimbic reward circuitry is implicated in the pathophysiology of stress-related illnesses such as depression and anxiety. Dopaminergic (DA) neurons in the ventral tegmental area (VTA) are a major target of stress. Previous work has shown that acute stress leads to a days-long activation of kappa opioid receptors (KORs) in the VTA. We hypothesize that similar changes may underlie the female-specific behavioral deficits induced by SCVS. If this hypothesis is correct, pre-stress treatment with NorBNI (10 mg/kg, ip) would prevent the stress-induced behavioral deficits observed in females. To test this, we used both male and female C57Bl/6J mice at 8-weeks old in a SCVS protocol (n=9 per group). Using dark-light box to assess anxiety-like behavior, we first confirmed that SCVS causes an increased latency to enter the light compartment in female mice only. Interestingly, this deficit is prevented by a pre-treatment with NorBNI. Next, we will inject the NorBNI post-stress to see if it can reverse this anxiety-like behavior in females. Together, this data indicates the important role of the kappa opioid receptor in the development of maladaptive behavioral responses in female mice.

Title: Structural and molecular signature in the Locus Coeruleus of the vulnerability to develop compulsive adjunctive drinking

Authors: *C. VELAZQUEZ-SANCHEZ[1], L. MARTI-PRATS[1], L. MURESAN[2], B. J. EVERITT[1], D. BELIN[1];
[1]Dept. of Psychology, [2]Cambridge Advanced Imaging Ctr., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Although the neural mechanisms underlying the vulnerability to develop compulsivebehaviours remain to be established, increasing evidence points to a role ofnoradrenergic (NE) mechanisms in the transition from impulsivity to compulsivity.We showed that chronic treatment with the noradrenaline reuptake inhibitor,atomoxetine (ATO), decreased impulsivity in highly impulsive rats, and selectivelyprevented the associated development of compulsive drinking in a schedule-inducedpolydipsia procedure (SIP).The effects of ATO on impulse control are mediated by the nucleus accumbens shell,the medial portion of which receives NE afferents from the Locus Coeruleus (LC). Wetherefore investigated the structural and cellular mechanisms within the LC that areassociated with the individual vulnerability to develop compulsive drinking.96 male Sprague Dawley rats trained under SIP for 21 days were

screened as high-or low-compulsive drinkers (HD or LD) based on their water intake. We theninvestigated whether LC neuronal ensembles are involved in mediating the anxiogenicproperties of the SIP, or the anxiolysis brought about by the adjunctive response or itscompulsive nature. Rats were challenged in a last session during which the waterbottle was removed for half rats so they were unable to express adjunctive drinkingbehaviour. Brains were harvested 45- or 90 min after the test and processed forRNAscope or immunohistochemistry in order to measure structural features of, andthe expression level of cellular activation or plasticity markers in different cell types inthe LC.Immunohistochemical analysis revealed that HD rats had a larger LC and more cFos+cells in the LC than LD rats. Also, at the population level, dimensional analysesrevealed that the size of the LC was correlated with the compulsive nature of theadjunctive behaviour.
RNAscope data confirmed that cFos expression was higher in the LC of HD than inLD rats, and further showed that it was restricted to GABA neurons, since cFosmRNAs were increased in GAD2 but not in GFAP+ or, following immunohistochemicalanalysis, in TH+ cells. Moreover, the inability to cope resulted in increased cFosexpression in LC astrocytes specifically in HD rats.These results show that an individual's vulnerability to develop compulsive drinking isassociated with structural differences in the LC, and the functional recruitment ofGABAergic neurons, while the inability to cope with distress is associated withactivation of LC astrocytes, suggesting a differential involvement of these twomicrocircuits in the LC in the vulnerability to switch to compulsivity.

Title: Differential effects of diazepam and yohimbine on hippocampal local field potentials during avoid-approach conflict in rats

Authors: M. T. ERICKSON, *A. D. REDISH;
Univ. of Minnesota, Minneapolis, MN

Abstract: Anxiety is thought to depend on evaluations of potential future threats, but the neural mechanisms by which this may occur remain unclear. To examine how hippocampus (HC) may relate to anxiety and decision-making, we examined effects of Diazepam and Yohimbine on HC local field potentials (LFP) in rats on the robogator task. In this task, a rat runs back and forth on a linear track for food rewards with a robot lurking near one reward site, lunging forward and

attacking on 20% of the laps. This task has been shown to induce anxiety-like behaviors in which the rat hesitates at the nest doorway (stretch-attend posture, SAP) and quits laps more often, returning to the nest without reaching the far food site (mid-track aborts, MTA). We recorded LFPs from dorsal HC of brown norway rats (6M, 5F) with silicon probes. Rats received Diazepam (2 mg/kg), Yohimbine (2.5 mg/kg), or their respective vehicle controls before each session. Diazepam increased hesitation (SAP) behaviors, but also decreased quit (MTA) behaviors, replicating previous work. Hesitation at the nest doorway coincided with increased sharp wave ripples (SWRs) in HC. Diazepam also reduced MTA events. Animals remained in theta throughout the MTA events. Yohimbine reduced running speed while the rats were running towards the robot, but not on the return journey. Diazepam decreased the incidence of SWRs at the pyramidal layer, decreased low gamma (40-80 Hz), and increased high gamma (80-140 Hz). Diazepam reduced both the power and central frequency of theta. Yohimbine increased low SWR frequencies (150-200 Hz) but decreased high SWR frequencies (200-250 Hz) and broadly inhibited power in the theta, low gamma, and high gamma ranges. Low gamma reflects inputs from CA3 while high gamma reflects inputs from Entorhinal cortex (EC), which would suggest that Diazepam is reinforcing internal hippocampal processing over inputs from EC, which could create the observed reduction in SWRs and could affect hippocampal replay. HC SWRs and theta play important roles representing future outcomes. Given how hippocampal circuits are disrupted by Diazepam and Yohimbine on this task, we expect effects on hippocampal representations of future outcomes could partially explain their effects on anxiety-like behaviors.

Title: Exposure to concomitant fluoxetine and aripiprazole leads to a depressive-like outcome in adult female c57bl/6 mice

Authors: *S. A. CASTILLO, C. AMAYA, D. PARDO, S. D. IÑIGUEZ;
Dept. of Psychology, The Univ. of Texas At El Paso, El Paso, TX

Abstract: Major depressive disorder (MDD) is a highly debilitating illness affecting millions across the globe. The first line of defense against this disorder is fluoxetine (FLX), a selective serotonin reuptake inhibitor. Unfortunately, FLX does not alleviate MDD symptoms in most patients - with close to 50% being resistant to this pharmacotherapeutic treatment. A current alternative approach for treatment-resistant MDD is the prescription of FLX in combination with the atypical antipsychotic aripiprazole (ARIP). This is surprising, given that the long-term consequences of this combination treatment (FLX+ARIP) have not been thoroughly assessed at

either the clinical or preclinical level. To make things worse, females are often excluded in studies that assess potential long-term consequences of drug exposure, despite making up more than half of the clinically depressed population. Thus, the purpose of this study is to examine if FLX+ARIP exposure influences reactivity to anxiety-inducing situations, as well as drug-seeking behavior, in later life. To achieve this, adult (postnatal day [PD] 70) female C57BL/6 mice were administered either vehicle (DMSO) or FLX (10 mg/kg) with aripiprazole (0.03 mg/kg) for 15 consecutive days (PD70-84). Twenty-one days later (PD105+), mice were tested on the open field, light/dark box, or cocaine (5 mg/kg) conditioned place preference (CPP) paradigm. The results showed that animals pretreated with FLX+ARIP displayed greater sensitivity to anxiety-inducing situations, and spent significantly less time in cocaine-paired environments, when compared to DMSO-treated controls. Likewise, mice with FLX+ARIP history displayed decreases in preference for cocaine-paired environments, when evaluated on the CPP test. Collectively, these data indicate that the combination treatment of FLX+ARIP induces an enduring anxiogenic and anhedonia-like behavioral profile - recapitulating some of the core symptoms of MDD. Of concern, this long-term enhanced sensitivity to anxiety-inducing environments and reduced preference to reward-related stimuli may reflect general dysfunction(s) of brain reward systems.

Abstract Distributed neural circuits in the prefrontal and limbic regions are known to be involved in the control of anxiety-like behaviors. Much less is known about the neural encoding of anxiety states, with the primary finding, thus far, being the presence of individual neurons that are selective for high or low anxiety states in the medial prefrontal cortex, the amygdala and the ventral hippocampus. The complexity of an affective state such as anxiety suggests that additional insights may be gained from the investigation of coding by ensemble activity patterns

- an approach that has proved effective in studies of other encoding problems in neuroscience.Inspired by these, here, we examine the joint neural ensemble activity patterns (or 'code') in mPFC using calcium imaging in mice engaged in a classic assay of anxiety, the elevated zero maze. Using a miniature fluorescence microscope, we longitudinally tracked the Ca^{2+} dynamics of mPFC neurons in freely moving mice as they traversed the exploration or avoidance zones of the elevated zero maze (EZM).Our data reproduce the classic results of subsets individual neurons being selective but go beyond to show that the joint activity patterns are distinct. These patterns occupy distinct subsets of n-d space, with the open arm representational cloud being denser (more stereotypical patterns), than that of the closed arm. An additional powerful finding is that the distinctive coordinated activity patterns between the two arms is not purely driven by the selective neurons. Surprisingly, sub-ensembles of neurons that are not individually selective also convey distinctive information about anxiety states. Results reveal a novel, distributed, coordinated neural code for anxiety states in the mPFC.

Abstract: Social interaction deficits seen in psychiatric disorders emerge in early-life and are most closely linked to aberrant neural circuit organization and function. Due to technical

limitations, we have had little understanding of the typical ontogeny of social behavior neural circuits or how early caregiving adversity impacts infant neurobiology to perturb lifelong social interaction. Using a suite of invasive procedures in awake, behaving young infant rats, including optogenetics, microdialysis and microinfusions, we charted the gradual increase in social behavior deficits following adversity-rearing and dissected circuits controlling this process. Persistently elevated dopamine in basolateral amygdala (BLA) was necessary and sufficient in initiating social behavior pathology, as demonstrated by manipulation of amygdala dopamine during adversity and during expression of social behavior deficits with the mother and peers. Taken together, these data highlight mesolimbic dopamine circuit organization and function as a potential therapeutic target in understanding behavioral deficits associated with psychiatric disorders.

Title: Marble burying behavior is influenced by sex-related chemosensory cues in adult sex-naïve male C57BL/6J mice

Authors: ***C. L. JIMENEZ CHAVEZ**, E. VAN DOREN, E. RIVERA, K. K. SZUMLINSKI; Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: In rodents, exposure to chemosensory cues from the opposite sex have be implicated in reward and motivation. For example, interaction with vaginal secretions from sexually mature female rodents have indicated a reduction in anxiety-like behaviors as they are believed to be naturally rewarding stimuli to sex-naïve males. Conventional preclinical behavioral paradigms of anxiety, such as the marble-burying assay, are often employed to measure levels of anxiety-like behaviors but are vulnerable to environmental perturbations (e.g. chemosensory cues) known to alter levels of anxiety and consequently affect marble-burying behavior. To understand the role of chemosensory cues in the marble-burying test, adult male (n=12) and female (n=10) C57BL/6J mice were subjected to marble-burying under three conditions: clean bedding, male soiled bedding, and female soiled bedding. Animals were separated by sex and tested in counterbalanced order in regard to the bedding type. On each test day, animals in the clean bedding group were ran first to avoid any lingering chemosensory cues from the used bedding

from previous testing. After confirming the absence of any carryover effects with the consecutive days of marble-burying, our results identified an anxiolytic effect with the adult male mice in female soiled bedding reflected via a significant decrease in total time spent burying marbles compared to the clean and male soiled bedding. This decrease in anxiety-like behavior demonstrates the influence of chemosensory stimuli in the reduction of anxiety-like behavior and thus an overall behavioral change in the marble burying behavior. Ongoing studies from our group will provide a behavioral profile for both male and female adolescent mice. These future results will provide further insight into the role on how chemosensory social stimuli can alter neurodevelopment during adolescence and result in altered affective responses. The importance in validating these behavioral models is imperative in maintaining the integrity of classic behavioral paradigms particularly with the expansion of behavioral profiling both males and females in preclinical studies.

Title: Deletion of vasopressin cells in the suprachiasmatic nucleus increases anxiety and sucrose consumption in male and female mice

Authors: *J. WHYLINGS[1], N. RIGNEY[1], G. J. DE VRIES[2,1], A. PETRULIS[1];
[1]Neurosci. Inst., [2]Dept. of Biol., Georgia State Univ., Atlanta, GA

Abstract: The suprachiasmatic nucleus (SCN) is critical for maintaining circadian rhythms, in part through central projections of arginine vasopressin (AVP). However, other functions of SCN AVP outside of rhythmic behavior have not been directly tested. Nuclei that receive AVP projections from SCN, such as the paraventricular nucleus of the hypothalamus, bed nucleus of the stria terminalis, and preoptic area, are important for typical expressions of anxiety-like behavior and social behaviors. Additionally, the SCN is involved in regulating immune responding, which also influences anxiety and social behaviors during sickness. However, whether SCN AVP is involved in sickness behavior has also not been directly tested. We examined the role of SCN AVP cells in the expression of anxiety, social, and sickness behaviors by selectively deleting SCN AVP cells using viral-based, Cre-dependent expression of a cell-death construct (activated caspase) in the SCN of adult male and female AVP-Cre expressing mice (or their Cre-negative littermates; C57/B6 background). We then characterized anxiety behavior, social behavior, and sickness behaviors (induced via i.p. injection of 0.5 mg/kg LPS) in

these animals. We found that SCN AVP cell ablation increased anxiety-like behavior in the elevated plus maze in both sexes, increased sucrose intake in both sexes, and increased urination in males. We found no effects of removing SCN AVP cells on social investigation or communication, sex behavior, aggression behavior, or sickness expression. These results support novel roles for AVP outputs from the SCN in regulating behavior.

Title: Pubertal Novel Rouxiella badensis subsp. acadensis (Canan SV-53) Mitigates LPS-Induced Depression in Adulthood in a Sex Specific Manner

Authors: *N. YAHFOUFI[1], E. AH-YEN[1], R. CHANDRASEGARAM[2], S. ALY[1], C. HAY[3], C. MATAR[1], N. ISMAIL[1];

Abstract: Puberty/adolescence is a critical period of development and a phase with high emergence of psychiatric disorders. During this period, the brain undergoes significant remodeling that affects behavior later in life. Exposure to stress during puberty triggers modifications in brain function resulting in the development of mental disorders in adulthood, such as depression. A single exposure to LPS during puberty resulted in enduring depression-like behaviour in female mice in adulthood. The objective of the current study is to examine the ability of a novel probiotic (*Rouxiella badensis* subsp. *acadiensis (Canan SV-53))*[1,2]treatment during puberty to reverse LPS-induced depression in adulthood. 5 weeks old CD1 mice (n=96: 48 males and 48 females) were daily provided the novel probiotic in 1%sucrose or 1%sucrose (control group) by oral gavage for 14 consecutive days. At week 6 old (puberty), mice received a single intraperitoneal injection of 1.5 mg/kg LPS or an equivalent volume of sterile saline. At 10 week old (adulthood), mice are exposed to forced swimming test and tail suspension test to assess depression-like behaviors. Both behavioral tests revealed the ability of *the* novel probiotic to reverse LPS induced immobility in females while no immobility changes were observed in males. Given the critical role 5-HT1A receptors in depression; immunohistochemistry was used to quantify these receptors in the hippocampus. In mice, a decrease in 5-HT1A receptors in projection areas is associated with depressive-like behaviors. Our results show that female adult mice with depressive-like behaviors presented a significant lower expression of 5-HT1A in CA1 while a decrease trend is observed in CA3 after LPS injection. The consumption of the novel probiotic *(Canan SV-53)* at puberty amplified 5-HT1A receptors expression in these specific

investigated areas while no changes were observed in males. On the other hand, pubertal LPS challenge correlated with an upsurge of the numbers of 5-HT1A receptor in the dorsal raphe nuclei in both males and females while the probiotic alleviated these changes and no difference was observed among probiotic-LPS and probiotic-saline groups in both sexes. Taken together, these findings indicate that exposure to this novel probiotic during puberty decreases LPS-induced vulnerabilities to depression-like behaviours later in life, in a sex-specific manner.

Title: The interplay between oxytocin and CB1 receptors in the endocrine, mesolimbic, and limbic systems of rats followed by the effects of chronic oxytocin intranasal administration in exercise and anxiety-like behaviors

Authors: P. A. MUÑOZ-RODRÍGUEZ, *A. P. RAMOS-ROLÓN, W. NORZE, L. G. RODRÍGUEZ-SANTOS, V. S. ENCARNACIÓN-CORTÉS, J. M. PADILLA-ESCALONA, L. L. MENDEZ-SANTACRUZ, C. S. MALDONADO-VLAAR;
Biol., Univ. of Puerto Rico Rio Piedras Campus, San Juan, PR

Abstract: Oxytocin (OT) is a neuropeptide primarily synthesized in the hypothalamus associated with social behaviors, stress responses, and drug-addiction. A previous study showed a cross-talk between the type 1 cannabinoid receptor (CB1R) of the endocannabinoid system (ECS) and oxytocin receptor (OTR) within the mesolimbic system to modulate anxiety-like behavior. Several studies support that intranasal oxytocin administration and voluntary wheel running are treatments endowed with anxiolytic properties. Additionally, other studies demonstrated that ECS is crucial for voluntary wheel running performance. For this reason and because the presence of OT and endocannabinoids in the limbic, mesolimbic, and endocrine systems has been associated with the anxiolytic response, the purpose of the present study was: (i) to examine whether OT intranasal pretreatment enhances voluntary wheel running behavior and potentiates the anxiolytic properties of exercise in adults male Sprague-Dawley rats and (ii) to characterize the OTR and CB1R expression within the endocrine, limbic, and regions. Rats were divided in

two groups, the first group received intranasal infusions of OT 1 µg /µl, 10 µl or vehicle in each nostril before being exposed to the running wheel two hours daily for 10 consecutive days. The second group received the same dose of OT or vehicle and was not exposed to the running wheel. Results showed that rats treated with OT, exercised more than those treated with vehicle. Using the Light and dark box as a behavioral paradigm, we found that OT potentiated the anxiolytic effect of exercise. Western blots showed that OT treatment significantly increased OT receptors within the pituitary gland of rats exposed to the running wheel. These findings suggest that when both treatments are provided, exercise upregulates OT receptor expression in specific regions related to OT regulation. Future biochemical studies are required to examine the potential cross-talk between OT and the ECS as mediators of the anxiolytic response and exercise performance. We are currently examining OTR's and CB1R's expression in other brain regions associated with anxiety-like behaviors to better understand the neurocircuitry underlying the anxiolytic response and the implications it can have as a treatment for drug addiction, sedentary lifestyle, and anxiety disorders.

Title: Early life exposure to environmental contaminant (PCBs) alters display of motivated and anxiety-like behavior in adolescent male and female rats.

Authors: K. M. FORTUNE[1], *Y. LOWE[2], S. T. RHODES[3], D. A. LIBERMAN[3], K. M. BELL[3], B. A. PLOURDÉ[2], A. E. DEVANEY[4], M. R. BELL[3,1,2];

Abstract: Polychlorinated biphenyls (PCBs) are a ubiquitous class of persistent organic pollutants and endocrine disrupting compounds. Beyond being implicated in a range of reproductive disorders, PCBs have profound effects on the developing brain. Previous research suggests that early life exposure to PCBs alters dopaminergic and neuroimmune endpoints, often in a sex-specific manner. Both systems are important in motivated behavior and substance abuse, which are also sex-differentiated and begin during adolescence. This experiment seeks to determine the effects of perinatal PCB exposure on motivated behaviors and ethanol intake in both male and female adolescent rats. Pregnant Sprague-Dawley rats were orally exposed to an environmentally relevant mix of PCBs (Arocolor 1242, 1248, 1254, 1:1:1, at 20 ug/kg / day) or

oil vehicle daily during gestation and offspring were behaviorally characterized in adolescence. Animals underwent a light-dark test on postnatal day 35. Males exposed to PCBs showed greater number of entries into, distances traveled in, and time spent in the light chamber, while PCBs only caused minor effects in females. Rats were then singly housed in their home cages over 12 days and provided the choice to drink from bottles that contained 1) water or saccharin (0.25% or 0.75%), to determine sweet preference as a measure of anhedonia OR 2) water or sweetened ethanol (3% - 12%), to determine inclination towards alcohol intake. Rats exposed to PCBs showed significantly greater saccharine intake than Oil exposed animals, especially among females at higher concentrations. However, only minor effects of PCB exposure were found on ethanol intake. The day after the last ethanol/saccharine test, the rats were pair-housed and their social behavior was immediately recorded for 15 minutes in the dark. Across sexes, PCB treated rats performed more play pounces than oil controls; it appears that males treated with PCBs were also quicker to pounce than oil controls. Conversely, females treated with PCBs were slower to show nape-contact. Together, these results indicate that perinatal PCB exposure alters motivation for non-social (sweet) and social (play) reward, in male and female adolescent rats. Ongoing analysis will determine effects on forced-swim tests. Before euthanasia, animals were exposed to a bolus gavage of ethanol or water, so neuroimmune responses to this challenge will also be determined and correlated with behavioral outcomes. Results could inform mitigation and therapeutic strategies to limit effects of environmental contaminants onpresentation of sexually differentiated mood disorders and maladaptive motivated behaviors during adolescence.

Title: Lead exposure disrupts rat's developmental milestones with lasting effects on anxiety-like behaviors: Implications for difficulties related to threat and safety learning in later-life

Authors: *J. N. JOSEPH[1], G. B. CRUZ[1], E. CABAÑAS[1], M. A. VASQUEZ[2], Z. AYAZ[1], J. C. SKEEN[1], E. B. KHAIRI[1], J. R. BONITTO[1], I. AHMED[3], K. P. LYNCH[3], V. D. HACKERT[3], W. ZHU[3], P. CADET[1], L. S. NEUWIRTH[3];
[1]Biol., [2]Chem. & Physics, [3]Psychology, SUNY Old Westbury, Old Westbury, NY

Abstract: Lead is neurotoxicant, that causes early neurodevelopment pathologies that persist into adulthood and manifest as affective, cognitive, and neurobehavioral disorders. Underrepresented minority children are frequently exposed to lead poisoning, and face

significant health disparities and quality of life challenges across their development due to deficits in cognition and aberrant behaviors. In rat models of lead poisoning, a pronounced negative effect of neurodevelopmental lead exposure is anxiety-like behaviors with reduced inhibitory responses that would otherwise serve to regulate threat and safety context/experience-dependent learning. In order to better understand these later-life difficulties, a dose-dependent rat model was employed to evaluate early- and late-developmental behaviors induced by lead poisoning. The present study evaluated the effects of Perinatal (from 4-weeks prior to breeding through parturition) lead exposure (150 ppm and 1,000 ppm) on rat pup's developmental milestone (DMBs) behaviors (i.e., body weight, body and tail length, righting reflex, positive and negative geotaxis, eye opening, ear pinnae detachment, cliff aversion, vibrissa reflex, forepaw grasping, bar level grip, and auditory startle response) from postnatal day (PND) 2-14 in Long Evans Hooded rats when compared to Control rats (0 ppm). Male and female Control rats did not significantly differ across these DMBs. However, developmental lead exposure altered the DMB profiles in a sex-dependent, more so, than a dose-dependent manner. These rat pups were then followed into adulthood (i.e., PND 36-60 and tested for locomotor activity in the Open Field (OF), anxiety-like behaviors in the Elevated Plus Maze (EPM), and threat and safety experience-dependent learning behaviors in the Active Avoidance Test (AAT). The effects of developmental lead exposure persisted into the later-life rat behaviors thereby increasing locomotor hyperactivity in the OF, increasing hyperactivity and anxiety-like behaviors in the EPM, and decreasing learning performance in the AAT. Taken together, the effects of early neurodevelopmental lead exposure disrupt the normal trajectory of critical DMBs that serve to organize local as well as broad ranging sensori-motor, cognitive, and affective systems that are critical during development. This work serves to increase the developmental psychobiology field's understanding of how psychopharmacotherapies can be investigated in specific contexts such as threat and safety learning, to better serve children in underrepresented minority communities to improve their developmental trajectories and quality of life outcomes.

Title: Dose dependent anxiogenic effect of levetiracetam exposure during pregnancy and lactation in juvenile and adult offspring of Wistar rats with an epilepsy model

Authors: *M. F. PINTO-GONZÁLEZ, N. A. MOY-LÓPEZ, J. GUZMÁN-MUÑIZ, M. ORTIZ, R. PEDRAZA-MEDINA;
Univ. of Colima, Colima, Mexico

Abstract: Maternal untreated epilepsy and classic anticonvulsive use during pregnancy are related with teratogenic effects over the central nervous system development. Levetiracetam (LEV), has shown less teratogenic effects on pregnancy outcomes, for which, it may be a safe option its use during pregnancy and lactation. However, LEV consumption in adult patients has reported increased anxiety as a side effect, bringing out the necessity to evaluate later in life behavioral changes related to perinatal development. Our aim was to analyze the effect of growing doses of LEV during pregnancy on an epilepsy model and its relationship with anxiety in juvenile and adult offspring. 12 nulliparous female Wistar rats at 90 days of age were divided in 6 groups with different conditions: 1) negative control, saline solution (SS); 2) Positive control LEV 25 mg/kg in SS (LEVSS); 3) LEV 25 mg/kg with previous exposition to Picrotoxin (PTX)-(LEV25); 4) 50 mg/kg LEV-PTX (LEV50); 5) 100 mg/kg LEV-PTX (LEV100); and 6) Exposure to PTX without LEV treatment (PTX). For the epilepsy model, 1.5 mg/kg of PTX or saline solution for 10 days were given to females before induction to pregnancy. Resulting female and male pups were considered as the study subjects (n=120, 20 per group). Anxiety evaluation was made on postnatal 42 (P42) and P90 using the elevated plus maze (EPM), results from EPM were analyzed by anxiety index. To see if there was an effect over mobility, open field test was also applied to identify changes in total distance moved and speed also at P42 and P90. According to data normality, One-way ANOVA was applied. At P42, results from the anxiety index showed no significant differences according to treatment ($F=0.672$, $P>0.05$); while at P90, there were differences between groups ($F=3.649$, sig=0.006), which post-hoc Tukey revealed corresponded to LEV100 group, who showed increased anxiety compared with LEVSS (P=0.002), LEV25 (P=0.029) and PTX (P=0.046) groups. By other hand, mobility also showed significant increase in distance traveled ($F=3.889$, sig=0.003), and speed ($F=3.892$, sig=0.003) when evaluated at P42, corresponding to groups LEVSS-LEV25 (P= 0.010) in distance traveled and LEV25-LEVSS (P=0.009) in speed. There were no differences at P90. When results were compared by sex using univariant analysis, there was no statistical significance neither in P42 or P90 ($F=1.609$, sig=0.163). Results suggest that LEV exposure during critical periods of brain development does not appear to have effects on anxiety during juvenile stages but on mobility, however, there are indicators of increased anxiety at high doses when evaluated during adulthood, indicating possible dose and age related changes.

Title: Role of prefrontal cortex afferents to the amygdala in regulation of defensive behavior

Authors: *C. D. BORKAR, Q.-S. LE, R. VUTUKURI, C. VO, A. RESENDEZ, J. FADOK; Tulane Univ., New Orleans, LA

Abstract: Exaggerated responses to the perceived threat are associated with anxiety and post-traumatic stress disorders. Previous studies demonstrated that animals exhibit behavioral scaling to favor flight responses over freezing behavior in the face of high threat intensity. Recently, we developed a modified Pavlovian threat conditioning model to induce freezing-to-flight shifts within a subject and revealed a mutually inhibitory neuronal motif in the central amygdala (CEA) involved therein. However, whether an integrated upstream brain network provides top-down regulation of action selection processes in the CEA is not yet understood. Herein, injection of fluorescent retrobeads into the CEA of mice retrogradely labeled a large number of cells in the dorsal peduncular nucleus (DP), along with fewer cells in the infralimbic region. Conditioning in the modified threat conditioning paradigm induced abundant cFos expression in CEA-projecting DP cells, suggesting activation of the pathway. Double neuronal tracing experiments showed that these projections were distinct from hypothalamus-projecting neurons known to elicit sympathetic responses. Viral labeling revealed that DP afferents to the CEA are predominantly positive for VGLUT1. Furthermore, these afferents strongly innervate the anterior part of the CEA, which contains a large population of CRH neurons known to regulate flight responses. Using in vivo optogenetic and DREADD techniques, inhibition of DP-CEA projections during conditioned stimuli leads to higher freezing and reduced flight, suggesting an important role in regulating defensive behavioral. Similarly, inhibition of this pathway during extinction training significantly increased freezing behavior and decreased flight. Collectively, our results suggest that rapid and flexible action selection in the CEA is regulated by top-down cortical afferents.

Title: The hippocampus-dependent trauma contextualization can prevent and treat PTSD-like memory

Authors: A. S. AL ABED[1,2,3], E. G. DUCOURNEAU[1,2], C. BOUARAB[1,2,4], A. SELLAMI[1,2], D. N. ABROUS[1,2], E. PACARY[1,2], M. KOEHL[1,2], A. MARIGHETTO[1,2], ***A. DESMEDT**[1,2]; [1]INSERM 1215, Bordeaux, France; [2]Bordeaux Univ., Bordeaux, France; [3]Col. of Hlth. and Science, The John Curtin Sch. of Med. Res., Eccles Inst. of Neurosci., Canberra, Australia; [4]The George Washington Univ., Washington D.C., MD

Abstract: Post-traumatic stress disorder (PTSD) is characterized by a paradoxical memory alteration with hypermnesia for salient traumatic cues and amnesia for the traumatic context. Clinical studies strongly suggest that a deficit in trauma contextualization would leave traumatic memory out of control and thus prone to be automatically reactivated upon trauma-related cues in any context through flashbacks. In this view, promoting the contextual memory of the trauma would prevent and/or treat PTSD-related hypermnesia. Yet, preclinical research focuses exclusively on the emotional hypermnesia, leaving unexplored the putative causal role of contextual amnesia and the underlying hippocampal alterations. Using the first animal model that precisely recapitulates PTSD-related hypermnesia and amnesia, we first show that compared to normal fear memory, PTSD-like fear memory is specifically associated with hippocampal hypoactivation and dendritic atrophy. Second, we show that optogenetic inhibition of the hippocampus (dCA1) during stress can produce PTSD-like memory in mice, whereas activating the dCA1 prevents its formation and promotes normal contextual fear memory. Third, the hippocampal dendritic atrophy is shown to be causally involved in PTSD-like memory formation, and blocking such neuronal atrophy prevents the formation of this abnormal fear memory. Finally, trauma re-contextualization, which is shown to be hippocampus-dependent, normalizes PTSD-like memory, promoting the expression of a long-lasting normal fear memory. These findings indicate that PTSD-like memory depends on contextual amnesia and that promoting the hippocampal function promotes a switch from PTSD-like to normal fear memory *via* trauma contextualization. Therefore, these data call for promoting therapeutic approaches of PTSD centered on trauma contextualization and its underlying hippocampal mechanisms.

Title: Intranasal NPY at High Doses to Females Can Prevent Development of Depressive Symptoms with Single Prolonged Stress PTSD Model

Authors: R. J. NAHVI, A. TANELIAN, C. NWOKAFOR, L. PEACOCK, *E. L. SABBAN; New York Med. Col., Valhalla, NY

Abstract: Sex is implicated in susceptibility of stress-elicited disorders. Women are twice as likely as men to develop PTSD, depression, anxiety disorders, social anxiety, and eating disorders. However, most of the studies in animal models examining putative therapeutics, including single prolonged stress (SPS), were performed mostly with males. Previous studies in males demonstrated intranasal NPY provided therapeutic relief of stress-elicited symptoms of SPS, but was ineffective in females at this dose (Nahvi et al, 2019). The overwhelming majority of studies found that NPY levels in many brain areas are lower in females than in male rodents. Thus, they may need a higher dose of exogenous NPY to attain a therapeutically significant concentration or the NPY system may not be as important in females compared to males. Here, we examined SPS as an appropriate model to elicit PTSD-associated symptoms in females. We evaluated whether intranasal NPY at higher doses is able to alter the development of SPS triggered behavioral impairments. Sprague Dawley females rats (7 weeks old), were purchased from Charles River. After 2 week accommodation, they were exposed to SPS and then immediately infused intranasally with one of several doses of NPY, starting with 600 µg/rat - 4 times the dose effective in males. After at least 14 days they were tested on several behavioral tests. SPS elicited significant depressive/despair like behavior on Forced Swim Test (FST), anxiety behavior on the open field and elevated plus maze (EPM), as well as impaired social interaction. On the FST, there was a dose-response effect of intranasal NPY, with 1200µg, but not 600µg, effectively preventing development of the SPS-elicited increased immobility (depressive-like behavior) as compared to stressed, vehicle-treated females. In a separate cohort of animals, females were infused intranasally with 600µg NPY, a dipeptidyl peptidase IV (DPP4) inhibitor, or both immediately after the SPS stressors. This inhibitor is expected to prevent N-terminal cleavage of NPY and increase activity at Y1R. ANOVA revealed significant differences and Tukey comparison showed that DPP4 inhibitor and 600µg NPY combined treatment, but not alone, was sufficient at preventing depressive-like behavior on the FST. The results demonstrate that SPS elicits behavioral manifestations of PTSD, such as depressive-like behavior, anxiety and social impairment in females. This was prevented with early intervention with a high dose of NPY, indicating its therapeutic potential also for females, although a higher dose will likely be required. Furthermore, NPY degradation may play a role in the higher dose requirement for females.

Title: Antidepressant Effects of Extinction Learning by Promoting Neuroplasticity in the vmPFC of Chronically Stressed Rats

Authors: *J. LIU, S. E. BULIN, L. F. FERREIRA, A. R. KNIPPENBERG, D. A. MORILAK; Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Posttraumatic stress disorder (PTSD) is a serious mental disorder, which affects 7-8% of the population in the USA. About half of patients with PTSD also have symptoms of major depression disorder (MDD). Treatment of co-occurrence of PTSD and MDD is complex. Our lab established a model of cognitive behavioral intervention in rats, namely extinction therapy, which resembles exposure-based cognitive behavioral therapy (CBT). We found previously that extinction learning ameliorated chronic unpredictable stress (CUS)-induced deficits in cognitive flexibility and active coping behavior in rats. Recently, exposure-based CBT has been demonstrated to be associated with significant reductions in depressive symptoms in PTSD or MDD patients. Thus, the potential antidepressant effects of extinction therapy are examined in the current studies. First, the antidepressant actions were evaluated in the forced swim test (FST), a widely used animal model to screen for potential antidepressant activity. The results showed that extinction learning reduced immobility and increased climbing in the FST 24 h following extinction, which was conducted 2 weeks after fear conditioning. We further found that extinction learning reversed CUS-induced anhedonia, a core symptom of MDD, in the sucrose preference test (SPT) in stressed male, but not stressed female rats. Then, we demonstrated that extinction learning significantly evoked c-fos expression in the ventral medial prefrontal cortex (vmPFC) of stressed rats. The antidepressant effects of extinction learning on CUS-induced anhedonia were blocked by inhibiting neuronal activity in the vmPFC during extinction learning. Furthermore, we found that extinction learning resulted in increased optogenetic potentiation (opto-LTP) of evoked responses in the mediodorsal thalamic - vmPFC pathway in stressed male, but not stressed female rats, which was consistent with the behavioral effects of extinction learning in the SPT. Taken together, these results demonstrate the potential antidepressant effects of extinction learning, which are associated with increased neuronal responsivity and neuroplasticity in the vmPFC.

Title: Combined traumatic stress and chronic alcohol exposure uniquely alters endogenous endocannabinoid system proteins in mice

Authors: *V. M. PIGGOTT[1,3], S. C. LLOYD[1,3], J. I. MATCHYNSKI[2,3,1], S. A. PERRINE[1,3,2], A. C. CONTI[1,3,2];
[1]Psychiatry and Behavioral Neurosciences, [2]Translational Neurosci. Program, Wayne State University, Sch. of Med., Detroit, MI; [3]Res. & Develop. Service, John D. Dingell VA Med. Ctr., Detroit, MI

Abstract: The cannabinoid (CB) system plays an important role in both stress and alcohol dependence as evidenced by enriched content of CB system components in brain regions that are involved in the reward pathway and limbic system. Pre-clinical studies report that anandamide (AEA) levels are decreased while 2-arachidonoylglycerol (2-AG) levels are increased in limbic-associated brain regions after acute and chronic stress. In alcohol-related animal studies, chronic alcohol exposure has been shown to increase AEA, but not 2-AG levels, in reward-related brain regions. While extensive research has shown that PTSD or alcohol dependence alone affects the CB system, the role of the CB system in the combined PTSD and alcohol dependence/withdrawal condition remains unclear. In this study, we used a mouse model of PTSD, single-prolonged stress (mSPS) combined with chronic intermittent ethanol (CIE) vapor exposure, to quantify AEA and 2-AG contents, and their hydrolase enzymes, fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MAG-L), respectively, in the prefrontal cortex, anterior striatum, nucleus accumbens, dorsal hippocampus, and amygdala. Adult male mice were exposed to mSPS/Control and CIE/Air, and AEA and 2-AG contents were analyzed by ultra-high-performance liquid chromatography-tandem mass spectrometry, while FAAH and MAG-L protein levels were analyzed by immunoblotting. Based on published reports mentioned above, we hypothesized higher AEA levels as a result of decreased FAAH protein levels with unchanged 2-AG and MAG-L levels in mSPS-CIE mice compared to the rest of the groups in reward-related brain regions. In limbic-associated regions, we hypothesized lower AEA and higher FAAH levels with higher 2-AG and lower MAG-L protein levels in mSPS-CIE mice

compared to the rest of the groups. Results showed that while AEA and 2-AG levels, as well as their hydrolase enzymes levels, remained the same among groups in the PFC, AEA and 2-AG levels increased in the anterior striatum in mSPS-CIE mice compared to mSPS-Air mice. In addition, 2-AG content decreased in the nucleus accumbens in mSPS-CIE mice compared to Control-Air and Control-CIE groups. In the dorsal hippocampus, Control-CIE mice had a higher AEA content compared to mSPS-CIE mice, and mSPS-Air mice had higher 2-AG content compared to the rest of the groups. Finally, Control-CIE mice had higher AEA content in the amygdala compared to the rest of the groups. Results in this study indicate that mSPS-CIE comorbidity impairs the CB system in the reward pathway, mainly driven by CIE exposure, and these results could help to examine a neurotherapeutic approach to reduce alcohol cravings in those with PTSD.

Title: Comparative Analysis of Behavioral Responses to Early Life Stress in Male and Female Rats

Authors: G. ALROUSAN, *F. ATROOZ, Z. AKBAR, S. SALIM;
Univ. of Houston, Houston, TX

Abstract: *Background*: Negative consequences of early life trauma/stress are often expressed much later in life as anxiety disorders, depression and in complicated cases as post-traumatic stress disorder (PTSD). The relationship between early life stress and/or trauma exposure and development of later life psychiatric symptoms in males versus females is not fully understood. This knowledge is critical for early intervention. Animal studies can offer useful insights. *Objective:* The goal of this study was to determine the impact of early life single prolonged stress (EL-SPS) on later life behavioral functions including anxiety- and depression-like behaviors in female and male rats. *Methods:* We utilized the early-life single prolonged stress (EL-SPS), a rodent model of PTSD. Male and female Sprague-Dawley rats at on post-natal day (PND) 25 were exposed to SPS. Assessment of anxiety- and depression-like behavior were performed at early adolescence (PND32), late adolescence (PND60) and adult stage (PND90). *Results:* EL-SPS induced anxiety-like behavior in female rats (SPS-F) at early life (PND32) as indicated by elevated plus maze test (EPM), while male SPS rats (SPS-M) developed anxiety like behavior at adult life (PND90). Interestingly, anxiety-like behavior was concurrent with depression-like behavior in both male and female groups as SPS-F showed depression like behavior at early life

(PND32) as indicated by sucrose preference test, while SPS-M showed depression-like behavior at PND90 as indicated by splash test. *Conclusions:* Our findings suggest differential impact of EL-SPS in male versus female rats. EL-SPS induced behavioral deficits in SPS-F rats (anxiety- and depression-like behaviors) at early life, deficits which disappeared at adult life. Interestingly, EL-SPS induced delayed behavioral deficits in SPS-M rats as anxiety- and depression-like behaviors were expressed much later at adult life in this group.

Title: A systematic review of the link between post-traumatic stress disorder and substance use disorders: insights from animal models

Authors: *G. GONZALEZ-CUEVAS[1], F. ALEN[2];
[1]Col. of Pharm., Idaho State Univ., Meridian, ID; [2]Complutense Univ. of Madrid, Madrid, Spain

Abstract: Post-traumatic stress disorder (PTSD) and substance use disorders (SUD) are chronic, debilitating human neuropsychiatric disorders that frequently co-occur. It is estimated that more than half of PTSD patients suffer from SUD, a rate 3-5 times higher than in the general population. Despite research advances over the past decades, neuropharmacological treatment of co-occurring PTSD and SUD remains poor, in part from ineffective preclinical animal models. Thus, the overarching goal of this review was to comprehensively synthesize the existing research and discuss the strengths and weaknesses of currently used animal models that aim to model comorbid PTSD and SUD. A systematic literature search on empirical findings over the last ten years was conducted on the PubMed electronic database. These results indicate that there are numerous gaps in the animal to human translatability of key mechanisms and pathogenesis of co-occurring PTSD and SUD in these models. This translatability is essential to identify novel therapeutic targets, and these findings demonstrate a critical need to stimulate this field of research with more translational preclinical models. This review points out the key research gaps that will need to be resolved in future studies in order to adequately address the link between PTSD and SUD.

Title: A novel prefrontal neurocircuit regulating fear-associated threat responding relevant to PTSD

Authors: *K. M. MCMURRAY[1], S. SHUKLA[2], R. SAH[3,4];
[1]Pharmacol. & Systems Physiol., [2]Univ. of Cincinnati, Cincinnati, OH; [3]Pharmacol. & Systems Physiol., Univ. of Cincinnati, Cincinnati, OH; [4]DVA, Cincinnati, OH

Abstract: Post-traumatic stress disorder (PTSD) is a debilitating disorder associated with fear dysregulation. While prior research primarily focuses on fear responses to external threats, recent evidence suggests PTSD patients show heightened reactivity to homeostatic stressor CO_2 inhalation (non-hypoxic). CO_2 inhalation triggers acidosis, representing a homeostatic stressor which evokes fear-associated defensive behaviors. A prior study in veterans found that pre-deployment CO_2 sensitivity predicted trauma-induced PTSD symptoms suggesting CO_2-sensitivity may predict vulnerability to develop PTSD following later trauma. We recently developed a rodent paradigm to examine the effect of CO_2-inhalation on PTSD relevant behaviors where prior CO_2 exposure compromised fear extinction in a contextual fear conditioning paradigm one week later. Importantly, neuronal activation within infralimbic (IL) cortex was significantly reduced *both* immediately following CO_2 and after delayed fear extinction deficits and correlated with CO_2 freezing. Collectively, our data support convergence of homeostatic CO_2-sensing nodes and extinction regulatory circuits, however, underlying neurocircuits are unknown. IL cortex has been strongly associated with fear extinction learning. Previously, we reported the subfornical organ (SFO) as a key site regulating CO_2-evoked fear. In recent studies, using viral tract tracing we identified direct SFO projections to the IL, but not other regions within medial prefrontal cortex such as prelimbic (PL) cortex, suggesting SFO-IL circuits may regulate the long term fear extinction deficits evoked by homeostatic threat, CO_2. Here, we used an intersectional chemogenetic strategy to test the hypothesis that inhibiting SFO-IL projections during CO_2-inhalation would attenuate the CO_2-evoked fear extinction deficits. Consistent with our hypothesis, DREADD-Gi mediated inhibition of the SFO-IL circuit significantly reduced CO_2-evoked defensive behaviors and prevented contextual fear extinction deficits. These data elucidate a novel SFO to IL projection that promotes convergence of homeostatic threat sensing and long-term modulation of fear memory. Our findings highlight the SFO as a novel hub through which interoceptive triggers can regulate vulnerability to external threats and trauma of relevance to PTSD.

Title: Identifying neuronal circuits mediating MDMA's prosocial effects by brain-wide activity mapping

Authors: *D. R. RIJSKETIC[1], P. LLORACH[1], S. R. SCHLOZMAN[1], Z. RASTEGAR[1], J. SALGADO[1], D. BARBOSA[1], D. CARDOZO PINTO[1], P. NEUMAN[1], M. HELL[2], K. BEIER[1], R. C. MALENKA[3], B. D. HEIFETS[1];
[1]Stanford Univ., Stanford, CA; [2]Federal Univ. of Juiz de Fora, Juiz de Fora, Brazil; [3]Stanford Inst. for Neuro-Innovation & Translational Neurosci, Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: Introduction: MDMA (a.k.a. ecstasy) shows promise in the treatment of PTSD, facilitating psychotherapy by producing strong feelings of social connection, empathy and trust. However, MDMA has abuse potential and long-term heavy use can precipitate neurological, psychiatric and cardiovascular complications. Improving on MDMA to develop a safe, scalable treatment requires understanding its therapeutic mechanism. We found that supraphysiological serotonin release in the nucleus accumbens accounts for MDMA's prosocial effect. Elucidating how this local pharmacological mechanism alters brain-wide activity could yield novel targets to mimic MDMA's therapeutic effects.
Methods: To image brain-wide neuronal activity, *TRAP2* mice (Targeted Recombination in Active Populations 2), in which the neuron firing-dependent *Fos* promoter drives CreER expression, were crossed to a reporter line (*Ai14*). In effect, 4-hydroxytamoxifen transiently enables CreER to trigger tdTomato expression. *TRAP2;Ai14* mice were singly housed and i.p. injected with saline or MDMA (7.5 mg/kg), along with 4-OHT (50 mg/kg). Mice were later regrouped and injected after 2 weeks with saline or MDMA. 90 minutes later mice were perfused with fixative, brains were bisected, made optically transparent (iDISCO+), immunolabeled, and imaged via light sheet microscopy. Using Ilastik and MIRAcL we detected active cells, registered the Allen brain atlas to images, and quantified regional cell counts.
Results: MDMA (333522 ± 17136 cells; N = 7) significantly increased the total number of tdTomato$^+$ (active) neurons compared to saline (160475 ± 36440 cells; N = 6). Counts from 491 grey matter regions were normalized to total counts. MDMA enhanced neuronal activity in several prefrontal cortical regions in both social and non-social contexts, including the prelimbic, agranular insular, infralimbic, anterior cingulate, and orbital areas. In the social context only, MDMA enhanced activity in several areas including the nucleus accumbens, lateral amygdalar nucleus, taenia tecta, rhomboid nucleus, and intermediodorsal nucleus of the thalamus. In the non-social context only, MDMA selectively, decreased activity in regions such as the pre/post subiculum, superior colliculus, red nucleus, and posterior pretectal nucleus.
Conclusions: Through unbiased whole-brain mapping of neurons differentially activated by saline vs MDMA in social and non-social contexts we identified a novel network of regions that may mediate some of MDMA's prosocial effects. Future work will test for causal links between these structures' activity and MDMA's effects on sociability and relief from traumatic experiences.

Title: Understanding Asthma-PTSD risk and comorbidity: Models and Mechanisms

Authors: ***E. N. JOHNSON**[1], I. LEWKOWICH[2], R. AHLBRAND[1], J. MCALEES[2], R. SAH[1]; [1]Univ. of Cincinnati, Cincinnati, OH; [2]Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: The experience of trauma is unfortunately common, however only 10-20% of trauma-exposed individuals develop PTSD. A subset of research in PTSD is dedicated to predisposition factors, and our lab focuses on the role of inflammation, a rising topic of interest in the field. We have specific focus on allergic asthma for which there is evidence of a strong association. Our objective was to determine if a model of chronic asthma would create changes in fear behavior, as well as determine the influence of immune players in those behavioral changes.Allergic asthma has historically been known by a prominent T helper cell, Th2, however recently, severe asthma has shown a mixed phenotype with Th2/Th17. Higher levels of IL-17a, one of the prominent cytokines of Th17, have also been noted in the plasma and saliva of PTSD subjects. A previous publication in our lab using a mouse strain prone to the mixed Th2/Th17 asthma phenotype and increased airway hyperresponsiveness (AHR) following house dust mite (HDM) exposure were found to have compromised fear extinction as well as increased IL-17a in the brain. Thus, we sought to determine the role of Th17/IL-17a in this altered fear outcome.We conducted fear conditioning in a mouse strain, Balb/c, that typically only develops a Th2 phenotype following HDM. To shift the immune response to Th2/Th17, we blocked the complement C5R receptor (C5R antibody) in the lungs. This intervention was previously demonstrated to induce increased AHR as well as the Th2/Th17. Significantly higher freezing during extinction was selectively observed in HDM mice treated with blocked C5R (Th2/Th17) while HDM-IgG control group (Th2) showed freezing similar to PBS groups. Preliminary tissue analysis revealed significantly reduced delta-FoSB within the infralimbic (IL) but not prelimbic cortex of HDM-C5R mice. In a separate cohort, animals underwent the same allergen and antibody intervention, and tissue was collected 72 hours after the last treatment to assess lung and brain cytokine and T cell milieu. Ongoing regional tissue measurements will reveal contributory molecular targets.These results indicate that the mixed Th2/Th17 phenotype seen in HDM-C5R animals produces altered fear extinction compared to the animals with only the Th2 phenotype seen in HDM-IgG control animals. Overall, our work provides novel information on

regulation of PTSD-relevant fear-behavior by inflammatory mediators Th17/17A, central to severe asthma. In addition to mechanistic understanding of the asthma-PTSD association, our studies will provide important insight on how peripheral immune mechanisms can regulate brain function and behavior.

Title: Estrous cycle modulation of conditioned fear extinction and relapse

Authors: *A. HOHORST;
Univ. of Colorado - Denver.

Abstract: Estrous Cycle Modulation of Conditioned Fear Extinction and Relapse Alyssa A. Hohorst, Margaret K. Tanner, Aleezah Balolia, Troy J. Hubert, Benjamin N. Greenwood. Women are at higher risk than men to develop common stress-related psychiatric disorders such as post-traumatic stress disorder (PTSD). Therefore, identifying effective treatment strategies for females is especially important. Prior research has shown that female sex hormones can modulate fear extinction learning. For example, female rats that learn fear extinction during pro-estrus, when levels of estrogen are high, tend to have better fear extinction retrieval compared to males and females that learn extinction in other estrous phases. Conditioned fear responding, however, tends to relapse after successful fear extinction, even when manipulations that enhance fear extinction are employed. Because protection from fear relapse, rather than strength of the fear extinction memory, per se, is most important in determining the long-term efficacy of extinction-based exposure therapy, it is critical to determine whether estrous cycle phase during fear extinction modulates conditioned fear relapse. The goal of this experiment was to determine whether estrous phase during extinction modulates extinction memory relapse. Estrous cycle of female, Long-Evans rats was monitored daily. All subjects were exposed to auditory fear conditioning in Context A. The following day, subjects were exposed to fear extinction training in Context B. Twenty four hours later, rats were re-exposed to the conditioned stimulus in either the same context used from extinction (Context B), to test fear extinction retrieval, or a different, novel context (Context C) to assess fear renewal. A week later, rats were placed into Context B and tested for spontaneous recovery of fear. Females in pro-estrus during fear extinction training showed less fear renewal and spontaneous recovery compared to males and females exposed to fear extinction training in other estrous phases. Preliminary results suggest that males and females, regardless of estrous phase, had similar extinction recall when tested in Context B

twenty four hours following extinction training. These data suggest that phase of the estrous cycle during fear extinction learning modulates conditioned fear relapse, whereby learning fear extinction during pro-estrus seems to be protective against later relapse. These results could have important clinical implications for the use of exposure therapy in females.

Title: Antalarmin reduces anxiety and binge alcohol consumption in mice exposed to predator odor stress

Authors: *V. MISHRA, R. SHARMA, M. PARIKH, P. SAHOTA, M. THAKKAR;
Truman VA Med. Center/University of Missouri, Columbia, MO

Abstract: Introduction: Anxiety and stress are intimately linked to alcohol abuse. People with anxiety and stress disorders display binge drinking, a common pattern of alcohol abuse. Evidence suggest that people drink alcohol in an attempt to alleviate anxiety. However, the exact relationship between anxiety and binge drinking is not clearly understood. We hypothesized that mice displaying anxiety-like behavior will show increased binge drinking. In addition, since stress promotes the expression and release of anxiogenic corticotropin releasing factor (CRF), blockade of CRF-1 receptor will attenuate anxiety and reduce binge drinking in mice exposed to predator odor. **Methods:** To test our hypothesis, anxiety-like behavior was induced by using predator odor. Drinking-in-the-dark (DID) paradigm was used to examine binge alcohol consumption. Two experiments were performed in C57BL/6J mice. Experiment 1 investigated the effects of anxiety-like behavior on binge drinking in mice. Experiment 2 examined the effect of systemic administration of CRF-1 receptor blockade on anxiety-like behavior and binge drinking. The selective CRF-1 receptor antagonist, antalarmin, was used. Blood alcohol concentration was measured to confirm binge drinking. Sucrose (10% w/v) consumption was also verified in separate groups of mice exposed to predator odor using the DID paradigm in both the experiments. **Results:** Mice displaying anxiety-like behavior following exposure to predator odor exhibit alcohol abuse behavior as evident by increased binge drinking without affecting sucrose consumption. Blockade of CRF-1 receptor by systemic administration of antalarmin attenuated anxiety and reduced binge drinking in mice exposed to predator odor.

Title: Time-course of inflammatory markers in the RISP model (Revealing Individual Susceptibility to PTSD-like Phenotype)

Authors: K. ALEXANDER[1], R. NALLOOR[2], K. BUNTING[2], ***A. I. VAZDARJANOVA**[3]; [2]Pharm & Tox, [1]Augusta Univ., Augusta, GA; [3]Charlie Norwood VA Med. Ctr., Augusta, GA

Abstract: Post-Traumatic Stress Disorder (PTSD), which develops as a consequence of trauma in a subset of exposed people, has several hallmark components: intrusive memories, avoidance, hyperarousal, and altered mood and cognition; and is in part a memory disorder. As PTSD is difficult to treat, it is important to reveal susceptibility and increase resilience before trauma. To this end, we have developed the RISP (Revealing Individual Susceptibility to PTSD-like Phenotype) in male rats which allows us to classify animals as Susceptible or Resilient to developing PTSD-like behaviors prior to trauma. We have previously reported that Susceptible, compared to Resilient rats, have a delayed fear extinction and long-lasting trauma-related startle response, as well as altered expression of plasticity-related immediate-early genes in the hippocampus and prefrontal cortex. Inflammation can adversely affect learning and memory and pro-inflammatory factors are elevated in people with established PTSD. We hypothesized that elevated pro-inflammatory factors are also a susceptibility factor. To test this hypothesis, we evaluated levels of IFNy, IL-10, IL-1b, IL-6, KC/GRO, and TNFa in plasma samples from classified rats at different stages of the RISP model: prior to trauma, and 1, 3 or 60 day post trauma. We found that Susceptible, compared to Resilient, rats have higher expression of IL-1b at 1, 3, and 60 days post trauma when normalized to their pre-trauma values. Susceptible rats also had higher expression of TNFa at 1 and 60 days post trauma. The preliminary time-course of inflammatory markers suggests that 1) a susceptibility state is associated with increased pro-inflammatory markers after trauma; and 2) the mild stressor, which is necessary to reveal susceptibility in the RISP model, may be triggering an inflammatory response prior to trauma. While these results are consistent with our hypothesis, further work is needed to elucidate the effect of exposure to the mild stressor on early inflammatory markers in specific brain regions associated with PTSD: prefrontal cortex, hippocampus, and amygdala, as well as assess whether mitigating this inflammatory response will confer resilience.

Title: A Randomized, Double-Blind, Placebo Controlled Phase 3 Study Assessing Safety and Efficacy of MDMA-Assisted Psychotherapy for the Treatment of Severe PTSD

Authors: *J. MITCHELL[1], C. NICHOLAS[2], A. LILIENSTEIN[3], B. YAZAR-KLOSINSKI[3]; [1]UCSF: Dept. of Neurol., San Francisco, CA; [2]Univ. of Wisconsin, Madison, WI; [3]Multidisciplinary Assn. for Psychedelic Studies, Santa Cruz, CA

Abstract: Introduction
Posttraumatic stress disorder is a prevalent mental health condition with substantial impact on daily functioning that lacks sufficient treatment options. Previous research has led to the designation of 3,4-methylenedioxymethamphetamine (MDMA) as a Breakthrough Therapy for treatment of post-traumatic stress disorder (PTSD) when administered as an adjunct to psychotherapy.
Objectives
Here we report the findings of the first randomized, double-blind, Phase 3 trial assessing the efficacy and safety of 3 sessions with a flexible dose of MDMA or placebo administered under direct observation to participants with severe PTSD (n = 100) as an adjunct to inner-directed psychotherapy.
Methods
Change in PTSD symptoms (CAPS-5) and functional impairment (SDS) were assessed by a central, blinded Independent Rater Pool at baseline and following each treatment session. Adverse events (AEs), concomitant medications, suicidal ideation and behavior were tracked throughout the study. Vital signs were measured during experimental sessions. The primary endpoint was 18 weeks post-randomization.
Results
Change in CAPS-5 and SDS, placebo and therapy-subtracted Cohen's d effect size, and a responder analysis will be presented. There were three serious AEs of suicidal ideation or behavior reported. MDMA was well tolerated, with some treatment emergent AEs occurring at greater frequency for the MDMA group during and after experimental sessions.
Conclusions
If MDMA-assisted psychotherapy significantly attenuates PTSD symptomatology and associated functional impairment, these results will form the basis for marketing authorization applications worldwide, including among participants with dissociative subtype of PTSD, depression, history of alcohol and substance use disorders, and adverse childhood experiences.

Title: Changes in inflammatory markers and trophic factors following sleep-focused treatments in military service members with and without PTSD

Authors: ***J. LEETE**[1], A. JIANG[1], C. DEVOTO[1], J. M. GILL[1], H. L. RUSCH[1,2];
[1]Natl. Inst. of Nursing Res., NIH, Bethesda, MD; [2]Dept. of Clin. Neurosci., Div. of Psychology and Osher Ctr. for Integrative Medicine, Karolinska Inst., Stockholm, Sweden

Abstract: Sleep disturbance is one of the most common residual symptoms following treatment for posttraumatic stress disorder (PTSD). PTSD has been associated with inflammation and disruption of trophic factors. Previous research suggests that sleep-focused treatments may lead to decreases in inflammation and restoration of trophic factors, but more research is needed, especially in comorbid sleep disordered and PTSD populations. This study examined the effect of standardized sleep therapy on sleep quality, posttraumatic stress symptoms, plasma-derived inflammatory markers [C-reactive protein (CRP) and interleukin 6 (IL-6)], and trophic factors [brain-derived neurotrophic factor (BDNF) and insulin-like growth factor 1 (IGF-1)] in sleep disturbed military service members with varying degrees of posttraumatic stress symptoms. Military service members (n=100, 98% male, mean age = 34.8 years) with insomnia and/or obstructive sleep apnea (OSA) were enrolled. Participants with insomnia received cognitive behavioral therapy for insomnia (CBT-I), participants with OSA received automatic positive airway pressure (APAP), and participants with comorbid OSA and insomnia received APAP and either CBT-I or sleep hygiene education. Baseline (week 1) and follow-up (week 12) visits included self-report questionnaires and blood draws, which were assessed with the SIMOA® HD-1 Analyzer. For analysis, participants were assigned to three groups according to baseline PTSD Checklist - Military Version scores: PTSD (n=29), Subclinical PTSD (n=39), and No PTSD (n=32). Pre-post analyses revealed improvements in sleep quality in the Subclinical PTSD (t_{31}=2.27, p=0.030) and No PTSD groups (t_{28}=2.83, p=0.008), but not in the PTSD group. In the PTSD group, levels of CRP decreased (t_{19}=2.70, p=0.014), while levels of BDNF (t_{15}=-2.37, p=0.032) and IGF-1 (t_{14}=-2.78, p=0.015) increased. In the Subclinical PTSD group, levels of IGF-1 (t_{17}=-2.71, p=0.015) increased, and in the No PTSD group levels of BDNF (t_{19}=-2.88, p=0.010) increased. In the PTSD group, posttraumatic arousal (t_{28}=3.01, p=0.005) decreased following treatment. Our findings suggest that standardized sleep treatments may reduce

posttraumatic arousal and alter peripheral inflammatory markers and trophic factor levels in military personnel with PTSD. While the participants with PTSD did not report significant improvements in self-reported sleep quality, we observed significant changes in biomarker concentrations. Measuring levels of inflammatory markers and trophic factors following sleep-focused treatments may provide added value for assessing treatment efficacy, and future research is warranted.

Title: Stability of hippocampal subfield volumes after trauma and relationship to development of PTSD symptoms

Authors: *K. WEBB[1], C. WEIS[1], A. HUGGINS[1], M. KALLENBACH[1], T. MISKOVICH[2], J. FITZGERALD[3], K. BENNETT[4], J. KRUKOWSKI[3], T. DEROON-CASSINI[5], C. LARSON[1]; [1]Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]VA Northern California Hlth., Martinez, CA; [3]Marquette Univ., Milwaukee, WI; [4]Montana VA Healthcare Syst., Fort Harrison, MT; [5]Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The hippocampus plays a central role in fear learning and memory. The majority of neuroimaging research on post-traumatic stress disorder (PTSD) has studied the hippocampus in its entirety. Although the extensive literature demonstrates changes in hippocampal volume are associated with PTSD, fewer studies have probed the relationship between PTSD symptoms and the hippocampus' functionally and structurally distinct subfields. We utilized data from a longitudinal study examining post-trauma outcomes to determine whether subfield volumes change over time after a trauma and whether specific subfields are significantly associated with, or predictive of, PTSD. We leveraged our unique study design sample to also investigate reliability of hippocampal subfield volumes using pipelines available in *FreeSurfer*. Two-hundred and fifteen trauma-exposed individuals were recruited from an urban Emergency Department. Two-weeks post-traumatic injury, participants underwent two consecutive days of neuroimaging (T1 and T2) and completed self-report assessments. Six-months later (T3), participants underwent an additional scan and were administered a structured interview assessing PTSD symptoms. First, we compared we compared reliability of hippocampal measurements at T1 and T2 (automatically segmented with FreeSurfer v6.0). We then examined the prospective

(T1 subfields) and cross-sectional (T3 subfields) relationship between volumes and PTSD. Finally, we tested whether change in subfield volumes between T1 and T3 explained PTSD symptom variability. None of the subfield volumes (T1) significantly predicted T3 PTSD symptoms. Hippocampal tail volumes (T3) were associated cross-sectionally with PTSD symptoms (T3) after controlling for other relevant variables. Tl - T2 reliability of all hippocampal subfields ranged from good to excellent (intraclass correlation coefficient (ICC) values > 0.83), with poorer reliability in the hippocampal fissure. Our results provided a novel examination of the predictive relationship between hippocampal subfield volumes in relation to PTSD in a large trauma-exposed urban sample and demonstrated that hippocampal tail volumes are associated with PTSD symptoms. In addition, we demonstrated *FreeSurfer* hippocampal subfield segmentation is a reliable tool. Although hippocampal subfield volumes may be an important marker of individual variability in PTSD, findings are conditional on the timing of the measurements (e.g. acute or chronic post-trauma periods) and analysis strategy (e.g. cross-sectional or prospective).

Title: Ventral hippocampal Egr1 expression is mechanistically implicated in mediating the role of ovarian hormone fluctuations on sex-specific psychiatric risk

Authors: *D. ROCKS[1], I. JARIC[1], E. F. GALLO[1], J. M. GREALLY[2], M. SUZUKI[2], M. KUNDAKOVIC[1];
[1]Fordham Univ., Bronx, NY; [2]Albert Einstein Col. of Med., Bronx, NY

Abstract: Females exhibit a two-fold increased risk for anxiety disorders compared to males. Due to the exclusion of females in animal research of the brain and behavior, little is known about the mechanisms driving this sex-specific risk. We previously demonstrated a role for ovarian hormone fluctuations in mediating sex-specific vulnerability to anxiety-related behavior in female mice. We found that the physiological drop in estrogen during the estrous cycle is linked to increased indices of anxiety-related behavior. Further, we identified widespread changes in neuronal chromatin accessibility and gene expression in the ventral hippocampus, a brain region relevant to anxiety, underlying this behavioral phenotype. Subsequent bioinformatic analyses indicated Egr1, an estrogen-responsive transcription factor, as a potential upstream regulator of differential chromatin accessibility and gene expression in females across the estrous cycle. To understand the mechanistic role of ventral hippocampal Egr1 expression in estrous

cycle-dependent behavioral changes, we used stereotaxic surgery to deliver an adeno-associated viral vector carrying Egr1 and GFP (or a GFP-only control virus) under control of a neuronal-specific promoter into the ventral hippocampus of ovariectomized(OVX) female (n=12/group) and male (n=12/group) mice. We demonstrate that OVX females, at baseline, exhibit high anxiety-related behavior in the open field (OF) and elevated plus maze (EPM) tests (n=8-12/group), similar to low-estrogenic intact females. Remarkably, overexpression of Egr1 in ventral hippocampal neurons of OVX females mimics the high-estrogenic state, as Egr1-OVX females display reduced anxiety-related behavior in the OF and EPM tests compared to GFP-OVX females. We observed no behavioral changes in male mice overexpressing Egr1, indicating that the effect of neuronal Egr1 expression on behavior is sex-specific. We explore differential expression and chromatin accessibility of Egr1 target genes relevant to neuronal function and behavior as a plausible mechanism by which neuronal Egr1 expression in the ventral hippocampus drives anxiety-related behavior. Previous results from our lab indicate an important role for sex hormone fluctuations in female-specific susceptibility to anxiety disorders. Here we demonstrate a mechanistic role for Egr1 in driving the low-anxiety phenotype associated with the high-estrogenic state. Cyclical Egr1 expression in intact female mice presents a plausible mechanism through which fluctuating ovarian hormones can confer sex-specific risk for anxiety-related phenotypes.

Title: Fkbp5 and early life stress impacts neuroendocrine response, depression and hippocampal cells in an age-dependent mechanism

Authors: M. CRIADO-MARRERO, *L. J. BLAIR;
Univ. of South Florida, Tampa, FL

Abstract: Early life stress (ELS) causes short and long-term changes in the brain. ELS adverse effects are linked with the etiology of mental health disorders like major depression. Studies suggest that ELS impacts coping abilities and cognitive functions in patients with depression by altering the hypothalamic-pituitary-adrenal (HPA) axis response, increasing peripheral inflammation, and evoking structural brain alterations. Although the underlying causes are unknown, polymorphisms in the FK506-binding protein 5 (FKBP5) gene, an endogenous

regulator of stress-neuroendocrine response, interact with childhood adversities to increase vulnerability to depressive disorders. We hypothesized that high FKBP5 protein levels combined with early life stress (ELS) would model some features of depression in mice including altered HPA axis and brain as well depressive-like behavior. To test this, we exposed males and females of a mouse model overexpressing FKBP5 in the brain (rTgFKBP5 mice), or littermate controls, to maternal separation for 14 days after birth. We assessed neuroendocrine, behavioral, and hippocampal changes in young adult and aged mice. Lower basal corticosterone (CORT) levels were detected in rTgFKBP5 mice, especially in females, when compared to control group. Aged, but not young, rTgFKBP5 mice showed increased depressive-like behaviors. Moreover, hippocampal neuron density was reduced in aged rTgFKBP5 mice, while microglia expression was induced by high FKBP5. However, these effects were reversed by ELS. Overall, our findings demonstrate that overexpression of FKBP5 impacts basal CORT levels, depressive-like symptoms, and numbers of neurons as well as microglia in the hippocampus in an age-dependent manner.

Title: Intergenerational Transmission of Existential Trauma (or Traumatic Stress): Reprogramming of the Brain Metabotranscriptome and Opportunity for Reversibility

Authors: *S. T. ALHASSEN, S. CHEN, A. D. SILVA, P. BALDI, G. ABBOTT, A. ALACHKAR;
Univ. of California, Irvine, Irvine, CA

Abstract: Traumatic stress transmission from pregnant mothers to the offspring increases the life-course susceptibility to depression and is a major risk factor for developing different neuropsychiatric disorders. Whether the intergenerational trauma transmission and its deleterious outcomes are a consequence of in-utero fetal neurodevelopment disruptions or from poor maternal care by traumatized mothers are still largely unknown. The purpose of this study was to further investigate the differences between the prenatal and postnatal mechanisms that are responsible for the effects on the offspring. On day 17 of gestation, female mice were exposed to a predator scent to induce stress to the animal. Pups of control (C) and stress (S) mice were raised by their biological mother (C/C and S/S) or were cross-fostered to a female of the other treatment (C/S and S/C for S pups with C mothers and C pups with S mothers respectively) within 48h of birth. The male mice were then selected for the study and underwent a series of

behavioral assays to understand the effects of the prenatal and postnatal stress conditions. We found that the exposure to traumatic stress during pregnancy induces in the offspring depressive-like behavior and social deficits. Metabolomics, transcriptomics and bioinformatics analyses reveal mechanisms that involve stress- and hypoxia-response energy metabolic pathways (mitochondrial ATP production). We also found that early pharmacological intervention, through the use of acetyl-L-carnitine (ALCAR) supplementation, was able to produce outlasting protection against the observed behavioral deficits. This study extends the knowledge on both predictive and protective values of ALCAR in vulnerable populations who are at high-risk to depression. Given ALCAR's unique features, such as the very high efficiency, multiple mechanisms of action, low cost, high safety profile, rapid onset of action, and outlasting antidepressant effects, it provides an innovative and unique prophylactic and therapeutic strategy, when administered in the right time of life.

Title: Mating and parenting experiences sculpture mood-modulating effects of oxytocin-MCH signaling

Authors: *L. ALHASSEN, J. PHAN, A. ARGELAGOS, W. ALHASSEN, B. VACHIRAKORNTONG, Z. LIN, O. CIVELLI, A. ALACHKAR;
Univ. of California, Irvine, Irvine, CA

Abstract: Oxytocin (OXT) and melanin concentrating hormone (MCH) are hypothalamic neuropeoptides that play a physiological role associated with maternal behavior and emotion. In this study, we illustrate the role of a hypothalamic circuit (OXT-MCH signaling) in regulating mood, parenting and mating, and depressive behavior. To understand how oxytocin-MCH signaling controls mood, we looked at maternal behaviors in an animal model that has OXT receptors deleted from MCH neurons in both sexually naïve females/males and postpartum mothers. A series of maternal and mood behaviors were carried out on both virgin and postpartum mothers, such as pups retrieval, maternal aggression, and forced swim. We show that deleting OXT receptors from MCH neurons increases and decreases depressive behavior in sexually naïve females and postpartum mothers. However, OXTR deletion from MCH neurons did not affect mood in naïve male. In spite of this, OXTR deletion from MCH neurons did not affect maternal behaviors, which is evidenced by the normal pups' retrieval, nest building, and maternal aggression in the OXTR-cKO mice. Overall, these findings suggest that this action is sexually dimorphic and dependent on maternal and mating experiences.To understand how

OXTR deletion from MCH neurons is associated with changes in neuronal activity, we looked at the alterations of Arc (activity-regulated cytoskeletal gene) expressions. Arc is an early gene that plays a crucial role in roles in neural plasticity in the frontal cortex involved in cognitive functions and emotions. We showed that there is an increase in Arc expression during late postpartum stage in various brain regions such as the LH, PVN, SON, VTA, and BLA, in both control and OXTR-cKO female mice. This is the first report on the remapping of Arc expression by maternal experience. Furthermore, this finding suggests that Arc expression can serve as a marker for mapping the neural substrates recruited by female brain to induce neuroplasticity and prepare females for parenthood. Together, the data suggests that the oxytocin-MCH pathway can serve as a potential therapeutic target for major depressive disorder and postpartum mood abnormalities.

Title: Investigating Lewis Rats as a Potential ADHD Animal Model for Cognitive Flexibility

Authors: *Z. MCKINNELL[1], T. MAZE[2], B. CHALLANS[2], L. PARKS[2], C. KING[1], B. PLAKKE[2];
[1]Psychological Sci., Kansas State, Manhattan, KS; [2]Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: If the mind were a TV, cognitive flexibility could be considered analogous to changing the channels, where each channel is a concept or stream of thought. Impairments in cognitive flexibility, where struggling to flip the channels occurs, are found in a wide range of psychiatric disorders. Attention deficit-hyperactivity disorder (ADHD) is a mental health disorder; classified by high levels of hyperactivity, impulsive behavior, and impaired decision-making. ADHD is one of the many dopamine (DA) linked mental health disorders that are implicated in cognitive flexibility impairments. Spontaneously hypertensive rats (SHRs) are the most common model of ADHD in animals, but some research has shown that Lewis rats show similar impairments in a variety of decision-making tasks (Panfil, In progress). Three different strains (Long-Evans, SHR, & Lewis) of rats were run through the attentional set-shifting task (ASST), which is the rodent equivalent of the Wisconsin Card Sorting Task and tests cognitive flexibility and attention (Birrell et al., 2000). To control for order effects, a Latin square counterbalancing procedure was used to ensure each pair of exemplars would be experienced in each phase across the rats (Tait et al., 2018). Data collection is still in progress, but a total of 18 rats have been run throughout the task thus far. Preliminary results indicate that SHR rats were

significantly impaired across the entire task, which replicates previous research with this strain (Cao et al., 2012). Lewis rats were not impaired across any phases of the task and even performed better than controls (Long-Evans) in some phases of the task. This offers evidence that the Lewis strain may be a good ADHD model for some timed decision-making tasks, but within the model of cognitive flexibility may not be an effective animal model of ADHD.

Title: What does the Sucrose Preference Test tell us about reward behavior? An analysis of licking behavior during SPT

Authors: *A. B. WULFF, S. M. THOMPSON;
Physiol., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: The Sucrose Preference Test (SPT) is widely used for studying hedonic behaviors and a loss of SPT is commonly used as a model for anhedonia, a key symptom of depression. In the SPT, the preference for a 0.5-2% sucrose solution over regular water, is tested by measuring volume drunk by experimental mice overnight. Despite its common use, we know little about how the volumetric sucrose preference is produced and if it is related to hedonic, metabolic, and/or memory processes. To get a better understanding of this, we measured the licking microstructure of mice as they underwent the SPT, using an in-house built capacitive lickometer. The lickometers were validated by a significant correlation between the licks at each bottle and the volume consumed overnight.
We found that stress-naïve mice preferred 1% sucrose when measuring the total number of licks, number of lick bouts, and the average number of licks-per-bout. There was a significant positive correlation between the lick preference and the volume preference. The significant correlation between the volume preference and the licks-per-bout preference is especially noteworthy because this measurement is related to the hedonic value of the consumed solution. This data supports the notion that the SPT does indeed measure hedonic processes in the test animals. In addition, we tested a small cohort of animals on the SPT, followed by a choice between 1% and 10% sucrose. Mice displayed a decrease in all licking behaviors for 1% sucrose, when given a choice of 10% sucrose, suggesting that licking behaviors and volume preference represents a relative hedonic value. We also found evidence that reward memory processes are involved in producing the SPT. First, on each night we found that drinking from the water bottle decreased,

while lick preference for sucrose increased, throughout the night, suggesting that the place of the sucrose bottle had to be memorized first. Furthermore, we found no evidence that mice would switch from the water bottle to the sucrose bottle during a session of drinking, further supporting the involvement of memory in producing the sucrose preference.
Finally, we subjected mice to chronic treatment with corticosterone, a stress-hormone known to produce anhedonia, and subsequent injection of psilocybin to determine how anhedonia and rapid-acting antidepressant treatment affected licking behavior during the SPT.
We conclude that the volumetric SPT does indeed measure hedonic processes, but also involves contributions from memory processes and possibly metabolic processes. Recording licking behaviors can thus be used as a supplement or substitution for the volumetric SPT.

Title: Investigating the neurobehavioral effects of high fat diet in male and female mice

Authors: *B. KLOCKE[1], C. THELEN[1], S. KOELLER[1], J. COFFEY[1], P. FLAHERTY[2], M. SCHULTZE[2], P. PITYCHOUTIS[1];
[1]Biol., Univ. of Dayton, DAYTON, OH; [2]Biol., Univ. of Dayton, Dayton, OH

Abstract: Major depression (MD) and obesity are two highly comorbid disorders that pose a significant public health problem. Indeed, rodent studies have shown long-term consumption of a diet high in fatty-acids (HFD) to elicit a depressive-like phenotype. Further, evidence from both clinical and preclinical research suggests that the symptomology and neurobiology of MD are sex-specific. However, the majority of preclinical research into the neurobiological mechanisms underlying the link between MD and obesity has focused on males, and the role of sex in obesity-related depressive neurobehavioral responses remains understudied. Specifically, little is known about the neurochemical systems underlying the sexually-differentiated behaviors observed in the HFD model. Thus, the goal of the current study was to elucidate the sex-specific behavioral and neurochemical effects of long-term (i.e., 16 weeks) HFD consumption in C57BL/6J mice of both sexes. Interestingly, our results showed sex-differentiated depressive-like behavior in HFD-fed mice, as only male mice exhibited reduced grooming behavior in the splash test. Both sexes exhibited anxiogenic behavior in the open field test and novelty-suppressed feeding test, as well as anhedonia as assessed by sucrose consumption. HFD consumption also altered regional brain neurochemistry assessed *ex vivo* using high performance liquid chromatography (HPLC) in a sex-specific manner. Interestingly, these brain region-dependent neurochemical alterations extended to the serotonergic, dopaminergic and glutamatergic neurochemical systems. Taken together, present results are the first to establish a sex-specific

behavioral response to HFD-fed mice, in addition to elucidating underlying region-specific neurochemical abnormalities.

Title: Adolescent exposure to vicarious social defeat stress and western-style diets leads to physiological dysregulation, decreases in reward sensitivity, and reduced antidepressant efficacy

Authors: *O. K. SIAL[1], T. GNECCO[1], *A. M. CARDONA[1], E. L. VIEREGG[1], E. CARDOSO[1], L. F. PARISE[2], C. A. BOLANOS-GUZMAN[1];
[1]Texas A&M Univ., College Station, TX; [2]Neurosci., Mt.Sinai Sch. of Med., New York, NY

Abstract: A dramatic increase in the prevalence of major depression and diet-related disorders in adolescents has been observed over several decades, yet the mechanisms underlying this comorbidity have only recently begun to be elucidated. Exposure to western-style diets (WSDs), high in both fats (45% kcal) and carbohydrates (35% kcal): i.e., high fat diet; HFD, has been linked to the development of metabolic syndrome-like symptoms and behavioral dysregulation in rodents, as similarly observed in the human condition. Because adolescence is a developmental period highlighted by vulnerability to both stress and poor diet, understanding the mechanism(s) underlying the combined negative effects of WSDs and stress on mood and reward regulation is critical. To this end, adolescent male C57 mice were exposed to vicarious social defeat stress (VSDS), a stress paradigm capable of separating physical (PS) versus emotional (ES) stress, followed by normal chow (NC), HFD, or a separate control diet high in carbohydrates (same sucrose content as HFD) and low in fat (LFD), while measuring body weight and food intake. These mice were subsequently tested for reward sensitivity and responsiveness to antidepressant treatment. No-stress control mice exposed to 5 weeks of NC or HFD showed no significant differences in body weight or social interaction. Interestingly, mice exposed to VSDS followed by HFD showed rapid weight gain 1week after initiation of WSD, with the ES-exposed mice showing significantly higher weight gain as compared to the PS-exposed and control mice. These mice also exhibited a reduction in saccharin preference, indicative of anhedonic-like behavior. To further delineate whether high fat was the major contributing factor to these deficits, LFD was introduced. The mice in the VSDS+HFD gained weight more rapidly than the VSDS+LFD

group. However, though LFD-exposed mice did not gain weight as rapidly as HFD-mice, both VSDS+LFD- and VSDS+HFD- mice exhibited attenuated response to chronic antidepressant fluoxetine. These data show that diets high in both fats and carbohydrates are responsible for both rapid weight gain and reduced reward sensitivity, and chronic LFD consumption, though it does not lead to rapid weight gain, both HFD and LFD-exposure after stress leads to reduced response to fluoxetine. Furthermore, findings indicate that exposures to WSDs and stress during adolescence leads to physiological and reward dysregulation, likely contributing to maladaptive behaviors, negative health outcomes, and reduced antidepressant efficacy in adulthood.

[1]Neuropharm., [2]Medicinal Chem., Tokushima Bunri Univ., Sanuki-city, Japan

Abstract: Phencyclidine (PCP), a well-known major hallucinogenic and dissociative drug of abuse, induces a broad range of schizophrenic-like symptoms. Pharmacologically, PCP is a dopamine D2 receptor agonist and an NMDA receptor blocker. We analyzed PCP effects on the molecular plasticity of dendritic spines in our new AiCE-Tg mouse line that expresses an enhanced green fluorescent protein (EGFP)-tagged CapZ marker. CapZ protein, which binds F-actin, has been shown previously to be increased in spines in LTP-induced regions, likely owing to rapid accumulation and/or regulated degradation. Plastic changes in EGFP-CapZ reflecting reorganization of spine proteins upon stimulation *in vivo* can be visualized directly in these transgenic mice. Previously, we showed that relative EGFP-CapZ signal intensification occurs in a small subset of dendritic spines located selectively in stimulated-side cortices of AiCE-Tg mice 20 min after unilateral visual or somatosensory stimulation. In this presentation, we present data (see Figure) showing that this stimulus-dependent right-left difference in EGFP-CapZ signal levels is abolished by PCP administration (~30 min). This inhibition may reflect an endophenotype of PCP-induced brain abnormality that has the potential to be utilized for development of novel therapeutic strategies for PCP abuse symptomatology and possibly for schizophrenia.

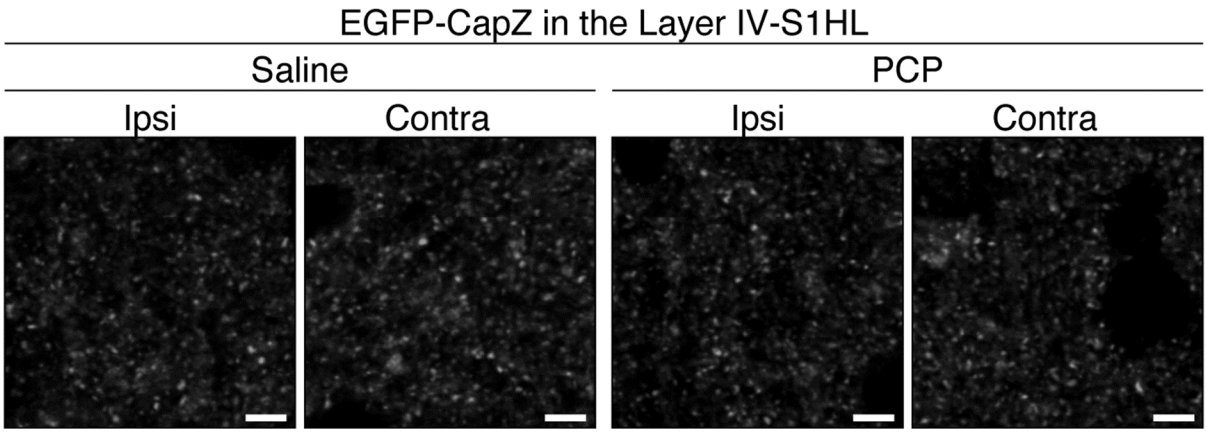

Figure: Contra-ipsi difference in spine EGFP-CapZ intensity was abolished by PCP. Spine-localized EGFP-CapZ looked generally similar in both sides, but for limited numbers of brighter puncta in the stimulated (contralateral) part of sensory cortex for the intact hind limb only in saline-injected AiCE-Tg. Quantitative analyses showed a significant right-left difference for the saline group, but not for the PCP group. Scale bars, 5 μm.

Title: The GABAA receptor Positive Allosteric Modulator, GT-002, has procognitive effects in rats

Authors: C. N. RYAN[1], M.-R. WITT[1], E. LORENC-KOCI[2], Z. ROGÓż[2], S. REHNMARK[1], *M. P. NIELSEN[1];
[1]Gabather, Stockholm, Sweden; [2]Dept. of Neuro-Psychopharmacology, Inst. of Pharmacology, Polish Acad. of Sci., Kraków, Poland

Abstract: The $GABA_A$ receptor ($GABA_AR$) is an ionotropic receptor and ligand-gated ion channel. Its endogenous ligand is γ-aminobutyric acid (GABA), and GT-002 is a $GABA_AR$ positive allosteric modulator (PAM) which has been examined in several preclinical studies in vivo. The aim of the studies being to assess the potential antipsychotic effects of GT-002 in social interaction and novel object recognition (NOR) performed in male Sprague-Dawley rats treated with MK-801 and to compare the effects of GT-002 to the antipsychotic drug clozapine (as an animal model of schizophrenia) and to the procognitive drug used in Alzheimer's patients,

Aricept, in its generic form donepezil in NOR, as an animal model cognition in Alzheimer's disease, and to establish whether the $GABA_A$ PAM, GT-002 can reverse the associated cognitive impairments seen in this model. As expected, MK-801 (0.1 mg/kg sc) impaired social interaction decreasing the duration of interactions and the number of episodes to about 50% when compared to controls, corresponding to the negative symptoms in schizophrenia. GT-002 at a dose of 3 mg/kg increased social interaction in terms of both parameters, increasing the duration and the number of interactions. Furthermore, 3 mg/kg GT-002 partially reversed the MK-801 induced deficits. Clozapine, used as reference drug, administered at a dose of 1 mg/kg partially reversed MK-801-induced deficits in the social interaction test while its higher dose (3 mg/kg) was ineffective possible due to sedative properties of this drug. Similarly as expected, MK-801 (0.1 mg/kg sc) impaired novel object recognition with rats exploring both objects equally during the recognition session, whilst rats receiving clozapine (1mg/kg) or GT-002 (1mg/kg) performed better than controls when tested one hour later. In NOR studies where the recognition session was performed 24 hours later, GT-002 at 3 mg/kg or donepezil at 1 mg/kg or 3 mg/kg significantly improved performance with rats spending more time investigating the novel object than controls. There was a corresponding significant increase in recognition index following administration of these drugs.These results indicate that GT-002 promotes social interaction (an animal model of the negative symptoms in schizophrenia) and enhances cognitive performance in NOR with similar efficacy to donepezil (Aricept) which is given to Alzheimer's patients to improve memory.

Title: Time and dose-dependent effects of acute nicotine on light-enhanced startle

Authors: *R. C. BARNET;
Col. William & Mary.

Abstract: Two experiments using Light-enhanced startle (LES) examined dose-dependent and time-dependent effects of acute nicotine on anxiety. In Experiment 1 rats were exposed to saline, .15 mg/kg, or .40 mg/kg (i.p.) nicotine and 5 minutes later were behaviorally tested in LES. Nicotine at both doses reduced the magnitude of LES in males but not in females. In females, the higher nicotine dose, .40 mg/kg increased LES (was anxiogenic) during later portions of the test session. In both males and females, within-session variation in LES suggested LES generally increased in magnitude as time since nicotine administration increased. In Experiment 2, longer

drug-to-test intervals were examined in order to explore possible time-dependent increases in LES produced by nicotine. In Experiment 2, rats were exposed to saline or .40 mg/kg nicotine and were behaviorally tested 15 min or 35 min after nicotine administration in LES. Trends in the available data suggested an anxiogenic profile of nicotine when tested 15 min following drug administration but an anxiolytic profile when tested 35 min following drug administration. At the short 5 min drug-to-test interval used in Experiment 1, findings contradict those in other experiments using the social interaction test of anxiety. Collectively, results suggest Light-enhanced startle is sensitive to dose and time-dependent effects of nicotine on anxiety. Possible differences between reflexive and non-reflexive measures of fear are discussed.

Title: The effects of the endocannabinoid receptors 2 (CB2) and voluntary wheel running in depression-like behaviors in rats

Authors: A. P. RAMOS-ROLÓN[1], *P. A. MUNOZ RODRIGUEZ[2];
[1]Biol., Univ. of Puerto Rico, Rio Piedras Campus, San Juan, PR; [2]Dept. of Biol., Univ. of Puerto Rico-Rio Piedras, San Juan, PR

Abstract: Theendocannabinoid system (eCB) has been implicated in the pathophysiology ofdepression. Studies have shown that CB2 receptor (CB2R) plays a role indepression-like behavior by modulating the serotonergic system. Other studiesrevealed that aerobic exercise is also involved in decreasing depression-likebehavior by upregulating 5-HT release. This project is aimed to observe if themanipulation of the CB2R would enhance the therapeutic effect of aerobicexercise in depression. In this set of experiments, we used the forced swimtest (FST) paradigm as a depression model in male Sprague Dawley rats. All ratshad access to 2hr of wheel running exercise (aerobic exercise model) for 5consecutive days. One group of rats received intraperitoneal (ip) injections of(+)-WIN 55,212-2 (1mg/kg), an agonist eCB receptors, and the other groupreceived the vehicle. On the 5th and last day, rats were submitted to the FSTbehavioral paradigm to measure depression-like behaviors. Behavioral resultsshowed no significant difference at the selected dose in exercise and sedentarygroups when compared to the controls. Further studies with higher doses will beconducted. In addition, biochemical analysis of the expression of CB2R withinthe medial prefrontal cortex and 5-HT 1A receptors within the hippocampus andamygdala will be conducted. It is expected that these findings will permit

abetter understanding of the neurocircuits underlining the depression-likeresponses and the interactions between exercise and the eCB.

Title: Clinical Trial of herbal tea on depressed associated with hyperlipidemia patients in Aga Khan University, Pakistan

Authors: *S. A. KHAN, A. KHAN, H. RAFIQ, H. MESIYA;
Aga Khan Univ., Karachi, Pakistan

Abstract: Abstract Objectives: Depression are one of the neuropsychological refers to constellation of sad mood, agitation, lack of interest and feelings of worthlessness. Many allopathic treatments are available in hospitality for the management of this disease to control their adverse effects. Although there is also the interest of developing countries to use alternative remedies for the treatment of psycho-neurological issues like depression. The present clinical trial was designed in the clinical trial unit of Aga Khan University, Karachi, Pakistan to determine the effect of chamomile and saffron tea bags as an adjuvant therapy in patients with mild to moderate depression using PHQ9 scale. **Methods**: 100 depressed patients visiting the outpatient psychiatry clinic at the Aga Khan University, Karachi, Pakistan after obtaining written consent were selected and randomly divided in control and test groups. The test subjects were given herbal tea bags, prepared with 20mg of chamomile and 1mg of saffron to be taken twice daily for a period of 4 weeks only as adjuvant therapy to their prescribed medicine. The controls received nothing and were advised to continue taking their prescribed medication. Depression in all the subjects was evaluated by the PHQ9 scale and serum samples were taken for evaluation of fasting lipid profile and serum tryptophan levels, both before the initiation and after one month of completion of the study. **Results:** Results revealed that one month of herbal tea intake as adjuvant therapy significantly reduced depression and fasting lipid profile in test subjects than controls. However, analysis of tryptophan levels analysis through HPLC method is to underway and results are pending. **Conclusions:** It is concluded from the present trial that the indigenous herbs have a potential to maintain blood lipid profile and alleviate of psycho-neurological deficits possibly through augmented tryptophan entry through blood brain barrier into brain; escalating serotonin synthesis. **Keywords**: neurophysiological deficits, herbal products, saffron, chamomile, PHQ-9. **Conflict of interest**: None to declare.

Title: CYP2D-mediated methamphetamine metabolism in rat brain alters striatal dopamine and serotonin release and behavioral sensitization

Authors: *M. R. STOCCO[1,3], A. A. EL-SHERBENI[1,4], B. ZHAO[1,3], M. NOVALEN[1,3], R. F. TYNDALE[1,3,2];

Abstract: Cytochrome P450 2D (CYP2D) enzymes metabolize many addictive drugs, including methamphetamine. Variable CYP2D metabolism in the brain may alter CNS drug and metabolite concentrations, consequently affecting drug response and chronic effects, including addiction liability and neuropsychiatric outcomes; components of these can be modeled by behavioral sensitization in rats. To investigate the role of CYP2D in the brain in methamphetamine-induced behavioral sensitization, adult male rats were pretreated centrally with a CYP2D irreversible inhibitor (or vehicle) 20 hr prior to each of 7 daily methamphetamine (0.5 mg/kg subcutaneous) injections; after 20 hr, CYP2D in the brain is inhibited, and the remaining inhibitor has been cleared from the brain. *In vivo* brain microdialysis was then used to assess brain drug and metabolite concentrations, and neurotransmitter release. CYP2D inhibitor (versus vehicle) pretreatment enhanced methamphetamine-induced stereotypy response sensitization. CYP2D inhibitor (versus vehicle) pretreatment also increased brain methamphetamine concentrations and decreased the brain *p*-hydroxylation metabolic ratio. With microdialysis conducted on day 1 and day 7 of the daily administration paradigm, CYP2D inhibitor (versus vehicle) pretreatment again exacerbated stereotypy sensitization, as well as enhanced dopamine and serotonin release in the dorsal striatum. Day 1 brain methamphetamine concentrations correlated with striatal dopamine and serotonin release, which in turn correlated with the stereotypy response slope across sessions (i.e. day 1 through day 7), used as a measure of sensitization. Thus, CYP2D-mediated methamphetamine metabolism in the brain was sufficient to alter brain drug concentrations, striatal dopamine and serotonin release, and behavioral sensitization. Moreover, acute (i.e. day 1) methamphetamine-induced neurotransmitter release may be an important predictor of subsequent behavioral sensitization. Together this suggests the novel contribution of CYP2D in the brain to methamphetamine-induced behavioral sensitization and suggests that the wide variation in

CYP2D6 in human brain may contribute to differential methamphetamine responses and chronic effects, including addiction liability and neuropsychiatric outcomes.

Title: Brain Region-specific molecular neuroadaptations in Male and Female Rats as Consequences of Methamphetamine Self-administration

Authors: *A. P. DAIWILE, S. JAYANTHI, J. L. CADET;
Mol. Neuropsychiatry Res. Br., NIH-National Inst. On Drug Abuse IRP, Baltimore, MD

Abstract: Brain Region-specific molecular neuroadaptations in Male and Female Rats asConsequences of Methamphetamine Self-administration Atul P. Daiwile, Subramaniam Jayanthi, and Jean Lud Cadet*Molecular Neuropsychiatry Research Branch, NIDA Intramural Research Program, Baltimore, MD 21224
Methamphetamine use disorder (MUD) is a neuropsychiatric disorder that inflicts significant health burdens throughout the world. Importantly, there are significant sex differences in use and relapse rates exist among human METH users. Some sex differences have also been reported in animal models of MUD. The molecular and biochemical bases for these behavioral differences remain to be determined. We have therefore begun to address some of these issues by using a METH self-administration model in order to identify potential differences in gene expression between female and male rats. Rats were trained to self-administer METH (0.1 mg/kg/injection, i.v.) using two 3-hours daily sessions (separated by a 30-minute off interval) for 20 days. Rats were then assessed for cue-induced drug seeking on withdrawal days (WD) 3 and 30. Rats were euthanized 24 hours after WD30. Prefrontal cortex (PFC) and hippocampus (HIP) were dissected to measure mRNA levels. We found that both female and male rats increased their METH intake during the 4 weeks of the experiment and showed incubation of METH seeking during withdrawal. Females had higher basal level expression of Hcrtr1 and Pdyn mRNAs in the PFC and HIP. Basal Crhr1, Crhr2, Hcrtr2, Oprk1 mRNA levels were higher in the PFC of females whereas Crh and Crhr1 mRNA levels were higher in the HIP of males. In females, METH caused significant decreases in Pdyn mRNA levels in the PFC and HIP whereas Pdyn mRNA expression was affected only in the HIP of males. There were METH-induced decreases in the expression of Oprd1, Oprk1, and Oprm1 in the female PFC, but increases in Oprk1 mRNA levels in the male PFC. In contrast, METH SA increased Crh and Crhr1 in the HIP of both sexes and Crhr2 only in the female HIP. Importantly only increased HIP Crh and Crhr1 mRNA levels correlated positively with incubation of METH craving in both sexes, supporting their potential

involvement and that of the hippocampus in the partial regulation of this phenomenon. When taken together, our results identified sexual dimorphic responses in rats that had self-administered METH and support the importance of understanding the molecular neurobiology of sex differences when developing therapeutic agents against METH use disorder.**Acknowledgement:** This work is supported Department of Health and Human Services/ NIH/ NIDA/ IRP.

Title: The dopamine D1-like receptor antagonist, SCH-23390, suppresses compulsive methamphetamine taking in the presence of punishment: molecular neuroadaptations in in brain regions of Sprague-Dawley rats

Authors: *S. JAYANTHI, M. T. MCCOY, B. LADENHEIM, J. L. CADET;
NIDA-IRP, Baltimore, MD

Abstract: Methamphetamine use disorder remains a pervasive public health problem. Nevertheless, its molecular substrates remain to be elucidated. Rats were trained to self-administer methamphetamine using long (9 hours) access to the drug. Rats were then exposed to increasing intensity of contingent footshocks (0.18 - 0.42 mA). While still receiving footshocks, rats were injected intraperitoneally with the dopamine D1 receptor antagonist, SCH23390, prior to each self-administration (SA) session. Cue-induced methamphetamine craving was recorded after 2, 7, and 30 days of withdrawal (WD) from methamphetamine SA. Dorsal striatum (DStr), nucleus accumbens, and hippocampus were used in RT-qPCR analyses to measure mRNA expression. Pretreatment with SCH23390 before sessions suppressed lever pressing in rats that had escalated their methamphetamine intake and had been separated into shock-resistant and shock-sensitive methamphetamine phenotypes by contingent footshocks. Stopping of SCH23390 administration led to re-emergence of compulsive methamphetamine taking in resistant rats. Resistant rats also showed greater cue-induced METH craving than shock-sensitive at WD7 and WD30. RT-qPCR analyses revealed significant increases in the expression of all D1 and D2-like subtypes of dopamine receptors, Fra1, Fra2, and Nr4a3 mRNAs in the DStr of only shock-sensitive rats whereas JunD expression was increased in the DStr of only shock-resistant rats. Incubation of methamphetamine craving correlated positively with increased expression of striatal JunD and hippocampus Nr4a2 expression. Differential changes in gene expression observed mainly in the DStr of rats support the notion that this brain structure may mediate, in part, incubation of methamphetamine craving, a potential indicator of relapse potential.

Title: Gene alterations in striatonigral projection neurons after prolonged withdrawal from methamphetamine self-administration

Authors: *R. ALTSHULER, K. GARCIA, X. LI;
Dept. of Psychology, Univ. of Maryland Col. Park, College Park, MD

Abstract: In both rodents and humans, methamphetamine (Meth) seeking progressively increases after withdrawal, a phenomenon termed incubation of Meth craving. We have previously demonstrated a critical role of the dorsal striatum (DS) in this incubation and associated gene alterations in both DS homogenate and relapse test-activated DS neurons. Here, we aimed to examine whether these gene alternations observed previously occur in a projection-specific manner and we focused on the major direct pathway, which projects from the DS to the substantia nigra (SN). We trained Sprague-Dawley male rats to self-administer Meth (0.1 mg/kg/infusion) or saline for 10 days (6 h/day). On withdrawal day 18, we injected Alexa Fluor 647-conjugated cholera toxin B (CTb, a retrograde tracer), bilaterally into the SN and collected the DS on withdrawal day 28. We then used fluorescence-activated cell sorting to isolate striatonigral projection neurons in the DS (CTb-positive neurons) and measured gene expressions of several candidate genes, including *Bdnf* and *Trkb*, glutamate receptors, epigenetic and ubiquitination enzymes. We found decreased mRNA expression of ubiquitin specific peptidase 7 (*Usp7)* in Meth rats compared to saline rats, with no changes of other candidate genes. These results demonstrate a projection-specific gene alterations associated with ubiquitin-proteasome system during incubation of Meth craving. Future studies will investigate the role of ubiquitin-proteasome system in the direct pathway in incubation of Meth craving.

Title: Psychomotor stimulant-induced locomotor sensitization in mouse: association with cAMP-dependent D1 receptor signaling

Authors: H. ZHANG[1], T. SALMAN[3], W. XU[4], S. DAHLKE[4], C. R. GERFEN[5], S. Z. JIANG[4], ***L. E. EIDEN**[2];
[1]NIH, NIMH-IRP, NIMH, NIH, MD; [2]NIH, NIMH-IRP, Bethesda, MD; [4]Section on Mol. Neurosci., [5]Lab. of Systems Neurosci., [3]NIMH-IRP, Bethesda, MD

Abstract: Increased locomotor activity after repeated administration is a behavioral hallmark of psychomotor stimulants (PSs) such as methamphetamine (MA) and cocaine (COC) that elicit increased post-synaptic availability of dopamine in the nucleus accumbens (NAc). It has been hypothesized that cellular plasticity, especially in D1 dopaminoceptive medium spiny neuron (D1-MSNs), upon repeated psychomotor stimulant administration underlies the engagement of behavioral circuits leading to increased appetitive drive for PS preference/self-administration. Examination of downstream pathways activated by dopamine (DA) in D1-MSNs have established a convincing link between activation of the MAP kinase ERK, and both locomotor sensitization and development of preference for COC self-administration in mice (Pascoli et al., Biol. Psychiatr.**76**: 917, 2014). Using conditioned place preference (CPP) as a behavioral index of increased preference for PS self-administration, we have determined that both COC-induced locomotor sensitization, and CPP, are associated with NCS-RapGEF2-dependent activation of ERK in NAc D1-MSNs (Jiang et al., BioRxiv doi.org/10.1101/2020.07.02.184754). Here, we asked whether or not MA elicits ERK activation upon repeated administration, as in the case of COC, and examined whether or not this is associated with alterations in the NAc transcriptome as a function of repeated MA administration. We confirmed that a daily dose of 2 mg/kg of MA on two successive days elicited a similar increase in locomotor activity, and activation of pERK in NAc, as 20 mg/kg COC. Furthermore, ERK phosphorylation was increased in NAc slices incubated with MA (10 uM). Transcriptome analysis (Affymetrix 2.0 mouse microarray) of NAc from MA-treated mice one hour after initial administration after MA, and one hour after the final of six daily treatments with MA revealed a set of core transcripts up-regulated after both single and repeated-dose regimens. The immediate-early gene c-Fos, was up-regulated by both single and repeated MA administration, and similarly regulated after administration of COC. Gs-coupled GPCR activation, shown to activate ERK via NCS-RapGEF2 in the NS-1 neuroendocrine cell line also resulted in up-regulation of c-Fos. We hypothesize that RapGEF2-dependent activation of ERK, and of ERK-dependent IEGs in D1-MSNs, may represent the signaling that leads, initially, to locomotor sensitization and upon repeated administration, to altered plasticity of D1-MSN output neurons leading ultimately to activation of a behavioral program for PS preference and self-administration.

Title: Effects of methamphetamine induced dopamine toxicity on striatal plasticity

Authors: *A. S. GIBSON, P. J. WEST, K. A. KEEFE;
Univ. of Utah, Salt Lake City, UT

Abstract: Methamphetamine (METH) is a highly addictive psychostimulant. Cognitive deficits are apparent in individuals with a history of METH abuse, and targeting cognitive function may be an efficacious approach to managing METH abuse and addiction. However, in order to develop a successful treatment for METH abuse, the consequences of METH-induced neurotoxicity must be better understood. METH exposure is known to be associated with damage to central monoamine systems, particularly dopamine signaling. Rodent models of such damage have revealed a decrease in the amplitude of phasic dopamine signals and significant striatal dysfunction, including changes in molecular, systems, and behavioral functions of the striatum. Importantly, phasic dopamine signals activate dopamine D1 receptors, which are involved in striatal synaptic plasticity, particularly long-term potentiation (LTP) in D1 receptor-expressing striatal medium spiny neurons. We therefore hypothesize that METH-induced dopamine neurotoxicity will diminish D1 receptor-dependent striatal plasticity in mice. To test this hypothesis, mice were treated with a METH binge regimen (4 x 10 mg/kg *d,l*-methamphetamine, s.c.). This binge regimen provides a reliable rodent model that recapitulates all of the known METH-induced neurotoxic effects observed in humans, including dopamine toxicity. Three weeks later, plasticity was assessed using white matter high frequency stimulation (HFS) and striatal field recordings. Under these conditions, LTP was induced in the dorsomedial striatum of saline-pretreated, but not METH-pretreated mice. Further, the LTP observed in saline-pretreated mice was abolished by the dopamine D1 receptor antagonist SCH23390, indicating that this LTP is D1 receptor-dependent. Finally, acute *in vivo* treatment with bupropion (50mg/kg i.p.) can restore LTP in striatal slices from METH-pretreated mice. Together these studies suggest that METH-induced neurotoxicity impairs D1-dependent LTP within the dorsomedial striatum, and that LTP can be restored with the FDA-approved drug bupropion. As a behavioral correlate to this plasticity deficit, experiments are currently ongoing to determine if METH-induced neurotoxicity impairs striatally-dependent motor learning, and if this deficit can also be rescued with acute bupropion treatment.

Title: Incubation of methamphetamine craving and associated synaptic plasticity in the nucleus accumbens core: comparison of male and female rats

Authors: *J. R. FUNKE, E.-K. HWANG, A. M. WUNSCH, M. E. WOLF;
Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: One of the intractable features of methamphetamine (METH) substance use disorder is the high rate of relapse, which occurs even after prolonged abstinence. Relapse can be induced by exposure to drug-paired cues leading to craving and subsequent relapse; this craving progressively intensifies during abstinence, a phenomenon termed 'incubation of drug craving'. In our incubation paradigm, rats undergo extended-access self-administration (SA) of METH for 6 hr/day for 10 days. A light cue is paired with each METH infusion. Rats then undergo cue-induced seeking tests during abstinence in which rats nose poke for presentation of the METH-paired light cue but do not receive drug. Previously, we found that cue-induced METH seeking increases during the first week of abstinence and remains elevated through Withdrawal Day (WD) 45 (Scheyer et al., Biological Psychiatry 2016). Furthermore, the accumulation of high conductance calcium (Ca^{2+})-permeable AMPARs (CP-AMPARs) in medium spiny neurons (MSN) of the nucleus accumbens (NAc) core mirrors this time course, and activation of these receptors is required for the expression of incubated craving. The overall goal of this project is to establish the rising and falling phases of METH incubation in both male and female rats, as well as CP-AMPAR accumulation during these time periods. Using a between-subject design, male and female rats undergo METH self-administration as described above and then undergo cue-induced METH seeking tests on WD1, WD7, WD30, and WD100. Estrous cycle is assessed in the female rats after each seeking test. Current data show that females follow the same trajectory as males during the rising phase of METH incubation, through WD30; tentatively, estrous cycle stage appears to have no impact on seeking. Similar to what we previously reported in male rats (Scheyer et al., 2016), after incubation of METH craving female rats showed increased synaptic CP-AMPAR levels in the majority of MSNs in the NAc core. Thus, this neuroadaptation is not sex-specific. Furthermore, there were no changes in presynaptic function as measured with paired pulse ratios. Future experiments will investigate the status of incubation on WD100, as well as CP-AMPAR levels in late withdrawal. Incubation of craving also occurs in abstinent human METH users, so it is important to define its time course and underlying mechanisms to develop strategies for relapse prevention in a clinical environment.

Title: Cerebellum-infralimbic anatomical map

Authors: *J. GUARQUE-CHABRERA, M. MIQUEL, K. KHODAKHAH;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Several findings support the existence of reciprocal loops between the medial prefrontal cortex (mPFC) and the cerebellum. Dysfunction of both areas underlie the phenotypes of several neuropsychiatric disorders, and may operate as a risk factor for drug addiction.
In rodents, the mPFC includes, among others, two areas that have shown to exhibit opposite roles in drug-related behaviors. The prelimbic cortex (PL) is involved in initiating cocaine-seeking, while the infralimbic cortex (IL) is responsible for the inhibitory control over drug-seeking. Miquel's lab has reported that either a cerebellar lesion in lobule 8 (L8) or IL deactivation facilitated the establishment of conditioned preference for cocaine-related cues. However, this effect was not replicated by PL deactivations. Cerebellum-IL functional relationships appear to be compensatory because simultaneous cerebellum-IL deactivations abolished the facilitative effect of separate deactivations. Moreover, unpublished results showed that IL but not PL deactivations during a repeated cocaine experience upregulates neuronal activity in the posterior vermis in rats. Additionally, we have observed disynaptic projections from the deep cerebellar nuclei (DCN) to the mPFC using transneuronal labeling. In fact, one of the relays for the cerebellum to modulate mPFC functions is the ventral tegmental area (VTA). Indeed, optogenetic manipulation of the cerebellar outputs targeting VTA were able to modulate reward-related behaviors.
Anatomical projections from the IL to the cerebellum have been poorly described and it is far to be clear through which brain regions the IL might regulate cerebellar activity. Neither, whether IL projections are monosynaptic or involve disynaptic pathways. Therefore, our goal is to characterize the cerebellum-IL loop in mice to create an anatomical map of this circuit. To establish the anatomical cerebellum-IL loop we used a combination of monosynaptic and transneuronal viral and classic tracing agents. Our results show that for the cerebellum-IL ascending pathway, L8 might contact the IL through the projections from the interposed DCN to the VTA. For the IL-cerebellum descending pathway, the IL might reach L8 through its projections to both interposed DCN and inferior olive.

Title: Anatomical, physiological and behavioral differences between four ventral pallidal projections

Authors: *N. BERNAT, Y. M. KUPCHIK;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The ventral pallidum (VP) is a central brain region in the reward system, implicated in many behaviors, but mostly as mediator of motivated behavior and addiction. Despite its involvement in major psychiatric pathology, it is yet to be explored in a projection-specific manner. In this research, we systematically characterize projection neuron subpopulations in the VP, defined by their projection sites: ventral tegmental area (VTA), medial dorsal thalamus (MDT), lateral hypothalamus (LH) and lateral habenula (LHb), as well as determine the involvement of relevant subpopulations in cocaine conditioning. To characterize each of these VP four subpopulations, we delineated anatomical patterns by employing rabies tracing methods, tissue clearing techniques and light sheet fluorescent microscopy. We also describe physiological characteristics of these projections by using retrograde tracing, whole-cell patch clamp and optogenetics. Finally, we use the cocaine conditioned place preference (CPP) behavioral model in combination with chemogenetic (DREADDs) tools to examine the relevance of each of the VP projections to positive reinforcement, driven by cocaine reward. We show that the four different VP projection neurons are largely non-overlapping populations, that receive different patterns of inputs from brain-wide sources and show different physiological traits. We also show that inhibiting the VP→VTA projection increases cocaine CPP, while inhibition of the VP →LH/LHb decreases cocaine CPP, compared with control. In summary, we identify specific functions to the different projections of the VP in cocaine conditioning. We also established differences in traits between the different subpopulations which emphasize the heterogeneity of the VP. This work would lay the foundations for future research on the VP and functional neuronal microcircuits in reward research and addiction.

Abstract: The prelimbic (PL) region of medial prefrontal cortex (PFC) has been implicated in both driving and suppressing cocaine-seeking behaviors. These seemingly opposing functions may be mediated by different efferent targets of PL projections, such as the nucleus accumbens (NAc) core and rostromedial tegmental nucleus (RMTg), which have contrasting roles in reward-seeking behaviors. We used conventional retrograde tracers to reveal distinct subpopulations of PL neurons projecting to NAc core vs. RMTg in rats, with very little overlap. To examine potential differences in input specificity for these two PL subpopulations, we then used Cre-dependent rabies virus (EnvA-RV-EGFP) as a monosynaptic retrograde tracer and targeted specific PL neurons via injections of retrograde CAV-Cre in either NAc core or RMTg. We observed a similar catalog of cortical, thalamic, and limbic afferents for both NAc- and RMTg-projecting populations, with the primary source of afferent information arising from neighboring prefrontal neurons in ipsilateral PL and infralimbic cortex (IL). However, when the two subpopulations were directly compared, we found that RMTg-projecting PL neurons received a greater proportion of input from ipsilateral PL and IL, whereas NAc-projecting PL neurons received a greater proportion of input from most other cortical areas, mediodorsal thalamic nucleus, and several other subcortical areas. NAc-projecting PL neurons also received a greater proportion of contralateral cortical input. Our findings reveal that PL subpopulations differ not only in their efferent target, but also in the input specificity from afferent structures. These differences in connectivity are likely to be critical to functional differences of PL subpopulations.

Title: Optogenetic mapping of the circuit by which the basolateral amygdala influences the activity of dorsolateral striatum medium spiny neurons

Authors: *A. BELIN-RAUSCENT, B. J. EVERITT, D. BELIN;
Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Although the basolateral amygdala (BLA) does not project directly to the anterior dorsolateral striatum (aDLS), it has been shown to exert control over its function. The BLA bidirectionally gates the response of subpopulations of medium spiny neurons (MSNs) in the aDLS to their major glutamatergic input from the cortex. The remote control whereby associative information processed in the amygdala can influence the function of the aDLS, the neural locus of control of habits, has far-reaching implications as it may subserve a mechanism by which the amygdala gates the progressive devolvement of control over the aDLS habit system over the course of the development of drug addiction. Our recent investigations of the neural mechanisms supporting this functional control have shown that, in drug-naive rats, electrical stimulation of the BLA applied 100 to 300 milliseconds before that of the motor cortex 1 (M1) elicits a bidirectional regulation of spike probability of the aDLS MSNs. We further showed that the control exerted by the BLA over the activity of aDLS MSNs depends on a polysynaptic network that involves antecedent glutamatergic mechanisms in the core of the nucleus accumbens (AcbC) to which the BLA projects. Here we used a projection specific expression of channelrhodopsin to investigate the role of the BLA-AcbC pathway in mediating the control of the BLA over aDLS MSNs activity. In anaesthetised rats, we combined the optogenetic stimulation of the specific BLA-AcbC pathway with extracellular in vivo recordings of the activity of the MSNs in the aDLS evoked by electrical stimulation of M1. Photostimulation of the terminals of BLA neurons in the AcbC was sufficient to bidirectionally modulate the activity of aDLS MSNs. As previously reported using electrical stimulation of the BLA, aDLS MSNs were shown either to up or down regulate their spike probability following photostimulation of the BLA-AcbC pathway. These data demonstrate that the BLA can exert control over the physiology of the aDLS indirectly through its direct projections to the AcbC. Further experiments will establish whether the AcbC mediates this influence on the aDLS via the ascending dopamine-dependent spiralling circuitry that has been shown to be necessary for the functional recruitment of aDLS dopamine dependent drug seeking habits.

Title: Abstinence from cocaine strengthens the excitatory input from the mPFC and BLA to VP-projecting accumbal D1-MSNs but not D2-MSNs

Authors: *K. INBAR, L. A. LEVI, Y. M. KUPCHIK;
Dept. of Med. Neurobio., Fac. of Medicine, The Inst. for Med. Res. Israel-Canada, The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Background:
Withdrawal from cocaine induces synaptic plasticity at glutamatergic inputs to nucleus accumbens (NAc) medium spiny neurons (MSNs). This plasticity is believed to control cocaine seeking by modulating two competing pathways arising from the NAc - 1) the direct pathway that promotes cocaine seeking and originates in D1 dopamine receptor-expressing MSNs (D1-MSNs) projecting to the ventral mesencephalon; and 2) the indirect pathway that decreases cocaine seeking and consists of ventral pallidum (VP)-projecting MSNs expressing the dopamine receptor D2 (D2-MSNs). Recent findings have identified D1-MSNs that project in the indirect pathway to the VP (iD1-MSNs) and promote drug seeking. Thus, the indirect pathway consists of both D1- and D2-MSNs. This therefore calls for a reexamination of the cocaine related synaptic changes along it. In this work, we ask whether abstinence from repeated cocaine exposure differentially alters the excitatory input from the medial pre-frontal cortex (mPFC) and the basolateral amygdala (BLA) to VP-projecting D1- and D2- MSNs in the NAc core and shell.
Results:
To this end we injected the VP of D1-tdTomato mice with RetroBeads and either the mPFC or BLA with ChR2. Mice received either cocaine or saline for 2 weeks in a conditioned place preference paradigm (CPP). After two weeks of abstinence, we recorded the AMPA to NMDA (A/N) ratio from mPFC-NAc or BLA-NAc synapses in VP-projecting D1- or D2-MSNs using the whole-cell patch clamp electrophysiology. We found that cocaine CPP and abstinence increased A/N ratio only in iD1-MSNs and did not affect the A/N ratio measured in D2-MSNs. While the A/N ratio recorded in BLA-iD1-MSN synapses was elevated in both the NAc core and shell compartments, the A/N ratio in mPFC-iD1-MSN synapses was increased only in the NAc shell. The increase of A/N ratio in mPFC-iD1-MSN but not BLA-iD1-MSN synapses was accompanied by a change in AMPA current rectification index.
Conclusions:
Our results suggest that even when focusing only on the MSNs projecting to the VP, D1- and D2-MSNs still undergo different synaptic changes following cocaine use and abstinence. This may be part of the mechanism allowing these two inputs to the VP to have opposite influence on behavior.

Title: Functional interactions between the dopamine transporter and kappa opioid receptor modulate the reinforcing efficacy to self-administer cocaine

Authors: *P. M. ESTAVE[1], L. B. KUIPER[1], K. M. HOLLERAN[1], A. K. KARKHANIS[2], S. R. JONES[1];
[1]Wake Forest Sch. of Medcine, Winston Salem, NC; [2]Binghamton University-SUNY, Binghamton, NY

Abstract: Chronic cocaine exposure leads to compensatory alterations of the mesolimbic dopamine system and kappa opioid receptor (KOR) system, which influence the reinforcing effects of cocaine. After extended cocaine exposure, KOR activity in the nucleus accumbens is augmented, and there is a decrease in cocaine's ability to bind to the dopamine transporter (DAT). Furthermore, literature suggests that the DAT and KOR form a physical complex, and that KOR activation promotes DAT function. Thus, this study focuses on how the DAT and KOR are functionally linked, and how these interactions may have influenced our earlier results showing that the dopamine releaser phenmetrazine and the KOR antagonist norBNI both decrease cocaine-motivated behaviors. Using *ex vivo* fast scan cyclic voltammetry, we investigated dopamine release and uptake kinetics in Sprague Dawley rats following 5 days of cocaine exposure (1.5 mg/kg/inf, FR 1 x 40), followed by 14 days of a progressive ratio (PR) schedule of reinforcement (0.1875 mg/kg/infusion). At baseline, there was lower electrically stimulated dopamine release and slower dopamine uptake in cocaine exposed animals compared to naïve controls. Next we examined DAT and KOR function through bath application of cocaine or the KOR agonist U50,488, respectively. We found that cocaine exposure attenuated cocaine potency at the DAT and increased KOR-mediated inhibition of dopamine release. To study the interaction between KOR and DAT in naïve animals, the IC50 dose of the KOR agonist U50,488 was applied to the slice, followed by a cocaine concentration response curve. Acute KOR activation lead to a decrease in cocaine potency at the DAT, similar to cocaine-exposed animals. A separate cohort of animals were treated with norBNI (10 mg/kg; i.p.) prior to cocaine exposure. Animals with norBNI treatment did not develop tolerance to cocaine's inhibitory effects at the DAT, appearing to be more similar to their naïve counterparts than animals with equivalent cocaine exposure. These studies suggest the potential benefit of dual-targeting the DAT and KOR for treatment of cocaine use disorder, which may allow for lower doses of dopamine agonists to be effective, decreasing abuse liability. Further studies are necessary to elucidate changes in complex formation after cocaine self-administration and treatment with KOR antagonists and dopamine releasers.

Title: Effects of Repeated I.P. Cocaine Injections on Locomotor Sensitization and Glutamatergic Plasticity in the Nucleus Accumbens

Authors: *A. M. FRANCE[1], T. L. FETTERLY[1], A. M. NIETO[1], T. E. ROBINSON[2], C. R. FERRARIO[1,2];

Abstract: The development and persistence of addiction is mediated in part by drug-induced alterations in the function of the nucleus accumbens (NAc), a region that mediates drug-craving and seeking behaviors. AMPA-type glutamate receptors provide the main source of excitatory drive to the NAc, and enhancement in transmission of calcium-permeable AMPAR (CP-AMPARs) within the NAc mediate cue-triggered drug-seeking. Previous work has shown that cocaine treatment regimens that result in psychomotor sensitization enhance subsequent drug-seeking and drug-taking behaviors. Furthermore, cocaine-induced locomotor sensitization followed by 14 days of withdrawal is accompanied by increases in the surface expression of GluA1 and GluA2 AMPAR subunits (consistent with increases in non-CP-AMPARs) and increases in AMPA/NMDA ratio in males. However, potential effects of cocaine-induced sensitization on AMPAR expression and synaptic transmission in females are poorly understood, and few studies have evaluated potential effects on CP-AMPAR transmission following sensitization regimens. Therefore, here male and female rats were given repeated systemic cocaine injections to induce locomotor sensitization (15 mg/kg, i.p, 1 injection/day, 8 days). Controls received saline (1 mL/kg, i.p.). After 14-16 days of withdrawal (WD), tissue from the NAc was biotinylated and western blotting was used to measure changes in the surface expression of GluA1 and GluA2. In addition, brain slices were prepared from separate sets of rats and whole-cell patch clamp approaches were used to measure effects on spontaneous EPSC frequency and amplitude, and sensitivity to the CP-AMPAR antagonist Naspm (200 μM). Repeated cocaine injections resulted in a progressive enhancement in locomotor activity in both males and females. We found slight increases in GluA1, but not GluA2 surface expression in males, and initial results show an increase in CP-AMPAR transmission and sEPSC frequency. In contrast in females, NAc AMPAR subunit expression in cocaine and saline treated groups was similar. Ongoing studies are examining potential changes in synaptic transmission in females. However, biochemical results suggest that although cocaine produced robust locomotor sensitization in both sexes, NAc AMPAR plasticity differs between males and females.

Title: Involvement of prefrontal cortex in the ability of ceftriaxone to attenuate cue-primed reinstatement of cocaine seeking

Authors: *J. R. MESA[1], V. HODGES[1], C. LOGAN[1], A. BECHARD[2], L. KNACKSTEDT[1]; [1]Univ. of Florida, Gainesville, FL; [2]SUNY Geneseo, Geneseo, NY

Abstract: Cocaine use disorder is a chronic condition marked by relapse even after months or years of abstinence. The intravenous self-administration model is used to model relapse in rodents. After establishing self-administration, the instrumental response made to obtain cocaine is then extinguished and can be reinstated by exposure to drug-associated cues and other stimuli. The antibiotic ceftriaxone shows therapeutic potential as it consistently attenuates cue-induced reinstatement to cocaine seeking. Ceftriaxone increases nucleus accumbens (NAc) glutamate transporter activity and NAc GLT-1 expression is necessary for ceftriaxone to attenuate reinstatement. Yet, overexpression of GLT-1 transporter is insufficient to prevent reinstatement to cocaine seeking. Thus, we hypothesize that ceftriaxone may also reduce the glutamate efflux that drives cue-primed reinstatement by altering activation of prefrontal cortex (PFC) glutamatergic efferents to the NAc. Here, we aim to measure the effects of ceftriaxone on reinstatement-induced expression of immediate early gene product Fos. Male Sprague Dawley rats underwent 12 days of cocaine self-administration followed by 2 weeks of instrumental extinction training during which time half of the rats received ceftriaxone (200 mg/kg IP, 6d). Rats then underwent cue-primed reinstatement testing before perfusion. Fos immunohistochemistry was used to measure neuronal activity in the prelimbic (PL) and infralimbic (IL) cortices. We found that ceftriaxone attenuated cue-induced reinstatement but had no effect on PL and IL fos expression. This is in contrast to our published findings in a model that utilized abstinence without instrumental extinction, in which ceftriaxone reduces cue-primed relapse and PL fos expression. Thus, the ability of ceftriaxone to attenuate NAc glutamate release following extinction is not due to overall decrease in PFC neuronal activation. Future directions will test whether ceftriaxone is able to reduce activity of specific NAc-projecting PFC neurons.

Title: The effects of Hypocretin Receptor 1 blockade on Incubation of Cocaine Craving and Associated Dopamine Terminal Adaptations

Authors: *P. J. CLARK, R. A. ESPAÑA;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Relapse remains a major obstacle to recovery from drug dependence. Across all major drugs of abuse, drug craving has been reported to intensify during periods of abstinence. This phenomenon, called *incubation of craving,* is thought to promote drug seeking, thereby increasing the risk of relapse. Despite recent progress, there continues to be a scarcity of treatment options for those suffering from persistent drug cravings. Furthermore, although dopamine signaling is known to regulate drug craving, dopamine's involvement in incubation of craving remains elusive. To investigate whether incubation of cocaine craving is associated with adaptations in dopamine neurotransmission, we trained rats to self-administer cocaine on an intermittent access (IntA) schedule of reinforcement followed by one week of abstinence. We found that IntA followed by abstinence produced robust incubation of cocaine craving. Using *ex vivo* fast scan cyclic voltammetry (FSCV), we then showed that incubation of craving was tied to higher cocaine potency at the dopamine transporter (DAT) within the nucleus accumbens. Next, we examined whether treatment with a hypocretin receptor 1 antagonist early in the abstinence could prevent incubation of cocaine craving and increased cocaine potency. We again trained animals to self-administer cocaine on an IntA schedule followed by one week of abstinence. On the first day of abstinence, rats were treated with a single dose of the hypocretin receptor 1 antagonist, RTIOX-276, or vehicle. We found, that vehicle-treated rats show robust incubation of cocaine craving whereas rats treated with RTIOX-276 did not incubate their craving. In addition, we show with *ex vivo* FSCV that cocaine potency at the DAT was reduced following RTIOX-276 treatment. Together, these data suggest that antagonism of hypocretin receptor 1 early in abstinence from cocaine may block incubation of cocaine craving as well as the dopamine terminal adaptations that may promote drug seeking.

Title: Hypocretin receptor 1 knockdown on dopamine vs GABA neurons in the ventral tegmental area differentially modulates processes underlying cocaine use disorder.

Authors: *E. M. BLACK, B. M. O'CONNOR, J. R. BARSON, R. A. ESPAÑA;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Dopamine is a typical target for treatments of cocaine use disorder, however these treatments have proven to be ineffective, intolerable, and often pose abuse potential themselves.

As such, a different treatment target is needed for cocaine use disorder. The hypocretin system has been shown to support cocaine use through actions on hypocretin receptor 1 in the ventral tegmental area and is thought to be a promising therapeutic avenue for cocaine abuse. To date, however, hypocretin-based treatment approaches have limited efficacy due to the lack of cell-specific manipulations of hypocretin receptor 1. This is particularly problematic for understanding the therapeutic potential of these treatments given that hypocretin receptor 1 are present on both dopamine and GABA neurons in the ventral tegmental area. In the present study we employed a combinatorial viral approach to selectively knockdown hypocretin receptor 1 on dopamine or GABA neurons allowing for the selective examination of hypocretin manipulations on cocaine abuse. Data demonstrate that specific knockdown of hypocretin receptor 1 on dopamine neurons leads to decreased dopamine dynamics in the nucleus accumbens core at baseline and in response to cocaine while knockdown of hypocretin receptor 1 in GABA neurons enhances the effects of cocaine. Further, the behavioral implications of specific hypocretin receptor 1 knockdown are being examined through cocaine self-administration studies. These findings provide a more comprehensive understanding of hypocretin modulation of dopamine neurotransmission in the nucleus accumbens core and may uncover potential targets for future development of treatment strategies for cocaine use disorder.

Abstract: The hyperpolarization-activated cation current (I_h) is a determinant of intrinsic neuronal excitability in various cells, including dopaminergic neurons (DA) of the ventral tegmental area (VTA). In contrast to other cellular conductances, the I_h activates through hyperpolarizing voltage steps to potentials negative to -55mV and depolarizes the membrane potential. Our laboratory demonstrated that cocaine sensitization, a chronic cocaine behavioral model, significantly reduces I_h amplitude in VTA DA neurons (Arencibia-Albite et al., 2012). After the development of cocaine sensitization, the spontaneous firing of VTA DA cells remains similar to control groups. Suggesting that I_h reduction could reduce cocaine-induced excitability as a homeostatic adaptation for neuronal excitability, although this relationship is still poorly understood. Through in vivo anesthetized single-unit extracellular electrophysiology, we explore the contribution of the I_h on VTA DA neurons spontaneous firing patterns. A key feature of evaluating spontaneous excitability is the detection of bursting activity. Bursting is defined as trains of two or more spikes occurring within a short interval and followed by a prolonged period of inactivity. Burst formation increases the reliability of information transfer. Rhythmic burst firing in thalamic relay neurons arises mainly from the interaction of two dominant currents, I_h and T type Calcium Channels (I_t) (McCormick & Pape, 1990). The I_h activation depolarizes the membrane potential towards the threshold activating I_t and generating a low-threshold Ca^{2+} spike. The generation of this Ca^{2+} spike activates a burst of fast Na^+ and K^+ dependent action potentials. This provides a possible mechanism on how I_h could influence burst firing in VTA DA neurons. To elucidate the contribution of I_h on VTA DA neurons spontaneous firing patterns, we perfused I_h blocker (ZD 7288, 8.3 μM) and evaluated its effect. I_h blockade significantly reduced firing rate, bursting frequency, and percent of spikes within a burst on VTA DA neurons. Using whole-cell patch-clamp, we determine the progressive reduction of the I_h after acute and chronic cocaine administration (15mg/k.g). In addition, I_h blockade significantly reduced acute cocaine-induced firing rate, bursting frequency, and percent of spikes within a burst on the low firing/high bursting VTA DA neuron group. These data suggest that the progressive reduction of I_h could serve as a homeostatic regulator of cocaine-induced spontaneous firing patterns related to VTA DA excitability.

Title: The mTOR inhibitor Everolimus blocks incubated cocaine-craving via inhibition of Akt1 in vmPFC subregions

Authors: *L. L. HUERTA SANCHEZ, A. S. CHIU, M. C. KANG, K. K. SZUMLINSKI;
UC Santa Barbara, Santa Barbara, CA

Abstract: A time dependent increase in PI3K/Akt/mTOR signaling, and a reduced Group 1 metabotropic glutamate receptor expression (mGlu1), in the ventromedial prefrontal cortex (vmPFC) has been found to be critical for the incubation of cocaine-craving during protracted withdrawal. In this study, immunoblotting was conducted in order to further elucidate the changes in withdrawal-induced protein expression within the prelimbic (PL) and infralimbic (IL) subregions of the vmPFC following cocaine addiction when given an acute oral pretreatment of the FDA-approved mTOR inhibitor, Everolimus. Rats self-administered IV cocaine for 10 days in which each cocaine delivery was paired with a light-tone stimulus complex and at 3- or 30-days withdrawal, rats underwent a 2-h test for cue-reinforced responding. Then, the IL and PL were dissected upon test completion and immunoblotting was conducted. Previously, we have shown that single oral dosing with Everolimus dose-dependently blocked incubated cocaine-seeking in rats. Here, immunoblotting demonstrated that rats in protracted withdrawal, when compared to rats in early withdrawal, showed an increase in the expression of Homer2a/b and phosphorylated Akt1, P70-rpS6 kinase, and rpS6 within the PL. In the IL, there was an increase in expression of p-Akt1 and p-P70-rpS6 kinase when compared to rats in early withdrawal. Therefore, we conclude that the "anti-incubation" effect of Everolimus were associated with the withdrawal-induced increase in Akt1 activity. These data further demonstrate Everolimus can be repurposed as a viable strategy to interrupt cocaine-craving and aid addiction recovery in protracted withdrawal.

Title: Synaptogyin-3 prevents cocaine-induced dopaminergic adaptations and promotes behavioral resiliency

Authors: *E. G. PECK[1], S. R. JONES[2];
[1]Physiol. and Pharmacol., Wake Forest Sch. of Med., Winston-Salem, NC; [2]Wake Forest Univ. Sch. Med., Winston Salem, NC

Abstract: Synaptogyrin-3 (SYG3) is a synaptic vesicle protein highly expressed in dopamine-containing neurons that directly interacts with the dopamine transporter (DAT), suggesting a role in synaptic dopamine dynamics. We tested the hypothesis that chronic exposure to cocaine will disrupt SYG3 function, leading to alterations in DAT that drive subsequent excessive cocaine

taking. Rats were trained to self-administer cocaine and, after successful acquisition, rats were tested on a progressive ratio (PR) schedule of reinforcement. Western blots indicated a significant positive correlation between relative SYG3 and DAT protein levels in the ventral tegmental area, and a significant negative correlation between SYG3 and PR breakpoint. We then overexpressed SYG3 in the VTA of naive rats to assess alterations in baseline behavior and terminal dopamine dynamics. Anxiety-like behavior was assessed using the novel open field test, elevated plus test, and social interaction test. In a separate cohort of rats, nucleus accumbens dopamine terminal function was assessed using *ex vivo* fast-scan cyclic voltammetry (FSCV). Overexpression of SYG3 in the VTA resulted in greater time spent in the center of the open field, as well as augmented dopamine release and reuptake kinetics in brain slices containing the nucleus accumbens. Together, these data suggest that SYG3 is a powerful modulator of dopamine kinetics and dopamine-related behavior, indicating this as a fruitful potential target for pharmacotherapeutics to treat cocaine use disorder.

Title: Acetylcholine Signaling Genes are Required for Cocaine-Stimulated Egg-Laying in C. elegans

Authors: *S. D. EMERSON[1], M. HAY[2], M. SMITH[1], R. EL BEJJANI[1];
[1]Interdisciplinary Neurosci. Program, Davidson Col., Davidson, NC; [2]Radboud Univ., Nijmegen, Germany

Abstract: Despite the toxicity and addictive liability associated with cocaine abuse, the mode of action of the drug is not completely understood, and effective pharmacotherapeutic interventions remain elusive. The cholinergic effects of cocaine are becoming increasingly appreciated, but the direct effects of cocaine on acetylcholine receptors, synthetic enzymes, and degradative enzymes have been the focus of relatively little empirical investigation. Due to its genetic tractability and anatomical simplicity, the egg-laying circuit of the hermaphroditic nematode, *Caenorhabditis elegans*, is a powerful model system to precisely examine the genetic and molecular targets of cocaine *in vivo*. Here, we report a novel cocaine-induced behavioral phenotype in *Caenorhabditis elegans*, cocaine-stimulated egg-laying. In addition, we present the results of an *in vivo* candidate screen of synthetic enzymes, receptors, degradative enzymes, and downstream components of the intracellular signaling cascades of the main neurotransmitter systems that control *Caenorhabditis elegans* egg-laying. Our results show that cocaine-stimulated egg-laying is dependent on genes involving in cholinergic neurotransmission, but not those involved in neurotransmitter systems known to control the behavior. In addition, our data suggest that

cocaine's effect on *Caenorhabditis elegans* egg-laying may intersect with its known effects on locomotion.

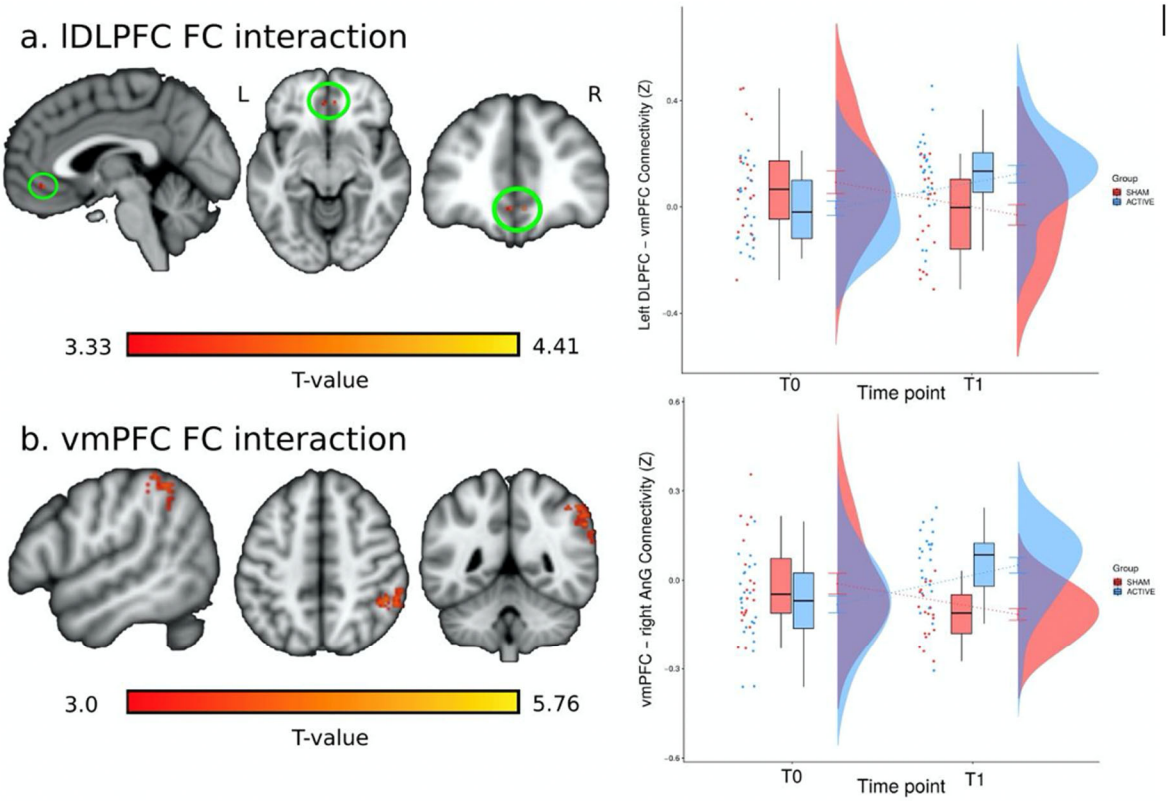
Abstract: Cocaine use disorder (CUD) is a global condition lacking effective treatment. Repeated magnetic transcranial stimulation (rTMS) is a technique that has shown promise by reducing craving and frequency of cocaine use, but little is known about its efficacy and physiological brain effects. Using a double-blind placebo-controlled randomized clinical trial (RCT) [NCT02986438], we sought to elucidate short- and long-term clinical benefits of 5-Hz rTMS as an add-on to standard treatment in CUD patients and discern underlying functional connectivity effects using magnetic resonance imaging. Forty-four randomly assigned CUD patients completed the 2-week double-blind acute phase [Sham (n=20, 2 female) and Active (n=24, 4 female)], in which they received 2 daily sessions of rTMS (5,000 pulses) on the left dorsolateral prefrontal cortex (lDLPFC). Subsequently, n=20 CUD patients continued to open-label maintenance (2 weekly sessions for up to 6 months). Measures were acquired at baseline, 2 weeks, 3 months and 6 months. Overall, 5-Hz rTMS plus standard treatment for 2 weeks significantly reduced craving (Sham group: baseline (T0), 2.6 SD: 2.8; 2 weeks (T1), 2.3 SD: 2.5 | Active group: T0, 3.9 SD: 3.6; T1, 1.5 SD: 2.4, p = 0.013, d=0.77) and impulsivity (Sham: T0, 60.8 SD: 17; T1, 59.8 SD: 21.4 | Active: T0, 64.8 SD: 16.8; 53.1 SD: 17.4, p = 0.011, d=0.79) in the Active group; decreased impulsivity correlated with increases in functional connectivity in lDLPFC-ventromedial PFC (vmPFC) (r=-0.35, p=0.02) and vmPFC-right angular gyrus (r=-0.34, p=0.03). Clinical and functional connectivity effects were maintained for 3 months but regressed

by 6 months of maintenance rTMS. We did not observe reduction of positive cocaine urine tests, however, self-reported frequency and grams consumed for 6 months were reduced.

Figure 1. Functional connectivity results of the acute phase.



a. lDLPFC-vmPFC significant interaction cluster; b. vmPFC-rAnG significant interaction cluster; right column shows the raincloud plots at each time point, where each data point represents the cluster's mean Z-value for each subject; lDLPFC = left dorsolateral prefrontal cortex; vmPFC = ventromedial prefrontal cortex; rAnG = right angular gyrus; FC = functional connectivity.

Title: Adolescent-onset oxycodone self-administration is associated with attenuated incubation of oxycodone craving in male rats

Authors: *K. T. GARCIA, R. D. ALTSHULER, X. LI;
Dept. of Psychology, Univ. of Maryland, Col. Park, College Park, MD

Abstract: Relapse is a major obstacle to curb the ongoing epidemic of prescription opioid abuse. We have previously demonstrated that oxycodone seeking in adult male rats progressively increases after abstinence from oxycodone self-administration (incubation of oxycodone craving). Although the onset of oxycodone use often occurs during adolescent, little is known about the effect of adolescent-onset opioid use on subsequent relapse behavior in adulthood. Here, we examined incubation of oxycodone craving in rats after adolescent-onset oxycodone self-administration. We trained adolescent (postnatal day 35 at start) and adult (postnatal day 77 at start) Sprague Dawley rats to self-administer oxycodone on a fixed ratio 1 schedule (0.1 mg/kg/infusion, 6 h/d for 10 d). Next, we tested both groups for relapse on abstinence day 1 and 15 after the last session of oxycodone self-administration. We found that adolescent rats self-administered less oxycodone during training, and exhibited decreased oxycodone seeking behavior on both abstinence day 1 and 15 compared with adult rats. These results demonstrated that incubation of oxycodone craving is attenuated in rats with adolescent-onset oxycodone self-administration, which is possibly due to decreased oxycodone intake during training. We are currently replicating these behavioral findings and will explore the neurobiological basis underlying these differences between adolescent and adult rats.

Title: The Effects of Adolescent Sucrose Exposure on Ethanol Self-Administration in Male and Female Adult Rats

Authors: J. WATSON[1], M. CRAWFORD[2], R. PARMAR[3], C. APPLING[4], L. EVANS[1], C. ALONSO[1], M. HOCHSTETLER[1], *A. M. GANCARZ[1];
[1]Psychology, California State University, Bakersfield, Bakersfield, CA; [2]Florida State Univ., Tallahasse, FL; [3]Biomed. Sci., Arizona State Univ., Tempe, AZ; [4]Univ. of Missouri, Columbia, MO

Abstract: Over the last 60 years, there has been a dramatic increase in the amount of sucrose that is consumed by all age groups. However, the greatest increase in sucrose consumption is seen in adolescents (Guthrie & Morton, 2000). Adolescence is a critical time of development that has been shown to influence adult drug use (Burke & Miczek 2014). Sucrose has been shown to activate the mesolimbic dopamine circuitry which is the reward circuity that is activated by drugs

of abuse (Volkow et al., 2012). Previous work from our lab and others indicates that exposure to sucrose in adolescence increases vulnerability to cocaine self-administration in adult male rats. Here, we sought to determine if adolescent sucrose exposure increases vulnerability to other drugs of abuse. We hypothesized both male and female rats that are exposed to sucrose in adolescence will self-administer more ethanol compared to water controls. To test this, rats were given noncontingent access to 10% sucrose solution or water (PND 28-42). Once the rats reached adulthood (PND 60), they were tested for ethanol self-administration for 16 days in 30-minute sessions. Active responses resulted in the delivery of 100 ul/presentation of 10% ethanol. Both male and female rats that were exposed to sucrose in adolescence administer a significantly greater number of infusions and emit significantly more active responses, but not inactive responses, compared to water controls. Taken together, these findings have important implications to the human condition, suggesting exposure to sucrose during the adolescent period may increase susceptibility to non-natural rewards in adulthood.

Title: Developmental impact of perigestational morphine exposure on the alcohol reward system of Sprague Dawley rats

Authors: *C. SEARLES, A. Z. MURPHY, H. HARDER, L. HANUS;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Approximately every fifteen minutes, a baby is born in the US experiencing neonatal opioid withdrawal syndrome (NOWS). NIDA reports that since 2004, the rate of NOWS has increased 5-fold. Remarkably, the long-term consequences of early life exposure to morphine are largely unknown. Clinical studies have established intrauterine exposure to drugs of abuse as a risk factor for adverse health outcomes in adult life, including propensity for drug use. Despite extensive knowledge about common mechanisms of action in the neural circuitry of reward that drive opioid and alcohol use, there is no data on the risks that those born with NOWS incur with alcohol use later in life. Here, we investigate the impact of perigestational opioid exposure on the mesolimbic reward system of male and female Sprague Dawley rats at postnatal and adolescent ages. To do so, our lab has developed a clinically relevant model for morphine exposure during early development spanning pre-conception to postnatal day 7. Using this model, we report age-specific changes in key components of the reward system, including mu opioid receptor (MOR) and potassium-chloride cotransporter (KCC2) expression. In addition, we explore microglia-

related expression and morphology in the VTA that have previously been shown to precipitate these changes. We also show changes in self-regulated alcohol consumption in perigestationally-exposed rats that is not a consequence of hyperactivity, as reflected in operant conditioning and open field testing.

Title: Maternal opioid exposure heterogeneously impairs offspring cognition and executive function in mice

Authors: *B. L. SMITH, C. J. LAAKER, A. FORD, A. HASSLER, T. M. REYES;
Pharmacol. & Systems Physiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: With the current U.S. opioid crisis, there is an epidemic of pregnant women using opioid drugs and a subsequent surge in the number of infants exposed to these drugs *in utero*. Opioid use during pregnancy has increased by more than 60% in the past decade. In humans, children born to mothers who reported opioid use during pregnancy often have cognitive delays, cognitive deficits, attentional problems, poor inhibitory control, and are more frequently diagnosed with ADHD. An animal model is required to understand the long-term consequences, develop interventions, and control for confounds in the clinical literature. To this end, we developed a maternal morphine model in mice and studied behavior and executive function in the offspring in 3 separate cohorts to enhance rigor. We treated female mouse dams with either saline (SAL, n = 7-11) or morphine (MO, n = 7-13) (10 mg/kg daily s.c.) starting 7 days prior to breeding, through gestation and lactation, until offspring were weaned on postnatal day (P)21. In the third cohort, we added a non-injected group of dams to control for the stress of daily injections (CON, n = 7). Experimenters were blinded for all offspring assessments.
To study executive function in adult offspring, we used the operant-based 5 choice serial reaction time task (5CSRTT). Male MO exposed offspring exhibited decreased motivation, decreased accuracy or correct responding, and a reduction in impulsive errors. Female MO offspring did not show these effects, but had increased impulsive errors and reduced sensitivity to the locomotion-depressing effects of MO when challenged as adults. One of our male MO cohorts did not have deficits in the 5CSRTT, but instead displayed a pattern of novelty-seeking behavior. We observed variability between cohorts, indicating that prenatal opioid exposure may induce heterogeneous effects between cohorts or serve as a subthreshold stimulus for inducing behavioral deficits. This makes it important to study other factors frequently present in opioid

using mothers.
Finally, we assessed gene expression after behavioral testing and in behaviorally-naïve cohorts at P1 and P21. In MO exposed offspring, we found evidence of microglial activation with increased expression of the Complement Receptor 3 (CR3) gene and toll like receptor genes in the prefrontal cortex at P21 and in the amygdala at P1. At P21, we found that maternal MO increased expression of the PSD95 gene, COMT, and PNOC in the prefrontal cortex, but not in the nucleus accumbens, amygdala, or ventral tegmental area. This is important because the COMT and PNOC genotype are implicated in NAS in humans, and COMT is related to executive function and ADHD.

Title: Prenatal Alcohol Exposure Reduces Power in a Translational Neurophysiological signal during Rodent Touchscreen Tasks

Authors: *S. L. OLGUIN[1], J. L. BRIGMAN[2];
[1]Univ. of New Mexico, albuquerque, NM; [2]Dept. of Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: Although it is well established that alcohol consumption during pregnancy can lead to poor outcomes in offspring, Fetal Alcohol Spectrum Disorders (FASD) remain the most common type of neurodevelopmental syndrome. The National Institutes of Mental Health (NIMH) has promoted the Research Domain Criteria (RDoC) initiative, which emphasizes the quantification of behavior more likely to reflect a specific neurophysiological circuit. Two domains that have been reported to be impaired in individuals with FASD include cognitive control utilizing a 5-Choice Continuous Performance Task (5C-CPT) and reward learning via probabilistic learning tasks (PLT). Importantly, these tasks can be integrated with electroencephalography (EEG) recordings in humans and dura-resting EEG-like recordings in rodents. Here, we integrated touchscreen analogs of these tasks with EEG-like recordings in a rodent prenatal alcohol exposure (PAE) model. Male and female mice were obtained from the NMARC where PAE is established via a drinking-in-the-dark model (10% EtOH with 0.066% saccharine for 4hrs/day throughout gestation; BAC: ~90mg/dL; controls=0.066% sweetened water, “SAC”). Beginning at 8-10 weeks, mice trained to touch white square target stimuli. Once responding rapidly and accurately mice underwent stereotactic surgery and fitted with dura-resting skull screws targeting

medial prefrontal, parietal, and motor cortices. After recovery and reminder to criterion, non-target trials (5 stimuli presented; withholding of response rewarded) were added at a 2:1 ratio for 5 days followed by recording at a 5:1 ratio for 12 days. Animals recorded on PLT for 5 days which consisted of 3 blocks of 20 trials with decreasing probability of reward (90/10, 80/20, and 70/30). Additionally, animals were recorded for 1 day on an additional task, progressive ratio breakpoint (PRBP), to examine the physical effort domain wherein PAE animals had to touch a single stimuli for progressively more responses in order to receive reward. We found that PAE impaired the ability to withhold responding to non-target stimuli during 5C-CPT and altered PLT performance at the most ambiguous probabilities. Importantly, when PAE animals displayed deficits in behavior, this tracked with decreases in power in relevant *a priori* regions of interest in the EEG-like signal. These results utilizing dura-resting EEG-like recording suggests that alterations in cortical activity can be used as a potential biomarker of PAE.

Title: Tolerance, dependence, and anti-addiction potential of endomorphin analog ZH853 following systemic administration in male rats

Authors: *A. T. AMGOTT-KWAN[1], J. E. ZADINA[1,2,3];
[1]Neurosci. Program, Tulane Brain Inst., New Orleans, LA; [2]Med. and Pharmacol., Tulane Univ. Sch. of Med., New Orleans, LA; [3]SE Louisiana Veterans HCS, New Orleans, LA

Abstract: Opioids continue to be the gold standard in pain treatment, but their long-term use is limited by side effects including addiction potential, tolerance, and drug dependence. We previously demonstrated the reduced tolerance of endomorphin analog ZH853 following chronic intrathecal infusion relative to that induced by morphine. Here, we expand our assessment of tolerance through a more clinically relevant model of systemic administration in male Sprague-Dawley rats. Dependence liability of ZH853 was also examined by assessing weight changes and withdrawal-induced mechanical hyperalgesia throughout 14 days of drug exposure and during spontaneous withdrawal. Chronic intravenous infusion led to reduced tolerance in ZH853-treated as compared to morphine-treated animals. Twice-daily injection of morphine inhibited normal weight gain, while ZH853 treatment had no effect on weight as compared to vehicle controls. Following cessation of drug administration, both morphine- and ZH853-treated rats exhibited weight loss, peaking at 48 hours into spontaneous withdrawal. Morphine-treated animals also exhibited withdrawal-induced mechanical hyperalgesia lasting several days, while no hyperalgesia was observed in ZH853-treated rats. These data further support the reduced

tolerance and dependence induced by ZH853 as compared to morphine. Lastly, current FDA approved opioid agonist therapies for opioid use disorder (OUD) are used to treat withdrawal symptoms during detoxification. The potential use of ZH853 as a treatment for OUD was investigated by measuring the ability of ZH853 administration to alleviate somatic signs of withdrawal in morphine-dependent male rats. Pretreatment of ZH853 led to a reduction in somatic signs of morphine withdrawal relative to vehicle-treated controls. Taken together, these findings support the potential use of ZH853 as a novel reduced side effect treatment for OUD.

Title: The Effects of Mitragynine, the Primary Mitragyna Speciosa (Kratom) Alkaloid, on Withdrawal from and Tolerance to Morphine in Rats.

Authors: ***J. D. ZUARTH GONZALEZ**[1], A. PATEL[1], R. C. PATEL[1], M. A. PATEL[1], L. R. GAMEZ-JIMENEZ[1], N. P. HO[1], F. LEON[2], M. MOTTINELLI[2], C. R. MCCURDY[2], L. R. MCMAHON[1], T. HIRANITA[1];
[1]Pharmacodynamics, [2]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: *Mitragyna speciosa* (kratom) has been used traditionally for centuries in Southeast Asian countries. Anecdotal evidence suggests that kratom is used to treat opioid dependence. However, scientific evidence to support the medical use of kratom is not firmly reported. The aim of the study was to assess preclinical efficacy of mitragynine (MG) against the expression and development of tolerance to and withdrawal from morphine (MOR) in Sprague-Dawley rats (eight rats per group). On day 1, a dose-effect function of MOR-induced antinociception (cumulative 1.0-56 mg/kg, i.p., every 15 min) was assessed using a hotplate assay at 52°C. On days 2-5, MOR tolerance and naltrexone induced withdrawal were produced by increasing MOR doses 10 mg/kg/day (10-40 mg/kg, b.i.d., every 12 hours). On day 6, a second dose-effect function reassessed MOR's potency to induce antinociception. On day 7, the presence of diarrhea as a withdrawal sign was assessed prior to and 30 min after an injection of the opioid antagonist naltrexone (10 mg/kg, i.p.). MOR tolerance development was demonstrated by a 7.9-fold rightward shift to the antinociceptive potency of MOR. Concomitant administration of 32 mg/kg mitragynine with MOR during the tolerance/withdrawal development regimen, decreased the rightward shift by 2.1 fold. Spontaneous withdrawal was not observed following the withdrawal

development regimen of MOR alone; however, diarrhea was induced by naltrexone in 100% of dependent rats. In MOR tolerant/dependent rats, MG (32 and 56 mg/kg) on days 6 and 7 did not affect the expression of antinociceptive tolerance to MOR but dose dependently decreased the expression of naltrexone-induced diarrhea by up to 50%. The effects of MG on the expression of tolerance to and withdrawal from MOR were further compared to those of FDA-approved medications for opioid dependence and withdrawal (buprenorphine and lofexidine). Buprenorphine, the μ-opioid receptor partial agonist, (1.0 mg/kg, i.p.) produced a 3.5-fold increase in tolerance to the MOR-induced antinociception and decreased naltrexone-induced diarrhea by 25%. In addition, lofexidine, the α_2-adrenergic agonist, (1.0 mg/kg, i.p.) produced a 4.0-fold decrease in tolerance to the MOR-induced antinociception and fully blocked naltrexone-induced diarrhea. Concomitant administration of MG with MOR effectively attenuated the development of MOR tolerance. Similarly to lofexidine, acute MG decreased the expression of naltrexone induced diarrhea. The results support the potential of MG as a medication to attenuate the development of opioid tolerance and treat the symptoms of opioid withdrawal.

Title: The effect of chronic cocaine administration on allopregnanolone levels in male and female rat brain and serum

Authors: ***M. H. MCFARLAND**[1], G. M. SANSBURY[2], M. M. F. MACHADO[4], T. K. O'BUCKLEY[2], G. BOERO[2], A. MORROW[2], D. L. ROBINSON[3];
[1]Univ. of North Carolina at Chapel Hill, Chapel hill, NC; [3]Bowles Ctr. for Alcohol Studies, [2]Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [4]Univ. Federal de São Paulo, São Paulo, Brazil

Abstract: Neurosteroids are compounds synthesized within the brain that influence neuronal activity, in part, via actions at γ-aminobutyric acid type A ($GABA_A$) receptors. Altered brain and serum levels of neurosteroids are associated with multiple psychiatric disorders. Furthermore, the endogenous GABAergic steroid (3α,5α)-3-hydroxy-5-pregnan-20-one, or allopregnanolone, a metabolite of progesterone, has emerged as a clinically beneficial therapeutic for the treatment of different diseases, which include post-partum depression, as well as substance use disorders. Although allopregnanolone has been shown to reduce cocaine-seeking and reinstatement in rats,

the underlying mechanism remains unclear. Additionally, increasing allopregnanolone levels via progesterone administration in cocaine-dependent individuals resulted in reduced cocaine craving and stress-induced arousal. Furthermore, studies have shown that chronic cocaine use was correlated with decreased levels of pregnenolone, a precursor to allopregnanolone. In this study, we hypothesized that chronic cocaine exposure in male and female rats would result in decreased levels of allopregnanolone in serum and brain regions involved in dopaminergic transmission and neurosteroidogenesis, such as olfactory tubercle, prefrontal cortex, dorsal and ventral striatum, and midbrain. To determine whether chronic cocaine use would decrease allopregnanolone levels, we administered 15mg/kg cocaine or saline to Sprague-Dawley rats daily for 14 days. We recorded locomotor activity and stereotyped behavior each day to assess for cocaine sensitization. We extracted allopregnanolone from brain tissue and serum and measured concentration with ELISA. Preliminary analysis (n=4 rats/sex/group) revealed no differences in allopregnanolone levels between cocaine and saline groups in any brain regions that were analyzed. However, females showed higher levels of allopregnanolone in serum and all brain regions examined except for ventral and dorsal striatum (main effect of sex, $p<0.05$). Furthermore, cocaine-exposed males presented no significant differences in serum allopregnanolone levels compared to saline controls (n=8 rats/sex/group) ($p<0.05$). These findings revealed that allopregnanolone levels vary across brain regions and by sex, which may play a part in sex differential responses to stress.

Iberoamericana, Mexico City, Mexico; [5]Psychology, Univ. Iberoamericana, A. C., Mexico, Mexico; [6]Univ. of Texas at El Paso, El Paso, TX

Abstract: Methylphenidate (MPD) is the main treatment for the attentional deficit and hyperactivity disorder (ADHD), but also it is widely misused as a psychostimulant. Most of the users usually start consuming during adolescent years when brain development continues. It has been reported several negative effects because of early exposure to psychostimulants. The lasting effects include behavioral impairments such as sensitization and obsessive drug-seeking,

cognitive impairments, mainly in memory and executive functions, and psychiatric disorders such as depression and anxiety. Socialization has been linked to cognitive improvement, increases neurogenesis and as a protector for developing psychiatric disorders. Our study aimed to evaluate the effect of socialization on these lasting negative effects of early exposure to methylphenidate. Twenty-eight male rats (34 days-old) were divided into 4 groups, socialization + methylphenidate, socialization + saline, isolated + methylphenidate, and isolated + saline. All four groups received methylphenidate (1.5 mg/kg) or saline (2ml/kg) intraperitoneal administration for 20 days twice a day. Animals were housed isolated or in a group depending on their group condition. All rats remained undisturbed until 90 days-old when memory and anxiety-like were evaluated. We hypothesize there will be significant differences between socialization and individual groups treated with MPD, and between individual conditions but there will not be significant differences between both socialization groups.

Title: The role of habitual behavior in punishment resistance differs for food and cocaine self-administration

Authors: *B. JONES, R. SMITH;
Texas A&M Univ., College Station, TX

Abstract: Addiction is characterized by compulsive drug use that persists even when faced with negative consequences. In animal models of addiction, some rats display a similar type of compulsive drug use and continue to self-administer IV cocaine despite receiving footshock. Recent work from our lab has demonstrated that punishment resistance is associated with increased utilization of a habitual response strategy, whereas punishment sensitivity is associated with increased utilization of a goal-directed strategy. Here, we wanted to investigate whether punishment would induce similar patterns of response-strategy switching in rats self-administering food. Male Sprague Dawley rats were trained on a seeking-taking chained schedule of reinforcement, in which presses on a seeking lever gave access to a separate taking lever. The seeking link of the chain required completion of a random ratio (RR20) or random interval (RI60) schedule, and the taking link was reinforced with either a food pellet or IV cocaine (0.5 mg/kg) under a fixed ratio (FR1) schedule. Following at least 12 days on the final seeking-taking reinforcement schedule, animals were exposed to 4 days of punishment testing, in which footshock (0.4 mA, 0.3 s) was delivered randomly on one-third of trials following

completion of seeking and prior to extension of the taking lever. Both before and after punishment testing (4 days prior to punishment, and then 4 days after rats had resumed self-administration), response strategy was assessed using outcome devaluation via satiety. Satiety was induced via pre-session access to food pellets (for food self-administering rats) or noncontingent IV cocaine (for cocaine self-administering rats). We found increased punishment resistance in rats trained to self-administer food, as compared to cocaine. Interestingly, punishment resistance for food self-administration was not associated with increased utilization of a habitual response strategy, unlike what we observed for cocaine self-administration. Therefore, punishment resistance in food self-administering rats appears to be goal-directed, while punishment resistance in cocaine self-administering rats is associated with increased habitual behavior. Together, these data indicate that punishment learning may be different for cocaine and food rewards, and that persistent habits may be a unique feature of compulsive cocaine seeking.

Title: The Role of ΔFosB in the Development of Drug Addiction: Identifying ΔFosB Transcriptional Targets in Nucleus Accumbens

Authors: *S.-Y. YEH, M. S. ESTILL, C. K. LARDNER, L. SHEN, E. J. NESTLER;
Nash Family Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Drug addiction exacts devastating impact on drug users and a tremendous burden on their family members, the economy, and the nation's public health. Although different in chemical structures and initial mechanisms affecting the brain, all classes of drugs of abuse induce the expression of the transcription factor ΔFosB in nucleus accumbens (NAc), the central node of the reward circuit. Genetically overexpressing ΔFosB in mouse NAc neurons increases cocaine-elicited compulsive behaviors, suggesting that the expression of ΔFosB in NAc is involved in the development of addiction. However, the molecular mechanisms of ΔFosB remain incompletely understood. Here, we extend early work on revealing ΔFosB transcriptional targets with chromatin immunoprecipitation (ChIP)-chip methodology, which interrogated promoter regions only, by leveraging the newer ChIP method, CUT&RUN (cleavage under targets and release using nuclease), to locate genomic loci with ΔFosB coverage genome-wide upon chronic cocaine exposure. Male and female mice ~8 to 10 weeks of age underwent 7 days of intraperitoneal cocaine or saline injections, and bilateral punches of NAc were collected 24 hours

after the last administration. Nuclei were isolated from NAc tissue with discontinuous sucrose gradients and subjected to CUT&RUN procedures. Thousands of ΔFosB binding sites were revealed through this approach, and, interestingly, one third of the loci are positioned at distal intergenic regions while less than 10 percent of the peaks are placed within 1 kilobase from known transcription start sites, suggesting that a primary function of ΔFosB is coordinating distal regulatory elements with transcription machinery. NAc is composed mainly of medium spiny neurons (MSNs) expressing either dopamine receptor D1 or D2; ΔFosB is prominently induced in D1-type MSNs after most drugs (only opioids induce ΔFosB in both cell types), and directs differential synaptic plasticity in these two types of neurons. Further extension of this CUT&RUN approach to D1- and D2-type MSNs within NAc will set the groundwork for understanding distinct roles of MSNs, and their adaptations to chronic drug exposure, in drug addiction.

Title: Drug-induced glutamate-to-GABA neurotransmitter switching impacts behavior

Authors: *M. PRATELLI[1,2], N. C. SPITZER[1,2];
[1]UC San Diego, San Diego, La Jolla, CA; [2]Ucsd, Kavli Inst. for Brain & Mind, San Diego, La Jolla, CA

Abstract: Repeated exposure to drugs of abuse influences brain activity and induces maladaptive neuroplastic changes that have been consistently associated with the appearance of drug-induced behavioral alterations. Some of these changes (e.g. altered neuronal activity in the prefrontal cortex) can be induced by drugs that have different targets but similar behavioral consequences. Neurotransmitter switching is a form of environmentally-induced neuroplasticity in which a subset of neurons loses its neurotransmitter and/or gains a different one. It is commonly triggered by sustained changes in neuronal activity and has been shown to modify behavior. Here we investigated whether exposure to drugs induces neurotransmitter switching and whether this causes drug-induced behavioral changes. We focused our experiments on two substances: phencyclidine (PCP) and methamphetamine. Although PCP is an NMDA receptor antagonist and methamphetamine increases monoamine signaling, both drugs acutely produce an increase in neuronal activity in the prefrontal cortex and cause cognitive deficits as well as locomotor sensitization. We used mice that express a Cre-dependent H2B-mCherry reporter and

a Cre recombinase under the promoter of the vesicular glutamate transporter 1 (vGluT1) to permanently label glutamatergic neurons. This allowed us to discover that both PCP and methamphetamine induce a subset of glutamatergic neurons in the prelimbic cortex (PrL) to acquire a GABAergic phenotype. Indeed, these neurons gain the expression of GABA, its synthetic enzyme GAD67, and its vesicular transporter, while at the same time showing a reduced expression level of vGluT1 compared to other glutamatergic neurons in this region. We then focused on PCP-treated mice to determine if this transmitter switch plays a role in PCP-induced changes in behavior. To prevent glutamatergic neurons from gaining GABA upon PCP exposure, we stereotaxically injected a Cre-dependent AAV expressing GAD1sh-interference-RNA in the PrL of vGluT1::Cre +/- mice. Remarkably, this prevented the appearance of PCP-induced cognitive deficits in the novel object recognition test, the spontaneous alternation task, as well as PCP-induced locomotor sensitization. These results identify a causal link between the gain of GABA in glutamatergic pyramidal neurons and PCP-induced behavioral alterations. We are now using a chemogenetic approach to selectively activate parvalbumin-positive PrL interneurons during PCP treatment, to test if manipulation of neuronal activity can suppress PCP-induced neurotransmitter switching and behavioral deficits. Abstract: Drug addiction is a multifactorial syndrome in which genetic predispositions and environment stress exposure constitute major risk factors for early onset, escalation and relapse of addictive behaviors. While it is well known that both social and non-social stressors play a key role in drug addiction, the genetic factors that make certain individuals particularly sensitive

to stress and thereby more vulnerable to become addicted are unknown. In an effort to map a complex set of G x E interactions—specifically *Gene x Chronic Stress*—here we leveraged a systems genetics resource: BXD recombinant inbred mice (BXD5, BXD8, BXD14, BXD22, BXD29 and BXD32) in addition to their C57BL/6J and DBA/2J parental lines. Utilizing the chronic social defeat stress paradigm (CSDS), we first showed that DBA/2J and BXD22 male and female mice are more susceptible to chronic social stress than C57BL/6J mice, as evidenced by stronger social avoidance and anxiety-like behaviors. Further, we observed sexual dimorphisms in response to CSDS amongst the BXD5, BXD8, BXD14, BXD29 and BXD32 lines. To investigate the interaction between genetics and vulnerability to prolonged exposure to non-social stressors, we exposed C57BL/6J, DBA/2J, BXD8, BXD22 and BXD29 male and female mice to the chronic variable stress paradigm (CVS). We observed that DBA/2J female mice are more sensitive to CVS when compared to C57BL/6J female mice (i.e., strong decrease in sucrose preference). Confirming the stress vulnerability of BXD22 mice observed after CSDS, BXD22 male and female mice after CVS displayed higher levels of anxiety-like measures than C57BL/6J mice. Interestingly, while BXD29 mice behaved like C57BL/6J after CSDS, both BXD29 female and male mice developed a higher anxiety profile following CVS when compared to C57BL/6J mice. Finally, we identified that DBA/2J and C57BL/6J mice pre-exposed to CSDS displayed differences in morphine sensitivity. Our results support the hypothesis that genetic variations in predispositions to stress responses influence sensitivity to morphine and *in fine* regulate the development of drug addiction. Characterization of the genetic, neurobiological, social and environmental factors that mediate addiction risk will fundamentally improve our understanding of individual variations in responses to drugs of abuse, and provide highly useful information for the development of new treatment strategies and eventually prevention measures.

Abstract: Cocaine use disorder (CUD) is a highly prevalent neuropsychiatric disease characterized by compulsive drug taking and repeated relapse. Despite the public health burden of CUD, there remains no FDA-approved medications for this brain disease. Identifying effective treatments for CUD is hindered by an incomplete understanding of which genes are most important in mediating addiction pathophysiology. In this study, we performed unbiased transcriptional network analysis on a published RNA sequencing (RNA-seq) dataset from 6 different brain regions of animals that underwent cocaine self-administration followed by prolonged (30 d) withdrawal plus relapse to identify gene networks associated with individual differences in addiction-like behavior. We ranked modules by their fold enrichment in genes whose expression is significantly correlated with an "addiction index" (AI), a composite score developed by machine learning to capture maladaptive, addiction-like behaviors during cocaine self-administration. We identify phosphodiesterase 1b (*Pde1b*), a Ca^{2+}/calmodulin-dependent enzyme that catalyzes the hydrolysis of cAMP and cGMP, as the strongest hub gene in module 504 (arbitrary number) in nucleus accumbens (NAc), the module with the strongest association with the AI of all gene modules in this brain region. To investigate the role of *Pde1b* in modulating addiction pathophysiology, we will pair clustered regularly interspaced short palindromic repeats (CRISPR)-based transcriptional regulation tools with viral delivery methods to selectively regulate *Pde1b* expression in the NAc. Our ongoing studies seek to validate that the CRISPR tools achieve robust and selective *Pde1b* regulation *in vitro* and *in vivo*. In future studies, we will investigate the effects of *Pde1b* regulation on addiction-like behaviors in mouse models of CUD. Given successful drug discovery efforts focused on other PDE isoforms, this work raises a novel therapeutic approach for this illness.

Title: Electrophysiological characterization of muscarinic excitation of dopamine neurons in the ventral tegmental area

Authors: *R. Y. CHEN[1], J. M. ELTIT[1], A. R. MCQUISTON[2];
[1]Physiol. & Biophysics, [2]Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Dopaminergic (DA) neurons in the ventral tegmental area (VTA) play a crucial role in reward and motivational behaviors, including the development of drug addictions. VTA DA neurons receive excitatory cholinergic inputs. Blockage of the M5 muscarinic receptor in DA neurons has been shown to attenuate drug-induced DA release and abuse-related behaviors, but the molecular mechanism is unknown. In this study, experiments were designed to identify the electrophysiological effects of muscarinic agonism involved in the modulation of action potential kinetics and firing patterns in VTA DA neurons. Whole-cell current-clamp and cell-attached patch-clamp experiments were performed on acute midbrain slices prepared from C57BL/6 mice (P14-P31). VTA DA neurons were identified by anatomical location, cell morphology, and electrophysiological properties. Muscarinic receptors were stimulated or inhibited by bath perfusion of the non-selective cholinergic agonist carbachol and the muscarinic antagonist atropine, respectively. In the presence of tetrodotoxin (TTX), carbachol depolarized membrane potential (by 2.68 ± 0.38 mV, n = 32) and decreased input resistance. Moreover, carbachol increased tonic firing frequency (by 1.72 ± 0.34 Hz, n = 12) without affecting firing regularity, frequency-current relationship, and HCN sag ratio in VTA DA neurons. Together with the depolarization, carbachol altered the shape of action potentials: this effect was reversed by restituting the original membrane potential using the clamping circuit. Atropine preapplication inhibited carbachol effects in all experiments. In addition, carbachol had no effects on sIPSCs in VTA DA neurons. Collectively, the current evidence suggests that activation of HCN channels, inhibition of potassium channels, and changes in inhibitory synaptic inputs do not mediate the carbachol-induced depolarization in VTA DA neurons, but points toward the participation of TTX-insensitive cation channels in this muscarinic receptor-mediated excitation.

Title: Structural coherence of white-matter projections to the nucleus accumbens predicts relapse to stimulant drug use in humans

Authors: L. TISDALL[1], ***K. H. MACNIVEN**[1], J. K. LEONG[2], B. KNUTSON[1];
[1]Psychology, Stanford Univ., Stanford, CA; [2]Psychological Sci., Univ. of Arkansas, Fayetteville, AR

Abstract: Nucleus Accumbens (NAcc) activity can predict relapse to stimulant use. Whether such functional associations are subserved by differences in the coherence of white-matter connections projecting to and modulating activity in the NAcc, however, is less clear. Previously, we found coherence metrics of ascending dopaminergic midbrain projections to the NAcc to be related to diagnosis of stimulant use disorder (SUD), but not relapse (MacNiven et al., 2020). Here, we tested whether the structural coherence of glutamatergic projections connecting the Medial PreFrontal Cortex (MPFC), Anterior Insula (AIns), and Amygdala (Amy) to the NAcc might predict relapse to stimulant use.
We analyzed Diffusion-Weighted Imaging data from a sample of 40 healthy controls (57% male, 32.7±11.8 years old) and 70 patients with SUD (81% male, 41.4±11.7 years). At 6 months follow-up, we retained comparable sub-samples of individuals who had abstained (n = 30, 80% male, 39.5±12.5 years) and who had relapsed (n = 28, 86% male, 42.3±10.9 years). To address methodological challenges such as crossing fibers and inter-subject anatomical variability, we fit a constrained spherical deconvolution model and conducted probabilistic tractography in individuals' native space. This method successfully resolved all of the sample's white-matter tracts. We subsequently tested if structural properties indicative of tract coherence (i.e., inverse radial diffusivity (1-RD)) could predict relapse 6 months after treatment release.
Correcting for multiple comparisons via permutation testing, lower 1-RD (i.e., lower coherence) in a cluster along the right AIns tract predicted relapse (OR = 0.41, z = -2.54, p = 0.01). Additionally, lower 1-RD in a cluster along the left Amy tract also predicted relapse (OR = 0.52, z = -2.12, p = 0.03). In contrast, MPFC-NAcc tract coherence did not predict relapse (but declined with age). Our results hold when controlling for age, gender and motion, as well as for other coherence metrics. Crucially, none of these coherence metrics were associated with SUD diagnosis.
Our findings suggest that structural properties of specific white-matter tracts are selectively associated with relapse to stimulant use but not diagnosis, and thus identify novel targets for prediction of relapse. The implication of structural projections from the AIns to the NAcc points toward incentivized inhibition as a potential mechanism for relapse, rather than aberrant value integration commonly associated with MPFC-NAcc projections. Future research may test these predictions by linking structural tract properties to functional brain activity and risky behavior in the context of relapse.

Title: Long-term Withdrawal from Compulsive Oxycodone Taking Results in Dose-Dependent Changes in Glutamate Receptor Expression in the Hippocampus

Authors: *A. J. SALISBURY, C. A. BLACKWOOD, J. L. CADET;
Mol. Neuropsychiatry, Natl. Inst. on Drug Abuse IRP, Baltimore, MD

Abstract: People suffering from opioid use disorder (OUD) exhibit cognitive dysfunctions. Cognitive dysfunctions have been shown to be accompanied with altered expression of glutamate receptors in the brain. AMPA, NMDA, and metabotropic glutamate receptors are important for many types of synaptic plasticity in the hippocampus. They are important for consolidation of memory and are thus promising targets for understanding drug seeking and relapse following long-term withdrawal. Yet, it is still unclear if altered expression of these receptors might occur in those who suffer from opioid use disorder. As a first step towards testing that possibility, we measured the expression of glutamate receptors in the hippocampi of Sprague-Dawley rats that had undergone oxycodone self-administration (SA). Rats were euthanized at 2 hours or 30 days after the last SA session. RNA was extracted from the hippocampi of rats and used in quantitative polymerase chain reaction (qPCR) analyses. We found that rats given long-access (LgA) to oxycodone took significantly more drug than short-access (ShA) rats. We were able to separate LgA rats into two separate phenotypes of high oxycodone intake (LgA-H) and low intake (LgA-L) rats. Quantitative PCR revealed that LgA rats exhibited increased mRNA expression of *GluA1-3, GluN2a-c, mgluR3, mGluR5, mGluR6,* and *mGlur8* subunits of glutamate receptors after 31 days but not after 2 hours of stopping the SA experiment. These results suggest that prolonged withdrawal from oxycodone SA may be associated with significant changes in glutamate receptor protein compositions. These studies offer additional insight into the potential basis of oxycodone-associated changes in learning and memory observed in some individuals who suffer from OUDs. These results suggest the need for more post-mortem studies focused on the hippocampus of patients who met diagnostic criteria for these disorders.

Title: A gradual backward shift of dopamine responses during associative learning

Authors: *R. AMO[1], A. YAMANAKA[2], K. F. TANAKA[3], N. UCHIDA[1], M. WATABE-UCHIDA[1];
[1]Dept. of Mol. and Cell. Biology, Ctr. for Brain Sci., Harvard Univ., Cambridge, MA; [2]Res. Inst.

Abstract: It has been proposed that the activity of dopamine neurons approximates temporal difference (TD) prediction error, a teaching signal developed in reinforcement learning theories. However, whether this similarity holds true during learning remains elusive. In particular, some TD learning models predict that the error signal gradually shifts backward in time from reward delivery to a reward-predictive cue. However, such a shift has not been demonstrated experimentally. In this study, we examined conditions in which such a shift can be detected. We sought to optimize our experimental conditions such that we can observe even a small signal on a trial-by-trial basis. To this goal, we used the methods that integrate signals from a large population of neurons (fiber fluorometry) and across time (i.e. slow measurements using calcium indicator or dopamine sensor). To resolve signals over time, we included a relatively long delay (e.g. 3 sec) relative to the sensors. Using these methods, we were able to detect a small "bump" between cue and reward on a trial-by-trial basis. As a result, we reliably observed a gradual backward shift of dopamine activity in the ventral striatum during learning of novel odor-reward association in naïve as well as in well-trained mice (naïve: 3.9±0.3 ms/trial, $p = 0.16 \times 10^{-4}$, n = 7 mice; well-trained: 9.4±0.9 ms/trial, $p = 0.65 \times 10^{-3}$, n = 5 mice) or reversal learning (nothing to reward: 27.1±1.6 ms/trial, $p = 0.37 \times 10^{-2}$, n = 3; air puff to reward: 30.2±4.8 ms/trial, $p = 0.33 \times 10^{-2}$, n = 5 mice). Our modeling confirms that integrating signals over time using slow measurements can indeed facilitate a detection of such a small and time-spread activity. These results establish that, at least in some conditions, a gradual backward shift of dopamine responses, a long-sought link between TD learning and dopamine activity, can be observed during associative learning. The shared dynamics of TD error and dopamine activity provide a critical evidence supporting the TD account of dopamine signals.

Title: Reward-specific ensembles in the nucleus accumbens core.

Authors: *A.-C. BOBADILLA[1], E. DERESCHEWITZ[2], L. VACCARO[1], J. HEINSBROEK[4], M. D. SCOFIELD[3], P. W. KALIVAS[2];
[1]Univ. of Wyoming, Laramie, WY; [2]Neurosci., [3]Anesthesia and Perioperative Medecine, Med. Univ. of South Carolina, Charleston, SC; [4]Dept. of Anesthesiol., Univ. of Colorado Denver, Anschutz Med. Campus, Aurora, CO

Abstract: Poorly regulated reward seeking is a central feature of substance use disorder. Recent research shows that rewarding drug-related experiences induce synchronous activation of a discrete number of neurons in the nucleus accumbens that are causally linked to reward-related contexts. Here we comprehensively characterize the specific ensemble of neurons built through experience that are linked to seeking behavior. We additionally address the question of whether or not addictive drugs usurp the neuronal networks recruited by natural rewards by evaluating cocaine- and sucrose-associated ensembles within the same mouse. We used $Fos^{CreERT2/+}$/Ai14 transgenic mice to tag cells activated by and potentially encoding cocaine and sucrose seeking. We tagged ~1% of neurons in the core subregion of the accumbens (NAcore) activated during cue-induced seeking for cocaine or sucrose. The majority of tagged cells in the seeking ensembles were D1-MSNs, and specifically activated during seeking, not during extinction or when mice remained in the home cage. To compare different reward-specific ensembles within the same mouse, we used a dual cocaine and sucrose self-administration protocol allowing reward-specific seeking. Using this model, we found ~70% distinction between the cells constituting the cocaine- compared to the sucrose-seeking ensemble. Establishing that cocaine recruits an ensemble of NAcore neurons largely distinct from neurons recruited into an ensemble coding for sucrose seeking suggest a finely tuned specificity of ensembles. The findings allow further exploration of the mechanisms that transform reward-based positive reinforcement into maladaptive drug seeking.

Title: Ventral Pallidal GABAergic Neuronal Activity Encodes Instrumental Reward Cues and Reward Anticipation

Authors: *A. SCOTT, D. PALMER, J. RICHARD;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Environmental cues are powerful modulators of motivated behavior. The ventral pallidum (VP) is a key neural node contributing to cue-driven motivated behaviors. Many VP neurons are excited by instrumental reward cues and the strength of this response in a subset of neurons predicts reward seeking behavior. However, the specific VP neuronal populations (cell-type and output pathways) involved in instrumental cue-driven reward seeking are unknown. Recent recordings from VP during a Pavlovian task found that cue- and reward-excited neurons are largely GABAergic, whereas cue- and reward-inhibited neurons are glutamatergic. Therefore, we hypothesized that cue-evoked responses in VP GABA neurons encode the vigor of cue-elicited reward-seeking in an instrumental task. To test this, we recorded calcium activity of VP GABA neurons using *in vivo* fiber photometry during an instrumental reward seeking task, the discriminative stimulus (DS) task. Male and female Long-Evans rats (n=6 per sex) underwent stereotaxic surgery a month before behavioral training started. VP GABA neurons were targeted using a mixture of one virus expressing cre recombinase under the control of the GAD1 promoter along with a cre-dependent virus for the genetically encoded calcium indicator GCaMP6f. Bulk calcium-dependent and independent signals were recorded via optic fiber implants that were inserted during surgery. Rats were trained to perform the DS task, where an auditory cue (the DS) is associated with availability of a 10% sucrose solution. Sucrose is delivered if the animal makes a port entry during the DS. A neutral stimulus (NS) is introduced after initial DS training and is never associated with reward delivery. As expected, we found that DS cues increased VP GABA neuronal calcium activity relative to the NS control cue. Additionally, these responses emerged across training as animals learned the task. VP GABA neurons also developed a post-port entry increase in calcium activity, at the time that reward is normally delivered. Interestingly, post-port entry responses were present even on trials where reward delivery is omitted. This suggests that this post-port entry VP GABA neuron response encodes reward anticipation or expectation rather than consumption or hedonic evaluation. Altogether, these data show VP GABA neurons encode information imperative for instrumental reward-seeking behaviors. Further research will examine downstream targets of VP GABA neurons and the functional role this population plays in reward seeking and consummatory behavior.

Title: Stress effects on prefrontal cortical function and effortful reward-seeking behavior

Authors: *P. K. PAREKH, J. KAMINSKY, J. ROSHGADOL, S. JOHNSON, C. XIA, C. LISTON;
Weill Cornell Med., New York, NY

Abstract: Title: Stress effects on prefrontal cortical function and effortful reward-seeking behavior
Deficits in effort valuation (EV), a cost-benefit analysis comparing the magnitude of anticipated rewards with effort expenditure required, are associated with psychiatric conditions including depression and schizophrenia. Exposure to chronic stress serves as a risk factor for the development of depressive symptoms such as anhedonia, which is characterized by impairments in reward processing and diminished EV. Prefrontal cortical function is critical to support EV however distinct projection pathways may encode varying aspects of learned reward and effort expectations to modulate behavior. In order to define the circuit mechanisms contributing to effortful reward seeking, mice were trained in a novel head-fixed EV task which allowed for simultaneous in vivo 2-photon calcium imaging. Corticostriatal neurons were targeted for imaging and found to exhibit statistically significant reward-predictive cue encoding, as expected. A comparatively smaller proportion of corticostriatal neurons were activated in response to an effort-predictive cue. High-dimensional encoding of reward-predictive cues was also determined by accurate decoding from population activity, while effort cue decoding remained largely at chance level. In order to model anhedonia-relevant behaviors, mice were exposed to chronic social defeat stress (CSDS) for 10 days and tested again in the EV task. Overall, mice showed reduced motivational and consummatory effortful reward seeking behavior following stress, with notable individual variability. The effects of CSDS on EV were uncorrelated with social interaction scores. CSDS also reduced the accuracy of decoding rewarded trials from corticostriatal population activity specifically during the reward consumption period. Ongoing studies are focused on comparing the roles of different PFC projection pathways in reward- and effort-predictive cue encoding and the effect of chronic stress on these circuits.

Title: Motor and reward-related computation on the cerebellar-nigral pathway

Authors: *J. YOSHIDA[1], S. WASHBURN[1], M. OÑATE[1], V. LOVALLO[1], F. NADIM[2], K. KHODAKHAH[1];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]New Jersey Inst. of Technol., Newark, NJ

Abstract: The cerebellum and substantia nigra pars compacta (SNc) contribute to motor control, and their dysfunction contributes to abnormal motor function (e.g., ataxia and Parkinson disease). We have recently found that the deep cerebellar nuclei (DCN, the main output of the cerebellum), send monosynaptic, excitatory projections to the SNc (DCN-SNc). The nature of the "information" that the cerebellum provides to the SNc remains to be established. As a first step to address this question, we measured calcium as a proxy for neuronal activity in DCN axons within the SNc, while the animal moved a lever or, as it performed a Pavlovian task. We found that 1) the DCN-SNc projections were bilaterally active when the animal unilaterally moved the lever, 2) In a simple Pavlovian task where reward was delivered at a same time as a sensory stimulus, the DCN-SNc projections showed robust activity with reward delivery, but not when reward was omitted, 3) In a random reward Pavlovian task where the value of the reward was changed concomitant with the same sensory stimulus, the DCN-SNc activity was correlated with the reward value, 4) The higher activity of the DCN-SNc projections when higher value rewards were delivered could not be solely attributed to difference in motor performance. Our findings suggest that in addition to conveying motor-related information, the cerebellum to the substantia nigra pathway may also contain information regarding reward, and its value. How and whether this information is used in reward processing, or in modulating movement vigor requires further scrutiny.

Abstract: The ability of animals to learn to associate environmental stimuli with the outcomes they predict is crucial for survival. The basolateral amygdala (BLA) is important for forming associations between predictive stimuli and either positive or negative outcomes. Release of the neuromodulator acetylcholine (ACh) is known to be related to learning and the BLA receives an abundance of cholinergic input, especially from the nucleus basalis of Meynert (NBM). During a cue-reward learning task, in which mice were trained to nose poke following an auditory tone to receive food reward, we recorded cholinergic signaling in the BLA. Convergent fiber photometric results using a genetically encoded fluorescent ACh sensor and a calcium indicator in NBM cholinergic terminal fibers in the BLA (NBM-BLA) showed that BLA ACh was released following reward-related events, and eventually shifted to the reward predictive tone as mice acquired the cue-reward contingency. Incorrect responses that resulted in punishment initially elicited BLA ACh release as well, but diminished as behavioral performance improved. Given the time-locking and plasticity observed in BLA ACh signaling in response to salient events during cue-reward learning, we hypothesized that manipulating cholinergic signaling would affect learning. Optogenetic stimulation of NBM-BLA cholinergic terminal fibers during learning enhanced acquisition rate and decreased incorrect responses compared to controls. Interestingly, this improvement in learning was observed when stimulation was contingent and non-contingent with behavior. Nicotine administration also led to a modest improvement in performance. We combined optogenetic stimulation with fluorescent ACh sensor recordings to compare differences in endogenous and evoked ACh release. In conclusion, BLA ACh signaling is important for cue-reward learning but the precise relationship between timing of release and the effect in the BLA of this cholinergic signaling remains to be determined.

Title: Trans-synaptic Investigation of Upstream Regulators of the Mesolimbic Pathway

Authors: *K. O. OGUNSEYE[1], J. KASPER[2], J. HOMMEL[2];
[1]Human Pathophysiology and Translational Med., [2]Pharmacol. and Toxicology, Univ. of Texas Med. Br. at Galveston, Galveston, TX

Abstract: The mesolimbic pathway is well-characterized as an important mediator of motivated behavior for substances of abuse, highly palatable food, and other reinforcers. However, it remains unclear which specific neurons project onto the mesolimbic pathway. Typically, mono-synaptic (i.e., region A to region B) viral tracing techniques have been utilized to investigate mesolimbic neurocircuitry. Utilizing novel trans-synaptic viral techniques, in which at least three brains regions can be mapped concurrently (i.e., region A to region B to region C), we aim to trace upstream brain regions acting as regulators of the ventral tegmental area (VTA) to nucleus accumbens (NAc) mesolimbic pathway. We used stereotaxic surgical methods to microinject a retrograde adeno-associated virus (AAV) 6 expressing the avian derived receptor TVA (CMV AAV6 TVA mcherry) into the nucleus accumbens of 11-week-old C57BL/6 male mice. After adequate expression of AAV6, we injected a G-protein deleted rabies virus enveloped by the avian sarcoma leukosis virus receptor (EnvA G deleted GFP Rabies) into the VTA. Utilizing immunohistochemical studies, we observed appropriate mcherry AAV6 expression at the primary site of infection, the NAc, and expression of GFP rabies in the VTA. Rabies expression was also identified in the lateral hypothalamus, periventricular region of the hypothalamus, sub paraventricular region of the hypothalamus, nucleus accumbens, and infralimbic cortex indicating that these brain regions project directly onto the VTA to NAc pathway. These results demonstrate successful neuro-tracing of inputs into the mesolimbic pathway. This study highlights neuroanatomical evidence of upstream regions that may have modulatory effects specific for directing mesolimbic activity and function. This viral-tracing strategy supports the elucidation of inputs more broadly into neural pathways instead of individual brain regions.

Title: Deletion of the glycine alpha 2 receptor enhances dopaminergic modulation of striatal MSN activity.

Authors: J. DEVOGHT, J.-M. RIGO, ***E. PICCART**, M. VAN DE VEN, B. BRONE;
UHasselt, Hasselt, Belgium

Abstract: The cortico-mesolimbic circuit comprises cortical glutamatergic and midbrain dopaminergic projections to the striatum, and integration of these inputs underlies adequate reward-motivated behaviour. We have earlier demonstrated that the homomeric glycine alpha 2

receptor (GlyRa2) plays a crucial role in the development of the cortico-mesolimbic circuitry: GlyRa2 knockout mice exhibit impaired proliferation and migration of cortical layer 5 projection neurons as well as striata medium spiny neurons, a shift in the excitation/inhibition balance of cortical projection neuron activity, and altered cortical input to the striatum at adult age. We next demonstrated that dopamine neuron basal as well as burst firing is unaltered in GlyRa2 knockout animals. Nonetheless, we also described changes is cortico-mesolimbically orchestrated behaviour. More specifically, we showed an exaggerated appetitively motivated response and enhanced increase in motor activity in response to d-amphetamine in GlyRa2 knockout mice, while leaving baseline motor activity unaltered. This led us to hypothesise that the GlyRa2 is crucial to integration of cortical and midbrain inputs to the striatum. To address this hypothesis, we performed whole cell patch clamp recordings on striatal medium spiny neurons. We elicited cortical currents using electrical stimulation, and triggered dopamine release to medium spiny neurons by optogenetic stimulation of dopaminergic terminals. We report enhanced dopaminergic modulation of activity of putative D1 MSNs in GlyRa2 knockout animals, compared to wildtype littermates. Next, to verify whether this enhanced dopaminergic modulation induces an increase in striatal activity in vivo, we measured expression of immediate early gene cFos, a commonly used indicator of neuronal activity, in response to d-amphetamine treatment. In agreement with the electrophysiological recordings do we report that d-amphetamine increases cFos-positive cells to a greater extent in GlyRa2 knockout animals. Moreover, 3-D processing revealed alignment of c-Fos-positive cells in strings that were longer after amphetamine stimulation. Taken together, we demonstrate a crucial role for GlyRa2 in signal integration in the adult striatum, which renders it an interesting target for the treatment of pathologies that are characterized striatal signal integration impairment, such as psychosis and drug addiction.

Title: Internal models of task structure shape mesolimbic and dorsomedial striatal dopamine

Authors: M. BLANCO-POZO[1], T. AKAM[2], T. E. J. BEHRENS[1], *M. E. WALTON[2];
[1]NDCN, [2]Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom

Abstract: The world is in continuous change, requiring animals to flexibly adapt their actions to new situations. It is thought that dopamine activity shapes flexible behaviour by conveying a reward prediction error (RPE) signal, used to update value estimates when predicted and actual outcomes differ. However, a key open question concerns what sources of value information inform dopaminergic RPE's. Specifically, we wanted to determine 1) whether whether dopamine activity is shaped by model-based computations using knowledge of the task structure in tandem with model-free updates, and 2) whether these signals are transmitted uniformly across projection targets in striatum. To address these questions, we trained mice on a probabilistic multi-step decision making task and recorded calcium activity in dopamine neuron cell bodies and axons, and dopamine release in striatal subregions, using fibre photometry (18 mice, 512 sessions, 184,645 trials). Mice chose between two first-step actions which led probabilistically to two second-step states where reward could be obtained. Reward probabilities in the second-step state were anticorrelated. We observed signatures of task structure knowledge in both mouse choice behaviour and dopamine signalling. When animals made a first-step choice, dopamine in the ventral tegmental area (VTA) and the nucleus accumbens (NAc) were modulated by both a 'model-free' component that directly reflected the previous outcome for a prior first-step choice, and a 'model-based' component that respected both the anti-correlated reward probabilities and transition probabilities mapping first-step actions to second-step states. At the same time, dopamine activity in dorsomedial striatum (DMS) was shaped by the model-based component, but not by the model-free one. When the second-step state was revealed, dopamine activity and release in the three regions was not only positively modulated by previous reward from the same second-step, but also negatively modulated by previous reward from the other second-step. This was consistent with behavioural evidence that the mice inferred a single latent variable that controlled both reward probabilities (i.e., that if one second-step state had high reward probability, then the other had a low probability); surprisingly, though, they updated this estimate using only rewards, and not reward omissions. In addition, dopamine signalling was influenced at different timepoints and timescales by other task factors such as reward rate, state transition likelihood and movement. Together, our results demonstrate heterogeneous influences on dopamine activity and release across projection regions.

Michigan State Univ., East Lansing, MI

Abstract: Divergent Effects of Orexin and Melanin Concentrating Hormone Optogenetic Stimulation on Cue Potentiated Feeding

Jenna Lee[1],* Lauren Raycraft[1], Nicollette Russell[1], & Alex Johnson[1,21]Michigan State University, Department of Psychology [2]Michigan State University, Department of Neuroscience

Environmental factors such as food related cues can stimulate eating in the absence of metabolic need, a behavior characterized as cue potentiated feeding (CPF). The feeding signals, Orexin (ORX) and Melanin Concentrating Hormone (MCH) are expressed in the lateral hypothalamic area (LHA) and play a critical role in regulating appetite. Chronic pharmacological or genetic knockdown of these neuropeptides prevents CPF, however the protracted timeframes underlying these perturbations constrain resultant interpretations. In the current study, we used acute optogenetic stimulation to determine with high temporal and spatial resolution, the role of ORX and MCH in CPF. Male and female transgenic ORX or MCH Cre-expressing mice were bilaterally injected with a Cre-dependent Channelrhodopsin virus into the LHA, thus permitting cell-specific activation with blue light stimulation. Mice were initially trained in Pavlovian Conditioning sessions to associate one auditory CS+ with the delivery of a sucrose solution and a different auditory CS- with no reward. Following satiety treatment, mice underwent CPF, during which they had unrestricted access to sucrose and received separate presentations of the CS+ and CS- cues, under stimulated (i.e., laser on) and non-stimulated (i.e., laser off) conditions. Primary results indicate that optogenetic stimulation in MCH-Cre mice facilitated CPF as indicated by increased rate of licking specifically during CS+ trials. Surprisingly, optogenetic stimulation in ORX-Cre attenuated licking for sucrose during CPF. However, an increase in food-seeking behavior was observed as indicated by elevated rate of entry to the area where sucrose was delivered. Thus, using acute optical stimulation we revealed ORX is critical for facilitating food-seeking and inhibiting overeating, whereas MCH promotes overeating behaviors during CPF. Therefore, these cell populations may facilitate the invigoration of feeding behavior through contrasting mechanisms. These results are discussed within a context of dynamic interactions between ORX and MCH LHA cells, which allow for rapid transitions between different appetitive states and could provide insight as to the neural mechanisms of overeating in our current obesogenic environment.

Title: Afferents to dorsomedial and dorsolateral striatum in the rat

Authors: *S. N. HANDEL, R. J. SMITH;
Texas A&M Univ., College Station, TX

Abstract: The dorsal striatum is known for its role in learning and motor processes. Within the dorsal striatum, there are two functionally distinct subregions: dorsomedial striatum (DMS) and dorsolateral striatum (DLS). DMS is integral for guiding goal-directed behavior, while DLS is recruited for habitual behavior. Given the divergence in functions of these subregions, we wanted to fully characterize the brain regions that project to DMS versus DLS with the aim of comparing their circuitry. Specifically, we examined striatal afferents by injecting retrograde tracers (cholera toxin β-subunit or Fluorogold) into DMS or DLS of male Sprague Dawley rats. We characterized the resulting retrograde labeling qualitatively as heavy, medium, or light based on the amount of labeled neurons per brain structure. We observed that both DMS and DLS received heavy input from cortex and thalamus, but there were notable differences in the pattern of labeling within these areas. Cortical afferents to DMS were primarily restricted to the medial prefrontal cortex, including medial and ventral orbitofrontal cortex (OFC), prelimbic cortex, and cingulate cortex. In contrast, cortical afferents to DLS were primarily restricted to lateral areas in frontal cortex, including frontal association cortex, primary and secondary motor cortices, and lateral OFC. DLS also received cortical inputs from primary and secondary somatosensory cortices and insular cortex. In terms of thalamic afferents, both DMS and DLS received input from central medial thalamic nucleus, paracentral thalamic nucleus, parafascicular nucleus, and portions of the ventral thalamic nuclei. Thalamic inputs differed for DMS and DLS in terms of density and topography across medial-lateral and anterior-posterior axes. Finally, both DMS and DLS received medium to light input from amygdala, substantia nigra, and dorsal raphe. Altogether, these data reveal that DMS and DLS share some common inputs, but that there are striking differences in cortical and thalamic inputs to DMS and DLS that may be critical to their distinct roles in goal-directed and habitual behavior.

Title: The role of superior colliculus inputs to the ventral tegmental area in appetitive Pavlovian conditioning

Authors: *C. L. POISSON, C. R. HERUBIN, B. T. SAUNDERS;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Appetitive Pavlovian conditioning relies on associations made between sensory stimuli ("cues") and rewarding outcomes. In our previous studies, we have shown that optogenetic activation of dopamine (DA) neurons in the ventral midbrain in the presence of a neutral visual cue is sufficient to create a Pavlovian association that promotes conditioned behavior in response to that cue (Saunders et al., 2018). Critically, the circuit mechanisms underlying the integration of cue-related sensory input into DA centers to form Pavlovian associations remain unclear. One candidate structure that could provide visual information about cues is the superior colliculus (SC), which receives direct retinal input, and sends projections to DA neurons in the ventral tegmental area (VTA). The SC is known to be necessary for cue-evoked neural activity in DA neurons, but the behavioral function of SC-VTA neurons is unclear. Here, we characterize the SC-VTA circuit and use optogenetics to modulate this pathway's activity during Pavlovian conditioning in rats. First, we used a dual-virus approach to determine which SC neurons innervate the VTA. This revealed projections from deep-layer SC that largely innervate the dorsal and lateral VTA. To manipulate activity of the SC-VTA pathway, we injected viruses expressing excitatory (ChR2) or inhibitory (eNpHR) opsins into deep layer SC and implanted an optic fiber over VTA. We next trained rats in a Pavlovian conditioning procedure wherein visual cues were paired with optogenetic manipulation of SC-VTA terminals. Behavioral analysis revealed that excitation of these neurons failed to drive conditioned (i.e., learned) behavior towards the cue, in contrast to our previous studies targeting DA neurons directly. Notably, a subset of ChR2 rats demonstrated turning behavior. Turning was contralateral to stimulation hemisphere, and time-locked to laser duration. This suggests that the SC-VTA neurons can drive movement invigoration, presumably via their activation of DA neurons, but do not directly cause Pavlovian learning. In ongoing experiments, we are testing the working hypothesis that subsets of SC inputs to different DA populations may invigorate actions, and/or alter attention to relevant sensory information during learning.

Title: Neuroanatomical characterization of cerebellar inputs to the dopaminergic system

Authors: *M. OÑATE, J. VERA, V. LOVALLO, N. WAZEED, K. KHODAKHAH;
Albert Einstein Col. of Med., Bronx, NY

Abstract: The emerging view of the cerebellum is in agreement with it prominent role in cognition in addition to motor control. Indeed, cerebellar impairment is implicated in a wide

variety of disorders, ranging from motor dysfunction such as dystonia or ataxia, or mental disorders like schizophrenia and autism. Recent work of our laboratory have described two underappreciated cerebellar pathways by which the cerebellum sends monosynaptic excitatory projections to the midbrain dopamine system; the substantia nigra pars compacta (SNc), and the ventral tegmental area (VTA). We have found that the cerebellum drives the activity of SNc and VTA neurons, producing dopamine release in downstream regions in the dorsal striatum and medial prefrontal cortex (mPFC), respectively; suggesting that the cerebellum might play a role in motor and cognitive functions through dopamine modulation. Despite the physiological characterization of these cerebellar pathways, detailed characterization of the connectivity of the neuronal sub-populations involved remains to be established. Using a combination of intersectional approaches with anterograde and retrograde tracers we characterized the neuroanatomical distribution, and the heterogeneity of the sub-circuits involved in these pathways. We injected AAV.Cre virus in the deep cerebellar nuclei (DCN) of *RCE* mice (harboring a R26R CAG-boosted EGFP reporter allele with a *loxP*-flanked STOP cassette upstream of the EGFP gene), to identify all the postsynaptic targets of the cerebellum through EGFP expression. Histological analysis of midbrain showed that the cerebellum targets TH-positive (presumed dopaminergic) and TH-negative neurons along the entire SNc and VTA. To identify the spatial distribution of these cerebellar inputs, we performed retrograde tracing using G-deleted rabies virus in DAT-Cre and GAD-Cre mice. We found that all three cerebellar nuclei (lateral, interposed and medial) contribute to these projections. Similar experiments complementing viral tracing with retroAAV virus from mPFC showed that a sub-population of the neurons in the VTA receive cerebellar inputs, and project to cortical areas, supporting the presence of a disynaptic cerebellar projection to the mPFC via the VTA. Characterization of the neuroanatomy and connectivity of the sub-circuits is essential if we are delineating the function and contribution of the cerebellum to dopamine release and cognitive processes.

Title: Investigating contributions of the ventral tegmental area to age differences in risky decision-making

Authors: *W. S. PYON, S. L. BLAES, C. A. ORSINI, R. J. DRAGONE, B. SETLOW, J. L. BIZON;
Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Decision-making is a complex cognitive operation that relies on the concerted effort of multiple brain regions. As-of-yet unidentified changes in these circuits as a result of age will eventually cause many of us to undergo a fundamental shift in the way we make decisions, shifting us away from riskier choices towards safer outcomes. This alteration in decision-making has been further corroborated in rats performing a risky decision-making task, in which given the option between a small, "safe" food reward or a large food reward accompanied by varying probabilities of a mild footshock, aged rats are more risk-averse than their young adult counterparts. To begin to determine the mechanisms underlying this age-related shift toward risk-aversion, and more specifically, the contributions of dopamine signaling from the ventral tegmental area (VTA), we took a two-part approach. First, to determine how VTA dopamine neurons contribute to risky decision-making, we employed optogenetics in young rats to selectively inhibit VTA neurons during performance of the risky decision-making task. Optogenetic inhibition of VTA dopamine neurons specifically during receipt of the large reward on trials when it was unpunished caused young rats to exhibit more risk-averse behavior in future trials. Second, to begin to determine how age differences in VTA activity might contribute to risky decision-making, we investigated age differences in functional connectivity among various brain regions, including the VTA. Young (9 months old; n = 15) and aged (24 months old; n = 9) rats were trained on the risky decision-making task. After reaching stable performance, rats were anesthetized and placed in an 11.1 Tesla Bruker MRI Scanner in which anatomical and resting state functional MR imaging was performed. Preliminary analyses comparing functional connectivity in young and aged rats indicate a significant reduction in correlated activity between the VTA and the basolateral amygdala in aged rats. Ongoing analyses are determining relationships between individual risk preference and functional connectivity in these and other brain regions implicated in risky decision-making.

Title: Sex- and duration-dependent neural circuit control of voluntary exercise behavior

Authors: *M. K. TANNER[1], K. BONAR[2], N. A. MOYA[1], A. A. HOHORST[1], J. K. P. DAVIS[2], J. JAIME[2], E. C. LOETZ[2], B. N. GREENWOOD[2];
[1]Integrative Biol., [2]Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: Incidence rates of stress-related psychiatric disorders are increasing and affect females at nearly twice the rate of males. Exercise can protect against the development of stress-related

disorders, however, participation in regular exercise is decreasing. Dopamine (DA) and the dorsal striatum (DS) are critical for movement, however, the specific DA-striatal circuits that motivate voluntary exercise are unknown. Identifying the neural circuits that motivate voluntary exercise in both sexes could lead to novel strategies to increase exercise participation and reduce the effects of stress. Rats given access to running wheels demonstrate robust voluntary exercise behavior that follows a pattern of two phases consisting of an acquisition phase, during which nightly running escalates, followed by a maintenance phase, during which running distance plateaus. The goal of this study is to identify the DA-striatal circuits that support the different phases of voluntary wheel running in both male and female Long-Evans rats. Using a pharmacological inactivation technique, we temporarily inactivated two DS subregions during both phases of exercise. In males and females during phases of the estrous cycle other than proestrus, inactivation of the dorsomedial striatum (DMS), a region important for goal-oriented behavior, reduced running during the acquisition phase, but not the maintenance phase. In contrast, inactivation of the dorsolateral striatum (DLS), which is a region important for habit formation, reduced running during the maintenance phase, but had no effect on running during the acquisition phase. Interestingly, we observed that females in proestrus, the phase of the estrous cycle when estrogen is the highest, rely on the DLS to support the acquisition of exercise behavior, rather than the DMS. Using fluorescent in situ hybridization, we quantified the activation of DMS and DLS neurons expressing D1 receptors and found that females activate the DLS during the acquisition phase of exercise, while males do not. These data suggest that the neural circuits supporting voluntary exercise behavior depend on both the phase of exercise and sex. Different striatal subregions could be targets for manipulations aimed at enhancing the initial acquisition vs. long-term maintenance of exercise behavior. Additionally, we used immunohistochemistry to stain for cFos+ cells to verify our ability to successfully inhibit only our region of interest and also to quantify neural activity in the DMS and DLS during the maintenance of exercise. Preliminary data suggests that inactivating the DLS of females during the maintenance of exercise decreases cFos+ cells only in the DLS.

Title: Differential activation of dopaminergic signaling pathways following right and left vagus nerve stimulation

Authors: *J. BROUGHER[1], C. A. THORN[2];
[1]Univ. of Texas At Dallas, Dallas, TX; [2]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus Nerve Stimulation (VNS) is an FDA approved therapy for the treatment of epilepsy and major depression. Vagus nerve cuff electrodes are traditionally placed around the left cervical branch of the vagus nerve, due to concerns that stimulation of the right vagus nerve is more likely to lead to adverse cardiac effects. Preclinical studies, however, suggest that cardiac side effects are no more likely to result from right VNS than from left VNS.
A recent study by Han et al. (2018) suggests that stimulation of the right vagus nerve is likely to produce a pattern of activation within the CNS that is distinct from that produced by left VNS. The authors report that optogenetic stimulation of gut-projecting vagal neurons in the right nodose ganglion (NG) led to greater activation of noradrenergic neurons in the locus coeruleus (LC) than did left NG stimulation, and only right NG stimulation led to activation of midbrain dopaminergic neurons in the substantia nigra pars compacta (SNc). Based on this work, we hypothesized that right cervical VNS delivered using traditional cuff electrodes should similarly result in stronger engagement of midbrain dopaminergic circuits compared to left cervical VNS. To begin to test this hypothesis, we examined whether rats would self-stimulate for VNS delivered on either the right or the left side. Fourteen adult female Long-Evans rats were randomly assigned to either the right (Group 1, n = 7) or left (Group 2, n = 7) VNS treatment group. After an initial acclimation session in which lever pressing was paired with food reward, rats received 5 days of self-stimulation sessions in which lever pressing was paired with a brief (0.5 sec) train of VNS pulses (0.8 mA, 30 Hz) and a visual cue. Rats then received 5 extinction sessions in which neither cues nor VNS were delivered. Group 1 rats pressed significantly more than Group 2 rats across all 5 days of self-stimulation and during the first two days of extinction. Extinction was followed by one session of cue-only reinstatement (no VNS), and then one final session in which both the cue and VNS delivery were reinstated. During these sessions, cue and VNS delivery for Group 2 rats was yoked to rats in Group 1, so that both groups received equal amounts of stimulation. Animals were sacrificed 90 minutes after the final stimulation session. Brain slices containing the LC, SNc, and ventral tegmental area (VTA) were made and stained for *cfos* expression. Preliminary data from ongoing analyses suggest that right VNS may result in increased TH+ VTA neuron activation compared to left VNS. Taken together these findings suggest a unique role of right cervical vagal fibers in activating dopaminergic signaling pathways.

Title: Prelimbic neurons signal approach-avoidance conflict

Authors: G. ROJAS-BOWE, A. CABAN-MURILLO, *H. BRAVO-RIVERA, S. N. AYALA-ROSARIO, J. PEREZ-TORRES, V. P. VALENTIN-VALENTIN, A. RIVERA-RIVERA, C. BRAVO-RIVERA, G. J. QUIRK;
Psychiatry, Univ. of Puerto Rico, Med. Sci. Campus, San Juan, PR

Abstract: In nature, animals must carefully evaluate when to approach rewards or avoid threats in risky environments. The neural mechanisms that underlie the resolution of approach/avoidance conflict remain unknown. We recently developed an approach/avoidance conflict task (Bravo-Rivera et al., in review) that pits food reward approach against threat (foot-shock) avoidance. In brief, male rats learn to avoid a tone-signaled foot-shock by stepping onto a platform and to seek a light-signaled reward by pressing a lever (located far from the platform). When the tone and light cues are co-presented, rats initially engage in lever pressing and then move onto the platform at the late phase of the trial to timely avoid the foot-shock. Pharmacological inactivation of the prelimbic (PL) cortex accelerated cue-induced avoidance, suggesting that PL delays avoidance to accommodate food-seeking under conflict conditions ($t_{(18)} = 2.71$, $p = 0.014$). Single-unit recordings revealed that populations of PL neurons distinguished the combined tone and light (conflict trials) stimulus from the tone-alone and light-alone (non-conflict) stimuli: 26.5% of all responsive cells (n = 207) responded exclusively to conflict trials, whereas 21.4% exclusively responded to the tone-alone trials, and 15% responded to the light-alone trials exclusively. Moreover, a subset of PL neurons signaled lever presses during the conflict trials, but not during the light-alone trials, whereas another subset displayed opposite responses. Whereas 28.8% of all responsive cells (n = 208) responded exclusively to pressing within the conflict trials, 38.0% exclusively responded to pressing within the light-alone trials. Furthermore, whereas a subset of PL neurons (47.4% of 78 responsive cells) signaled platform mounts occurring exclusively under conflict trials, another subset (37.2%) exclusively responded to mounting under the tone-alone trials. These findings suggest that PL signals conflict-relevant stimuli and the appropriate behavioral response.

Title: Diet induced obesity induces neuroinflammation in the lOFC

Authors: *L. T. SEABROOK, T. KENNEY, T. TAYYAB, M. SOBEY, M. QIAO, S. BORGLAND;
Univ. of Calgary, Calgary, AB, Canada

Abstract: The lateral orbitofrontal cortex (lOFC) receives sensory information about food and integrates these signals with expected outcomes to guide future actions, and thus may play a key role in a distributed network of neural circuits that regulate feeding behaviour. An obesogenic diet induces microglial activation and inflammatory markers in hypothalamus and hippocampus[1] and induces cognitive dysfunction. However, so far, no studies have explored the effects of diet-induced or obesity induced neuroinflammation in the OFC. We hypothesized that access to an obesogenic diet produces neuroinflammation and synaptic changes in the OFC. Mice had either a 7-day, a 3-month exposure to a high fat diet (HFD) or chow. We used immunohistochemistry to identify markers of microglia and astrocytes and used slice electrophysiology to record neuronal activity in the OFC. Weight gain was significantly greater in mice exposed to HFD for 3 months compared to 7days. The expression of the microglial marker, Iba-1 was increased in the lOFC of 3-month, but not 7-day exposed mice. Furthermore, the number of cells expressing Iba-1 was significantly greater in 3-month than 7-day HFD exposed or chow fed mice. Expression and number of cells expressing of the astrocyte marker, S100, was increased in 3-month but not 7-day HFD exposed or chow fed mice. Both 7-day and 3-month exposure to a high fat diet suppressed inhibitory synaptic transmission onto lOFC neurons and increased their excitability. Finally, while short term exposure to a high-fat diet does not alter goal-directed behaviour, goal directed behaviour was impaired in obese mice. Taken together, synaptic changes in the lOFC can occur early on in diet exposure, inflammatory mechanisms appear at later stages of diet exposure. Thus, future work will assess how inflammatory mechanisms in the lOFC during obesity influence goal directed behaviours.

Title: Firing mode-specific functions of the locus coeruleus: heterogeneity within the basolateral amygdala

Authors: *K. POWER, A. GHOSH, T. OMOLUABI, T. SEPAHVAND, C. REINHARDT, S. TORRAVILLE, Q. YUAN;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: The locus coeruleus (LC) is a noradrenergic brainstem nuclei with widespread projections that allow it to be involved in a variety of functions such as wakefulness, arousal, learning, and the stress response. The LC has two modes of activity (firing), phasic and tonic, which have traditionally been understood to be involved in optimal task performance and disengagement from tasks respectively. The LC has long been thought to operate as a homogeneous unit that is activated as a whole in order to release noradrenaline in a spatially non-specific manner. Recent advances in technology have allowed us to develop a more nuanced understanding of LC function, indicating the role of heterogeneity or modular organization at both the LC and its downstream projection sites. Recent work has implicated the role of phasic and tonic LC activity in the signaling of positive and negative valence respectively. The basolateral amygdala (BLA) receives dense innervation from the LC and is likewise involved in positive and negative valence via two distinct subpopulations. We hypothesized an interaction between modes of LC activation and the activation of these two subpopulations of the BLA; more precisely, we hypothesized that phasic and tonic LC activation would bias activation towards the nucleus accumbens (NAc)- and central amygdala (CeA)-projectors of the BLA respectively. Adult tyrosine hydroxylase-Cre rats underwent surgeries to receive the light-sensitive ion channel channelrhodopsin-2 (ChR2) via viral vector AAV-DJ-EF1a-hChR2(H134R)-mCherry in the LC, an optic cannula in the LC for optostimulation, as well as the retrograde tracer cholera toxin subunit-B (CTB) in the NAc and CeA for the labelling of subpopulations within the BLA. Next, rats underwent phasic, tonic, or no optostimulation in the presence of a neutral odor before sacrifice and transcardial perfusion. Tissue from the BLA underwent cFos immunohistochemistry and was imaged for cFos and CTB overlap via fluorescence microscopy. Phasic and tonic LC optostimulation biased activation towards BLA NAc- and CeA-projectors respectively, while the no light control group showed no bias of activation towards either subpopulation. Further, analysis of the ventral tegmental area (VTA) revealed that phasic LC optostimulation caused greater activation of the VTA as well as greater activation of VTA NAc-projectors than tonic and no light control groups. We are currently investigating adrenergic receptor distributions in the BLA that might account for its LC firing mode-specific activation patterns. This work is furthering our understanding of the mechanisms underlying the firing mode-specific functions of the LC.

Title: Distinct neuronal ensembles within the central nucleus of the amygdala regulate extinction learning

Authors: *B. P. LAY, M. D. IORDANOVA;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Correlational data from histochemical and physiological studies suggest that the central nucleus of the amygdala (CN) is involved in learning when expected events are omitted. Attempts at delineating the causal contribution of CN neurons to this learning have targeted the entire nucleus indiscriminately, disrupting the function of neurons. Recent research using selective approaches have uncovered that not all neurons within a brain area are recruited during learning. Rather, a specific neuronal ensemble supports learning with distinct subsets of neurons likely having different functional roles. We sought to determine the functional role of CN neurons that have been explicitly activated by the omission of an expected reward. c-Fos is a widely used marker for neuronal activity and here, we used the Daun02 inactivation procedure to assess the causal role of *activated* c-fos-expressing CN neurons in updating reward expectations during extinction. In the present study, male *fos-lacZ* transgenic rats were trained to expect the delivery of a food reward upon the presentation of an auditory cue. Subsequently, rats received non-reinforced exposure to the reward-associated cue to generate conditions of reward omission, that is extinction, and examine the effect of this on learning. Cell inactivation with Daun02 took place ninety minutes following the start of the non-reinforced session, presumably when the neurons that detected the reward omission were activated and the corresponding c-fos levels were at peak. This led to disruption in behaviour indicative of impaired retrieval of the extinction memory compared to rats that received a vehicle infusion, which left those neurons intact. Additional data show that further extinction learning was retarded in the absence of the neuronal ensemble in the CN. Moreover, inactivating these extinction-responsive CN neurons resulted in greater spontaneous recovery and reinstatement. Lastly, this disruption in behaviour was specific to the CN and not due to drug diffusion into the basolateral amygdala.

Title: The Psychometric Properties of the Pavlovian Instrumental Transfer Task in an Online Adult Sample

Authors: *N. PAREDES[1], S. ZOROWITZ[2], Y. NIV[2];
[1]California State University, Northridge, Northridge, CA; [2]Princeton Neurosci. Inst., Princeton, CA

Abstract: How we decide to act is governed not only by the expected value of an action but also by the valence of its expected outcome (Guitart-Masip et al., 2014). Pavlovian biases are evident in our tendency to approach reward and inhibit action in the face of punishment, and variability in their expression is implicated in multiple psychiatric disorders including anxiety, schizophrenia, and addiction. Previous research (Moutoussis et al. 2018) has suggested that a popular measure of Pavlovian bias, the Pavlovian-instrumental transfer (PIT) task has unacceptable psychometric properties (e.g. low test-retest reliability), calling into question the task's utility for studying individual differences. However, this work measured behavior on the task in an adolescent sample over an 18-month period, raising the question whether the previous results reflect unreliability of the task or development-related changes in the sample.
To resolve this question, we conducted a longitudinal study of Pavlovian bias in an adult sample. We recruited 103 participants from Amazon Mechanical Turk to complete the PIT task in four separate sessions across 28 days. Participant retention in our sample was high with more than 85% of our sample completing at least 3 sessions. We used a hierarchical Bayesian framework (Rouder & Haaf, 2019) to estimate both the within-session stability and between-session test-retest reliability of the parameters from a standard reinforcement learning model (Guitart-Masip et al., 2014) of behavior on the task.
We replicated the classic behavioral findings such that participants on average exhibited greater accuracy in the Pavlovian congruent conditions (go to win and no-go to avoid losing) and worse accuracy in the Pavlovian incongruent condition (no-go to win and go to avoid losing). We found that the within-session stability across parameters was acceptable (mean = 0.689, range = [0.291, 0.852]). We also found that between-session test-retest reliability of parameters was unacceptable (mean = 0.197, range = [0.121, 0.325]). Test-retest reliability was unacceptable irrespective of session, and was driven by strong practice effects after the first session. Corroborating previous findings, we found that the commonly used Pavlovian Instrumental Transfer task has unacceptable test-retest reliability over a short timescale (4 weeks). Our results suggest that the task's poor psychometric properties are largely driven by practice effects. We conclude by proposing a new version of the task with a trial structure that should preclude task-set learning and thereby improve test-retest reliability.

Title: Compulsive oxycodone intake increases phosphorylation of proteins of the mitogen-activated protein kinase/ mitogen-stress-activated (MAPK-MSK) signaling cascade

Authors: *M. T. MCCOY[1], C. A. BLACKWOOD[2], B. LADENHEIM[2], J. L. CADET[3]; [1]DHHS/NIH/NIDA/IRP, Baltimore, MD; [2]NIH/NIDA, Baltimore, MD; [3]Nih/nida/Intramural Res., Baltimore, MD

Abstract: The abuse of oxycodone leads to opioid use disorder (OUD). However, very little is known about the neurobiological effects that might lead to increased prevalence of addiction in humans. Previous reports from our lab and those of others have demonstrated that the potential involvement of the striatal mitogen-activated protein kinase/ mitogen-stress-activated (MAPK-MSK) signaling pathway in the biochemical effects of several drugs of abuse. As a first step towards identifying the molecular mechanisms involved in OUD, we have measured potential changes in the phosphorylation states of proteins involved in the MAPK-MSK pathway in the dorsal striatum of rats during early withdrawal from escalated oxycodone self-administration (SA). Male Sprague-Dawley rats were trained to press a lever to self-administer oxycodone or saline for one 3h training sessions during the first week followed by 6h sessions during the second week then 9h for the remainder of the SA experiment. At the end of the first week, animals were split into 3 groups: saline SA rats, short access (ShA) rats that took oxycodone for 3h, and long access takers (LgA) rats that took the drug for 6h-9h. At the end of oxycodone SA we isolated tissue from the dorsal striata to perform postmortem biochemical and molecular analyses. We found that rats given long access, but not short access, to oxycodone escalated their drug intake to differential degrees, with some rats (LgA-H) taking very large amounts of oxycodone whereas others (LgA-L) consumed significantly less drug. Biochemical analyses revealed that the LgA-H animals showed increased MSK1/2 protein phosphorylation. We also found increased phosphorylation of CREB and histone H3 proteins that are targets for MSK proteins. Moreover, quantitative PCR studies revealed increased striatal expression of AMPA receptor subunits. When taken together, these observations suggest that the consumption of high amounts of oxycodone can result in MSK1/2-dependent histone phosphorylation that is associated with increased mRNA expression of AMPA receptors. The identification of MSK1/2 signaling pathway as a target for oxycodone exposure may open up potential avenues for pharmacological interventions against opioid use disorder.

Title: Chemogenetic inhibition and excitation of globus pallidus neurons in reward downshift and open field tasks: Motor or emotional effects?

Authors: *M. R. PAPINI, S. GUARINO, C. HAGEN, Q. NGUYEN;
Psychology, Texas Christian Univ., Fort Worth, TX

Abstract: The role of the external globus pallidus (GPe) in the emotional and motor components of reward downshift (RD) and open field (OF) tasks was studied using chemogenetic manipulations. The RD task is a model of frustrative nonreward that suppresses licking after a downshift in sucrose concentration. The OF task assesses locomotion in anxiety-inducing illuminated arenas. Groups of rats received bilateral infusion of the inhibitory hM4D(Gi) or excitatory hM3D(Gq) designer receptors into the GPe. After recovery, animals received 5-min access to either 32% sucrose (inhibitory treatment) or 12% sucrose (excitatory treatment) on RD sessions 1-10, and 2% sucrose on sessions 11-14. On session 15, rats were exposed to a 15-min OF test. Vehicle or clozapine N-oxide (CNO) was administered 30 min prior to RD sessions 11-14 and OF test. Consistent with either a motor or an emotional effect on licking, GPe inhibition reduced licking after a 32-to-2% sucrose downshift, whereas GPe excitation increased licking after a 12-to-2% sucrose downshift in the RD task. However, even though total distance traveled in the OF test was not affected by either GPe inhibition or excitation, the typically higher activity in the periphery relative to the central area of the OF was either reduced under GPe inhibition or eliminated under GPe excitation. These results are more consistent with an emotional function, rather than a motor function of GPe neurons in these tasks.

Title: Locus Coeruleus activation patterns differentially modulate exploratory behavior and olfactory discrimination learning

Authors: *A. GHOSH, F. MASSAELI, K. D. POWER, T. OMOLUABI, S. E. TORRAVILLE, J. B. PRITCHETT, V. D. STRONG, C. REINHARDT, X. CHEN, G. M. MARTIN, C. W.

HARLEY, Q. YUAN;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Locus coeruleus (LC) is the main source of forebrain norepinephrine. LC neurons are known to spike in phasic and tonic patterns. Theories suggest distinct functional roles for two activity patterns- high frequency phasic activity (10-20 Hz) is related to focused attention and cortical encoding of salience, whereas tonic activity is related to quiet wakefulness at low frequency (0.5-2 Hz) and anxiety at high frequency (5-10 Hz). In this study we address how different LC activation patterns differentially modulate associative learning in a food-reward based go/no go odor discrimination paradigm. We also examine the roles of LC activation patterns in general exploratory behavior. We infused TH-cre rats with AAV-DJ-EF1a-DIO-hChR2(H134R)-mCherry in the LC (control rats were infused with AAV-DJ-EF1a-DIO-mCherry), followed by bilateral optical cannular implantation 3 weeks later. Photostimulation of the LC with 10-Hz phasic (either 300 msec on, 1700 msec off; or 10 sec on, 20 sec off), 10 Hz tonic and 25 Hz tonic patterns was carried out during behavioral tests. Our results show that exploratory behavior was enhanced by phasic stimulation and greatly reduced by 25 Hz tonic photostimulation. Both phasic patterns facilitate discrimination learning of similar odors, but not dissimilar odors, in a food retrieval paradigm. This is congruent with previous finding that NE enhances pattern separation and plasticity in the piriform cortex (PC). Pharmacological blockade of adrenoceptors (with phentolamine and alprenolol) in PC impaired similar odor discrimination learning regardless of photostimulation. In contrast, D1 receptor antagonist (SCH23390) infusion in the PC prevented LC photostimulation induced learning facilitation. Similar results were observed when ventral tegmental area (VTA) was blocked with local lidocaine infusion, indicating an LC-VTA-PC dopamine circuitry being responsible for the phasic pattern mediated facilitation. 10 Hz tonic photostimulation did not change odor discrimination learning. VTA immunohistochemical experiments showed higher cFos activation in TH+ neurons following phasic, but not tonic stimulation, further supporting the involvement of the LC-VTA dopamine circuit. Overall, our results indicate that LC firing patterns critically influence general and discrimination behavior through engaging differential down-stream circuitry.

Title: Functional role of insular cortex in the establishment of taste preference conditioning

Authors: *K. G. MEDINA-MEDINA, B. LINARES-CABALLERO, F. BERMÚDEZ-RATTONI, D. OSORIO-GÓMEZ;
Neurociencia cognitiva, Inst. De Fisiologia Celular - UNAM, Mexico city, Mexico

Abstract: Taste recognition is essential for animal's survival, this ability allows them to identify between nutritious and toxic substances. The establishment of taste preferences has an important adaptive role, since the organisms have to recognize tastants that are related to positive postingestive effects. There is scarce information about the brain structures involved in exteroceptive and interoceptive information processing necessary for the establishment of conditioned taste preference (CTP). However, it has been proposed that the insular cortex (IC) processes information about bodily states, including visceral and taste modalities. Importantly, the IC also plays a key role in the acquisition and consolidation of recognition memories through glutamate-dependent mechanisms. In this regard, the aim of this study is to assess whether the IC has a functional role during the establishment of taste preference memories. We evaluated the effects of NMDA receptor antagonist (APV) into the insular cortex on CTP establishment. Accordingly, bilateral guide cannulae were implanted on the IC in male Wistar rats. After recovery, rats were water deprived for 24 hours and baseline consumption were calculated for three days. On the acquisition day, the animals were given two bottles of 30 mL of saccharin (0.3%) and allowed to drink for 15 minutes, 30 minutes later, APV (0.1 µl) or SS was injected into the IC and afterwards animals were injected i. p. with glucose (350 mg/kg). Long-term memory was evaluated 72 hours later in a two-bottle session test. Our results demonstrate that NMDA receptors blockade within the IC hinders CTP establishment. Additionally, we evaluated whether the blockade of NMDA receptors impairs memory acquisition or consolidation processes; to achieve this, we administered APV or SS after the acquisition session; specifically, animals were allowed to drink saccharin (0.3%) from two bottles of 30 mL and injected i.p. with glucose, 30 minutes later APV or SS was administered into the IC. Short-(4 hrs) and long-(72 hrs) term memory were assessed. Results show that NMDA receptors blockade within the IC impairs long-term memory but spares short-term memory. Our results demonstrate that the IC plays a key role in CTP establishment through NMDA receptors activity, particularly the activation of NMDA receptors is related to the consolidation of taste preference memories.

Title: Effects of reward delays on sign- and goal-tracking behaviors: A preliminary study on changes in response frequency on the time course of reward delay

Authors: *T. SATO[1], T. YAMAKUNI[2,3];
[1]Social Welfare, Nagano Univ., Ueda, Japan; [2]New Industry Creation Hatchery Ctr. (NICHe), [3]Res. Ctr. of Supercritical Fluid Technology, Grad. Sch. of Engin., Tohoku Univ., Sendai, Japan

Abstract: In instrumental learning situations where an anticipated reward presentation is delayed from a correct behavioral response to acquire a reward, various behaviors that do not directly contribute to appetitive results are observed. Of these behaviors, we determined how frequencies of sign-tracking and goal-tracking behaviors change depending on the reward delay's time course. We measured lever-pressing and nose-poke responses to acquire a pellet in a Skinner box by using seven well-trained male C57BL/6N mice under delay lengths of 0 (no delay), 10, 20, 30, and 40 seconds from pressing the lever to the presentation of a pellet. The frequency of lever-pressing and nose-poke responses at the second, third, and fourth 10-second intervals within the five reward delays was estimated by calculating the difference between the number of these responses observed in the trials with 10 and 20 seconds, 20 and 30 seconds, and 30 and 40 seconds delay lengths. The results showed that nose-poke responses appeared most frequently at the fourth 10-second interval than the former three intervals, while lever-pressing responses were more frequent at the first and second intervals than at the latter two intervals. Data analyses made using Kendall's rank correlation also indicated that the estimated number of lever-pressing responses at the second 10-second interval was negatively correlated with that of the lever-pressing responses at the third (r = -0.68, p = 0.033). However, the former correlated positively with the estimated number of nose-poke responses at the fourth interval (r = 0.78, p = 0.015). This suggests that the animals that pressed the lever more frequently during the earlier period showed the same response less frequently later, followed by a higher increase in nose-poke responses. A transition process from sign tracking to goal tracking when withholding a reward could be affected by the response frequency of a frustrated animal in the earlier period. On the other hand, the total number of correct responses to acquire a pellet, as an index of performance of learning in this task, appeared to be related to neither the frequency of the lever-pressing nor nose-poke responses in the second, third, and fourth 10-second intervals (r < 0.40). A medium but insignificant correlation (r = 0.52, p = 0.099) was identified between the total of correct responses and that of the lever-pressing response in the first 10-second interval, suggesting that learning performance in the whole session may be moderately related to the number of lever-pressing responses in earlier but not in later intervals. This work was supported by JSPS KAKENHI #24530917 and #18K03182.

Title: Comparing motivation and attention in sign-tracking behaviors

Authors: K. MAWULOM KINDEDJI[1], ***F. HUPPÉ-GOURGUES**[2];
[1]Psychologie, Univeriste de Moncton, Moncton, NB, Canada; [2]Psychologie, Univ. De Moncton, Moncton, NB, Canada

Abstract: Some animals attribute more importance to the reward cues than the rewards themself. This behavior is called ‘‘sign-tracking’’ and it is observable in several spices as well as in humans. It has been previously found that sign-tracking (ST) behaviors may contribute to the development of addiction and other compulsive behavioral disorders. Recent publications been shown to link sign-tracking to a poor sustained attention, suggesting differences in the cholinergic system. However, sign-tacking behaviors has also been shown from a motivational perspective, in particular in the dopamine system. Given that sign-tracking behavior can have motivational or attentional origins, it would be important to quantify the contribution of each. To answer this question, 21 Long-Evans rats (13 females and 8 males) were first classified as either sign-trackers or goal-trackers according to their result to Pavolvian conditioned approach. This test has classified 6 rats as STs and 7 rats as GTs. They were then further tested by completing the sustained attention task to assess their attentional performance and motivation. To evaluate their performance the relative number of good answers (hits), false alarms, correct rejections and misses were used to measure their attentional performance while the omission rate and reward retrieval time were used to measure their motivation. No significative differences were observed between the animals in regard to their attentional performance. However, there was a significant difference in the rate of omission. Precisely, STs demonstrated less omissions than GTs. In the conditions in which we have tested our rats, our results suggest that sign-tracking behavior has a greater correlation with motivation than it has with attention. Thus, motivation can lead sign-trackers to have behaviors that have little ecological value and make them vulnerable, for example, to addiction disorders.

Title: Chronic administration of D2/3 agonist ropinirole enhances the ability of win-paired cues to drivedevelopment oflong-lasting preference for riskychoice in a rat gambling task

Authors: *L. MORTAZAVI[1], T. HYNES[2], S. KAUR[3], C. A. WINSTANLEY[3];
[1]Psychology, Stanford Univ., Stanford, CA; [3]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Dopamine replacement therapies (DRTs) such as ropinirole are common treatments for Parkinson's Disease (PD). While effective in mitigating the motor symptoms of PD, they can induce development of impulse control and gambling disorders in a considerable proportion of patients with chronic use. To investigate the mechanisms by which DRTs precipitate these conditions, we tested the effects of chronic administration of D2/3 receptor agonist ropinirole on animal models performing a rat Gambling Task (rGT). Male Long-Evans rats (N=112) received either saline, 2.5 or 5 mg/kg/day ropinirole via subcutaneously implanted osmotic pumps over 28 days while they acquired the rGT. In this task, animals choose between four options with varying probability and magnitude of winning sucrose pellets or losing time. Half of the animals were trained on a cued version of the task where delivery of rewards was paired with audiovisual cues. We found that only in the animals performing the cued rGT, administration of ropinirole, specifically during the acquisition phase of the task, biased rats towards the high-risk/high-reward options. This risk preference remained and became progressively more pronounced long after termination of drug treatment. Furthermore, consistent with previous research on the rGT, motor impulsivity was dissociable from choice effects in that it only increased transiently but returned to normal levels before the end of the drug delivery period. These findings suggest a critical role for D2/3 activity to specifically modulate the ability of win-paired cues to increase preference for risky choice. Put together with previous work, this effect may be especially powerful and long-lasting when options are being sampled and evaluated but not after a preference has been shaped.

Title: Infralimbic cortical control of current versus previous behavioral state

Authors: M. C. BROOMER, *M. E. BOUTON;
Univ. of Vermont, Burlington, VT

Abstract: In instrumental learning, extensive training of a response generates habit. The transition from goal-directed to habitual behavior is often considered unidirectional, but this is not necessarily the case; certain manipulations switch a behavior from habit back to action. We identify the infralimbic cortex (IL) as critical to this process: Pharmacological inactivation of IL converted an extensively trained behavior that had renewed as an action back to habit status but

did not affect a behavior that had only been action. We also examined the role of IL in contextual fear extinction and its reacquisition, where IL had parallel effects. In each of two experiments, 32 male Wistar rats were implanted with bilateral cannula to IL and food deprived to 90% free-feeding weight. In Experiment 1a, rats received limited lever-press training in one context, then extensive training of the same response in another context (all reinforced on an RI 30-s schedule) prior to reinforcer devaluation via taste aversion learning. (Paired rats received pairings of the sucrose-pellet reinforcer and injections of lithium chloride (LiCl).) Prior to a test of lever pressing in extinction, half the rats received an infusion of baclofen/muscimol (B/M) to IL and half received saline. Testing in the minimal training context, which prior work suggested would renew goal-direction, revealed a devaluation effect in saline animals, but not B/M animals, as if action had renewed but returned to habit under IL inactivation. In a second experiment, a separate cohort of rats received limited training in a single context (RI 30-s schedule) prior to reinforcer devaluation. Here, both B/M and saline rats exhibited a devaluation effect, suggesting IL inactivation had no effect on an instrumental response that had been only an action. These results suggest that, instead of controlling habit performance (the canonical view), IL inactivation removes a "recency" effect and returns the preceding behavioral state. To further test this idea, the rats in Experiment 1a underwent contextual fear conditioning, extinction, and reacquisition in Experiment 1b. IL inactivation was tested after extinction or reacquisition in different groups. The effect of IL inactivation interacted significantly with test phase: B/M rats tested after extinction showed heightened freezing relative to saline, suggesting a suppression of extinction (a well-known effect), but in rats tested after reacquisition, there was an opposite trend in which inactivated animals showed recovery of extinction performance, as if the reacquired fear memory was removed and behavior was returned to the preceding state of extinction.

Title: Investigating mechanisms unique to memories associated with methamphetamine and cocaine

Authors: *M. HAFENBREIDEL[1], S. B. BRIGGS[1], S. E. SILLIVAN[1], A. B. HALL[1], M. ARZA[1], A. TILLER[1], L. LIN[2], S. KHAN[2], M. D. CAMERON[2], G. RUMBAUGH[3], C. A. MILLER[1];
[1]Neuroscience; Mol. Med., [2]Mol. Med., [3]Neurosci., Scripps Res., Jupiter, FL

Abstract: Persistent drug-associated memories perpetuate substance use disorders (SUD) by inducing motivation to seek drug. We previously reported that methamphetamine (METH)-associated memories can be disrupted by systemic or intra-basolateral amygdala (BLA) administration of Blebbistatin, which inhibits the actin motor ATPase nonmuscle myosin II (NMII), leading to actin depolymerization. The effect is specific, as it does not interfere with other memories (e.g., fear or cocaine; COC) or have the same effect in dorsal hippocampus (dHPC) or nucleus accumbens (NAc). Therefore, to determine mechanisms underlying this selectivity, we examined the differences between METH and COC. We used RNA-seq to identify potentially unique transcriptional changes in BLA, NAc, and dHPC tissue collected after the final METH, COC, or saline CPP conditioning session. Sequencing revealed relatively large differences between METH and COC-conditioned mice in BLA. One gene selectively upregulated in METH- compared to COC-treated mice was *crhr2.* Corticotrophin releasing factor (CRF) binds to CRF receptor 1 (CRF1; gene: *crhr1*) and CRF receptor 2 (CRF2; gene: *crhr2).* Others have found selective roles for CRF1 in COC-associated memories and sensitization, and CRF2 in METH sensitization, but its role in METH-associated memories was unknown. Therefore, we infused mice in BLA with vehicle (veh) or CRF2 antagonist (Astressin-2B, AS2B) before each CPP conditioning session. AS2B-treated mice did not express a METH CPP when tested 48 hours later, indicating CRF2 is necessary for METH-associated learning. Next, to determine if CRF2 was necessary for memory formation or consolidation, mice were infused with veh or AS2B after the final (METH) conditioning session. AS2B-treated, but not veh-treated, mice expressed a METH CPP; possibly due to an anxiolytic effect of AS2B. To test this, mice were tested in elevated plus maze and open field following similar methods. Results suggest that veh infusions increased some anxiety measures, but not following AS2B infusions. To control for this, mice were habituated by receiving mock infusions prior to each conditioning session. CRF2 inhibition after the final conditioning session was not sufficient to disrupt the memory, indicating that CRF2 must be blocked early during METH-associated memory acquisition to disrupt the memory. Here, we began to assess the differences between two stimulant drug-associated memories, which allows for a better understanding of SUDs, including identifying the mechanism(s) responsible for METH-associated memory's selective vulnerability to NMII inhibition. These may yield avenues to target other pathogenic memories.

Title: Investigating the behavioural effects of win-associated cues, outcome-associated cues, and randomly occurring cues on risky decision making

Authors: *B. A. HATHAWAY[1], K. M. HRELJA[1], C. B. W. HARRIS[1], T. J. HYNES[1], C. A. WINSTANLEY[2];
[2]Psychology, [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Win-associated cues can enhance disadvantageous risky choice in both humans and rodents. Indeed, the impact of reward-paired cues on behaviour is a major component of many theories of addiction. However, the role of specific elements of such cues in producing this behavioural effect has not been thoroughly investigated. Accordingly, the present experiments assessed the effect of four different cue administration paradigms on risky decision making. Three cohorts of 32 to 48 male Long-Evans rats were trained on 5 variants of the rat Gambling Task (rGT), a rodent analog of the human Iowa Gambling Task. Optimal performance on this task is attained by avoiding the two high-risk, high-reward options (P3 and P4) and instead favouring the options associated with lower per-trial gains (P1 and P2). The standard cued version of the task features the addition of reward-paired audiovisual cues that scale in magnitude and complexity with reward size. In each cohort, 8 to 16 rats were trained on either the standard cued or uncued rGT. Sixteen rats in each cohort were trained on one of three variants of the cued task. The first variant reversed the cues, such that the longest and most complex cue was paired with the smallest reward. The second variant delivered cues during every outcome - both wins and losses. The third variant randomly delivered cues with a 50% probability across both winning and losing trials.
As observed in previous experiments, there was a higher proportion of risk-preferring rats on the standard cued task compared to the uncued task. The reverse-cue variant produced a similar choice profile to the standard cued task. Outcome-associated cues increased risky choice to an even greater degree. Conversely, rats trained on the random-cue variant did not exhibit this cue-induced risk preference. These results suggest that audiovisual cues do not need to occur only during rewarded trials in order to drive risky choice. However, the cues do need to be predictive, as random cues did not significantly alter behaviour compared to the uncued task.

Abstract: Escalation of alcohol self-administration facilitates the transition from alcohol use to compulsive drinking, which is a worldwide biomedical concern. Alcohol research has largely focused on understanding the neural mechanisms underlying excessive or compulsive alcohol intake. Less is understood of the neural substrates underpinning individual differences in alcohol preference and seeking, and how escalation arises in some individuals but not others. The size, heterogeneity and complexity of mammalian reward circuits make investigating variation in alcohol preference extremely difficult. In *Drosophila*, the neural circuits required for encoding valence are well-studied and include identifiable connections, genetic and/or biochemical profiles and characterized temporal changes underlying learning. We developed a 3-day operant paradigm to evaluate self-administration of volatilized pharmacological doses of ethanol in *Drosophila,* and demonstrated population variance in ethanol self-administration. Almost 30% of flies escalated self-administration of a dose of ethanol which increased average velocity. This starkly contrasts with population self-administration patterns observed for known appetitive or aversive odors. We also demonstrate a requirement of mushroom body α'3 circuitry in escalation of ethanol self-administration, and reveal subtle behavioral features associated with manipulating mushroom body α'3 neurons that predict escalation of ethanol self-administration. Our data demonstrate that *Drosophila* express innate preferences for self-administering ethanol and that manipulating learning and memory circuits impacts the trajectory of those expressed preferences. Results allow for a useful experimental approach to study alcohol use and abuse disorders.

Title: Sex chromosome complement and gonadal status contributions to ethanol intake, preference, and relapse-like behavior

Authors: *E. A. SNEDDON, L. RASIZER, N. CAVALCO, A. JAYMES, N. OSTLIE, A. K. RADKE;
Psychology, Miami Univ., Oxford, OH

Abstract: Background: The diagnosis of alcohol use disorder (AUD) in women is on the rise in the United States. Rodent models show behavioral sex differences in different aspects of ethanol (EtOH) drinking behaviors such as escalation and relapse. The mechanisms associated with increased vulnerability to EtOH in females are still unclear. The four-core genotype (FCG) mouse model allows for the investigation of sex chromosome complement and gonadal status on behavior. We used the FCG mouse model to investigate the influence of gonadal hormones and sex chromosomes on EtOH intake and relapse susceptibility. **Methods:** FCG mice were given access to EtOH in their home cage about 6 hours into the light cycle. Mice had access to two bottles for 24-h. One bottle contained reverse-osmosis (RO) drinking water and the other bottle contained EtOH in RO water (v/v). EtOH concentrations increased from 5%, 10%, 15%, and 20%. Mice were exposed to each concentration of EtOH for a total of 5 drinking sessions. After the last 20% EtOH session, mice underwent a 6-day EtOH deprivation period. After each deprivation period, mice were reintroduced to 20% EtOH for 24-h. This cycle of deprivation and re-exposure was repeated for a total of 5 deprivation sessions. At least two weeks following deprivation, water consumption was measured in one 24-h session and 2.5% sucrose consumption was assessed over five 24-h drinking sessions. **Results:** Mice with female gonads and XX chromosomes consumed greater amounts of EtOH. Mice with XX chromosomes preferred EtOH to a higher degree than mice with XY chromosomes. Mice with XX chromosomes drank more EtOH during deprivation sessions when consumption was expressed as a percent of baseline. Mice with female gonads consumed greater amounts of water when EtOH was present and alone. No differences were observed between groups on sucrose intake. **Conclusions:** Female gonads and XX chromosomes were associated with greater amounts of EtOH intake. Also, mice with XX chromosomes had a higher preference for EtOH and were more prone to relapse. These results indicate individuals with XX chromosomes may have a predisposition to prefer alcohol and have a higher susceptibility to relapse than individuals with XY chromosomes. Water consumption was increased in mice with female gonads during EtOH and control drinking sessions. There was no association between gonadal status or sex chromosome complement on sucrose intake. These findings indicate that EtOH intake,

preference, and relapse-like behavior may be differentially regulated by gonadal status vs. sex chromosome complement and suggest novel, future avenues for investigating the neural mechanisms of female vulnerability to alcohol.

Title: Development of compulsive-like binge quinine-adulterated alcohol drinking in male and female C57BL/6J mice

Authors: *M. M. MCVEY, M. R. BAUER, S. L. BOEHM, II;
Psychology, Indiana Univ. - Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Alcohol use disorder (AUD) is a chronic disease that is characterized by an inability to control alcohol use despite negative consequences, or compulsive alcohol drinking (American Psychiatric Association, 2013). The bitter compound quinine has been used to model compulsive-like drinking in mice. Mice with previous alcohol exposure will drink quinine-adulterated alcohol (QuA) at the same level as unadulterated alcohol, despite the negative consequence of the taste, whereas mice that are alcohol-naïve will drink significantly less QuA. Here we investigated the establishment of compulsive-like quinine-adulterated front-loading and 2-hour binge alcohol drinking in male and female C57BL/6J mice after 3 weeks of either alcohol or water exposure using a mouse model of binge drinking, Drinking-in-the-Dark (DID). We hypothesized that after 3 weeks of binge-like drinking, mice will display compulsive-like QuA consumption. The mice (n=12/group) were allowed free access to 20% ethanol for 2 hours each day for a total of 26 days. On days 22, 24, and 26, the mice were given QuA (0.5mM quinine in 20% ethanol) during DID in place of the 20% ethanol. Bottles were read and intakes were measured at 30-minutes and 2-hours into DID. On day 26, immediately following DID, blood ethanol concentrations (BECs) were determined with retro-orbital sinus eye bloods. We found that both male and female alcohol history mice binge-drank significantly more QuA than water history mice ($p < 0.0001$), and alcohol history mice drank the same amount of QuA as unadulterated alcohol at baseline (i.e. the day prior to QuA; $p > 0.05$). Alcohol history mice front-loaded significantly more QuA than water history mice suggesting that alcohol history mice were motivated to a greater extent than water history mice to consume the QuA ($p < 0.0001$). Importantly, alcohol history mice front-loaded significantly less QuA than unadulterated alcohol at baseline suggesting that the mice find the QuA solution aversive as they are less willing to drink it prior to post-alcohol absorption effects ($p < 0.0001$). After three weeks

of binge-like drinking, both male and female C57BL/6J mice displayed compulsive binge-like QuA drinking; this pattern did not fluctuate between three QuA exposures. BECs were significantly higher in the compulsive-like alcohol history mice than the non-compulsive water history mice on day 26 ($p < 0.05$). These data provide a robust two-criteria model of compulsive-like alcohol drinking in male and female C57BL/6J mice. This model can be used to advance the mechanistic and neurobiological underpinnings of compulsive-like alcohol drinking and AUD.

Title: Relating alcohol consumption behavior to ligand bias at the kappa opioid receptor

Authors: *A. R. FRENCH[1,2], A. M. GUTRIDGE[1], Q. H. ROYER[1], R. M. VAN RIJN[1,2]; [1]Medicinal Chem. and Mol. Pharmacol., [2]Purdue Inst. for Integrative Neurosci., Purdue Univ., West Lafayette, IN

Abstract: The kappa opioid receptor (KOR) is a G protein coupled receptor that regulates pain, motivation, and reward. While activation of the KOR can cause desirable pharmacological effects, including the inhibition of addictive drug reward and analgesia, KOR activation also causes a host of undesirable effects such as sedation and dysphoria. Some of these physiological outcomes have been associated with different signaling pathways at the KOR. For example, previous work has shown that KOR-mediated dysphoria and sedation are dependent on signaling proteins recruited by arrestin. Accordingly, these findings have driven the development of "biased" ligands at the KOR that signal preferentially through arrestin-independent pathways with the aim of designing therapeutics at the KOR that treat pain or drug dependence without side effects. However, the relationship between KOR and drug reward is complex and both time- and drug-exposure specific: in drug naïve animals, the KOR can either inhibit or potentiate the reward of addictive drugs such as alcohol depending on the timing of agonist administration relative to drug exposure. With more drug exposure, and as an individual enters severe drug dependence, the KOR system becomes dysregulated, driving the negative symptoms of withdrawal that in turn promote further drug seeking and relapse. Thus, while the role of KOR in modulating drug seeking makes it an attractive target for therapeutics treating dependence, the complex nature of this regulation means further understanding is needed to properly design and carry out treatment through the KOR. To this end, we investigated whether differentially biased KOR agonists would uniquely modulate alcohol use in mice. For this we relied on KOR agonists

that were deemed to be G-protein-biased (HS666), balanced (U50,488), and β-arrestin 2-biased (nalfurafine), as assessed in *vitro* assays. We then administered these three KOR agonists to male and female wild-type and β-arrestin 2 knockout C57BL/6 mice (n≥8) trained to consume 10% ethanol in a two bottle choice drinking-in-the-dark paradigm. Our results appear to suggest that β-arrestin 2 signaling does not drive KOR-mediated elevation in drinking, and that sedation, as measured by hypolocomotion, and alcohol use are interdependent physiological effects at the KOR. Our results suggest biased signaling at the KOR is not a driving factor behind the pharmacological effects of KOR activation on alcohol intake, in stark contrast to the delta opioid receptor, where alcohol use is tightly correlated with arrestin recruitment.

Title: Selective inhibition of PDE4B reduces binge-drinking in two C57BL/6 substrains

Authors: *K. K. SZUMLINSKI[1], C. L. JIMENEZ CHAVEZ[1], C. D. BRYANT[2], M. A. MUNN CHERNOFF[3];
[1]Univ. California-Santa Barbara, Santa Barbara, CA; [2]Boston Univ., Boston, MA; [3]Univ. of North Carolina Chapel Hill, Raleigh, NC

Abstract: The cyclic AMP (cAMP)-hydrolyzing phosphodiesterase 4 (PDE4) enzyme family is a critical component of signaling pathways implicated in many neurological conditions, including Alcohol Use Disorder. For example, treatment with the prototypical non-selective PDE4 inhibitor Rolipram lowers voluntary alcohol intake under limited-access drinking procedures. The PDE4 family consists of 4 subtypes (PDE4A-D) and the advent of isozyme-selective inhibitors currently enable dissection of their relative roles in regulating brain and behavior, with fewer off-target effects. To this end, the present study determined the effects of the PDE4B-selective inhibitor A33 on alcohol versus sucrose intake in a murine model of binge-drinking, as well as on alcohol-induced changes in motor behavior. For this, female and male C57BL/6NJ mice (B6NJ; n=7-8/sex) and male C57BL/6J mice (B6J; n=11; female study on-going) were presented concurrently with 10, 20 and 40% alcohol for 2h/day. Using a within-subjects design, mice were pretreated (30 min prior) with 0, 0.03, 0.1, 0.3 or 1.0 mg/kg A33, with the order of dosing randomized across subjects. Three to four days were allowed between dosing to examine for potential carry-over effects. Following characterization of the dose-response function for alcohol intake, the effects of the 1.0 mg/kg A33 dose on the intake of a

20% sucrose solution was determined. The same mice were then examined for the effects of 1.0 mg/kg A33 upon locomotion activity, intoxication on a rotorod and sedation induced respectively by 1.5, 3 and 4 g/kg alcohol. In these latter assays, mice underwent 2 days of testing during which half of the mice received either vehicle or A33 30 min prior to the alcohol injection and testing and then received the opposite pretreatment prior to testing the next day. A33 pretreatment dose-dependently reduced binge-alcohol intake in both substrains, with significant reductions detected at the 0.03 mg/kg dose in male and female B6NJ mice and at the 0.1 mg/kg dose in male B6J mice. Pretreatment with 1.0 mg/kg A33 did not alter sucrose intake in B6J males, but augmented sucrose intake by B6NJ mice. No A33 effect was detected for alcohol-induced locomotor activity, intoxication or sedation in either substrain. These data provide novel evidence that selective inhibition of PDE4B is sufficient to reduce binge alcohol-drinking, without reducing the intake of a non-drug reinforcer or altering sensitivity to alcohol's psychomotor effects. If relevant to humans, such findings pose PDE4B inhibition as an effective pharmacotherapeutic strategy for reducing heavy or problem drinking, with low likelihood of off-target or negative side-effects.

Title: Effect of oxytocin treatment on ethanol intake in group-housed male and female C57BL/6J mice

Authors: *H. FULENWIDER[1], M. CARUSO[1], M. ROBINS[1], A. E. RYABININ[2];
[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: Alcohol use disorder (AUD) is a prominent public health problem affecting approximately 9 million men and 5 million women in the United States alone. Notably, the relationship between social environment and AUD is complex, in that one's social group may serve to provide support and promote sobriety or to encourage drinking and increase the risk of relapse. Not surprisingly, oxytocin, a neuropeptide system with established roles in various social behaviors, has recently been identified as a potential modulator of alcohol intake, with preclinical studies demonstrating that systemic oxytocin treatment tends to attenuate voluntary consumption. Therefore, we sought to identify the effects of repeated, systemic oxytocin treatment (i.p.) on voluntary ethanol intake in group-housed male and female C57BL/6J mice.

Mice were housed in Herdsman 2 (HM2) cages to enable the tracking of individual water and ethanol intake while allowing for continuous social interaction among cagemates. We found that under baseline conditions, group-housed females consumed significantly more g/kg ethanol than males, an effect largely mediated by females' lower average body weight when compared to males. Following 4 consecutive treatments of 3mg/kg oxytocin, both males and females decreased ethanol intake, but not water intake, relative to vehicle-treated controls. Importantly, though, this effect varied between treatment days. Additionally, the high temporal resolution provided by the HM2 system allowed for the identification of compensatory increases in ethanol intake approximately 12hr after oxytocin was administered, a phenomenon that could present significant issues when considering treatment in patient populations. Therefore, future studies will assess the effects of oxytocin over longer periods of repeated treatment and the potential of additional oxytocin receptor agonists to decrease ethanol consumption.

Title: Effect of chronic sugar consumption on ethanol preference in adolescent and adult male rats

Authors: *M. RESÉNDIZ[1], G. VERA[2], A. RANGEL[1], M. I. MIRANDA[1];
[1]Inst. De Neurobiología, UNAM, Querétato, Mexico; [2]Inst. De Neurobiología, UNAM, Querétaro, Mexico

Abstract: The exacerbated consumption of sugar and its cognitive processing involves the activation of the brain reward system, in which areas such as the prefrontal cortex (PFC) mediate learning and behavior related to the reinforcement of the consumption of sweet substances. On the other hand, it is known that the late maturation of PFCs during adolescence is related to the early appearance of the intake of addictive substances such as ethanol. However, few studies have analyzed the impact of high sugar consumption and its relationship with the consumption of addictive substances, such as ethanol, particularly when it is present in sugary alcoholic mixtures. Given that alcohol intake usually begins in adolescence through these alcoholic mixtures, the objective of this study was to evaluate, in adolescent (5 weeks at the beginning of the experiments) and/or adult (9 weeks) male rats, the preference for the consumption of sugary ethanol, after prolonged and permanent sugar exposure.Male Wistar rats were housed individually and kept at 23 °C, in a reverse light-dark cycle. All behavioral procedures were performed during the dark phase of the cycle; food pellets were available *ad libitum*. Rats were

randomly assigned to the groups: Naive (N) or Chronic (C), with access to water or sugar, respectively, as the only liquid available for 24 hrs/21 days. Bodyweight, liquid, and food intake were recorded daily. After 21 days, the chronic group was divided into a subgroup with continuous access to sugar (CND) and a subgroup deprived of sugar, with access only to water (CD), between each of 4 preference tests (24 h each) of sugary ethanol (10% ethanol-10% sugar) vs. water.In groups CND and CD, both adolescent and adult rats, the chronic consumption of sugar-induced a suppressive intake effect of the sugary ethanol solution during the 4 preference tests. However, despite always preferring water, only adolescent CD rats increased their consumption of sugar-ethanol mixture from the second preference test. When analyzing the data independently, between rats with high or low sugary ethanol consumption, the effect of sugar deprivation -between preference tests- was related to significantly higher sugary ethanol consumption in adolescent rats compared to adults.Taken together, the results suggest that adolescent rats have a higher susceptibility to sugar deprivation that could be related to late brain maturation as well as decision-making and increased impulsive and risk-seeking behaviors, such as the initiation of use of addictive substances.

Title: Dose-dependent differences of ethanol-induced conditioned place preference in juvenile and adolescent male and female sprague-dawley rats

Authors: ***T. M. NELSON**[1], D. Q. PHAM[1], D. FRANCO[1], E. A. BATES[1], T. A. GONZALEZ[1], S. D. INIGUEZ[2], A. R. ZAVALA[1];
[1]Psychology, California State Univ., Long Beach, CA; [2]Psychology, The Univ. of Texas, El Paso, TX

Abstract: Ethanol, the type of alcohol consumed, is the most abused recreational drug in the United States. Ethanol use commonly begins during adolescence, a period of brain development that is susceptible to ethanol's effects, leading to long-term changes in reward pathways. Surprisingly, studies that have used the conditioned place preference (CPP) paradigm, a validated animal model of drug reward, have shown that adolescent rats do not readily demonstrate ethanol-induced CPP. To further characterize ethanol preference in adolescence, we

hypothesized that sex differences would emerge across adolescence and that low doses of ethanol are necessary for adolescent male rats to demonstrate ethanol-induced CPP. Rats underwent a 10-day CPP procedure to assess ethanol preference during early adolescence (postnatal day (PD) 23-32) in experiment 1 and adolescence (PD 31-40) in experiments 2 and 3. On day 1, preference for a two-chamber CPP apparatus was assessed during 15 min (experiment 1 and 2) or 20 min (experiment 3) sessions. On days 2-9, rats were conditioned with saline in their initially preferred chamber or ethanol in their initially non-preferred chamber on alternating days for 15 min. On day 10, the preference for the ethanol-paired chamber was assessed using identical procedures to day 1. In experiments 1 and 2, rats were randomly assigned to receive an injection of ethanol (0.0, 0.5, 1.0, or 2.0 g/kg, intraperitoneally) before being placed in the ethanol-paired chamber. Similarly, in experiment 3, rats were randomly assigned to receive an injection of ethanol (0.0, 0.0156, 0.0313, 0.0625, 0.125, 0.5, or 2.0 g/kg, intraperitoneally) before being placed in the ethanol-paired chamber. In experiment 1, regardless of sex, rats demonstrated ethanol-induced CPP when administered the highest dose of ethanol (2.0 g/kg). In experiment 2, sex differences emerged as female rats continued to prefer a high dose of ethanol (2.0 g/kg). However, male rats exhibited an increased preference for the ethanol-paired chamber only with the lowest ethanol dose (0.5 g/kg). In experiment 3, male rats demonstrated a robust preference for ethanol when administered low ethanol doses (0.0625, 0.125 g/kg). Overall, sex differences did not emerge in preadolescence, as both male and female rats exhibited a strong preference for ethanol. However, during adolescence, ethanol preference shifted in male rats, as only low doses of ethanol resulted in a preference for the ethanol-paired chamber. Establishing preclinical models that allow for the examination of ethanol reward in adolescence is crucial in understanding the neurobiological mechanisms that underlie ethanol abuse in adolescents.

Title: Internal desynchronization and ethanol consumption in female rats

Authors: *C. MEYER[1], K. SCHOTTNER[2], S. AMIR[3];
[1]Concordia University, CSBN, Montreal, QC, Canada; [2]CSBN, [3]Concordia Univ., Montreal, QC, Canada

Abstract: To meet the demand for a 24-hour-business service in our modern society, the number of workers in abnormal working time, such as shift work, increased by 29% from 1997 to 2010 (Rydz et al., 2020). Shiftwork is associated with a higher incidence of alcohol abuse, especially

among women. However, there is a fundamental lack of knowledge regarding the underlying mechanism in the female organism, as most studies investigate the adverse effects of chronodisruption focusing on males. Women might be more vulnerable to chronodisruption as a result of endocrine imbalances. An impaired gonadal hormonal rhythm affects the clock gene *Per2* in brain regions related to mood and reward (Perrin et al., 2006). Blunted rhythms in *Per2* expressions were observed in a sub-set of mood-regulating brain areas in animals showing anxiety-like behaviors (Landgraf et al., 2016). Moreover, *Per2* knockout animals display alterations in the glutamatergic system, associated with an increased alcohol intake (Spanagel et al., 2005). We hypothesize that an impaired *Per2* expression in brain areas related to mood and reward might be exacerbated in the presence of dysregulated gonadal steroids, thus contributing to increased susceptibility in behavioral changes related to mood and reward. To address this, we exposed adult female rats to an internal desynchrony inducing 11:11 h light/dark (LD22) schedule. During the experiment, female rats had voluntary access to an intermittent two-bottle alcohol paradigm, followed by an ethanol abstinence period. Animals are tested for ethanol preference, and we evaluated mood and reward behavior. The estrus robustness was assessed via locomotor activity. Our findings indicate that internal desynchronization suspends the regular estrus cycle and augments alcohol preference. Under acute ethanol withdrawal, animals show a higher sucrose preference, whereas prolonged ethanol abstinence increases anxiety-like behavior and reduces natural marble-burying behavior. These data highlight the critical link between dysregulated gonadal steroids and behavioral alterations.

Title: Kappa-opioid receptor stimulation in the nucleus accumbens shell differentially and selectively affects ethanol drinking along a rostro-caudal axis

Authors: *B. E. PIRINO[1], A. T. GARGIULO[1], G. R. CURTIS[1], A. N. KARKHANIS[2], J. R. BARSON[1];
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Psychology, Binghamton University- SUNY, Binghamton, NY

Abstract: The kappa-opioid receptor (KOR) and its cognate ligand, dynorphin, are canonically understood to produce negative affective states and, thus, to influence motivated behavior; however, a growing body of evidence demonstrates that the KOR within the nucleus accumbens (NAc) shell exerts opposing effects on affective behaviors, depending on the site of its stimulation. Importantly, no research to date has demonstrated that KOR stimulation in the NAc shell affects ethanol intake. Thus, to determine if KOR stimulation in the NAc shell can impact ethanol drinking, and if this depends on its rostro-caudal location, we trained adult, male Long-Evans rats to drink 20% v/v ethanol under an intermittent access two-bottle choice paradigm for 8-10 weeks and then bilaterally microinjected the selective KOR agonist U-50,488H (0.008, 0.08, 0.8 and 8.0 nmol) vs. saline vehicle (0.3 µl), prior to daily ethanol access, in the rostral, middle, or caudal NAc shell, using a within-subject Latin-square design. Then, to determine if the observed effects were selective for ethanol drinking, we trained a separate group of rats to drink 2.5% w/v sucrose under the same intermittent access model and then microinjected them within-subject prior to daily sucrose access with U-50,488H (0.8 and 8.0 nmol) or saline vehicle (0.3 µl), into either the rostral or caudal NAc shell. We found that, in rats trained to drink ethanol, while KOR stimulation in the middle shell had no effect on ethanol intake, stimulation in the rostral shell decreased ethanol consumption and stimulation in the caudal shell instead increased it. In contrast, in rats trained to drink sucrose, KOR stimulation in neither the rostral nor the caudal shell affected sucrose intake. These results demonstrate that KOR stimulation at distinct rostro-caudal points in the NAc shell induces opposing and selective effects on ethanol drinking. In light of prior research demonstrating that rostral KOR stimulation induces positive affective states while caudal stimulation induces negative affective states, the present findings appear to be consistent with the idea of the “dark side of addiction,” whereby rostral KOR stimulation reduces, and caudal stimulation enhances, ethanol drinking.

Title: Sex differences in operant alcohol self-administration in rats following a covid-19 induced abstinence

Authors: H. N. CARLSON[1], **S. C. GIRONDA**[1], S. R. PITCAIRN[1], M. I. ALLEN[2], J. L. WEINER[1];
[1]Wake Forest Sch. of Med., Winston-Salem, NC; [2]Wake Forest Univ., Winston-Salem, NC

Abstract: Although men have a higher incidence of developing alcohol use disorder than women, this gap is narrowing and women may also be more sensitive to the maladaptive CNS effects of excessive alcohol use. Unfortunately, relatively few non-human animal studies have addressed possible sex difference in alcohol drinking-related behaviors. To begin to address this gap in our knowledge, we investigated whether there were any sex-specific outcomes associated with varying durations of alcohol abstinence in Long Evans rats. Male and female rats (8/gp) were trained to complete a 20 lever press response requirement to receive access to a sipper tube containing a 10% alcohol solution for a 20 minute free consumption period. After a baseline period of responding, rats underwent a series of increasing periods of forced abstinence, culminating in a 74 day abstinence necessitated by a Covid-related lab shutdown. Extinction probe trials, during which no amount of lever pressing resulted in delivery of the sipper tube, were conducted during the baseline period and following each abstinence period, to assess seeking behavior. All phases of acquisition, maintenance, and extinction probe responding were performed at the same time of day to reduce external variables. No significant sex differences were noted in the acquisition rate of alcohol self-administration. During a two week baseline, females consumed significantly more alcohol than males but there were no sex differences in extinction responding. A 2- and 10 day forced abstinence period had minimal effects on alcohol intake and the 10-day abstinence transiently reduced extinction responding in both sexes. Interestingly, following the post-Covid abstinence period, male rats showed a transient decrease in alcohol intake and extinction responding, while neither measure was affected in females. Finally, after baseline responding had been re-established in both cohorts, we found that females were more resistant to quinine adulteration of the alcohol solution. Together, these findings reveal the female rats are markedly less sensitive to the effects of prolonged abstinence on appetitive and consummatory alcohol drinking-related measures and may be more prone to exhibit compulsive drinking behaviors.

Title: Long-term but not short-term alcohol binge drinking leads to changes in the gut microbiota and the fecal metabolome in adult male baboons

Authors: *D. PIACENTINO[1], S. GRANT-BEURMANN[2], C. VIZIOLI[3], X. LI[4], V. RUIZ-RODADO[5], M. R. LEE[1], P. V. JOSEPH[3], C. F. MOORE[6], C. M. FRASER[2], E. M. WEERTS[7], L. LEGGIO[1];
[1]NIH/NIDA, Baltimore, MD; [2]Inst. for Genome Sci., Univ. of Maryland Sch. of Med., Baltimore, MD; [3]NIH/NIAAA, Bethesda, MD; [4]NIH/CC, Bethesda, MD; [5]NIH/NCI, Bethesda, MD; [7]Div. of Behavioral Biol., [6]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Binge drinking is a pattern of drinking that brings the blood alcohol (EtOH) level (BAL) to over 0.08 g/dL in about 2 hours. It's a public health problem, causing 45,000 deaths in the US each year. Research is lacking on the role of the microbiota-gut-brain axis on EtOH binge drinking. We previously showed that EtOH binge-like exposure induces a significant and detrimental decrease in gut microbial α-diversity in Wistar rats. Here, we investigated whether EtOH binge drinking is associated with significant changes in the gut microbiota and/or in fecal metabolites related to gut microbial dysbiosis in adult male baboons of the sp. *Papio Anubis*. We studied three groups: **S**=**S**hort-term EtOH exposure group, self-administering EtOH for 2-3 yrs (*N*=5); **L**=**L**ong-term EtOH exposure group, self-administering EtOH for >10 yrs (*N*=4); **C**=**C**ontrol group, self-administering Tang®, an isocaloric nonalcoholic drink, for 8 yrs (*N*=5). Daily blood draws confirmed that L and S binge drank 7 dd/week, with BALs constantly >0.08 g/dL (range=0.09-0.15 g/dL) after a 2-hour self-administration period. Fecal samples were collected in two conditions: **D**=during 3 days of active **D**rinking (dd 1-3) and **A**=during 3 days of **A**bstinence (dd 4-6). Diet did not vary among animals. Gut microbiota analysis consisted of DNA extraction and 16S rRNA gene sequencing, analysis of microbial species diversity, and comparison of relative taxonomic abundances through Linear Discriminant Analysis Effect Size (LEfSe). Fecal metabolomics relied on UPLC-MS/MS, which identified 564 metabolites. ANOVA and linear mixed-effects models were used for data analysis. The baboons did not differ significantly in age and weight. Microbial α- and β-diversity were significantly decreased in L *vs.* S and C (p's<0.001). At LEfSe, the genera *Lactobacillus* and *Streptococcus* showed high relative abundances in L, the family *Ruminococcaceae* in S, the family *Anaeroplasmataceae* in C (p's<0.01). Microbiota-generated metabolites of aromatic amino acids increased in L *vs.* S and C (p's<0.01). Secondary bile acids produced by the gut microbiota increased in both L and S *vs.* C (p's<0.05). In line with long-term EtOH exposure, mucosal damage markers (N-acetylated amino acids) increased in L *vs.* S and C (p's<0.05). The gut microbiota and the fecal metabolome did not significantly differ under conditions D and A. These novel findings suggest that changes in the gut microbiota and the fecal metabolome occur after long- but not short-term EtOH binge drinking. These changes are not affected by acute forced withdrawal from chronic EtOH exposure. Future research will need to examine if prolonged and sustained abstinence restores the normal gut microbiota.

Abstract: Alcohol use disorder (AUD) is a chronically relapsing disorder, characterized by loss of control in limiting intake, and sometimes involving intermittent periods of abstinence and relapse. Little is understood about how alcohol deprivation during periods of abstinence alters the molecular landscape, and consequently behavior. Using a new *Drosophila melanogaster* alcohol deprivation model, we identify how alcohol deprivation alters spontaneous behavior, uncover the associated neural structures, and determine correlated changes in gene expression in the brain. Using high content behavioral tracking approaches, we found that repeated alcohol experiences followed by a period of alcohol deprivation induce behavioral features associated with a negative affect state, including changes in social behavior. We mapped the behavioral features to activation of specific regions in the brain and found that the mushroom body and surrounding neuropil were involved in the social behavioral shifts associated with alcohol use as well as alcohol deprivation. Using RNAseq, we found brain-wide alterations in gene expression, implicating genes associated with sensory responses, and neural plasticity. Immunity genes became upregulated following daily repeated alcohol exposures, and persisted with one or two days of alcohol deprivation, suggesting a persistent change in molecular function. Our study provides the framework for understanding how alcohol deprivation alters the molecular landscape in neural circuits, thus initiating behaviors that can prompt relapse into alcohol use and abuse.

Title: A single alcohol pre-exposure alters dorsolateral striatal AMPA receptor dependent binge and quinine-adulterated alcohol drinking in C57BL/6J mice.

Authors: *M. R. BAUER, M. M. MCVEY, S. L. BOEHM;
Indiana University, Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Compulsive alcohol drinking is a defining characteristic of alcohol use disorder and the dorsolateral striatum (DLS) is implicated in regulating this inflexible behavior. Synaptic restructuring occurs following long-term use of alcohol leading to hyperactivation of ionotropic glutamate receptors. Glutamatergic afferents bind post-synaptic AMPA-gated GABAergic medium spiny neurons in the DLS, a brain region involved in the development of behavioral compulsivity. AMPA receptors (AMPARs) have been implicated in both goal-directed (dorsomedial striatal dependent) and DLS dependent inflexible behaviors with DLS inhibition altering inflexible behavior including habit and compulsion. The AMPAR antagonist, NBQX, has been shown to reduce alcohol consumption when administered systemically in mice (Bauer, Garcy, & Boehm, 2020) or into the DLS of rats (Corbit, Nie, & Janak, 2014). However, much remains unknown about the role of AMPARs in the control of binge-like alcohol drinking or compulsive alcohol drinking in mice. The purpose of this experiment was to antagonize DLS AMPARs during compulsive-like quinine-adulterated alcohol (QuA; 0.5 mM) drinking and non-compulsive binge-like alcohol drinking using Drinking-in-the-Dark (DID). C57BL/6J mice were given a total of 21 days of either a binge alcohol history, to establish a compulsive-like phenotype, or a water history to serve as alcohol naïve controls, prior to infusion. On days 22 and 24 mice were given a bilateral infusion of one of three concentrations of NBQX (0, 0.3, or 1 μg; n = 7-11/group) into the DLS, immediately prior to DID. We found that DLS NBQX reduced 2-hour alcohol drinking in male water history mice ($p < 0.01$) and reduced 2-hour QuA drinking when QuA was the second solution presented (i.e. following a single alcohol pre-exposure) in male water history mice only ($p < 0.05$; n = 3-6). We also found that NBQX trended toward reducing 20-minute front-loading of alcohol in female alcohol history mice only ($p = 0.07$). Importantly, locomotor activity was not disrupted by NBQX at any dose (p's > 0.05). Together, these data suggest that DLS infusion of NBQX reduces alcohol drinking in male water history mice, QuA drinking in male water history mice but only after an initial alcohol pre-exposure, and alcohol front-loading in female alcohol history mice only. These results demonstrate the importance of DLS AMPA receptors for prevention of binge-like alcohol drinking in naïve male mice, the relevance of a single alcohol pre-exposure on DLS mechanisms, namely susceptibility to AMPAR antagonism, and demonstrates that DLS mechanisms of binge-drinking differ by sex. This work was supported by NIH/NIAAA grant AA07611.

Title: The vulnerability to develop compulsive alcohol drinking as a coping strategy is mediated by the kappa opioid system

Authors: *L. MARTI-PRATS, C. GIULIANO, A. BELIN-RAUSCENT, M. FOUYSSAC, C. VELAZQUEZ-SANCHEZ, X. ZHANG, B. J. EVERITT, D. BELIN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Most individuals drink alcohol recreationally and enjoy its positive and anxiolytic effects. However, a subset of vulnerable individuals progressively lose control over intake and develop the compulsive alcohol seeking and drinking that is a key feature of alcohol use disorder (AUD). While the psychological and neural basis of this vulnerability are complex, it is well established that the medication of an internal distress as a coping strategy is an important factor in AUD, as indicated by the recent exacerbation of problem drinking associated with social isolation in response to the COVID-19 pandemic lockdowns. However, the underlying neural and behavioural mechanisms are not well understood. Here, we developed a novel procedure that enables the identification of inter-individual differences in drinking alcohol to cope with distress, as measured in a Schedule-Induced Polydipsia procedure (SIP). We causally tested the hypothesis that this individual tendency to drink alcohol as a coping mechanism predicts an increased vulnerability to develop compulsive, quinine-resistant, alcohol drinking that is mediated by the dynorphin/kappa opioid receptor (KOR) system, long associated with negative emotional states. Two cohorts of Sprague-Dawley rats were exposed to SIP, a procedure in which intermittent food delivery triggers a state of internal distress that some rats learn to cope with by developing adjunctive anxiolytic behaviours, such as excessive intake of freely available water. We showed that while some rats learned to cope with distress triggered by the SIP procedure by drinking water, as evidenced by a profound decrease in anxiety as measured in an elevated plus maze task, others only acquired this adjunctive, anxiolytic response when alcohol, but not water, was available. The subpopulation that acquired alcohol adjunctive drinking did not differ from those adjunctively drinking water in terms of alcohol exposure, but they persisted in drinking alcohol when adulterated with quinine. Hence, only those rats that drank alcohol to cope with distress went on to drink alcohol compulsively. Furthermore, acute administration of the KOR antagonist norbinaltorphimine, decreased alcohol intake selectively in this vulnerable

subpopulation, suggesting an important role of the dynorphin/KOR system in the use of alcohol to self-medicate distress. These results suggest that acquisition of alcohol drinking under negative reinforcement, associated with an alteration of the dynorphin/KOR system, enhances the later likelihood of developing compulsive drinking in individuals that had been unable to learn to cope with negative states by alternative means.

Title: Adolescent ethanol exposure alters neuronal firing patterns during conditioned approach in orbitofrontal cortex and nucleus accumbens of female rats

Authors: *J. A. POCHAPSKI[1], A. GÓMEZ-A[2], S. J. STRINGFIELD[3], H. JAGGERS[2], C. DANNENHOFFER[2], C. A. BOETTIGER[4], C. DA CUNHA[1], D. L. ROBINSON[2];

Abstract: Adolescence is a critical period of brain development. Exposure to drugs of abuse, including alcohol, during the adolescent period can lead to impairments in cortical and limbic brain regions that are still developing. While many adverse and persistent consequences of adolescent intermittent ethanol (AIE) exposure have been described in male rodents, behavioral and neuronal changes promoted by AIE exposure in females are less described. The present study examined the effect of AIE exposure on neuronal activity in the orbitofrontal cortex (OFC) and nucleus accumbens (NAc) of female rats during Pavlovian conditioned approach (PCA). Sprague-Dawley rats received AIE (5g/kg i.g. ethanol, 2-day-on/2-days-off) or water control (CON) throughout adolescence (P25-54). At approximately P70, rats began PCA training. During the PCA sessions, a 30-second conditioned stimulus (CS), presented as a cue light and lever extension, predicted delivery of a 20% sucrose reward. Electrode arrays were implanted in the OFC and NAc allowing single unit neuronal activity recordings during the PCA sessions and also during a reward omission session. Based on a major expression of a sign tracking (ST) phenotype in both groups and to better focus on the effects of AIE, we conducted analysis only in ST animals (AIE: n=14 rats; CON: n=8 rats). AIE-exposed rats exhibited less reward receptacle interaction, represented by a more negative elevation score (ES) in the baseline

session ($P \leq 0.05$), although this difference disappeared during the reward omission session. OFC neurons in AIE rats displayed greater excitation at CS onset and CS offset during the baseline session (P's≤ 0.05) and at CS onset during the omission session ($P \leq 0.05$). These data describe a stronger neural response to cues in the OFC of rats after AIE exposure compared to control rats. AIE exposure also promoted a decrease in NAc neuronal firing rates during the receptacle entry after CS onset ($P < 0.01$). The firing rate to CS onset in a subset of neurons in the OFC and NAc predicted subsequent conditioned approach in a trial-by-trial analysis. The proportion of these correlated neurons was higher in the NAc of AIE-exposed rats than CON in the baseline session ($P < 0.01$), and the difference disappeared in the omission session. In contrast, correlated neurons in the OFC did not differ between AIE and CON rats in the OFC on baseline day, but was smaller in AIE rats on omission day ($P \leq 0.05$). In summary, these results describe persistent AIE-promoted changes in fronto-limbic processing of conditioned cues and approach, indicating that adolescent alcohol exposure can produce lasting effects on the neurocircuitry of reward-motivated behavior.

Title: Abstinence Driven Changes in Functional Brain Network Activity when Viewing Alcohol Cue Imagery

Authors: *H. PETERSON[1], P. J. LAURIENTI[2];
[1]Wake Forest Sch. of Med., Winston-Salem, NC; [2]Radiology, Wake Forest Hlth. Sci., Winston-Salem, NC

Abstract: Alcohol is a leading risk factor for substantial health loss and global disease burden, but cessation of alcohol consumption is highly associated with stress and alcohol cravings, which drive risk of relapse. An increased understanding of the physiology underlying alcohol abstinence will help to illuminate these and other underlying risk factors and contribute to increases in global health. To examine the biological effects of abstinence, this study recruited daily drinkers without symptoms of an alcohol use disorder (AUD), who drink frequently enough that abstinence was a novel or unusual state. These daily drinkers followed their typical consumption pattern and abstained for four sequential days, respectively, in randomized order. Functional MRI (fMRI) data was collected on the fourth day of each experimental period.

During scanning, participants viewed a series of neutral images, followed by a series of alcohol related images. Functional connectivity of the Default Mode Network (DMN) and the Salience Network (SN) was compared across the imagery tasks and the drinking states. Significantly stronger connections were found within both networks during the alcohol viewing task, with no significant difference observed between the neutral and alcohol tasks in a control network. Furthermore, in the SN, this strength difference was only observed following abstinence (no significant difference across tasks following normal drinking), and the increase in connectivity strength during alcohol cue viewing was significantly stronger during abstinence compared to normal drinking in the DMN. These findings suggest an increase in self-referential thinking and selective attention during alcohol cue viewing driven by alcohol abstinence and the personal experiences associated with it: the neutral cues seem personally irrelevant and are filtered for inattention rather than detection, while the alcohol cues are personally significant to the daily drinkers and become highly salient, even after only a brief period of abstinence.

Title: Approach-avoidance conflict resolution: Sex differences and relationship with voluntary ethanol drinking and compulsive seeking

Authors: *T. A. MCNAMARA, R. ITO;
Psychology, Univ. of Toronto, Scarborough, ON, Canada

Abstract: Alcohol use disorder (AUD) presents a significant health and financial burden for society. Women, although diagnosed with AUD at a lower rate, are susceptible to faster progression to problematic drinking than men. Additionally, women suffer more severe negative health consequences as a result of AUD. Despite this, female subjects are underrepresented in preclinical AUD research. One major component of AUD, compulsive alcohol seeking, may be instigated by an aberrant approach-avoidance conflict resolution, or the inability to avoid a stimulus that simultaneously signals rewarding and aversive outcomes. We had previously shown that repeated cocaine exposure biases male rats towards approach of conflict cues, but little is known about how conflict resolution relates to ethanol drinking in females. The current study used 28 Long-Evans rats of each sex to examine sex differences in approach-avoidance conflict behavior and determined the ability of conflict-induced approach/avoidance tendencies to predict future drinking. First, rats underwent a y-maze conditioning paradigm in which they learned to associate distinct visuo-tactile bar cues with sucrose (appetitive), footshock (aversive), or no outcome (neutral). On the conflict test, the rats were presented with an arm lined with both

appetitive and aversive cues, and an arm containing neutral cues, with the time spent in the conflict vs. neutral arms used to assess approach/avoidance tendencies in the face of conflict. Subsequently, animals were trained to self-administer 20% v/v ethanol on a FR3 15-min schedule. Rats were then challenged with a progressive ratio test, extinction, and mild footshock delivery during ethanol consumption. The following sex differences were observed: 1) males demonstrated greater approach tendencies than females on the conflict test, 2) females, however, displayed higher levels of drinking and reached higher breakpoints in the progressive ratio test, and 3) females lever pressed at higher rates and consumed more ethanol in the face of footshock administration. Approach-avoidance tendencies were not related to ethanol consumption, but higher conflict-induced approach tendencies were associated with increased resistance to footshock in both males and females. This work highlights novel sex differences in approach-avoidance conflict behavior while replicating known sex differences in ethanol drinking. Most significantly, this work identifies approach tendencies in the face of motivational conflict as a potential predictor of compulsive drinking.

Title: Investigating the sex-specific effects of socialization on voluntary ethanol consumption using vapor self-administration in rats

Authors: *C. D. WALKER[1], H. G. SEXTON[3], M.-L. RISHER[2];
[1]Biomed. Res., [2]Biomed. Sci., Joan C. Edwards Sch. of Med., Huntington, WV; [3]Biomed. Res., Joan C Edwards Sch. of Med., Huntington, WV, WV

Abstract: Introduction: Social interactions are crucial in adolescent development. Adolescence is characterized as a transitional developmental period between childhood and adulthood that is associated with increased freedom and new experiences that are often peer-influenced. During adolescence, there is a higher prevalence of alcohol consumption, which is in part due to the heightened social facilitating and rewarding effects of alcohol. Previous work shows that excess alcohol consumption during adolescence increases the risk of developing an alcohol use disorder (AUD) later in life. However, the contributions of social interaction and sexual dimorphism in alcohol consumption are not fully understood. Currently, there are several rat models used to study the characteristics of ethanol (EtOH) use and the emergence of AUD. However, many require the addition of a sweetener to coerce EtOH consumption, which has been shown to

confound results in adolescent rats. Here we use a novel self-administration vapor system to investigate the sexual dimorphic nature of socially facilitated EtOH consumption without added sweeteners.
Methods: Adolescent (PND30) and adult (PND70) male and female Sprague-Dawley rats used nosepoke initiated self-administration vapor chambers administering 20mg/L of vaporized EtOH or air (control) in response to each nose poke. Animals underwent intermittent EtOH vapor access every other day for a total of 40 sessions. All animals underwent 10 sessions with their cagemate (social) followed by 10 sessions in isolation, 10 day forced abstinence, 10 isolation sessions, and 10 social sessions.
Results: We observed that while female rats consumed more EtOH than age-matched males, male rats increase EtOH preference over sessions regardless of age. All rats consumed more EtOH during the first social session than the subsequent isolated sessions. There was an increase in EtOH consumption in adult females during the second social session compared to the previous isolated sessions that was not observed in males.
Conclusion: These data reveal that female and male rats are vulnerable to socially facilitated EtOH consumption regardless of age. This is consistent with human data showing that alcohol consumption increases among adolescents and young adults in social settings. However, only male rats demonstrate escalation across sessions indicating that they may be more vulnerable to the development of EtOH dependence. These data demonstrate that the self-administration vapor system is an effective alternative to other methods of voluntary EtOH administration for investigating factors that contribute to alcohol use and escalation during adolescence.

Title: The development of depression-like behavior and alcohol self-administration following exposure to repeated variable stress in female mice: Interaction between age and endogenous dynorphin

Authors: *S. AHMEDYAR, K. LUTFY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Prolonged activation of endogenous dynorphin-kappa opioid receptor (DYN-KOR) system via chronic stress has been implicated in the development of neuropsychiatric disorders as well as in alcoholism. Prevalence of depression is higher in women and individuals aged 18-35 (SAMHSA, 2017). In a preliminary study, we evaluated the impact of age and the role of

DYN-KOR system in the development of negative affective states that occur following repeated variable stress (RVS) exposure in female mice. RVS paradigm was developed to mimic the variable stress events associated with post-traumatic stress disorder. We also assessed the effect of depression-like behavior on alcohol consumption in an age-related manner. Naïve female preprodynorphin (ppDYN) null mice and their littermates/controls underwent a 10-day RVS exposure followed by alcohol self-administration using (6%, v/v) alcohol (ethyl alcohol) in the home cage. Younger mice lacking DYN (n=4) span 1.4-2.5 months, older mice lacking DYN (n=2) between 11-12 months, and age-matched wild-type (WT) littermates/controls (n=4-5 per age group) were used. The 10-day RVS model consists of forced swim test (FST) at temperatures (15°C, 32°C), physical restraint, and elevated plus maze. Experiments were repeated twice with mice from each genotype and age group, except for old mice due to low availability of KO mice. Experimenter was blind to the mouse genotype. All data were analyzed by repeated measures three-way ANOVA (mean ± S.E.M.) followed by Tukey's *post-hoc* test with significance set at $p<0.05$. Our results revealed an interaction between endogenous DYN and age regarding the development of depression-like behavior and initial alcohol self-administration. Young DYN null mice exposed to RVS exhibited greater depression-like behavior as evident by an increase in immobile time in the FST compared to young WT mice and old DYN null mice. Correspondingly, there was a decrease in swim and escape time. Initial alcohol intake (EtOH g/days/mouse kg) was higher in young mice lacking DYN compared to WT. These differences were not observed in old mice of the two genotypes. Together, these results suggest that there is an influence of age in the development of negative affective states following exposure to RVS and endogenous DYN may serve as a protective role in the brain against stress-induced depression-like behavior in young female mice. Moreover, the neuropeptide attenuates initial alcohol consumption in young but not old female mice. In conclusion, endogenous DYN may serve as an internal brake to reduce the development of depression-like behaviors and the subsequent increase in alcohol self-administration in young female mice.

Title: High baseline lateral habenula firing correlates with low motivation to seek ethanol in an intermittent access to ethanol paradigm

Authors: *S. TANDON;
Univ. of Utah.

Abstract: Many adults consume alcohol regularly; however, only some vulnerable individuals develop alcohol use disorder (AUD). This variability in the risk for alcohol abuse is multifactorial and includes differences in behavioral traits. The lateral habenula (LHb) is known to mediate aversive state-related behavioral responses. Interestingly, in both humans and rodents, depression-like symptoms are associated with high LHb activity. Moreover, there is a high co-morbidity between major depressive disorder and AUD in humans. Hence, we wanted to determine whether individual variation in LHb activity and behavioral state in ethanol-naïve rats affect their home-cage ethanol drinking patterns. Thus, in this study, we determined the correlation between individual variability in baseline LHb neural activity, the negative-affective state-related ultrasonic vocalizations (USVs; 22-28 kHz), and the extent of ethanol use over time. To do so, we surgically implanted a unilateral 16-wire electrode array in the LHb of adult male Long Evans rats (n=11). Rats were placed in sound-insulated chambers for two hours, where they were free to explore while we simultaneously recorded neuronal signals from their LHb and their ultrasonic vocalizations. Next, these rats underwent an intermittent access to ethanol (IAE) paradigm, where they received 20% ethanol for 24 hours on alternate days and ad-libitum water in their home cages for four weeks. The change in ethanol intake over time differed between rats, with some rats escalating their ethanol intake in the four weeks, while other rats showed no meaningful change in ethanol intake over time as compared to the first session. We found a significant negative correlation between average LHb firing rates and changes in ethanol intake in the first week of IAE, such that rats with higher baseline LHb activity did not escalate their ethanol intake with more sessions. We also found a weak positive correlation between the number of 22-28 kHz USVs and the average baseline LHb firing rates of these rats. These results indicate that higher baseline LHb neuronal activity in individual rats is associated with decreased motivation to seek ethanol during the early stages of ethanol consumption. Currently, we are determining the correlation between the number of 22-28 kHz vocalizations and the positive affective state vocalizations (50-55 kHz) emitted by adult male Long Evans rats rats (n=12) prior to their ethanol sessions each week in the IAE paradigm and the increase in ethanol intake over time.

Title: Intermittent access to alcohol drives increased colocalization of glutamate and GABA markers in ventral pallidum

Authors: *R. GAO, G. BADGER, M. CARPIO, A. SOOD, C. A. CAYTON, J. M. RICHARD; Univ. of Minnesota, Minneapolis, MN

Abstract: Compulsive use is a major characteristic of alcohol use disorder. Aversion-resistant drinking is a model of compulsive alcohol use, in which animals continue to consume alcohol despite its adulteration with bitter quinine. Neuroadaptations in corticostriatal inputs to nucleus accumbens are important for aversion-resistant drinking, but it remains unclear how these changes impact downstream mediators of aversion-related behaviors. Ventral pallidum (VP) is a major output of the nucleus accumbens known for its role in reward and addiction. Recent work has ascribed reward-related functions largely to VP GABA neurons, whereas VP glutamate neurons mediate aversion-related behaviors. Despite this, whether or how VP is involved in aversion-resistant alcohol drinking remains unknown. In this study, we examined how intermittent access to alcohol (IAA) alters VP neurons and their activity during aversion-resistant drinking. Here, Wistar rats (M:F = 17:19) were allowed to voluntarily drink 15% alcohol with or without adulteration of 0.03 g/l quinine in operant chambers after different durations of IAA experience (3, 8 and >14 weeks). After a final alcohol plus quinine drinking test, brains were quickly extracted and flash frozen. We applied fluorescence *in situ* hybridization (RNAscope) on VP slices, labeling vesicular glutamate transporter 2 (*Slc17a6* [*Vglut2*]), Glutamate Decarboxylase 1 (*Gad1*), and c-fos (*Fos*) RNA to evaluate cell-type-specific activity. Longer IAA increased alcohol consumption, specifically in male rats, but all exposure groups were resistant to quinine adulteration. As predicted, in rats with 8 and >14 weeks of IAA, a lower proportion of *Vglut2*-positive neurons were *Fos*-positive. Interestingly, we found that rats with > 14 weeks of IAA also had a higher proportion of *Vglut2*/*Gad1* co-labeled neurons in VP. Female rats also had a higher proportion of *Vglut2*/*Gad1* co-labeled neurons, but this sex difference did not depend on the length of alcohol exposure. Altogether, these results suggest that intermittent alcohol experience both 1) blunts recruitment of (aversion sensitive) glutamate neurons in VP, and 2) increases co-expression of glutamate/GABA neurons markers, potentially altering downstream co-release. Both effects could contribute to aversion-resistant drinking. Additionally, sex differences in *Vglut2*/*Gad1* co-expression may impact both baseline aversion processing and the development of aversion-resistant drinking. Alterations in cell-type specific activity or co-release in VP are promising targets for further efforts to investigate the mechanisms underlying compulsive alcohol use.

Title: Binge drinking induces age-dependent protein changes in the mouse BNST

Authors: *S. L. SCUDDER, C. L. JIMENEZ CHAVEZ, T. N. KELLEY, K. K. SZUMLINSKI; Psychological & Brain Sci., Univ. California-Santa Barbara, Santa Barbara, CA

Abstract: Patterns of alcohol consumption differ across age groups and age of drinking onset can contribute to adult drinking behavior and likelihood of developing an alcohol use disorder. Binge drinking in particular is highly prevalent amongst adolescents and serves as a risk factor for substance abuse later in life. In rodent models, behavioral manifestations of withdrawal symptoms are more pronounced in adult drinkers relative to adolescents, despite increased consumption in younger animals. Multiple weeks of daily binge ethanol drinking produces robust changes in neuronal activity and protein expression in brain areas such as the nucleus accumbens and the bed nucleus of the stria terminalis (BNST). While the latter region is thought to be essential for controlling an animal's propensity to binge drink, little is known about the age dependence of alcohol-evoked changes in protein expression and neuronal physiology therein. To address this, adolescent (P28) and adult (P56) C57BL/6J mice of both sexes were allowed to voluntarily binge drink during daily 2-hour drinking-in-the-dark sessions for two weeks. Mice were subjected to behavioral evaluations of negative affect and tissue was collected from the anterior dorsal BNST for Western blotting. As in previous studies, adolescent mice consumed more alcohol during sessions on average and showed reduced measures of negative affect at an early withdrawal timepoint. In the BNST, levels of calcium/calmodulin-dependent kinase II alpha (CaMKIIalpha) and extracellular signal-regulated kinase (ERK) were more elevated after drinking in adolescents compared to adults. This engagement of BNST proteins involved in excitatory synaptic scaffolding and plasticity could contribute to adolescent resilience to withdrawal symptoms. Future studies will explore age-dependent differences in BNST plasticity electrophysiologically and examine changes in this region after prolonged withdrawal.

Title: Lrrk2, a Parkinson's-associated protein, regulates striatal D1 receptor function and alcohol drinking in mice

Authors: *D. DA SILVA E SILVA[1], A. MATSUI[1], A. MAMAIS[2], E. MURRAY[1], D. RON[3], M. R. COOKSON[2], V. A. ALVAREZ[4];
[1]NIH, Bethesda, MD; [2]Lab. Neurogenetics, Natl. Inst. Aging, NIH, Bethesda, MD; [3]UCSF, San Francisco, CA; [4]Lab. on Neurobio. of Compulsive Behaviors, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: The transition from hedonic to compulsive drinking is a hallmark of alcohol use disorders. Alcohol exerts acute and chronic actions on striatal circuitry and function, which are thought to promote compulsive-like alcohol drinking despite negative consequences. Leucine-rich repeat kinase 2 (Lrrk2) is a protein with high expression in the striatum which has been shown to regulate dopamine receptor function. Mutations in the Lrrk2 gene are the most common cause of genetic form of Parkinson disease and have been shown to impair D1 receptor internalization and to enhance D1R signaling. In this study, we test the hypothesis that Lrrk2 in striatal neurons regulates dopamine receptor signaling to affect alcohol reinforcement and compulsive-like drinking. We found that acute alcohol administration or alcohol drinking decrease LRRK2 phosphorylation and its kinase activity. The alcohol induced inhibition of LRRK2 kinase activity was seen preferentially in the dorsomedial striatum (DMS), a region involved in mediating goal directed actions. We generated cell-specific knockout mice and evaluated whether a lack of Lrrk2 gene in different neuron types in the striatum would affect alcohol consumption in mice. Mice with global deletion of Lrrk2 or cell-specific deletion of Lrrk2 in D2-expressing neurons in the striatum showed no difference in alcohol drinking compared with littermate controls, however, deletion of Lrrk2 in D1R-positive neurons (D1-Lrrk2 KO) produced an increase in alcohol consumption relative to littermate control mice. When trained to self-administer alcohol in an operant self-administration task, D1-Lrrk2 KO mice also showed higher responding and intake. In addition, these mice also showed higher breakpoints and drinking was more resistance to shock punishment and taste adulteration. These results indicated higher motivation to consume alcohol and more compulsive-like alcohol drinking in mice lacking Lrrk2 in D1 MSN. We further explore possible mechanisms underlying these observations and found that D1 receptors function is enhanced in D1-Lrrk2 KO mice. D1-Lrrk2 KO mice show an upward shift in the dose response to the locomotor effects of D1-like agonist. Moreover, electrophysiological recordings from D1R positive neurons in the DMS of D1-Lrrk2 KO mice showed an increase in the excitability of these cells in response to D1-like receptor agonist compared to D1R neurons of littermate wild type mice. These findings suggest that loss of Lrrk2 in direct-pathway striatal neurons causes an upregulation of D1R response, both at the cellular and behavioral level, which is conducive to excessive drinking and compulsive-like alcohol use.

Title: The role of the nucleus accumbens shell in alcohol use despite negative consequences in rats

Authors: *A. J. MCDONALD, I. ALONSO LOZARES, D. SCHETTERS, Y. VAN MOURIK, T. J. DE VRIES, N. J. MARCHANT;
Anat. & Neurosci., Amsterdam UMC, Amsterdam, Netherlands

Abstract: Alcohol use is widespread across most societies. While most people can control their alcohol use, a vulnerable sub-population may develop alcohol use disorder (AUD), characterized by continued use of alcohol despite negative consequences. We used a rodent model of alcohol use despite negative consequences, to identify neurobiological differences that may underlie addiction-like behavioral vulnerability. We and others have previously shown that this approach reliably identifies two sub-populations of rats. One group substantially decreases alcohol use in the face of punishment (punishment-sensitivity, controlled use) and another group continues alcohol use despite negative consequences (punishment-resistance or insensitivity, addictive-like behavior). In this study we aim to identify the role of the nucleus accumbens shell (NAcSh) in this divergent response to punishment of alcohol use. We trained Long-Evans outbred rats (n=60, m/f) to self-administer alcohol, and then introduced punishment of alcohol self-administration with response-contingent foot-shock. We found a significant proportion of rats persisted with alcohol self-administration in the face of mild punishment. Interestingly, we found that more female rats developed punishment-resistant alcohol use compared to male rats. In one group of rats (n=24) we used immunohistochemical detection of the neuronal marker of activity c-Fos to identify brain activity associated with punishment-resistant alcohol use. We found that lower c-Fos expression in NAcSh was associated with punishment-resistant alcohol use, compared to punishment-sensitive rats, and rats tested without punishment. To test for a causal role of NAcSh activity in punishment-resistant alcohol use, in another group of rats (n=36) we used chemogenetic inhibition (hM4Di) of NAcSh throughout different phases of the experiment. We found that chemogenetic inhibition of NAcSh had no effect on either unpunished alcohol self-administration or motivation for alcohol in a progressive ratio test. During punishment however, NAcSh inhibition increased alcohol self-administration in the punishment-resistant rats. In an unpunished probe test, alcohol-seeking was induced in all rats regardless of punishment-sensitivity. This work identifies an important role of NacSh in the expression of behavioral control in response to alcohol use despite negative consequences. Understanding the contribution of NAcSh, and associated neural circuits, in the suppression of addictive-like behavior will provide us with a greater understanding of the neurobiological underpinnings of AUD, and may lead to future treatment developments.

Title: Comparative effects of selective chemogenetic inhibition of projections from basolateral amygdala to nucleus accumbens core and the ventral subiculum to nucleus accumbens shell on an operant alcohol self-administration task

Authors: *H. N. CARLSON[1], J. WEINER[2];
[2]Dept. of Physiol. and Pharmacol., [1]Wake Forest Univ., Winston-Salem, NC

Abstract: Emerging evidence suggests inputs from the basolateral amygdala and ventral subiculum to the nucleus accumbens play a prominent role in a wide array of motivated behaviors, including those associated with drugs of abuse. However, there remains a paucity of research evaluating the involvement of these circuits in alcohol-drinking related behaviors. Thus, the present experiments aimed to characterize the comparative contributions of these projections on motivation for alcohol in an operant self-administration task designed to methodologically dissociate discrete phases of appetitive and consummatory behavior. Male Long-Evans rats (N=16) were trained to complete a 20 lever press response requirement to receive access to a sipper tube filled with a 10% ethanol solution for free consumption. Additionally, extinction probe trials during which no amount of lever pressing resulted in delivery of the sipper tube were included in the experimental design to assess responding independent of immediate reinforcement. Following training, animals received surgery for viral injection of inhibitory (Gi) DREADDs into either the BLA or vSub and bilateral guide cannula implantation into the NAcC or NAcSh, respectively. Following recovery and baseline behavior monitoring, counterbalanced injections of clozapine n-oxide (30, 100, and 300 nM) or vehicle (ACSF) were delivered once weekly 5 minutes prior to behavioral testing, such that each animal received each dose once. Histological confirmation of viral expression and cannula placement is ongoing. We report that temporary inactivation of either the BLA-NAcC or vSub-NAcSh reduced extinction probe responding with minimal effects on intake, suggesting that both circuits play an important role in appetitive, but not consummatory, alcohol-drinking related behaviors. Furthermore, inhibition of BLA-NAcC, but not vSub-NAcSh, produced a significant alteration in extinction responding for sucrose. Together, these studies have further elucidated novel circuits that might be targeted by pharmacological treatment for alcohol seeking.

Title: Chronic intermittent ethanol dependent hyperexcitability of the basolateral amygdala to ventral subiculum projection and intrinsic activity of the ventral subiculum

Authors: *E. C. BACH[1], S. EWIN[2], H. CARLSON[2], J. L. WEINER[3], A. BALDASSARO[2]; [1]Wake Forest Baptist Med. Ctr., Winston Salem, NC; [2]Wake Forest Baptist Med. Sch., Winston Salem, NC; [3]Wake Forest Univ. Sch. Med., Winston Salem, NC

Abstract: The hippocampus has been implicated in the pathophysiology of alcohol use disorder (AUD) in both human and animal studies. While perturbations in hippocampal function are known to contribute to the cognitive deficits associated with AUD, there is a growing appreciation that this brain region, and particularly the ventral domain, also plays a role in the negative affective symptoms of this disease, as well as those of comorbid conditions like generalized anxiety disorder and post-traumatic stress disorder. The ventral hippocampus (vHC) receives strong excitatory input from the basolateral amygdala (BLA), a central hub of emotional processing that is also known to play an integral role in AUD and comorbid affective conditions. Rodent studies have shown that the BLA-vHC projection bidirectionally modulates anxiety-like behaviors and both brain regions exhibit hyperexcitability in animal models of AUD and anxiety/stressor disorders. However, no studies to date have examined the effects of chronic alcohol on the BLA-vHC circuit. In the present study, we used ex vivo electrophysiology and optogenetics to examine the effects of a well-established rodent model of AUD, chronic intermittent ethanol exposure (CIE), on BLA-vHC synaptic transmission as well as putative intrinsic vHC synaptic activity, in male Long-Evan rats. We discovered that the BLA primarily innervates pyramidal neurons in the subicular region of the vHC (vSub) and that withdrawal from CIE significantly increases excitatory and inhibitory neurotransmission in the BLA-vHC circuit. Notably, CIE led to an overall increase in excitatory/inhibitory ratios along with an increase in the AMPA/NMDA ratio, and no change in pair-pulse ratios, consistent with a postsynaptic increase in excitability. CIE treatment also led to an increase in intrinsic network excitability as evidenced by an increase in sEPSC frequency and the duration of elevated spontaneous excitatory neurotransmission. Overall, our findings suggest that a hyperexcitable state in BLA-vSub specific inputs, as well as intrinsic inputs to vSub pyramidal neurons, may contribute to the negative affective behaviors associated with CIE.

Title: Clock genes in the shell region of nucleus accumbens regulate binge drinking in mice

Authors: *R. SHARMA[1], M. PARIKH[2], V. MISHRA[1], P. SAHOTA[1], M. THAKKAR[1];
[1]Research, Neurol., [2]Truman VA Med. Center/University of Missouri, Columbia, MO

Abstract: INTRODUCTION: Binge drinking is a deadly pattern of alcohol abuse and poses a serious threat to the health and economy of society. Clinical and preclinical studies suggest that misalignment in circadian timing due to genetic variation in clock genes is strongly associated with alcohol abuse, however, the neuroanatomical basis for such a relationship is unknown. The shell region of nucleus accumbens (NAcSh) is well-known for its role in binge drinking. Hence, we ask if clock genes in the NAcSh regulate binge drinking? **METHODS:** To address this question, two experiments were performed on C57BL/6J mice exposed to extensively used, 4-day drinking-in-the-dark (DID) paradigm. The first experiment examined the effects of binge drinking on the expression of circadian clock genes (Clock, Per1, and Per2) in the NAcSh and suprachiasmatic nucleus (SCN). Mice were euthanized on Day 4 after four hours of alcohol consumption and brains were processed for RT-PCR. The second experiment determined the effects of antisense-induced knockdown of circadian clock genes in the NAcSh, using bilateral guide cannula above the NAcSh, on binge drinking. On Day 4, one hour prior to the onset of alcohol exposure, mice were bilaterally infused with either a mixture of Clock, Per1 and Per2 antisense oligodeoxynucleotides (AS-ODNs; Antisense group) or nonsense/random ODNs (R-ODNs; Control group) into the NAcSh. Blood alcohol concentration was measured to confirm binge drinking. Separate groups of mice, infused with AS or R-ODNs were used to examine sucrose (10% w/v) and water consumption using the DID paradigm. Microinfusion sites were histologically verified using cresyl violet staining. **RESULTS:** As compared to sucrose, binge alcohol consumption increased the expression of circadian genes in the NAcSh but not in the SCN. Knockdown of clock genes in the NAcSh caused a significant reduction in the amount of alcohol consumed during four hours of binge drinking as compared to the control treatment. No differences were found in sucrose and water consumption. **CONCLUSIONS:** Our results suggest that the circadian misalignment of clock genes in the NAcSh plays a crucial role in binge drinking.

Title: Cholinergic interneurons in the shell region of neucleus accumbens promotes binge drinking in mice

Authors: *M. PARIKH, R. SHARMA, V. MISHRA, P. SAHOTA, M. THAKKAR; Research, Neurol., Truman VA Med. Center/University of Missouri, Columbia, MO

Abstract: Background: Binge drinking is the most common and deadly pattern of alcohol consumption. However, the underlying neuronal mechanism is not clearly understood. Since cholinergic interneurons, present in the nucleus accumbens (NAc), are crucial for reward and addiction, we hypothesized that chemogenetic activation of CIN in the NAc will increase binge drinking.**Methods:** To address this question, we used C57BL/6J transgenic mice expressing Cre-recombinase in the cholinergic neurons. Mice were bilaterally infused either with excitatory DREADD (Gq, AAV/hSyn-DIO-hM3Dq-mCherry; 500nL/side) or non-specific virus (Ns, AAV/hSyn-DIO-mCherry; 500nL/side; Control) in NAcSh and left them undisturbed for 21 days to allow it to express. Next, mice were subjected to binge alcohol consumption using the extensively used, 4-day drinking-in-the-dark (DID) paradigm. On Day 4, two hours prior to the onset of alcohol exposure, mice either received clozapine-N-oxide (CNO; 5 mg/Kg; Ns-CNO and Gq-CNO; for CIN activation) or saline (Ns-Saline and Gq-Saline; Controls). Blood alcohol concentration was measured to confirm binge drinking. Separate groups of mice, infused with Gq or Ns, were used to examine sucrose (10% w/v) using the DID paradigm. Microinfusion sites were histologically verified using choline acetyltransference (ChAT) immunofluorescence.**Results:** As compared to the Controls, mice in the Gq-CNO group displayed a significant increase in the amount of alcohol consumed during four hours of binge drinking on day 4 of the DID paradigm. No differences were found in sucrose consumption.**Conclusions:** Our results suggest that binge drinking is regulated by CIN neurons in the NAcSh.

Title: Cd5 knockout mice exhibit reduced sensitivity to the sedative effects of alcohol and alcohol consumption

Authors: *B. M. WILLIAMS[1], A. J. PAYNE[2], J. D. OBRAY[3], C. J. CHAPMAN[2], C. A. SMALL[2], J. N. BRUNDAGE[2], J. T. YORGASON[4], S. K. WEBER[5], S. C. STEFFENSEN[6];

Abstract: Cluster of differentiation 5 (CD5), a transmembrane protein expressed in both T and B lymphocytes, modifies inhibitory synaptogenesis during development and displays altered expression profiles following chronic ethanol (EtOH) use. Specifically, the number of CD5+ B cells is reduced during EtOH withdrawal while the number of T cells is increased. Given recent research suggesting that some of EtOH effects are accounted for by neuroimmune interactions, we assessed the effects of EtOH on neuronal activity in the ventral tegmental area (VTA), dopamine release in the nucleus accumbens (NAc), and behavior in CD5 knockout (KO) mice vs wild-type (WT) controls. There was no significant difference in baseline firing rate or EtOH inhibition of VTA GABA neurons or evoked DA release in the NAc of CD5 KO vs WT mice. However, CD5 KO mice were characterized by markedly reduced DA overflow (i.e., frequency response) compared to WT mice. CD5 KO mice were characterized by lower baseline locomotor activity in the open-field paradigm, with reduced sensitivity to EtOH sedation (0.5 - 2.0 g/kg) and loss of righting reflex (4.0 g/kg) compared to WT mice. In a 24-hr access two-bottle choice drinking paradigm, CD5 KO mice exhibited markedly less consumption of EtOH than WT mice (9.4 vs 19.1 g/kg/day). These results suggest that CD5 KO mice are less sensitive to some of the effects of EtOH and that peripheral neuroimmune mechanisms involving CD5 may be a factor in EtOH consumption and sedation.

Title: Mechanisms underlying alcohol augmentation of COVID-19 pathologies

Authors: H. ZHOU[1], W. HUANG[2], C. HODGKINSON[3], A. MONTERO[2], D. GOLDMAN[3], *S. L. CHANG[2];
[1]Dept. of Biol. Sci., [2]Dept. of Biol. Sci. & Inst. of NeuroImmune Pharmacol., Seton Hall Univ., South Orange, NJ; [3]Lab. Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism Lab. of Neurogenetics, Rockville, MD

Abstract: The coronavirus disease 2019 (COVID-19) pandemic is a worldwide crisis caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Many COVID-19 patients present with fever in the early phase, with some progressing to a hyperinflammatory phase.

Ethanol (EtOH) can increase intestinal permeability to gut-derived microbial endotoxins, leading to systemic inflammation. We hypothesized that exposure to EtOH can thereby augment SARS-CoV-2-induced inflammation. Unfortunately, medical records of COVID-19 patients are sparse for drinking history. Therefore, this study utilized an *in silico* bioinformatic approach to examine the relationship between EtOH consumption and COVID-19 pathologies. Molecules associated with EtOH exposure were identified by analysis with QIAGEN Knowledge Base (QKB). Molecules associated with COVID-19 were identified from published literature on COVID-19, QIAGEN Coronavirus Network Explorer (QCNE), and analysis of the RNA-Sequencing data of autopsied lungs of COVID-19 patients retrieved from the Gene Expression Omnibus (GEO) database to identify genes whose expression was perturbed by COVID-19. QIAGEN Ingenuity Pathway Analysis (IPA) was used to analyze molecules associated with both EtOH and COVID-19. Our analysis suggests that EtOH exposure may augment the effects of SARS-CoV-2 infection on hepatic fibrosis signaling pathway, cellular metabolism and homeostasis, inflammation, and neuroinflammation, and that EtOH may enhance the activity of key meditators including cytokines, such as interleukin (IL)1β, IL6, interferon (IFN)γ, and tumor necrosis factor (TNF) and transcription factors, such as hypoxia inducible factor (HIF)1α, JUN, Nuclear factor (NF)κB, and signal transducers and activators of transcription (STAT) while inhibiting the activity anti-inflammatory mediators, such as glucocorticoid receptor (GR) and peroxisome proliferator-activated receptor (PPAR)/retinoid X receptor (RXR). Furthermore, five of these inflammatory mediators, IL1β, IL6, TNF, JUN, STAT, were mapped to ten out of fourteen pathways, including high mobility group protein (HMGB)1, IL1, and IL-6 signaling pathways, predicted to associate with SARS-CoV-2 proteins. This augmentation of symptoms by alcohol can be more fully explored when more complete medical records are available from a large cohort.

Title: Rodent 3D motion capture system uncovers distinct behavioral effects of cannabinoids in freely moving mice

Authors: *B. M. IGNATOWSKA-JANKOWSKA[1], A. GURKAN-OZER[1], A. KUCK[1], M. NIPHAKIS[2], D. OGASAWARA[2], B. CRAVATT[2], M. UUSISAARI[1];

Abstract: One of behavioral effects of cannabinoid CB_1 receptor activation is inhibition of locomotor activity. However, effects of endogenous cannabinoids on behavior have not been extensively studied. Here we aimed to assess whether enhancing endocannabinoid signaling produces effects similar to exogenous cannabinoid agonists.To elevate signaling of endocannabinoids 2-Arachidonoylglycerol and Anandamide we used selective inhibitors (MJN110 and PF3845, respectively) of Monoacylglycerol lipase and Fatty Acid Amide Hydrolase, enzymes responsible for their degradation. High-speed, high-resolution 3D motion capture system (Qualisys) was used to track movement (3D trajectories and velocity of markers) during voluntary locomotor tasks: open field exploration, vertical and horizontal climbing, beam walking, aerial righting reflex.The results revealed distinct behavioral phenotypes induced by different cannabinoids. Low doses of synthetic cannabinoid agonist CP55,940 (0.03, 0.1, 0.3 mg/kg) produced significant bidirectional, task-dependent effects: a decrease of activity and widened stance in the open field, but increased activity in the vertical climbing task (n=10). MJN110 (1.25, 2.5 mg/kg) significantly increased the activity both in the open field and climbing task (n=12). PF3845 significantly decreased locomotor activity (10, 30 mg/kg) in both tasks without affecting stance width (n=12). Moreover, MJN110 (1.25 mg/kg, n=12) increased escape behavior in the open field. In our models, CB1 receptor antagonist AM251 (3 mg/kg) induced significant decrease in activity in all tasks, that was more pronounced than inhibition caused by PF3845 and occluded stimulatory effects induced by MJN110.The results suggest that selective elevation of 2-AG and AEA signaling results in distinct, bidirectional effects on behavior that are different from exogenous cannabinoid agonists. Furthermore, the work highlights the strength of 3D motion capture as precise and sensitive tool to evaluate wide range of behaviors in rodents.

Title: The effects of acute and chronic cannabis sativa and indica consumption on decision-making strategies used by rodents gambling: a cross-over design

Authors: *M. R. LYSENKO-MARTIN[1], C. P. HUTTON[2], H. BRODIE[1], C. A. WINSTANLEY[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]BC Government, Victoria, BC, Canada

Abstract: Cannabis is being legalized globally at increasing rates, making it pressing to understand how acute or chronic exposure to cannabis perturbs decision-making and leads to addiction. The impact of cannabis exposure on decision-making can be quantified using a validated rodent assay of cost-benefit decision-making, the rat Gambling Task, in which exposure to cue-paired probabilistic rewards triggers neurobiological adaptations leading to a pro-addiction phenotype. Long-Evans male rats (N=32) were orally dosed with *Cannabis sativa*, *Cannabis indica*, or a vehicle-control solution daily for 25 days, and regularly performed the cued rat Gambling Task. Animals then underwent a washout period of 40 days with no drug or gambling, after which a treatment cross-over was performed where animals previously given vehicle were chronically dosed with *sativa*, and those previously given *sativa* were given vehicle, and their decision-making strategies were again evaluated on the free choice portions of the gambling task. This cross-over was performed because it is important to distinguish whether decision-making strategies were selected due to the influence of the drug on choice or the influence of the drug on learning. A linear mixed-effects model was used to evaluate rodent risk-profiles. Acutely, rodents exposed to *sativa* exhibited biased decision-making in favour of riskier choices, compared to the optimal response strategies used by *indica*-exposed and control rats. Over chronic use, *sativa*-exposed rats caught up to controls and began to exceed the optimal decision-making strategies compared to all other groups. When the groups were switched after a washout period, choice preference remained unchanged in all groups, but rodents receiving *sativa* took longer to make a choice and completed fewer trials. These results suggest that regular consumption of *sativa* may delay cued reward learning by initially biasing users towards high-risk/high-reward decisions, while *indica* does not impair optimal decision-making on a gambling task. All animals in all conditions end up learning the most optimal choice preference, but the time they take to do so, and the impulsiveness with which they perform, are negatively affected by *Cannabis sativa.*

Title: Exposure to high-THC cannabis smoke during gestation alters development and anxiety of Sprague Dawley rat offspring

Authors: T. SANDINI[1], A. ROEBUCK[2], M. HERDZIK[1], D. MCELROY[1], T. ONOFRYCHUK[1], S. ORVOLD[1], A. ZAGZOOG[1], Q. GREBA[1], R. LAPRAIRIE[1], *J. G. HOWLAND[1];

Abstract: Rationale and Objective: Cannabis use among pregnant women is a growing public health concern. With recent legalization of cannabis in many jurisdictions, there is an urgent need to understand the impact of its use during pregnancy on fetal neurodevelopment and behavioural outcomes in exposed offspring. Currently, there is limited data regarding the effects of exposure to the smoke of combusted cannabis flowers in preclinical rodent studies. To address this limitation, we tested the effects of repeatedly exposing female Sprague Dawley (SD) rats during pregnancy on behaviour of the male and female offspring. **Methods**: Rats were exposed to the smoke of combusted cannabis flowers in two experiments using a commercially available system from La Jolla Alcohol Research, Inc. In experiment one, we performed an acute dose response experiment to assess plasma levels of Δ9-tetrahydrocannabinol [THC] and its metabolites following exposure to the smoke generated by combusting 60, 200, or 600 mg of a commercially available strain of cannabis flower (Aphria 'Mohawk'; 19.51% THC, <0.07% cannabidiol [CBD]). In a second experiment, pregnant SD rats were exposed to 200mg of cannabis smoke (n = 12) or a room air control (n = 10) daily from gestational day (GD) 6 to 20. We used this model to determine the effects of prenatal cannabis smoke exposure on maternal reproductive parameters and long-term behavioral alterations of male and female adulthood offspring. **Results:** Plasma THC levels were approximately 1 ng/mL and 10 ng/mL in rats exposed to 200 or 600 mg of cannabis, respectively. 11-OH-THC and 11-COOH-THC were also significantly increased in a dose-dependent manner. Exposure of pregnant rats to the smoke generated by combusting 200 mg of cannabis flower from GD6 to GD20 significantly decreased body temperature in the cannabis exposed dams immediately following each session. However, maternal weight gain, food intake, gestational length, litter number, and litter weight were not altered. There was a significant increase in the male-to-female ratio in the cannabis-exposed litters. In young adulthood, both male and female cannabis smoke-exposed offspring spent less time exploring the inner zone of an open field. Analysis of sociability and cognition in the offspring are in progress. **Conclusions**: These results demonstrate that repeated exposure to high-THC containing cannabis smoke during gestation alters sex ratios of the offspring and anxiety-like behaviors in the offspring.

Title: Dissociable changes in spike and wave discharges following exposure to injected cannabinoids and smoked cannabis in Genetic Absence Epilepsy Rats from Strasbourg

Authors: *A. J. ROEBUCK[1], Q. GREBA[2], T. J. ONOFRYCHUK[2], D. L. MCELROY[2], T. M. SANDINI[2], A. ZAGZOOG[2], J. SIMONE[3], S. CAIN[4], T. P. SNUTCH[4], R. LAPRAIRIE[2], J. G. HOWLAND[5];

Saskatchewan, Saskatoon, SK, Canada

Abstract: In the last decade there has been significant interest in the use of cannabinoids for treatment of many epilepsies including absence epilepsy (AE). Genetic Absence Epilepsy Rats from Strasbourg (GAERS) model many aspects of human AE including the presence of spike-and-wave discharges (SWDs) on electroencephalogram (EEG) and behavioural comorbidities, such as elevated anxiety. Compared to Non-Epileptic Control (NEC) rats we have recently identified regional alterations in the endocannabinoid system in GAERS and shown that treatment with a type 1 cannabinoid receptor positive allosteric modulator reduces SWDs. However, the effects of cannabis plant-based phytocannabinoids have not been tested in GAERS. Therefore, we investigated how SWDs in GAERS may be altered by the 2 most common phytocannabinoids, Δ^9-tetrahydrocannabinol (THC) and cannabidiol (CBD), and exposure to smoke from 2 different strains of cannabis. Animals were implanted with bipolar electrodes in somatosensory cortex and EEGs recorded for 2 hours. Injected THC (1-10 mg/kg, *i.p.*) dose-dependently increased SWDs to over 200% of baseline. In contrast, CBD (30-100 mg/kg, *i.p.*) produced an ~50% reduction in SWDs. Exposure to smoke from a commercially available strain of high-THC cannabis (Mohawk, Aphria) increased SWDs in GAERS. This effect may be strain/dose-dependent as a low-THC/high-CBD strain of cannabis (Treasure Island, Aphria) did not significantly increase or decrease seizures. Lastly, pre-treatment with a CB1R antagonist (SR141716A) did not prevent the high-THC cannabis smoke from increasing SWDs suggesting that the THC-mediated increase is not CB1R-dependent. Together these experiments provide initial evidence that acute phytocannabinoid administration exerts biphasic modulation of SWDs and may differentially impact patients with AE.

Title: Impact of adolescent THC exposure on reward-related behavior in adulthood

Authors: *B. HALBOUT[1], C. HUTSON[1], L. HUA[2], J. MONTESINOS[2], S. V. MAHLER[3], S. B. OSTLUND[1];

Abstract: Adolescent brains are particularly vulnerable to the adverse effects of cannabis exposure, which include increased risk of exhibiting neuropsychiatric disorder and neurocognitive dysfunction. Preclinical studies have established that repeated endocannabinoid receptor stimulation during adolescence can induce long-term cognitive and behavioral dysregulation in adult animals. Notably, these studies indicated that adolescent cannabis exposure can induce long-lasting alterations in reward consumption and reward-motivated behavior. We probed the specific long-term effects of adolescent tetrahydrocannabinol (THC) exposure on hedonic, motivational, and cognitive components of reward-seeking behavior in rats. Long-Evans male rats (n=9-10 / group) were exposed to THC (5 mg/kg) or vehicle for 14 days starting at either PD 30 (adolescent) or PD 90 (adults). Behavioral testing was then conducted after a 30 days washout period so that rats exposed to THC or vehicle during adolescence were adult at time of tests. In a first set of experiments, we found that adolescent-THC exposure (vs. age-matched vehicle exposure) leads to decreased consumption of palatable food reward (sweetened condensed milk; SCM) but does not significantly alter more selective measures of hedonic or motivated feeding. In contrast, rats exposed to THC as adults engaged in more bouts of SCM consumption, suggesting a heightened motivational state. This interpretation was confirmed during subsequent operant progressive ratio testing - adult THC exposure resulted in a persistent increase in willingness to exert effort for food reward. A second set of experiments revealed that rats' ability to select actions in a flexible, goal-directed manner (based on action-outcome representation) was not altered by THC exposure. We also conducted a test of impulsivity, in which rats were reinforced for withholding their reward-seeking behavior for intervals of at least 30 seconds (differential reinforcement of low rates 30 s). Relative to vehicle controls, we found that the adult-THC group displayed excessive premature reward seeking, interfering with their ability to earn reward. In contrast, the adolescent-THC group displayed more efficient reward seeking, in that they were better at waiting than vehicle controls.Overall, our findings confirm previous studies that had shown that repeated endocannabinoid receptor stimulation during adolescence is sufficient to induce long lasting changes in reward consumption in adult rats. Our study shows distinct effect of repeated THC exposure on motivational influence of reward seeking depending on whether it took place during adolescence or adulthood.

Title: Appetitive, antinociceptive, and hypothermic effects of vaped and injected D9-tetrahydrocannabinol (THC) in rats: exposure and dose-effect comparisons by strain and sex

Authors: *C. F. MOORE[1], C. DAVIS[1], M. TAFFE[2], E. WEERTS[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Univ. of California San Diego, La Jolla, CA

Abstract: Rationale: Advances in drug vapor exposure systems have enabled evaluation of α-9-tetrahydrocannabinol (THC) vapor effects in laboratory animals. The purpose of this study was to 1) establish a range of parameters of THC vapor exposure in rats sufficient to produce a behavioral dose-effect curve in a battery of tasks sensitive to THC; and 2) to investigate sex differences in the effects of THC vapor exposure and THC injection (intraperitoneal, IP) on these behaviors in two strains of outbred rats. **Methods:** Male and female Sprague Dawley and Wistar rats (N=22, 5-6/sex per group) received THC via passive vapor exposure (200 mg/ml; 5 conditions) and IP injection (1-20 mg/kg) in a within subject design. The effects of vaped and injected THC on progressive ratio responding for food pellets. Nociception with a tail withdrawal assay and measurements of body temperature were also assessed during a 5-hr test period for evaluation of time course of effects. Plasma THC concentrations were assessed after THC vapor and 10 mg/kg IP THC. **Results**: THC vapor produced dose related increases and decreases in motivation to obtain food under the progressive ratio schedule. 1-20 mg/kg IP THC reduced breakpoints. Vaped and injected THC produced exposure and dose-dependent antinociception and hypothermia. Sex and strain differences in THC effects were also observed. Plasma THC concentrations were higher after 10 mg/kg IP THC (152 ng/mL) compared to the highest vapor exposure condition tested (38 ng/mL), but magnitude of behavioral effects were comparable. **Conclusions**: THC vapor exposure produced reliable, dose orderly effects on food-maintained behavior, nociception, and body temperature that are comparable to effects of IP THC, although there were differences in the time course of behavioral outcomes.

Abstract: In humans, proactive threat-coping enhances the individual perception of control over a threatening environment (agency). This can result in the suppression of Pavlovian freezing responses. We used the signaled active avoidance test (SigAA) in rats to model proactive actions that suppress freezing. The cannabinoid-1 receptor (CB1r) and endocannabinoids (eCBs) are known for facilitating plasticity in neuronal circuits for defensive responses, reward seeking, and negative reinforcement. We hypothesize that SigAA responses are facilitated by cannabinoid-dependent plasticity in the nucleus accumbens (NAcc), stimulated by glutamatergic projections from the basal amygdala (BA). Using pharmacological, chemogenetic and optogenetic inhibition, we show that glutamatergic projections from BA to NAcc subregions underlie the acquisition of SigAA responses. We found a correlation between the success to acquire SigAA responses and eCB levels in the brain, which could be a biomarker for proactive responses. SigAA responses were modulated pharmacologically by systemic manipulation of CB1R, or locally by altering CB1R signaling in NAcc. Nevertheless, preliminary results indicate that the systemic CB1r-agonist administration failed to rescue SigAA responses during optogenetic inhibition (BA-NAcc). Ongoing experiments seek to assess molecular, cellular and network mechanisms using different approaches: Cre-dependent chemogenetics combined with pharmacological manipulations of CB1r in NAcc, Cre-dependent fiber photometry to examine endocannabinoid dynamics *in vivo* in NAcc, quantification of the levels of CB1r and eCB in the brain and serum of animals, using mass spectrometry, correlating to their performance to learn

SigAA responses. These data suggest that the novel use of endocannabinoid-based drugs combined with proactive learning strategies might have a lasting effect in modulating defensive responses. An adapted approach in humans could help to reduce anxiety disorder symptoms.

Title: Social reward prevents extended access cocaine self-administration and incubation of cocaine craving in male and female rats

Authors: ***M. VENNIRO**, Y. SHAHAM;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: We recently developed a community-reinforcement model using operant social reward to promote abstinence in rats. We found that social choice-induced abstinence prevents methamphetamine and heroin self-administration and decreases incubation of craving. Here, we determined the effect of social reward on intermittent- and continuous-access cocaine self-administration, and incubation of cocaine craving. We also determined parameters to reverse social preference. Methods: In experiment 1, we trained male and female rats for social self-administration (6 days) and then for cocaine self-administration, initially continuously (2-h/day; 4 days), and then either continuously (12-h/day) or intermittently (5-min ON, 25-min OFF × 24) for 8 days. We assessed relapse to cocaine seeking after 1 and 15 days. Between tests, the rats underwent either forced or social choice-induced abstinence. In experiment 2, after establishing stable preference for social interaction, we manipulated the delay for both rewards or social reward alone, or the fixed-ratio schedule requirements for social reward. Results: The rats self-administered more cocaine during continuous access, but the inter-infusion-interval was higher during intermittent access. Social reward prevented incubation of cocaine craving independent of access conditions and sex. The rats' social preference decreased by increasing the delay for both rewards or for social reward alone, or by increasing the fixed-ratio requirement for social reward. Conclusions: The protective effect of operant social reward generalizes to cocaine self-administration and incubation of cocaine craving. Delaying the social reward or increasing the effort to obtain it increases cocaine choice. This human-relevant choice procedure can be used to identify brain mechanisms of individual differences in addiction vulnerability and testing novel medications. Title: Effects of chronic stress on cocaine seeking behavior in male and females rats

Authors: *R. J. MORALES SILVA[1], G. MARRERO CRISTOBAL[2], U. GELPI DOMÍNGUEZ[2], G. RODRIGUEZ TORRES[1], J. K. ALVARADO TORRES[1], M. T. SEPULVEDA-ORENGO[1];
[1]Dept. of Basic Sci., [2]Dept. of Psychology, Ponce Hlth. Sci. University-School of Medicine/Ponce Res. Inst., Ponce, PR

Abstract: Post-Traumatic Stress Disorder (PTSD) and Substance Use Disorder (SUD) are generally studied independently in preclinical studies, although they can occur concurrently in patients. PTSD patients exhibit higher rates of SUD. Exposure to stressful or traumatic events can lead to the development of PTSD, and stress has been associated with a higher probability of relapse. Two important brain structures involved in the development of PTSD and SUD are the basolateral amygdala (BLA) and the nucleus accumbens (NAc), the latter being part of the reward circuitry. It has been shown that activation of BLA-NAc projecting neurons increases self-stimulation in optogenetic experiments, but it is not known how stress may alter this projection. Previous studies have shown that modified single prolonged stress reduces cocaine self-administration in rats. Moreover, rats exposed to single prolonged stress had a reduced cue-induced reinstatement of cocaine-seeking behavior, without any effects on acquisition and extinction of cocaine self-administration. Early life stress also facilitates the development of cocaine addiction, but it did not alter the reinstatement of cocaine-seeking behavior. All these studies used different models of PTSD in rodents and a short-access cocaine self-administration paradigm. However, the effects on extended-access cocaine self-administration have not been reported. Our objective is to determine the effects of chronic stress on cocaine-seeking behavior in male and female rats. We hypothesized that unescapable footshock before cocaine self-administration will increase cocaine-seeking behavior in both sexes. To test this hypothesis, we used unescapable footshock for a period of 5 days at an intensity of 0.50mA, presented randomly. After development of chronic stress, animals underwent 6-hour sessions of extended-access cocaine self-administration for 10 days, followed by a 30 day forced abstinence period. Subsequently, we performed cue-primed and drug memory retrieval tests to address cocaine-seeking behavior. Preliminary data show that unescapable footshock before cocaine addiction leads to increased cocaine-primed memory retrieval after withdrawal in male and female rats. Interestingly, female rats show increased cue-primed memory retrieval in the stress group compared with the control group. This was not observed in male rats. These results suggest that chronic stress before cocaine exposure increases the susceptibility to cocaine after forced

abstinence in male and female rats. Although cue-induced cocaine-seeking appears to work differently in male versus female rats, these results need to be confirmed.

Title: Biobehavioural basis of the flexible inflexibility that characterises maladaptive drug-seeking at relapse

Authors: ***D. J. BELIN**[1], M. FOUYSSAC[2], Y. PENA OLIVER[3], M. PUAUD[2], C. GIULIANO[2], B. J. EVERITT[2];
[1]Psychology, [2]Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [3]Psychology, Univ. of Sussex, Brighton, United Kingdom

Abstract: While motivationally relevant drug-paired conditioned stimuli (CSs) trigger activation in the nucleus accumbens in recreational drug users, in chronic users or individuals with a diagnosed addiction they trigger the activity of, and dopamine release in, the dorsal (or dorsolateral) striatum (DLS), the activation of which is the best predictor of long-term relapse.The psychological and behavioural significance of the functional engagement of the DLS in drug addictive behavior has not yet been elucidated. We have long suggested that it reflects the development of habitual control over drug-seeking behaviour to emphasize the inflexible engagement in drug foraging activities by addicted individuals in order to acquire and use the drug. In the real world, the distinction between motivational control of the initiation of drug-seeking and its later performance is especially important in that drug seeking is also motivated by response-produced drug-associated CSs - conditioned reinforcers - that invigorate instrumental seeking responses and bridge delays to the procurement, and eventually use, of the drug, hence playing a key role in relapse during abstinence.The neural basis of cue-controlled cocaine seeking, operationalised as second-order schedules of reinforcement (SOR), is well established. However, the influence of a long history of cocaine seeking under the control of the conditioned reinforcing properties of drug-paired cues on the tendency to relapse has not been investigated. Here, in a series of longitudinal studies combining functional neuroanatomy and causal manipulations of the dorsal striatum in behaving rats we showed that a long (several weeks) history of cocaine seeking under a SOR, at a time when it depends upon the DLS habit system, results in aberrant drug seeking at relapse after abstinence. We further showed that this exacerbated tendency to relapse depends on the dorsomedial striatum-dependent goal-directed

system that is transiently engaged by the inability of an individual to perform drug seeking habits during abstinence and independently of withdrawal from, or unavailability of, cocaine.These data suggest that a prolonged history of cocaine seeking under the conditioned reinforcing effects of cocaine-paired cues results in the recruitment of neural mechanisms that establish maladaptive drug seeking habits, or incentive habits. Incentive habits underlie the DLS-dopamine dependent inflexible initiation of drug seeking behaviour However, when they cannot be performed, or expressed, they perpetuate vigorous drug seeking behaviour via the transient engagement of the pDMS goal-directed system in a drug-independent manner.

Title: Hierarchical cue control of cocaine seeking in the face of cost

Authors: *V. L. COLLINS, K. N. BORNHOFT, B. T. SAUNDERS;
Univ. of Minnesota, Minneapolis, MN

Abstract: Drug addiction is characterized by intermittent, persistent drug seeking despite rising costs. Drug-associated cues are a powerful trigger of this behavior, capable of inciting relapse in recovering addicts. We set out to model three key aspects of human drug use in rats: the intermittent, binge-and-stop nature of drug intake, the motivational conflict of drug seeking in the face of escalating negative costs, and the ability of different types of drug cues to modulate seeking and spur relapse. Critically, we found that the ability of proximal cues to trigger relapse was gated by the presence of a global cue signaling drug-availability within the animal's environment, suggesting that hierarchical cue interactions exert an important modulating influence on drug-seeking motivation. Dopamine release within the nucleus accumbens core (NAc) has been implicated in cue-induced relapse of drug seeking. It is less clear, however, if dopamine signaling may encode hierarchical drug-related learning states where drug cues interact to guide seeking. To address this, we measured changes in dopamine receptor activity within the NAc with fiber photometry, using the genetically encoded dopamine sensor dLight. Our data suggests that the dopamine preferentially encodes drug availability over delivery with continued use and is modulated by escalating cost. Together, these results demonstrate hierarchical cue control of drug seeking despite cost, and point to a role for NAc core dopamine in this process.

Title: Behavioral and neurobiological substrates underlying discriminative stimulus-control of cocaine seeking in rats

Authors: *O. R. DRAKE, M. B. BRENNER, V. A. LENNON, S. J. WEBER, L. E. KOMER, R. MADANGOPAL, L. A. RAMSEY, B. J. TUNSTALL, J. M. BOSSERT, Y. SHAHAM, B. T. HOPE;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Persistent susceptibility to cue-induced relapse is a cardinal feature of addiction. Discriminative stimuli (DSs) signal drug availability (DS+) or unavailability (DS-) and control drug seeking prior to relapse. We previously used a trial-based procedure to train rats to self-administer cocaine under DS-control and demonstrated that DS-controlled cocaine-seeking persists up to 300 abstinence days. Here we investigate the behavioral and neurobiological substrates underlying persistent DS-controlled cocaine seeking. We first investigated individual contributions of DS+ and DS- to cocaine seeking in our task by measuring non-reinforced lever-presses during 4 trial types 21 days after cocaine self-administration: no DSs, DS+ only, DS- only, both DSs. Rats' responding was low during 'no DSs' and 'DS- only' trials, intermediate when 'both DSs' were presented, and maximal during 'DS+ only' trials. Next, we used GABAA+GABAB receptor agonists (muscimol+baclofen, M+B) to examine the role of prelimbic (PL) and infralimbic (IL) subregions of medial prefrontal cortex (mPFC) in DS-controlled cocaine seeking and taking. M+B microinjections into IL, but not PL, reduced DS-controlled cocaine seeking on abstinence day 21. M+B injection into either area had no effect on DS-controlled cocaine self-administration. Finally, we used ex vivo whole-cell recordings and found that M+B suppressed electrically evoked excitatory postsynaptic current magnitude and decreased spontaneous EPSC frequency in mPFC neurons. Our data indicate that DS+ and DS- independently control the expression and suppression of DS-controlled drug seeking in our task. Further, DS-controlled drug seeking during abstinence is mediated in part by neural activity in IL but not PL.

Title: Acquisition rates of cocaine self-administration are affected by estrous stage and naive terminal state

Authors: *M. I. MAUTERER[1], S. R. JONES[2];
[1]Wake Forest Univ. Sch. of Med., Winston Salem, NC; [2]Wake Forest Univ. Sch. Med., Winston Salem, NC

Abstract: Cocaine Use Disorder (CUD) is a debilitating mental illness that affects over 1 million people in the United States annually. Despite a recent rise in CUD cases, including a tripling in overdose deaths since 2012, there remains no FDA approved pharmaceutical to treat CUD. This is partially due to the fact that the majority of cocaine research has focused on male behavior and neurobiology. However, recent clinical and preclinical work indicates distinct sex differences in cocaine abuse vulnerability. Thus, it is likely that many compounds are failing in clinical trials due to a lack of knowledge regarding how biological sex impacts CUD development. Though males consistently exhibit greater cocaine consumption, females show significant increases in other aspects of CUD-like behavior including motivation for cocaine, escalation of intake, and acquisition of cocaine taking. In rodents, it has been repeatedly shown that females in the estrus phase of the estrous cycle exhibit the highest levels of CUD-like behaviors suggesting that ovarian hormones may play a critical role in modulating this vulnerability. Further, despite the integral role of the mesolimbic dopamine system in CUD, there has been little work done to directly asses interactions between the estrous cycle and the mesolimbic dopamine system in the context of CUD. Here, adult Sprague-Dawley rats trained to self-administer cocaine show that female rats in the estrus stage of the estrus cycle exhibit significantly greater acquisition behaviors, notably time to acquisition, as well as increased cocaine potency at the dopamine transporter (DAT). When collapsed by cycle there appears to be no difference in DAT function between males and females, however, females in estrus show significantly greater DAT sensitivity to cocaine compared to males and females in non-estrus. This is significant as many studies rule out sex and the estrous cycle as potential influences on behavior and neurobiology based on a lack of difference between males and females not separated by cycle stage. This work demonstrates that by not staging intact females, it is possible to miss cycle specific effects that may not be initially evident by comparing just males and females. Further, we show that while males appear to show no “preference” for acquisition dose, females exhibit significantly greater acquisition behavior at lower doses. This effects does not appear to be due to alterations is cocaine potency at the DAT which are mostly unchanged across sex and dose. Together, this data suggests that sex differences significantly complicate acquisition and that greater emphasis on this aspect of drug taking is required in CUD research.

Title: Impact of sleep on incubation of cocaine craving and dopamine terminal adaptations following abstinence

Authors: *I. P. ALONSO, E. A. ZIHAL, R. A. ESPAÑA;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Finding effective and tolerable treatments for cocaine addiction has been extremely challenging due to the high rates of relapse. Clinical and animal studies have shown a progressive intensification of cocaine seeking and craving during abstinence, increasing the likelihood of relapse. In addition, sleep disruptions are commonly observed during recovery from chronic cocaine use and manifest as abnormal sleep architecture which is posited to promote incubation of cocaine craving. While the neural mechanisms underlying the association between sleep disruption and incubation of cocaine craving are unclear, accumulating evidence suggests that alterations in mesolimbic dopamine (DA) neurotransmission may contribute to these processes. To determine to what degree cocaine craving is associated with sleep disruptions and whether this involves DA terminal adaptations, adult female and male rats underwent intermittent access to cocaine self-administration followed by a period of imposed abstinence. Incubation of cocaine craving was assessed by cue-induced drug seeking test on abstinence day 1 and 7. To examine sleep disruptions, sleep/wake activity was recorded before cocaine exposure and throughout the abstinence period. Changes in DA release and uptake in the nucleus accumbens were then recorded using fast scan cyclic voltammetry on day 8 of abstinence following the seeking test. Intermittent access to cocaine followed by abstinence engendered a significant intensification of cocaine seeking, decreases in REM sleep, and increases in DA release and uptake compared to cocaine naïve rats. Based on these findings, we then tested whether restoring sleep during abstinence prevents incubation of cocaine craving via normalization of DA terminal function. Sleep restoration was achieved by exposing the rats to a continuous movement of a rotating bar near the floor of a custom-designed chamber during their normal active period (dark phase) to accumulate sleep pressure and enhance sleep quality during their normal inactive period (light phase). Restoring sleep attenuated incubation of cocaine craving and reversed DA terminal adaptations. These results suggest that sleep disruptions might not only be a symptom of cocaine withdrawal, but also an important factor for promoting incubation of cocaine craving.

Title: Cocaine preference over sucrose in a rat model of voluntary abstinence is associated with increased cocaine relapse and vOFC activation

Authors: *G. ROJAS[1], Y. PADOVAN- HERNANDEZ[1], L. A. KNACKSTEDT[2];
[2]Psychology, [1]Univ. of Florida, Gainesville, FL

Abstract: Cocaine use disorder (CUD) is characterized by high rates of relapse after long periods of abstinence. Contingency management (CM) is an effective behavioral treatment for CUD, offering non-drug rewards to maintain abstinence. However, relapse typically occurs once CM is discontinued. Thus, choice-based "voluntary abstinence" is a translationally relevant rodent model of abstinence that has not yet been used following cocaine self-administration. We hypothesized that the combination of voluntary abstinence (VA) and ceftriaxone would reduce relapse to cocaine-seeking once VA was stopped. Ceftriaxone is a beta-lactam antibiotic reliably found to attenuate cocaine-seeking after instrumental extinction and forced abstinence. Here, we trained 25 male Sprague-Dawley rats to self-administer sucrose pellets (5 d, 2 hr/d). Rats next self-administered intravenous cocaine (12 d, 2 hr/d). Discrete and contextual sucrose- and cocaine-associated cues were used. Rats then underwent either VA or forced abstinence for 14 days. During VA, rats experienced 20 trials/d during which they chose between sucrose and drug levers to receive the associated reinforcer. Half of the rats received ceftriaxone (200 mg/kg IP) during the last 7 days of VA. Rats assigned to forced abstinence were handled daily but did not go back to the operant environment during abstinence. On day 15, a 2 hr relapse test was conducted; only the drug-paired and inactive lever were available, with cocaine-associated cues. Rats were perfused immediately after the relapse test for the quantification of Fos protein expression. The majority of rats preferred the sucrose lever during VA; however, 33-44% of vehicle and ceftriaxone-treated rats continued to prefer cocaine to sucrose. Relapse to cocaine-seeking was equivalent between groups. However, the amount of cocaine intake during VA positively correlated with the number of cocaine lever presses during the relapse test. Relapse-induced Fos expression was greater in the vOFC in the VA group relative to forced abstinence, indicating that this brain region may be engaged by choice-based abstinence. Both of these effects were present only in vehicle-treated rats, indicating that ceftriaxone treatment alters the relationship between relapse and both cocaine-choice and vOFC activity, possibly via increasing VTA activity during relapse. In conclusion, these results are the first to indicate that cocaine-experience rats show a range of preference for sucrose over cocaine during VA, and this choice was not influenced by the anti-relapse medication ceftriaxone.

Title: Cell Subtype Transcriptional Role of Nab2 in Cocaine Action

Authors: *E. CHOI, R. CHANDRA, M. MCGLINCY, A. CHOW, M. LOBO;
Dept. of Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Drug abuse is a debilitating chronic disease which is a leading cause of disability around the world. Exposure to psychostimulants, such as cocaine, is associated with molecular and functional imbalance in the two medium spiny neuron subtypes (MSNs) in the NAc, the dopamine receptor 1 and 2 enriched MSNs (D1-MSNs and D2-MSNs). We have previously reported the bidirectional alterations of a transcription factor, early growth response 3 (Egr3), that is up-regulated in D1-MSNs and down regulated in D2-MSNs with repeated exposure to cocaine. Interestingly, we observed that the NGFI-A binding protein 2 (Nab2), corepressor of Egr3, is also bidirectionally altered in D1-MSNs and D2-MSNs, but in the opposite direction to the Egr3 expression. The role of Nab2 in cocaine induced behavior, however, remains largely elusive. In this study, we developed a CRISPR targeted transcription activator and inhibitor tools that can be targeted to precise loci in selective neuron subtypes. In cell culture, our constructs, which code for catalytically dead dCas9 fused with VP64 for transcription activation, or KRAB for transcription inhibition, were transfected into Neuro2A cells along with sgRNA targeting for early growth response 3 (Egr3) and NGFIA-binding protein 2 (Nab2). Egr3 mRNA level was significantly down regulated in cells transfected with the sgRNA targeting Egr3. Consistent with this, Nab2 mRNA level was significantly down regulated in cells with Nab2 targeting sgRNA. These constructs were packaged into AAVs for *in vivo* delivery into the brain. In mice that received the CRISPR I AAV targeted for Nab2, we observed a significant KD of Nab2 protein expression. We then assessed locomotor behavior during exposure to cocaine, when Nab2 transcription was inhibited in D2-MSNs using the CRISPR I AAV, we found reduced locomotor behaviors in this group. Together, our study demonstrates a distinct role of Nab2 in D1 and D2 MSNs. Our future studies, in which we plan to perform cocaine self-administration in these mice with CRISPR mediated Nab2 overexpression and knockdown in D1 and D2 MSNs, and subsequent RNA sequencing from NAc tissues of these mice after the self-administration will further test our hypothesis and shed light into the molecular mechanisms occurring in D1 and D2 MSN NAc cell subtypes after cocaine operant self administration.

Abstract Currently there are no FDA approved pharmacological agents to alleviate cocaine use disorder, and cocaine use fatalities have tripled since 2011. Adenosine monophosphate-activated protein kinase (AMPK) is a heterotrimeric enzyme vital for regulating cellular oxidative stress through sensing ATP:AMP levels. Cocaine increases oxidative stress through manipulation of dopaminergic transmission. Following cocaine self-administration and extinction the amount of phosphorylated (active) AMPK (pAMPK) in the nucleus accumbens core (NAc) is decreased. Metformin, an FDA approved type 2 diabetes drug, is found to increase pAMPK levels and shows efficient blood-brain barrier permeability, unlike other pAMPK activators. We hypothesized that intracranial microinjections of metformin into the NAc would curb active lever presses in a cue-induced reinstatement paradigm by returning AMPK function back to a baseline level. In this study we utilize metformin to reduce cue-induced cocaine seeking in male and female rats after cocaine self-administration and extinction. Women have been seen to escalate towards cocaine addiction faster and have an increased risk of relapse compared to men. Intracranial microinjections of metformin (125 micrograms/hemisphere) into the NAc reduced cue-induced reinstatement of cocaine seeking in both male and cycling female rats. We employed a sucrose self-administration paradigm to check if intracranial metformin's effect was due to a general attenuation of appetitive behavior and found that metformin did not decrease sucrose seeking in males but did in females. We performed locomotor assay analysis to control for effects on activity and found that intracranial microinjections of metformin did not decrease locomotor activity. Further exploration of metformin's effects towards curbing cocaine reinstatement could prove beneficial towards treating cocaine use disorder and provide more information on AMPK signaling.

Title: CRF_2 receptor knockdown in the nucleus accumbens attenuates cocaine anticipation in rats

Authors: *M. Z. LEONARD[1], H. COVINGTON III[1], S. L. FULTON[3], I. S. MAZE[3], K. A. MICZEK[1,2];
[1]Dept. of Psychology, Tufts Univ., Medford, MA; [2]Dept. of Neurosci., Tufts Univ., Boston, MA; [3]Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Cocaine-dependent individuals experience intense drug cravings in anticipation of imminent drug availability. Increased arousal in states of drug-expectation may heighten the propensity to seek and consume drug. The present studies examine accumbens-specific actions of the stress peptide corticotropin releasing factor (CRF) as a candidate mechanism for maladaptive arousal evoked by drug-predictive stimuli. We show that CRF is released in the nucleus accumbens (NAc) immediately preceding drug-reward opportunity (i.e. cocaine availability), and this coincides with a rise in extracellular dopamine (DA). Interestingly, we find that infusion of CRF into the NAc stimulates DA release in a CRF-R_2-dependent manner in cocaine-experienced rats, whereas CRF-R_2 activation was ineffective in naïve animals. To clarify the role of NAcC-CRF-R_2 on instrumental behavior directed towards cocaine procurement, rats were first trained to self-administer cocaine under a chained schedule of reinforcement (FI-FR) in order to dissociate *anticipatory* ('drug-seeking') from *consummatory* ('drug-taking') behavior. Completion of FI-5 was followed by 5 min of continuously reinforced (FR1) responding for cocaine. On consecutive days, rats received bilateral infusions of siRNA designed to target either CRHR2, or a scrambled control, into the NAc. Knockdown of CRF-R_2 selectively attenuated cocaine-seeking responding during the FI link of the chain schedule without affecting subsequent cocaine intake. Behavior returned to baseline 36-hours after the last injection. These data suggest the CRF-R_2 may be specifically involved in generating arousal during cocaine expectation, whereas the unconditioned aspects of drug-reward are differentially controlled. Because qPCR analysis of the NAc revealed no differences in CRF-R2 transcript levels between cocaine-experienced and drug-naïve rats; ongoing studies examine potential contributions of CRF binding protein (CRF-BP) - a known modulator of CRF-R_2 activity - to cocaine-dependent behavioral outcomes.

Title: Exposure to a ketogenic diet blocks the formation of a conditioned place preference for cocaine in young adult Sprague-Dawley rats

Authors: *L. A. MARTINEZ, M. HUSTON;
Neurosci., Trinity Col., Hartford, CT

Abstract: Ketogenic diets (KD) are high fat, low carbohydrate and adequate protein formulations that have traditionally been used as a treatment for epilepsy; however, there is growing evidence that these diets have broader therapeutic potential for disorders featuring disruptions to brain structure/function, including drug addiction. Previously we have found that administration of a KD to young adult male and female Sprague-Dawley rats blocks the development of locomotor sensitization and decreases stereotyped behaviors exhibited in response to repeated cocaine injections. These effects led us to speculate that the rewarding effects of cocaine are also disrupted by KD diet exposure. To determine if this is indeed the case, male and female Sprague-Dawley rats were placed on a strict 6.6:1 (fat:[carbohydrates+protein], by weight) KD or standard diet (SD) at 5 weeks of age and then were maintained on those diets for 3 weeks prior to behavioral testing. Rats then underwent conditioned place preference (CPP) testing using a biased design in a two-chamber apparatus. Briefly, rats underwent an initial 15-min pretest with free access to both chambers, followed by a series of 30-min daily conditioning sessions with either cocaine (Coc; 15 mg/kg) or saline (Sal) in the initially non-preferred chamber and saline in the initially preferred chamber on alternating days. Rats underwent a final 15-min posttest to determine the effects of conditioning on their preference for the initially non-preferred chamber. Rats maintained on a KD failed to develop a CPP for 15 mg/kg cocaine, whereas SD rats did form a robust CPP for this dose. These results suggest that administration of a KD diminishes the rewarding properties of cocaine, providing further evidence in support of the therapeutic potential of these diets in drug addiction.

Abstract: Psychostimulant addiction represents a public health crisis leading to tremendous morbidity. Despite this, there are no FDA-approved medications for treatment of psychostimulant use disorders. Burgeoning research has detailed the important connections between the resident population of bacteria in the gut, the gut microbiome, and the

pathophysiology of neuropsychiatric disease. Robust literature implicates bacterially-derived Short-Chain Fatty Acid (SCFA) metabolites in altering transcriptional profiles and chromatin structure in the brain. Recent work from our group demonstrated that acute depletion of the gut microbiome results in enhanced reward and altered gene expression in a mouse cocaine place preference model, and that repletion of SCFAs reverses these effects. However, the role of gut microbiome and its metabolites in modulating cocaine-seeking behavior after prolonged abstinence is unknown. Given that prevention of relapse following abstinence is the most clinically challenging issue in treating patients with substance use disorders, studies examining the effects of microbiome manipulations in relapse relevant models are critical for the development of translational strategies in this space. For these studies, depletion of gut bacteria and their metabolites was induced in Sprague-Dawley rats via addition of antibiotics in their drinking water and compared to untreated controls. To identify specific mechanistic contributions of SCFA, the metabolites were replenished via addition to drinking water in animals with depleted gut microbiomes. Rats were trained to self-administer cocaine and subjected to either within-session threshold testing to evaluate motivation for cocaine at a range of doses or 21 days of abstinence followed by a cue-induced cocaine-seeking task to model relapse behavior. Nucleus accumbens was isolated and tissue processed for RNA-sequencing analysis. Animals lacking a complex gut microbiome show significantly increased cocaine-seeking behaviors and altered expression of synaptic plasticity genes. In the absence of a normal microbiome, repletion of bacterially-derived SCFA metabolites reverses behavioral and molecular changes associated with microbiome depletion. Molecular analyses reveal marked changes in activity-dependent gene expression in antibiotic-treated rats compared to controls. These findings suggest that gut bacteria via their metabolites may serve as homeostatic regulators of gene expression in the brain, and suggest the microbiome has potential as a translational research target.

Title: Chemogenetic stimulation of VTA dopamine neurons causes cumulative deficits in decision making and enhanced addiction vulnerability

Authors: *T. HYNES, K. HRELJA, C. CHERNOFF, L. CALDERHEAD, S. KAUR, C. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Addiction is a complex affliction, characterized not only by the use of drugs, but also by deficitsin cost/benefit decision making. A critical biological factor in the development of addiction isaberrant dopamine (DA) neurotransmission. Biological sex is also an important consideration.Investigating such phenomena is difficult in humans, because of the profound influence thesocio-political construct of gender has on behaviour. We therefore sought to longitudinally probethe complex intersection of addiction, decision making, sex, and DA neurotransmission bycombining our cued rat gambling task (crGT; a rodent assay of cost/benefit decision making) withoperant intravenous cocaine self-administration and chemogenetic manipulations of DAneurons. We infected the VTA DA neurons of female and male rats with an excitatory designerreceptor, before training them in our crGT. Prior to daily crGT training sessions, we administeredclozapine-N-oxide to activate the receptor and increase the excitability of VTA DA neurons duringtask performance. Once rats achieved stable crGT performance, we allowed them to self-administer intravenous cocaine. We also quantified the psychomotor reactivity to cocaine in agroup of otherwise cocaine-naïve rats. Chemogenetic stimulation of VTA DA neurons causeddeficits in decision making and increased the propensity of both sexes to self-administer cocaine.Moreover, this manipulation resulted in a phenotype which was hyperactive at baseline and thatexhibited a heightened psychomotor response to cocaine. These findings suggest that VTA DAneurons are a critical node in decision making and that repeated stimulation of VTA DA neuronscan pre-sensitize the DA system, rendering female and male rats more vulnerable to addiction-like behaviour.

Abstract: Chronic cocaine administration induces sex-dependent increases in locomotor activity and behavioral sensitizationTrombley A.T[1,2], Gheidi A.[1], Sadik N.[1], Matchynski, J.[1,2], Karavidha K.[1], Kallakuri S.[1], Brummelte, S.[2,3], Perrine S.A.[1,21]Department of Psychiatry and Behavioral Neurosciences, [2]Translational Neuroscience Program, [3]Department of Psychology, Wayne State University, Detroit, MI.Binge-pattern cocaine use is an on-going public health concern with recent increased prevalence for both women and men. Repeated cocaine exposure has been

shown to induce locomotor sensitization in both female and male rats. To investigate the biological basis of potential sex differences in locomotor sensitization, we measured the effects of cocaine on locomotor activity and behavioral sensitization in both female and male rats as well as characterized the estrous phase of female rats. Adult Wistar rats (N=32, n=16/sex, or n=8/group) received either cocaine (15 mg/kg via intraperitoneal injection 3 times daily, one hour apart) or saline (1 ml/kg via same schedule) for 14 days. Locomotor activity was measured at baseline and on days 1 and 14 to be used as an index of behavioral sensitization. Estrous phase tracking via vaginal lavage (or sham procedure in males) was conducted to characterize estrous phase and determine the impact of estrous on female's behavior. Preliminary results indicate that both male and female rats showed increased locomotor activity acutely after cocaine (day 1) and after chronic cocaine (day 14) administration. However, this effect was significantly heightened in females. Estrous data are currently being analyzed and will be presented. These results further validate that sex differences in cocaine-induced behaviors have a biological underpinning and emphasize the need to better understand sex-differences in models of drug abuse.

Abstract: Drug overdose is an increasingly large problem in the United States. In 2018, there were 67,367 reported drug overdose deaths in the United States. Of these drugs, opioids, including those with synthetic narcotics were the leading drugs to cause overdoses with a total number of deaths occurring at 46,802. Cocaine follows behind opioids at a total number of deaths by overdose of 14,666. While, opioid overdoses can be combated pharmacologically there is no safe and effective pharmacological agent to combat cocaine overdose. Our lab is exploring the ability of cocaine antagonists to be used in a similar fashion to interventions used in opioid misuse. We are seeking to understand how cocaine induced changes to locomotion and anxiety might be ameliorated by examining the effects of a potential cocaine antagonist (PCA1) on mouse behavior in the open field and elevated plus behavioral tasks. To address hormone mediated differences in behavioral response to cocaine both male and female mice were tested. Estrus stage of female mice was tracked using non-invasive vaginal lavage and automated analysis of behavior was performed using ezTrack. In this exploratory work, our results show

that that PCA1 alone can induce behavioral changes in control mice. Future work will examine the behavioral changes of PCA1 in combination with cocaine.

Title: Diazepam attenuates the effects of cocaine on locomotion, 50 kHz ultrasonic vocalizations and phasic dopamine release in the nucleus accumbens of rats

Authors: *W. N. SANCHEZ LUNA[1,2], J. POCHAPSKI[2], L. JESSEN[2], M. ELLENBERGER[3], R. SCHWARTING[3], D. L. ROBINSON[4], R. ANDREATINI[2], C. DA CUNHA[2,1];

Abstract: Currently, there is no effective drug to treat cocaine use disorders, which affect millions of people worldwide. Benzodiazepines are potential therapeutic candidates since microdialysis and voltammetry studies have shown that they can decrease dopamine release in the nucleus accumbens of rodents. In addition, we have recently shown that diazepam blocks the increase in dopamine release and 50 kHz ultrasonic vocalizations induced by amphetamine in rats. Here we tested whether the i.p. administration of 2.5 mg/kg diazepam in adult male Wistar rats could block the effects of 20 mg/kg cocaine (i.p.) on electrically evoked dopamine release in the nucleus accumbens measured by fast-scan cyclic voltammetry, 50-kHz USVs, and locomotor activity. Cocaine injection increased evoked dopamine release in up to 3-fold by within 5 min and was significantly higher than baseline for at least 90 min. The injection of diazepam 15 minutes later attenuated the cocaine effect by nearly 50% and this attenuation was maintained for at least 30 min. Stimulant drugs, natural rewards and reward predictive cues are known to evoke 50 kHz ultrasonic vocalizations (USVs) in adult rats. In the present study, cocaine increased by 12-fold the number of 50 kHz USVs of the flat, step, trill, and mixed kinds. This effect was

maximum 5 min after cocaine injection and, although it decreased exponentially with time, it lasted at least 40 min. Diazepam significantly blocked this effect for the entire duration of the session. The distance travelled by control rats during a 40-min session of exploration in an open field was maximum in the first 5 min and decayed exponentially until the end of the session. Cocaine-treated rats travelled significantly longer distances as compared to the control group, while diazepam significantly attenuated cocaine-induced locomotion by up to 50%. These results suggest that the neurochemical, affective, and stimulant effects of cocaine can be mitigated by diazepam.

Title: Neurite orientation dispersion and density imaging in cocaine use disorder

Authors: *J. RASGADO TOLEDO[1], A. SHAH[2], M. INGALHALIKAR[2], E. A. GARZA-VILLARREAL[1];
[1]Univ. Nacional Autónoma de México, Querétaro, Mexico; [2]Symbiosis Intl. Univ., Maharashtra, India

Abstract: Cocaine use disorder (CUD) is characterized by a compulsive search for cocaine that chronically produces cognitive deficits, including lack of inhibition and decision-making. Several studies have shown that cocaine users exhibit brain volume and diffusion-based white-matter alterations in a wide variety of brain regions. However, the non-specificity of standard volumetric and diffusion-tensor methods to detect structural micropathology may lead to wrong conclusions. To better understand microstructural pathology in CUD, we analyzed 60 CUD participants (3 female) and 43 non-CUD controls (HC; 2 female) retrospectively from our cross-sectional Mexican SUD neuroimaging dataset (SUDMEX-CONN), using multi-shell diffusion-weighted imaging and the neurite orientation dispersion and density imaging (NODDI) analysis which aims to more accurately model microstructural pathology. We used Viso values of NODDI that employ a three-compartment model in white (WM) and gray-matter (GM). These values were correlated with clinical measures, including psychiatric severity status, impulsive behavior and pattern of cocaine and tobacco use in the CUD group. As hypothesized, we found higher whole-brain microstructural pathology in WM and GM in CUD patients than controls. ROI analysis revealed higher Viso-NODDI values in superior longitudinal fasciculus, cingulum, hippocampus cingulum, forceps minor and Uncinate fasciculus, as well as in frontal and parieto-

temporal GM structures. We also found correlations between significant ROIs and impulsivity, onset age of cocaine use and weekly dosage with Viso-NODDI. However, we did not find correlations with psychopathology measures. Overall, microstructural pathology seems to be present in CUD both in gray and white matter, however their clinical relevance remains questionable.

Abstract: *In Vitro* and *In Vivo* Pharmacological Comparison of Mu-Opioid Receptor Activity of the Kratom (*Mitragyna speciosa*) Alkaloid Mitragynine and its Metabolite 7-HydroxymitragynineSamuel Obeng[1,2], Francisco León[2], Luis F. Restrepo[1], Morgan E. Reeves[1], Lea R. Gamez-Jimenez[1], Avi Patel[1], Nicholas P. Ho[1], Tobias Braun[1], John D. Fortner[2], Morgan L. Crowley[2], Victoria L.C. Pallares[1], Marco Mottinelli[2], Carolina Lopera-Londoño[2], Christopher R. McCurdy[2], Lance R. McMahon[1], and Takato Hiranita[1]Departments of Pharmacodynamics[1] and Medicinal Chemistry[2], College of Pharmacy, University of FloridaThe μ-opioid receptor (MOR) pharmacology of mitragynine and its 7-hydroxy metabolite have not been fully established. For both we assessed binding affinity and efficacy *in vitro*, as well as discriminative stimulus and antinociceptive effects in rats. Both mitragynine (MG) and 7-hydroxymitragynine (7-MG) had higher binding affinities at human MOR (K_i values 77.9 and 709 nM, respectively) than at the human κ- (KOR) or δ-opioid receptors (DOR). MG was identified as a MOR antagonist while 7-MG was identified as a MOR partial agonist (E_{max}=41%) using the [^{35}S]GTPγS functional assay. In Sprague Dawley rats trained to discriminate 3.2 mg/kg morphine from vehicle (i.p.), MG produced a maximum of 72% morphine-lever responding. Whereas morphine produced a maximum of 65% MG-lever responding in a separate group of rats trained to discriminate 32 mg/kg MG from vehicle (i.p.), other MOR agonists (i.p.) produced high percentages of morphine-lever and MG-lever responding (respectively): 7-MG (100% and 98%), fentanyl (100% and 80%), buprenorphine (100% and 79%), and nalbuphine (99% and 98%). MG (up to 56 mg/kg, i.p.) did not produce significant antinociception, whereas 7-MG (17.8 mg/kg, i.p.) produced robust antinociception in the hotplate assay with the temperature set at 52 °C. Naltrexone (0.032 mg/kg, i.p.) antagonized the discriminative stimulus, rate-decreasing, and antinociceptive effects of morphine and 7-MG. Conversly, naltrexone (0.032 mg/kg, i.p.) antagonized the discriminative stimulus effects of MG, but not its rate-decreasing effects. Pretreatment with MG (5.6 mg/kg, i.p.) potentiated the discriminative-stimulus effects of morphine but antagonized the antinociceptive effects of morphine. Striking differences in MOR efficacy *in vitro* are consistent with 7-MG having greater MOR efficacy than MG *in vivo*. MG exerts both MOR antagonist and agonist activity depending on the MOR efficacy required.Supported by DA25267 and DA48353.

Title: Effect of chronic delivery of the mixed MOR/NOP agonists BU08028 and AT-201 on relapse to heroin seeking and taking in a rat model of opioid maintenance

Authors: L. ALTIDOR[1], I. FREDRIKSSON[1], A. SHEKARA[1], H. KORAH[1], S. HUSBANDS[2], N. T. ZAVERI[3], A. SULIMA[4], K. RICE[4], Y. SHAHAM[1], *J. M. BOSSERT[1];

Abstract: Background: Maintenance treatment with opioid agonists (buprenorphine, methadone) decreases opioid use and opioid relapse. Using a modified ABA context-induced-reinstatement procedure, we recently found that chronic delivery of either buprenorphine or the novel mu opioid receptor (MOR) partial agonist TRV130 decreases relapse to oxycodone seeking and taking in rats. Here, we tested the effects of the mixed MOR/nociceptin opioid receptor (NOP) partial agonist AT-201 and the buprenorphine analog BU08028 in our model. Methods: We trained male and female rats to self-administer heroin (6-h/d, 14-d) in context A; infusions were paired with a discrete tone-light cue. We then implanted Alzet osmotic pumps containing BU08028 (0, 0.03, or 0.1 mg/kg/d) or AT-201 (0, 3.8, or 12 mg/kg/d) and performed three relapse-related tests: (1) extinction responding reinforced by heroin-associated discrete cues in non-drug context B, (2) reinstatement of heroin seeking induced by re-exposure to context A, and (3) reacquisition of heroin self-administration in context A. Results: Chronic BU08028 delivery had no effect on extinction responding in context B or context-induced reinstatement of heroin seeking in context A, but *increased* reacquisition of heroin self-administration in context A. The experiment with AT-201 is ongoing and we will present the results at the meeting. Conclusions: In our rat model of opioid maintenance, chronic BU08028 delivery had no effect on extinction responding and context-induced reinstatement, but unexpectedly, increased reacquisition of heroin self-administration. To the degree that our results from the model translate to humans, they suggest that mixed MOR/NOP agonists would not be an effective opioid maintenance treatment.

Abstract: Background: We recently developed a rat model of incubation of oxycodone craving after electric barrier-induced voluntary abstinence and showed a time-dependent increase in drug seeking on abstinence days 15 and 30 compared to day 1. Here, we studied the role of ventral subiculum (vSub) neuronal ensembles in this new form of incubation using the activity marker Fos, muscimol+baclofen (GABA agonists) inactivation, and the Daun02 chemogenetic inactivation procedure. **Methods:** We trained either Sprague-Dawley or Fos-lacZ transgenic male and female rats to self-administer oxycodone (0.1 mg/kg/infusion, 6-h/d) for 14 days. We then introduced an electric barrier of increasing intensity (0.1 to 0.4 mA) near the drug-paired lever that caused cessation of oxycodone self-administration. We tested Sprague-Dawley rats for relapse to oxycodone seeking in the absence of shock and drug on abstinence day 15 and extracted the brains for Fos-immunohistochemistry, or tested the rats after vSub injections of vehicle or muscimol+baclofen on abstinence days 1 and 15. We tested the Fos-lacZ transgenic rats for relapse to oxycodone seeking on abstinence day 18 after selective inactivation of relapse test-activated Fos neurons in vSub on abstinence day 15 using the Daun02 inactivation procedure. **Results:** Relapse after electric barrier-induced abstinence was associated with increased Fos expression in vSub, and both local inactivation of vSub and selective inactivation of vSub Fos-expressing neuronal ensembles decreased "incubated" oxycodone seeking. **Conclusions:** Results demonstrate a role of vSub neuronal ensembles in incubation of opioid craving after cessation of drug taking due to adverse consequences of drug seeking. Title: Female rats exhibit increased oxycodone demand and withdrawal-associated anxiety in a rat model of oxycodone-alcohol polysubstance use

Authors: C. WILKINSON, G. ROJAS, L. A. KNACKSTEDT;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: From 2007-2017, co-use of oxycodone and alcohol accounted for 14.3-15.4% of all opioid overdose deaths involving prescription opioids (Tori et al., 2020). The compounding effects of alcohol and oxycodone co-use on respiratory depression increases the likelihood for

fatal overdose, highlighting a need for investigations of oxycodone-alcohol polysubstance use (PSU). The present study investigates the effects of alcohol-oxycodone PSU on intake, behavioral economic demand, withdrawal symptoms, and relapse to oxycodone seeking in male and female rats. Forty Sprague-Dawley rats (half male) were permitted daily access to oxycodone only (OXY, n=18), oxycodone+alcohol (OXY+ALC, n=18), or alcohol only (ALC, n=4) groups. OXY and OXY+ALC rats self-administered intravenous oxycodone (0.1 mg/kg/infusion) for 3 hr/day followed by 6 hr access to water only (OXY rats) or both water and 20% (v/v) ALC (OXY+ALC rats). ALC rats self-administered sucrose pellets followed by 6 hours access to ALC and water in the home cage. After 6 days of self-administration on a fixed-ratio (FR) FR-1 schedule, followed by 6 days on an FR-3 schedule of reinforcement, oxycodone demand was assessed by increasing FR requirements across sessions. FR requirements increased every two days on a quarter logarithmic scale (FR-6, FR-10, etc.) until zero reinforcers were earned on both days. Rats re-established oxycodone self-administration on an FR-3 schedule of reinforcement for 2-3 days before extinction training and cue-induced reinstatement testing. Rats were assessed for anxiety-like behavior once and somatic signs of withdrawal at two different time points throughout the experiment, 24 hr after the last drug intake. In both males and females, oxycodone intake was reduced in the PSU group, however, female ALC+OXY rats exhibited greater anxiety-like behavior in withdrawal and increased demand for oxycodone. These results indicate that oxycodone-alcohol PSU can lead to greater withdrawal symptoms and increased motivation to seek oxycodone in females. Such results confirm the importance of considering PSU and sex differences in rodent models of substance use disorder.

Title: The Role of VTA Afferents in Opioid Withdrawal-Induced Aversion

Authors: *S. MONROE, A. K. RADKE;
Psychology, Miami Univ., Oxford, OH

Abstract: The ventral tegmental area (VTA) is a dopaminergic region that plays a central role in reward-related behaviors and is implicated in drug addiction. Withdrawal from opioids is characterized by modulations of VTA activity and profound expressions of aversion, which may lead to relapse. However, our understanding of the role the VTA plays in this behavior is complicated by the fact that it receives projections from multiple brain regions, often with different neurotransmitter profiles. These issues preclude a deeper understanding of the neurobiological mechanisms of opioid addiction, which is necessary to develop better treatments.

In order to better understand VTA circuitry as it relates to opioid withdrawal-induced aversion, we chose two regions that send GABAergic projections to the VTA and that have been shown to inhibit dopamine release in the presence of aversive stimuli. The rostromedial tegmental nucleus (RMTg) and the nucleus accumbens (NAc) shell were chemogenetically inhibited during morphine withdrawal to assess their contribution to the development of conditioned place aversion (CPA).
C57BL/6J mice received pENN.AAVrg.hSyn.HI.eGFP-Cre.WPRE.SV40 bilaterally in the VTA to retrogradely infect afferent neurons. pAAV-hSyn-DIO-hM4D(Gi)-mCherry was bilaterally injected into the RMTg or NAc medial shell. Controls received pAAV-hSyn-DIO-eGFP. Mice were subjected to CPA by receiving a cocktail of clozapine-n-oxide (CNO, 1.0 mg/kg) and morphine (10.0 mg/kg), followed by naloxone (2.5 mg/kg) and confined to one side of a conditioning box. The opposite side of the conditioning box was paired with CNO and saline. Data were presented as the time spent on the withdrawal-paired side of the box before and after conditioning. Morphine-induced locomotion and somatic withdrawal experiments served as positive controls.
Inhibition of the RMTg's projection to the VTA did not affect withdrawal-induced CPA, but control experiments verified that the circuit was successfully targeted. It is possible that the RMTg does not play a central role in aversion to morphine withdrawal, but further experimentation is needed. Inhibition of the NAc's projection to the VTA is ongoing, but we hypothesize that inhibiting it will reduce the severity of CPA to morphine withdrawal. Given the seriousness of aversion during the withdrawal phase and its role in relapse, addressing this behavioral phenomenon is critical to gain a better understanding of the neural mechanisms underlying opioid addiction.

Abstract: Opioid use disorder (OUD) has become a leading cause of death in the US, yet current therapeutic strategies remain highly inadequate. To identify novel potential treatments for OUD, we screened a targeted selection of over 100 drugs, using a recently developed opioid self-

administration assay in zebrafish. This paradigm showed that finasteride, a steroidogenesis inhibitor approved for the treatment of benign prostatic hyperplasia and androgenetic alopecia, reduced self-administration of multiple opioids without affecting locomotion or feeding behavior. These findings were confirmed in rats; furthermore, finasteride did not interfere with the antinociceptive effect of opioids in rat models of neuropathic pain. Steroidomic analyses of the brains of fish treated with finasteride revealed a significant increase in dehydroepiandrosterone sulfate (DHEAS). Treatment with precursors of DHEAS reduced opioid self-administration in zebrafish, in a fashion akin to the effects of finasteride. Our results highlight the importance of steroidogenic pathways as a rich source of therapeutic targets for OUD and point to the potential of finasteride as a new option for this disorder.

Title: In Vitro Pharmacological Characterization of Novel Fentanyl Analogs

Authors: *V. L. C. PALLARES[1], S. OBENG[1], M. MOTTINELLI[2], C. R. MCCURDY[2], L. R. MCMAHON[1], T. HIRANITA[1];
[1]Pharmacodynamics, [2]Medicinal Chem., Univ. of Florida, Gainesville, FL

Abstract: Fentanyl and its analogs are used as heroin adulterants, constituents of counterfeit prescription pills, and in isolation as abused drugs. Fentanyl and its analogs appear to have contributed to the rapidly increasing opioid overdose cases in the United States. Thus, there is the clear need to understand the pharmacology of novel fentanyl analogs. Here, the *in vitro* pharmacological effects of fentanyl were compared to those of six analogs of fentanyl [acryl fentanyl, β-hydroxythio fentanyl, cyclohexyl fentanyl, 4-fluoroisobutyrfentanyl (FIBF), furanyl fentanyl, and tetrahydrofuranyl fentanyl]. Using cell membranes expressing human opioid receptors, the affinity and efficacy were determined by radioligand receptor binding and [^{35}S]GTPγS functional assays, respectively. The affinities of fentanyl at mu- (MOR, [^{3}H]DAMGO), kappa- (KOR, [^{3}H]U69,593), and delta-opioid (DOR, [^{3}H]DADLE) receptors were 7.96, 202, and 539 nM, respectively. Affinities of furanyl and acryl fentanyl at MOR were 3.8- and 1.6-fold higher than that of fentanyl, respectively. Affinity of furanyl fentanyl at KOR was 1.6-fold higher than that of fentanyl. Affinities of furanyl, acryl, and β-hydroxythio fentanyl at DOR were 8.5-, 3.0-, 1.5-fold higher than that of fentanyl. Among the six analogs of fentanyl

tested, affinities of cyclohexyl fentanyl were the lowest at all three opioid receptor subtypes (Ki values greater than or equal to 1,030 nM). The E_{max} values of fentanyl at mu- (%DAMGO), kappa- (%U69,593), and delta-opioid (%SNC80) receptors were 107%, 54.5%, and 41.0%, respectively. All of the fentanyl analogs except furanyl (69.8%) and cyclohexyl (13.3%) fentanyl were full agonists at MOR (87.0% to 105%). Naltrexone (18.4 nM; 10 × Ki value at MOR) produced 13- and 7.5-fold rightward shifts in the concentration-effect functions of fentanyl and acryl fentanyl, respectively. At KOR, E_{max} values ranged from 3.86% (tetrahydrofuranyl fentanyl) to 47.1% (β-hydroxythio fentanyl), whereas at DOR, E_{max} values ranged from 8.67% (cyclohexyl fentanyl) to 52.4% (acryl fentanyl). With the exception of cyclohexyl fentanyl, these results suggest that the relatively high affinities and efficacies of the fentanyl analogs at MOR could contribute to opioid overdoses. Further, the similar affinity and efficacy profiles of fentanyl and acryl fentanyl among the three opioid receptor subtypes indicates that replacing the ethyl group with a vinyl group does not result in significant changes in binding affinity and efficacy; however, replacing the ethyl group with a cyclohexyl group results in a significant reduction in binding affinity and efficacy at MOR.

Abstract: Mitragynine (MG) is an abundant alkaloid in the botanical *Mitragyna speciosa* (kratom). MG is converted into 7-hydroxymitragynine (7-OH-MG) by the cytochrome P450 3A isoform (CYP3A). Both MG and 7-OH-MG are μ-opioid receptor (MOR) ligands, and it appears that MG has lower efficacy (i.e., intrinsic activity) than 7-OH-MG. The extent to which *in vivo* conversion to and pharmacological actions of 7-OH-MG contribute to the effects of the parent compound MG has not been established. We hypothesized that inhibiting the conversion of MG into 7-OH-MG would increase the potency of MG *in vivo*. Ketoconazole (KTC) is a CYP3A inhibitor; we demonstrated it does not bind MOR *in vitro* up to 10μM. In separate groups of rats

trained to discriminate either MG (32 mg/kg, i.p.) or morphine (3.2 mg/kg, i.p.) from vehicle, KTC (56 mg/kg, p.o.) produced 4.2- and 4.7-fold leftward shifts, respectively, in the dose-effect functions of MG to increase drug-appropriate responding. However, KTC did not significantly modify the potency of MG to decrease rates of operant responding for food. Moreover, MG did not produce antinociceptive effects in a hotplate assay at 52°C even in the presence of KTC. The effects of KTC to increase the potency of MG to produce discriminative stimulus effects were pharmacologically selective inasmuch as KTC did not significantly increase the potency of morphine to produce discriminative stimulus, rate-decreasing, and antinociceptive effects. KTC also produced a 9.7-fold increase in the potency of 7-OH-MG to produce morphine-like discriminative stimulus effects, and a 4.1-fold increase in the potency of 7-OH-MG to produce antinociceptive effects. However, KTC did not modify the potency of 7-OH-MG to decrease operant response rates. Collectively, these results demonstrate that inhibition of CYP3A increases the potency of not only MG but also 7-OH-MG, suggesting that CYP3A metabolizes both MG and 7-OH-MG. Given that CYP3A mediates the metabolism of many clinically used medicines, and/or is inhibited or activated by various drugs, caution is warranted regarding CYP3A mediated drug-drug interactions in kratom users.

Title: Plasticity changes in prelimbic neurons projecting to nucleus accumbens after heroin self administration, abstinence and relapse in Drd1- and Drd2-Cre rats

Authors: R. D. COLE[1], J. D. OTIS[1], *J. F. MCGINTY[2];
[1]Neurosci., Med. Univ. of South Carolina, Charleston, SC; [2]Neurosci., Med. Univ. South Carolina, Charleston, SC

Abstract: The cellular mechanisms underlying dysregulation of neurons in the prelimbic (PL) cortex that project to the nucleus accumbens (NAc) in relapse to drug-seeking after heroin self-administration (SA) are unclear. We investigated changes in intrinsic and synaptic plasticity in PL-NAc core neurons in wildtype (WT) and in Drd1-Cre+ and Drd2-Cre+ rats after heroin SA followed by abstinence with or without relapse. Sixty-six male and female Long Evans wildtype (WT), Drd1-Cre+ (D1), and Drd2-Cre+ (D2) rats were implanted with a jugular catheter and

their nucleus accumbens core (NAc core) infused with retrogradely transported AAVrg-hSyn-eGFP (WT) or AAVrg-hSyn-DIO-eGFP (Cre+) to isolate PL-NAc projecting neurons. After recovery, rats received yoked saline or were trained to self-administer heroin on a FR1 schedule for 14 days Following 7d homcage abstinence, a subset of rats underwent a cued relapse test (CRT) prior to whole-cell patch clamp recordings of PL->NAc neurons in oxygenated aCSF containing 100 μM picrotoxin. Current-clamp was employed to examine intrinsic cellular activity and voltage-clamp was used to characterize synaptic plasticity, including baseline sEPSCs and AMPA to NMDA ratios. Overall AP firing in PL->NAc neurons was significantly higher in WT heroin-abstinent rats (17.0±2.8) than in saline-treated rats (11.55±0.6; p=0.04) with no change in rheobase. Moreover, PL->NAc neurons in heroin-abstinent WT rats had greater sEPSC amplitudes (15.2±1.2pA vs 11.6±1.2pA; p=0.049) and sEPSC frequencies (2.9±0.2Hz vs 1.7±0.3Hz; p<0.01) than WT saline rats. AMPA/NMDA were significantly higher in the heroin group (1.6±0.2) than in the saline group (0.9±0.1; p<0.01). Similarly, $Drd1^+$ PL-NAc neurons in heroin-abstinent rats exhibited greater overall AP firing (19.6±0.7) than in saline $Drd1^+$ neurons (13.8±4.2; p=0.02). Moreover, in heroin-abstinent $Drd1^+$ rats, both amplitude and frequency of sEPSCs in PL->NAc neurons were significantly greater than in saline-treated rats. In contrast, AP firing in PL->NAc neurons did not differ, but sEPSC frequency was increased, in heroin-treated vs. saline-treated $Drd2^+$ rats. Following CRT, $Drd1^+$ PL->NAc neurons exhibited significantly less AP firing and decreased sEPSC amplitude and event frequency whereas cells in $Drd2^+$ rats remained unaffected. This study demonstrates heroin-induced neuroadaptations in PL->NAc neurons following 7 days of abstinence in WT rats are due to increases in intrinsic neuronal excitability and synaptic plasticity. Furthermore, these changes appear to be expressed predominantly by $Drd1^+$, but not $Drd2^+$, PL->NAc neurons after abstinence and reversed by cued relapse.

Title: Differential immediate-early gene expression during context-induced and context-independent heroin-seeking behaviors in rats

Authors: *J. L. RITCHIE, J. L. WALTERS, A. N. LACEY, J. M. GALLIOU, S. E. SWATZELL, T. A. BROWN, J. N. ROLAND-MCGOWAN, R. A. FUCHS;

Abstract: Opioid abuse and overdose are major public health concerns, and a key impediment to the treatment of opioid addiction is drug relapse precipitated by exposure to drug-associated

environmental stimuli. The present study aimed to map neural substrates involved in goal-directed and habitual aspects of heroin-seeking behavior following abstinence in an instrumental model of drug relapse. To this end, male Sprague-Dawley rats were trained to lever press for heroin infusions in a distinct environment (i.e., Paired context) during at least 10 daily sessions. Next, the rats were exposed to an alternate environment with no access to drug or operant levers (i.e., Unpaired context) during 14 daily sessions. After forced abstinence, rats received a non-reinforced test session in the Paired or the Unpaired context, each with or without lever access. Brain tissue was collected immediately after the test session, and standard immunohistochemistry protocols were used to assess changes in the expression of c-Fos and zif268 immediate-early genes (IEGs), markers of neuronal activation and plasticity, in 42 brain regions. Our results indicated that heroin-seeking behavior was more robust in the Paired context than in the Unpaired context. Different groups of cortical and subcortical brain regions exhibited significant changes in IEG expression in response to (a) exposure to the Paired context vs Unpaired context with lever access, (b) lever access vs no-lever access independent of context, or (c) exposure to the Paired context depending on lever access. Furthermore, network activation analysis revealed that Paired context exposure with lever access resulted in the coupling, whereas Unpaired context exposure with lever access resulted in the uncoupling, of brain networks critical for goal-directed and habitual drug-seeking behaviors. These findings expand upon existing literature and may provide the rationale for future studies investigating the causal contributions of novel brain regions and novel circuits to heroin relapse.

Title: Oxycodone Exposure Modulates Dopamine Transmission in the Nucleus Accumbens

Authors: ***K. SAMSON**, R. ESPAÑA;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Opioid use disorder is a pervasive public health issue, particularly, prescription opioids have been integral in the progression of the opioid crisis over the past two decades. A major barrier in successful treatment of opioid use disorder is the difficulty for substance users to maintain long periods of drug abstinence, owing to high relapse rates. Therefore, it is paramount to further our understanding of the neural processes underlying the risk for relapse. Interestingly,

humans exhibit an increase in drug craving over time, termed incubation of drug craving. However, the neurobiological mechanisms underlying this incubation phenomenon remains unclear. Dopamine neurotransmission in the mesolimbic pathway has been established in substance use disorder, but remains largely unexplored with incubation of opioid craving. To examine to what extent incubation of opioid craving is associated with alterations in dopamine neurotransmission, female and male rats self-administered oxycodone under an intermittent access schedule of reinforcement. Following self-administration rats underwent a 14-day, forced abstinence period. Cue-induced seeking tests were conducted at the beginning and end of abstinence to assess incubation of oxycodone craving. Eighteen hours after the second seeking test, we conducted fast scan cyclic voltammetry recordings in a slice preparation. Preliminary results suggest individual differences in both oxycodone intake and propensity to incubate oxycodone craving, which was similar in females and males. Further, we found that dopamine neurotransmission in the nucleus accumbens was disrupted following oxycodone exposure but did not appear to differ between rats that displayed incubation of oxycodone craving and those that did not. These observations suggest that exposure to oxycodone may differentially influence future drug craving, but it remains unclear whether changes in dopamine neurotransmission underlie these differences.

Abstract: **Abstract:** The neuronal activity marker Fos is widely used to identify neuronal ensembles of reward seeking and relapse. However, previous studies require immunostained brain sections for targeted ensemble identification of specific regions. Recent advances in tissue clearing and immunostaining allow for unbiased characterization of neural activation patterns across intact mouse brains. The lack of rat-specific analysis pipelines has limited the use of this approach in rats. Here, we optimized the iDISCO+ immunolabelling procedure and developed an open-source analysis pipeline called CVA-ML (Clear Volume Analysis with Machine Learning)

to identify brain-wide ensembles of context-induced reinstatement of oxycodone seeking.
Methods: We trained male Sprague-Dawley rats to self-administer oxycodone (6-h/d, 14-d) in context A and then extinguished their lever pressing in context B. We then tested for reinstatement of oxycodone seeking in both contexts A and B. We perfused and extracted the rats' brains 90 min after reinstatement tests and used our rat-optimized iDISCO+ pipeline to label Fos-positive nuclei. We imaged cleared brains using light-sheet fluorescence microscopy (LSFM) and used CVA-ML to map reinstatement-associated ensembles across the whole rat brain.
Results: We observed reliable context-induced reinstatement of oxycodone seeking after extinction of operant responding in a non-drug context. We labelled brains for Fos, imaged them using LSFM, and used CVA-ML to analyze Fos-expression patterns in these 3D datasets.
Conclusions: We present an open-source CVA-ML pipeline for whole brain activity mapping in rats. We demonstrate the application of this pipeline to identify the functional connectome underlying context-induced reinstatement of oxycodone seeking.

Title: Lack of effect of different pain-related manipulations on opioid self-administration, choice, and reinstatement of drug seeking

Authors: *D. J. REINER[1], E. TOWNSEND[2], J. MENENDEZ ORIHUEL[1], S. APPLEBEY[1], S. CLAYPOOL[1], M. BANKS[2], Y. SHAHAM[1], S. S. NEGUS[2];
[1]IRP/NIDA/NIH, Baltimore, MD; [2]Virginia Commonwealth Univ., Richmond, VA

Abstract: Background: Pain increases the risk of opioid addiction and opioid-induced pain relief may function as a negative reinforcer to increase opioid taking. However, experimental pain-related manipulations generally do not increase intravenous opioid self-administration in rodents. This discrepancy may reflect insufficient learning of pain-relief contingencies or the confounding impact of pain-related motor impairment. Here we determined if pairing noxious stimuli with opioid self-administration would promote pain-related reinstatement of opioid

seeking or increase opioid choice over food.
Methods: In Experiment 1, rats self-administered fentanyl in the presence or absence of repeated intraplantar capsaicin injections in distinct contexts to model context-specific exposure to acute cutaneous inflammatory pain. After capsaicin-free extinction in both contexts, we tested if capsaicin reinstated fentanyl seeking. In Experiment 2, rats self-administered heroin after intraperitoneal (i.p.) lactic acid injections to model acute visceral inflammatory pain. After acid-free extinction, we tested if lactic acid would reinstate heroin seeking. In Experiment 3, we tested if treatment with either repeated lactic acid or intraplantar Complete Freund's Adjuvant (CFA; to model sustained inflammatory pain) would increase fentanyl choice over a food reinforcer.
Results: In Experiments 1 and 2, neither capsaicin nor lactic acid reinstated opioid seeking after extinction, and lactic acid did not increase heroin-induced reinstatement. In Experiment 3, lactic acid and CFA decreased reinforcement rate without affecting fentanyl choice.
Conclusions: These results extend the range of conditions across which pain-related manipulations fail to increase opioid seeking in rats and suggest that enhanced opioid-addiction risk in humans with chronic pain involve factors other than enhanced opioid reinforcement and relapse.

Title: In vitro and in vivo pharmacological comparison of a synthetic analogue of the primary Mitragyna speciosa (kratom) alkaloid mitragynine

Authors: *M. L. CROWLEY[1], S. OBENG[2], V. L. C. PALLARES[2], F. LEÓN[1], L. R. GAMEZ-JIMENEZ[2], T. HIRANITA[2], L. R. MCMAHON[2], C. R. MCCURDY[1];
[1]Medicinal Chem., [2]Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: With the ongoing opioid epidemic, opioid-dependent individuals have turned to the Southeast Asian indigenous tree, *Mitragyna Speciosa* (Kratom), to curb the undesirable opioid-induced adverse effects associated with continual use of opioids. Mitragynine is the major bioactive constituent in the plant, accounting for up to 66% of crude alkaloid extract, and exerts an important pharmacological effect to mitigate the opioid-induced adverse effects via the μ-opioid (MOR) and α_2-adrenergic ($A\alpha_2R$) receptors. To better understand the structure-activity

relationship of mitragynine at these targets, structurally simplified analogues were synthesized and assessed for affinity and efficacy at opioid and α_{2C}-adrenergic receptors *in vitro* and *in vivo*. In a radioligand receptor binding assay, affinities (Ki values) of mitragynine at human μ-, κ-, δ-opioid, and α_{2C}-adrenergic receptors were 709 ([^{3}H]DAMGO), 1,530 ([^{3}H]U69,593), 6,800 ([^{3}H]DADLE), and 4,040 nM ([^{3}H]RX821002), respectively. Among the mitragynine analogues, affinities of MLC-1, a C_1-modified analog, at μ-, κ-, δ-opioid, and α_{2C}-adrenergic receptors were 2.1-fold lower, 1.8-fold higher, 2.9-fold lower, and 2.5-fold higher compared to mitragynine. In a [^{35}S]GTPγS functional assay at MOR, Emax values of mitragynine and MLC-1 were less than 4.0% relative to DAMGO. In rats trained to discriminate mitragynine (32 mg/kg, i.p.), MLC-1 (17.8 mg/kg, i.p.), the MOR agonist morphine (up to 56 mg/kg, i.p.), and the Aα_2R agonist lofexidine (up to 0.56 mg/kg, i.p.) produced 77.2%, 70.4%, and 74.1% mitragynine-lever responding, respectively. In rats trained to discriminate morphine (3.2 mg/kg, i.p.), MLC-1 (up to 32 mg/kg), mitragynine (up to 56 mg/kg, i.p.) and lofexidine produced 31.9%, 56.6%, and 23.9% morphine-lever responding, respectively. In a hotplate assay at 52°C, maximum possible antinociceptive effects of morphine, mitragynine, MLC-1, and lofexidine were 89.4%, 1.1%, 25.6%, and 43.3%, respectively. In these rats, maximum hypothermic effects of lofexidine, mitragynine, MLC-1 and morphine were 4.9°C, 1.0°C, 1.5°C, and 0.18°C, respectively. The present results suggest that C_1- modification of mitragynine results in no dramatic change in *in vivo* activity at μ-opioid and α_{2C}-adrenergic receptors; however, a slight shift toward the Aα_2R activity was observed. Further structural simplification of the mitragynine scaffold is required to understand the structure-activity relationship at both μ-opioid and α_{2C}-adrenergic receptors.

Title: Behavioural and neurobiological basis of the individual vulnerability to develop compulsive heroin seeking

Authors: ***M. FOUYSSAC**[1], M. PUAUD[1], M. SIDDLE[2], B. J. EVERITT[1], D. BELIN[1]; [1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. Col. London, London, United Kingdom

Abstract: Addiction has been hypothesised to result from a transition from volitional, recreational drug use to compulsive drug seeking seen in vulnerable individuals. The neural and behavioural factors underlying the vulnerability to switch to compulsive drug use for stimulant

drugs are increasingly being understood. Here we present a new procedure to measure compulsive heroin seeking behaviour in order to identify behavioural and molecular markers of the vulnerability to develop this characteristic of heroin addiction that is a major burden on individual and society. In this novel procedure, heroin seeking in a drug-free state, maintained by heroin-associated cue presentations over prolonged periods, was challenged by the contingent presentation of electric footshocks in a large cohort of rats with an extended history of heroin seeking and use. Marked individual differences in the tendency to seek heroin compulsively enabled the investigation of the behavioural and molecular endophenotypes of this vulnerability. In a series of longitudinal studies, drug naive rats were tested for several addiction-relevant traits including anxiety, decision making, sensation and novelty seeking as well as reward (sweetness) preference, prior to being trained to seek heroin under the influence of the conditioned reinforcing properties of heroin-paired cues for several weeks (a second-order schedule of reinforcement). The compulsive nature of heroin seeking behaviour was then measured over several sessions during which mild footshock punishment was delivered contingent on seeking responses prior to, but not during, the administration of heroin. An individual's tendency to engage in vigorous cue-controlled heroin seeking and to resist punishment was shown to be predicted by both a high anxiety trait and sign tracking phenotype. This individual vulnerability was associated with an alteration in the adenosinergic system in the nucleus accumbens. Rats identified as highly compulsive had higher mRNA and protein levels of the adenosine 2A receptor in the ventral striatum as compared to low compulsive rats. The expression of adenosinergic proteins was further shown to predict compulsive heroin seeking at the population level. Together, these data indicate that high anxiety and a propensity to ascribe incentive value to conditioned stimuli predict the vulnerability to develop compulsive heroin seeking behaviour that may be mediated by alterations in the adenosinergic system in the ventral striatum. These data offer new avenues to developing both preventative and potential therapeutic targets to decrease compulsive heroin seeking, a key characteristic of heroin addiction.

Title: Cellular, molecular, and functional changes in the brain following acute and chronic fentanyl exposure: Effect of age and gender

Authors: *D. LAM[1], A. SEBASTIAN[1], S. K. G. PETERS[1], M. E. MENDEZ[1], N. R. HUM[1], C. A. VALDEZ[2], N. O. FISCHER[1], G. G. LOOTS[1], H. A. ENRIGHT[1];

[1]Biosci. and Biotech. Div., [2]Nuclear and Chem. Sci. Div., Lawrence Livermore Natl. Lab., Livermore, CA

Abstract: Background: The CDC has reported that 70, 237 people have died from a drug overdose and out of those drug overdose deaths, two thirds involved an opioid, like Fentanyl. Fentanyl is one of the most frequently used synthetic opioids in medicine where it has established itself as an analgesic for patients undergoing surgery, and in the proper management of chronic pain. Unfortunately, due to its heroin-like euphoric effects, in the past two decades fentanyl has found itself involved in a number of illicit and lethal drug overdosing cases. Fentanyl, like morphine, binds to mu-opioid receptors (MOR) in many brain regions, and this binding event can lead to addiction, impairment of cognitive functions, and inhibit nociception, arousal, and respiration. Clinical evidence suggests gender differences between children and adults in response to opioids, such as: significant ventilation depression in young female children; higher rates of opioid abuse in men and greater negative side effects (e.g., nausea and vomiting) in women. However, it is not clear how gender differences contribute to the differential response observed in acute and chronic exposure to synthetic opioids, such as fentanyl. Methods/Results: In this study, we examined the effects of acute (i.e., single dose) and sub-chronic (i.e., daily dosing for 5 days) exposure to 50 μg/kg of fentanyl to the brains of female and male postnatal (P14-18) and adult (6-8 weeks) rats. Immunohistochemistry and bulk RNA-sequencing was used to characterize the cellular and molecular changes in the cortex, hippocampus and cerebellum. To examine the effects of opioid use on neuronal function, neurons from postnatal and adult rat brains sub-chronically exposed to fentanyl were harvested and cultured on a multi-electrode array to monitor neural network formation and maturation. Conclusion: Collectively, the findings of this study will determine whether age and sexual dimorphism following acute and sub-chronic fentanyl exposure can be determined by cellular, molecular, and functional changes in the brain. Evaluating these factors will be important to identify whether the age and sex of the warfighter, treated with fentanyl, is susceptible to the adversive effects of the synthetic drug.

Title: Mu opioid receptors in vGluT2-expressing glutamatergic neurons modulate opioid reward

Authors: *K. C. REEVES[1], M. KUBE[1], G. G. GRECCO[1], B. FRITZ[1], B. MUNOZ[1], F. YIN[1], Y. GAO[1], D. HAGGERTY[1], H. HOFFMAN[1], B. K. ATWOOD[2];
[2]Pharmacol. and Toxicology, [1]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Much research has focused on the role of mu opioid receptor (MOR)-mediated regulation of GABA transmission in opioid reward. MORs also regulate glutamate transmission and much less is known about the role of these MORs in drug reward. Previously, we found that MORs inhibit glutamate transmission at thalamostriatal synapses that express the type 2 vesicular glutamate transporter (vGluT2). To explore the role of MORs in vGluT2-expressing neurons in opioid-related behaviors, we created a transgenic mouse that lacks MORs in vGluT2-expressing neurons (MORflox-vGluT2cre). A variety of behavioral assessments were performed on adult male and female MORflox-vGluT2Cre positive (+) knockout mice with cre negative (-) littermate controls, with a focus on opioid reward. MORflox-vGluT2cre mice do not acquire conditioned place preference for a low doses (0.05, 0.5 mg/kg) of the opioid, oxycodone, but acquire conditioned place aversion for a higher dose (5 mg/kg), whereas control mice acquire conditioned place preference for all tested doses. In two-bottle choice oral consumption assessment, MORflox-vGluT2cre mice consume less oxycodone and have reduced preference for oxycodone over water, compared to controls. MORflox-vGluT2cre mice also lack oxycodone-induced locomotor stimulation, but show no basal differences in locomotor activity, compared to controls. Interestingly, MORflox-vGluT2cre mice display baseline withdrawal-like responses following the development of oxycodone dependence that are not seen in controls. In addition, unlike controls, withdrawal-like responses do not increase following challenge with the opioid antagonist, naloxone. Other MOR-mediated behaviors, including oxycodone-induced antinociception and sucrose consumption, are intact in MORflox-vGluT2cre mice. Additionally, MORflox-vGluT2cre mice do not differ from controls in basal or oxycodone-induced plasma corticosterone levels, a measure of stress. These data reveal that MOR modulation of glutamate transmission is a critical component of opioid reward. Current research is focused on identifying the neurocircuitry of MOR modulation of glutamate transmission and role of these neurocircuits in opioid reward. We selectively deleted MORs in the thalamus, a region with a high density of vGluT2 neurons, by stereotaxically injecting AAV.CamKii.Cre.GFP into the thalamus of 6-week-old male and female MORflox mice. Control mice were injected with AAV.CamKii.GFP. Deleting thalamic MORs did not affect acquisition of oxycodone conditioned place preference, suggesting this population of MORs does not play a significant role in opioid reward.

Title: Detecting individual differences in response to opioids using Raman spectroscopy

Authors: *C. A. MADISON[1], S. CHAVVA[1], P. WELLMAN[2], S. MABBOTT[2], S. EITAN[2]; [1]Texas A&M Univ., College Station, TX; [2]Texas A&M Univ., COLLEGE STATION, TX

Abstract: Both personality and social environment were suggested to influence the development of opioid use disorder (OUD). Similarly, we demonstrated using rodent models that both social environment and individuals' sociability levels influence the response to opioids. Mice can be divided, based on their sociability levels, into Socially Avoiding (SA) and Socially Exploring (SE). We previously demonstrated that SE mice are more sensitive to the sensitizing effects of opioids. In contrast, SA mice are more sensitive to opioids' effects on stress and pain. This suggests that the positive reward system is likely mediating abuse escalation in SE individuals, while the negative reinforcement is likely mediating abuse escalation in SA individuals. Although opioid use disorder is a serious and relapsing mental health disease, in contrast to other chronic disorders, there are no objective diagnostic tools for early detection or to monitor disease progression. Raman spectroscopy is used in other biomedical fields for both research and as a diagnostic tool, but is underutilized for the study of OUD. In this project, we have demonstrated that by using Raman spectroscopy, we can detect baseline differences between SA and SE mice, as well as in their responses to morphine. SA and SE mice were treated with saline or morphine. Different brain areas were examined, including the amygdala, nucleus accumbens, ventral tegmental area, prefrontal cortex, and hippocampus. We observed molecular differences between saline-treated SA and SE mice. This indicates that individual differences in sociability levels could possibility be detected and assessed using Raman spectroscopy. Repeated exposure to opioids altered brain molecular composition in both SA and SE mice. However, differential responses were observed in the response to morphine in SA and SE mice. These results suggest that SA and SE individuals have differential behavioral and molecular responses to opioids, and that treatment for OUD should be tailored to individuals based on their personalities and social interactions style. Thus, these methodologies are expected to provide insights into potential need to individualize the care for OUD patients, as well as markers to be used for objective diagnosis of the development of trajectory of OUD in humans.

Title: Increased fentanyl consumption in male and female C57BL/6 mice after chronic witness defeat stress

Authors: *D. FRANCO, M. E. FOX, A. WULFF, M. K. LOBO;
Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Synthetic opioids, like fentanyl, have accelerated rising opioid related drug overdose. Thus, there is a critical need to investigate factors that may facilitate the development of opioid use disorder. Social stress is linked to escalated cocaine and alcohol consumption in preclinical research. However, Chronic Social Defeat Stress (CSDS), a paradigm used to achieve social stress, often produces social and physical stress. Since opioids have inherent analgesic properties, it is important to delineate between analgesic and rewarding effects when examining the potential stress-sensitization of opioid consumption. Chronic Witness Defeat Stress (CWDS), a validated paradigm that only produces social stress, allows examination of stress-sensitized opioid consumption. The goal was to evaluate stress induced changes in fentanyl consumption using CWDS and escalating fentanyl two-bottle choice paradigms. Male and female C57BL/6 mice completed 10 days of CWDS, in which subjects indirectly experienced the direct social defeat of a male C57BL/6 intruder mouse by a male CD1 aggressor. A social interaction (SI) test was completed to determine susceptible (avoidant behavior) and resilient (approach behavior) groups. Afterward, mice completed a 15 day escalating fentanyl two-bottle choice paradigm that comprised of three distinct periods of forced fentanyl access, each characterized by a higher dose of fentanyl (i.e. 5, 10, and 15 μg/mL). Periods of forced fentanyl access were followed by a choice day of voluntary fentanyl consumption wherein mice had access to fentanyl and water. A second SI test was completed to assess susceptible and resilient behavioral groups after fentanyl exposure. Overall, CWDS elicited stress-induced increases in fentanyl consumption. Resilient and susceptible male mice consumed more fentanyl in all three forced access periods compared to controls. Female mice voluntarily consumed more fentanyl compared to resilient mice and had higher fentanyl preferences compared to control and resilient mice during the third choice day. Susceptible male mice subjected to CSDS preferred and consumed more fentanyl compared to resilient mice during the second period of forced and voluntary fentanyl access. Thus, CWDS and CSDS paradigms can yield stress induced changes in fentanyl consumption. Resilient male and female mice also displayed a decrease in social interaction after completion of the fentanyl

two-bottle choice paradigm, suggesting that fentanyl exposure itself can negatively impact social behavior. Overall, our findings suggest that social stress can increase vulnerability to opioid misuse in susceptible and resilient populations.

Abstract: Opiate addiction has quickly become a health crisis in the United States. The Council of economic advisors estimates that the opioid crisis will have a cost of 2.5 trillion dollars from 2018 to 2022. Efforts to reduce the number of opiate addicts have led to the development of new treatment options, such as medication replacement therapies (methadone, buprenorphine) and behavioral (exposure) therapies. Despite their relative success, a high number of opiate addicts' relapse, and many die of drug-related overdoses. We used preclinical models of addiction to understand the molecular mechanisms underlying opioid-seeking behaviors. Previously, we created an mRNA profile of the Ventral Striatum/ Nucleus Accumbens (VS/NAc) of rats who had undergone morphine extinction. We found an increase in bdnf mRNA in animals who successfully extinguished morphine place preference. Although BDNF has been associated with extinction of addictive behaviors, whether this increase at the messenger level could be translated into active protein expression, remains to be determined. Here, we measured BDNF expression in the VS/NAc of animals that underwent extinction of morphine place preference by using Western blots. In accordance with our previous finding, we found an increase in BDNF protein expression in VS/NAc of animals in the extinction group. Given that BDNF expression in VS/NAc is naturally low, we questioned whether this BDNF could be axonally transported as well, from other brain regions of the reward circuit ie., hippocampus and amygdala. In the hippocampus we found a significant increase of BDNF in animals that successfully extinguished morphine place preference, while in the amygdala, we found this increase not only in animals of the extinction group, but also in animals showing extinction failure. The observed increase in BDNF expression in the VS/NAc validates our previous findings and suggests BDNF's viability as a potential future pharmacological target for the extinction of opioids.

Title: Neuronal correlates of opioid-induced risk-taking behavior in the prelimbic cortex.

Authors: ***C. B. QUAVE**[1], A. M. VASQUEZ[1,2], E. P. BORA[1], C. L. CHIDOMERE[1,3], D. S. ENGELKE[1], F. H. DO MONTE[1];

Abstract: Opioid misuse is associated with impaired risk-related decision making. However, the neural correlates of opioid-induced risky motivated behavior are unclear. Working with the hypothesis that altered prefrontal cortex activity underlies opioid-induced risk taking, we employed an approach-avoidance conflict model using a modified conditioned place preference protocol combined with a fear-inducing predator odor. Adult male Long-Evans rats implanted with single-unit electrodes in the prelimbic cortex (PL) were injected with saline or the opioid drug morphine and placed in the side of the apparatus least preferred at baseline. Conditioning with saline (n=18) or morphine (n=20) occurred on alternating days over a 10-day period. After 72 h of forced abstinence, morphine-treated rats showed increased preference for the drug-paired side when compared to saline controls ($p<0.01$). Immediately following preference testing, a conflict test began in which a predator odor stimulus (cat saliva) was placed in the previously drug-paired side. During conflict, saline-paired rats demonstrated a clear aversion to the paired side. In contrast, morphine-paired rats continued to enter the paired side despite the presence of predator odor, suggesting an increase in risk-taking behavior. Single-unit recordings from PL neurons revealed a significant suppression in neural activity after acute administration of morphine (22%), but not saline (6%, $p<0.05$). During the last day of conditioning, PL cells no longer exhibited drug-induced suppression of firing rates, suggesting that repeated morphine administration causes a physiological adaptation in PL activity. During the conflict test, the spontaneous firing rates of most PL cells in the saline group were inhibited (53%) rather than excited (7%; $p<0.05$), though this pronounced inhibition-to-excitation ratio was not observed in the morphine group (35% inhibited vs. 33% excited; $p=1.0$). Together, our results indicate that repeated opioid exposure leads to enhanced expression of reward-related memory and a neuronal

adaptation to opioid effects in PL. Additionally, repeated administration of opioids increases risk-taking responses during motivational conflict and such behavior correlates with decreased inhibitory tone in PL neurons.

[3]Department of Psychological and Brain Sciences, Indiana University Bloomington, Multidisciplinary Science Building II 120, 702 North Walnut Grove Ave., Bloomington, IN 47405-2204.The current wide-spread scope of the opioid epidemic continues to be defined by an escalating number of fatalities resulting from accidental opioid overdoses. Respiratory depression is usually the cause of a fatal opioid overdose, when the neurons of the preBötzinger complex, a nucleus in the brainstem that controls reflexive inspiration, become desynchronized due to mu opioid receptor activation. Prior literature has shown cannabinoid receptor agonism may enhance opioid effects, yet it is unknown whether cannabinoids enhance or mitigate opioid-induced respiratory depression. In this study we sought to define the role of the cannabinoid receptor 2, CB2R, in respiratory function using selective agonists to determine the effects of CB2 activation on respiratory depression alone and

when combined with morphine sulfate (MS) in CD1 mice. Utilizing whole body plethysmography, selective CB2 agonism with AM2301 did not induce respiratory depression nor did the phytocannabinoids, THC, CBD, and BCP. In contrast, a selective synthetic CB1 cannabinoid, AM356, induced respiratory depression. Moreover, AM2301 the CB2 agonist, significantly prevented morphine-induced respiratory depression when drugs were administered in combination. These findings show mitigation of opioid induced respiratory depression can be achieved with activation of CB2Rs, and not CB1Rs. These data support CB2R agonists as an adjunct to opioid therapy, reducing the harmful, and potentially lethal, opioid-induced respiratory depression.

Title: Chronic morphine exposure induces cell type specific changes in the intrinsic electrophysiological properties of mouse hypocretin/orexin (H/O) neurons

Authors: *E. A. BERRY[1], S. JAVED[1], R. MCGREGOR[2], M. ISHIBASHI[3], J. M. SIEGEL[2], C. S. LEONARD[1];
[1]Dept Physiol., New York Med. Col., Valhalla, NY; [2]Dept Psychiat, Univ. California Los Angeles, North Hills, CA; [3]Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: H/O neurons regulate arousal, feeding, and reward – a point recently punctuated by the discovery that human heroin addicts have H/O neurons that are ~22% smaller and 54% more numerous than those in age-matched subjects (Thannickal et al. 2018). To investigate how chronic opioid exposure functionally impacts H/O neurons, we made whole-cell recordings from H/O-EGFP neurons in acute brain slices from male mice (9-18 w) treated with either morphine (50 mg/kg/day) or saline for 14 days. With investigators blind to treatment for all experiments, we first used standard immunohistochemistry to verify that morphine altered soma size of H/O-EGFP neurons, since only 40-70 % of H/O neurons express EGFP in these mice. We found that the average somatic cross-sectional area was 17% smaller in morphine treated mice (n=4, ~100 neurons/mouse) compared to saline treated mice (n = 4, ~90 neurons/mouse; $p < 0.05$). We next examined sEPSCs and the intrinsic properties of H/O-EGFP neurons (n~30 neurons, from 6 mice in each treatment group). We found that morphine treatment did not change the proportion of D- or H- type H/O neurons (saline n=18/13 D/H type, morphine n=17/14 D/H type) which we

distinguished by characteristic membrane responses dominated by A-type K^+ current in H-cells (Schöne et al. 2011). Morphine treatment also did not alter spontaneous firing, sEPSC amplitude, input resistance or cell capacitance, although there was a trend toward increased capacitance and decreased sEPSC amplitudes for H cells ($p = 0.07$). In contrast, morphine treatment selectively altered spiking in H cells. These neurons showed an ~43% increase in rheobase, an ~10% decrease in action potential amplitude and an afterhyperpolarization minimum that was ~3 mV less negative (t-test, $p < 0.05$) than in H-cells from saline treated mice. A specific decrease in H-cell excitability was further indicated by an analysis of repetitive firing which found that H- but not D- cells had F-I relations that were right-shifted and reduced in slope following morphine. Moreover, the firing patterns for H-cells, but not D-cells shifted from one of continuous firing throughout the current pulse toward more clustered and inconsistent firing. Collectively, these data underscore the functional heterogeneity among H/O neurons and indicate that in addition to inducing structural plasticity, chronic morphine differentially decreases excitability of H-type H/O neurons. This implies their encoding and transmission of information is impaired following chronic morphine exposure and suggests that alterations in the electrophysiological properties of H-type H/O neurons may contribute to opiate addiction.

Title: Chemogenetic Inhibition of Midbrain Dopamine Neurons During Object Exploration Enhances Future Novel Object Discrimination

Authors: S. FLEURY[1], A. SØRENSEN[2], U. GETHER[2], S. MINGOTE[1];
[1]Advanced Sci. Res. Ctr., CUNY Grad. Ctr., New York, NY; [2]Neurosci., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: It is well established that dopamine (DA) neurons in the ventral midbrain signal novelty by increasing their bursting activity, while decreasing it after repeated inconsequential stimulus presentations. Thus, the lack of DA neuron burst activity is a physiological signature that a particular stimulus has become familiar. Here, we tested the hypothesis that decreasing DA neuron activity while animals explore objects for the first time enhances familiarization and improves subsequent novel object discrimination.
Novel object recognition is dependent on the amount of pre-exposure to the familiar object. We show that two familiarization sessions spread out over two days produce robust novelty discrimination, while only one familiarization session is not sufficient to cause novelty discrimination during the novel object recognition task. The lack of exploration on the novel object is thought to reflect a stage of equal attention allocated to the familiar and novel stimulus,

which is interpreted as a weakened memory of the previously seen familiar stimulus. To investigate whether decreasing DA neuron activity prompts gain-of-function in novelty recognition, we chemogenetically inhibited DA neurons in the ventral tegmental area (VTA) during the familiarization session of the novel object recognition paradigm that results in poor novelty discrimination.
We injected an AAV *flp*-dependent hM4D into the VTA of TH-*flp* transgenic mice to selectively inhibit TH-positive DA neurons. The selectivity of the viral strategy was verified via immunohistochemistry staining. The virus was then activated via injection of Clozapine N-oxide dihydrochloride (CNO; i.p.) 30 minutes before trial. We found that inhibiting DA neurons during the familiarization phase resulted in enhanced discrimination during the novelty task in experimental animals compared to control animals. To confirm these results were due to an effect on familiarization processes, we conducted further trials in which DA neurons were only inhibited after the familiarization phase and during subsequent novel object recognition session. Under this manipulation, we did not see an improvement in discrimination. These results suggest that suppressing DA activity ameliorates novelty discrimination by enhancing familiarity.

Title: Characterizing a brainstem to midbrain circuit involved in nicotine aversion

Authors: ***C. LIU**[1], A. J. TOSE[1], Y. ZHU[1], J. W. DE JONG[1], K. T. BEIER[2], S. LAMMEL[1]; [1]Univ. of California, Berkeley, Berkeley, CA; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Decades of research have demonstrated a crucial role of ventral tegmental area (VTA) dopamine (DA) neurons in mediating the brain's response to natural rewards and the reinforcing effects of addictive drugs. However, recent studies have revealed that the VTA is a heterogeneous population of neurons, with DA cells in the medial VTA signaling aversion. Here, we leverage the dose-dependent properties of nicotine to understand how the midbrain DA system responds to an addictive drug that is rewarding at low doses and aversive at high doses. Using anatomical tracing, electrophysiology, and in vivo fiber photometry, we demonstrate that an aversive dose of nicotine strongly activates an inhibitory input from the laterodorsal tegmentum (LDT) to the VTA and that this functional input can inhibit VTA DA cells to affect downstream DA release in the nucleus accumbens (NAc). Aversive nicotine both inhibits a pathway that signals reward by decreasing DA release in the lateral shell of the NAc (NAcLat)

and activates a pathway that signals aversion by increasing DA release in the ventromedial shell of the NAc (vNAcMed). Importantly, ablating LDT GABA neurons alters the DA release patterns in response to an aversive dose of nicotine. Together, these results introduce a circuit mechanism for nicotine aversion that involves subcircuits regulating both reward and aversion and implicates a long-range brainstem input to the midbrain as a mediator of this effect.

Title: Potential Application of FSNY-1 as Smoking-Cessation Drug

Authors: B. BUNCE[1], R. HILL[2], M. J. FORSTER[2], *R. A. SHETTY[3];
[2]Pharmacol. and Neurosci., [3]Dept. of Pharmacol. and Neurosci., [1]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: A novel compound, FSNY-1 was tested for its ability to inhibit the biphasic psychomotor stimulant and depressant effects of nicotine in mice. Different groups of young mice were pretreated with FSNY-1 or the positive controls varenicline and mecamylamine and placed into chambers for recording of locomotor activity after an injection of 1.6 mg/kg nicotine. A negative control group was pretreated with the peripheral ganglion-blocking agent, hexamethonium, prior to nicotine injection. FSNY-1 and hexamethonium selectively blocked the stimulant phase of nicotine's effect occurring 30-60 minutes following injection, whereas mecamylamine attenuated both the depressant (0-30 min following injection) and stimulant phases of nicotine's action. Mecamylamine fully reversed both phases of nicotine's action and did not affect locomotor activity when given alone at the effective dose. Varenicline partially reversed the depressant effect and fully reversed the stimulant effect of nicotine but had a significant depressant effect when injected alone at the effective doses. Based on these results, it is possible that FSNY-1 will be useful in the treatment of nicotine dependence with fewer side effects than varenicline. It is significant that hexamethonium, which does not cross the blood-brain barrier, had a profile identical to FSNY-1. This outcome supports the conclusion that ability to block autonomic outflow may be a sufficient condition for clinical efficacy. Thus, inhibition of the peripheral actions of nicotine may represent a significant target for new drug development.

Abstract: Presenting author: Author e-mail: Sebastian Ortegon Sortegon@miners.utep.edu**Title:**Insulin resistance enhances the reinforcing effects of nicotine in a sex-dependent manner.**Authors:**S. Ortegon; B. Cruz; F. Matos-Ocasio; A. Rodriguez-Crespo; K. P. Uribe; K. I. Galindo; K. M. Serafine; A. Nazarian; L. E. O'Dell. Department of Psychology, The University of Texas at El Paso.**Abstract:**Clinical studies have shown that persons with diabetes are more susceptible to the tobacco use; however, it is unclear whether this due to greater pleasurable effects of nicotine. Our laboratory employs rodent models of diabetes to study the behavioral effects of nicotine. The present study used female and male rodents to examine sex differences in the reinforcing effects nicotine following a chronic high-fat diet (HFD) regimen that induced insulin resistance. Briefly, adult female and male rats received a HFD regimen for 8 weeks and controls received a regular diet (RD). Separate groups of HFD-treated rats received a low dose of streptozotocin (STZ; 25 mg/kg/sc) to facilitate insulin resistance. To determine the magnitude of insulin resistance, all rats first received an insulin injection and glucose levels were assessed 15, 30, 60, 120, and 180 minutes later. The rats were then given extended (23 hour) access to intravenous self-administration (IVSA) of 3 increasing doses of nicotine. Each nicotine dose was delivered for 4 consecutive days with 3 intermittent days of drug abstinence. Our major finding was that the HFD regimen induced insulin resistance, which enhanced the reinforcing effects of nicotine relative to their respective RD controls. Regarding sex differences, the magnitude of this effect was greater in female versus male rats that were insulin resistant. Together, our results suggest that insulin resistance, a hallmark feature of diabetes, enhances the reinforcing effects of nicotine particularly in females. These data imply that greater vulnerability to tobacco use in persons with diabetes is due to enhanced rewarding effects of nicotine.

Title: Short-term increases in risky choice following nicotine vapor exposure in rats

Authors: ***P. GINER**[1], L. MAYNEZ-ANCHONDO[2], S. ORTEGON[2], M. BLANCO[1], A. E. LILEY[3], K. P. URIBE[2], N. W. SIMON[3], I. A. MENDEZ[1];
[1]Sch. of Pharm., [2]Psychology, The Univ. of Texas At El Paso, El Paso, TX; [3]Psychology, Univ. of Memphis, Memphis, TN

Abstract: Increased frequency of use, higher nicotine concentrations, and unique additive chemicals associated with electronic nicotine delivery systems (i.e., e-cigarettes) results in different pharmacokinetics and pharmacodynamics for nicotine, relative to that seen with conventional cigarettes. Unfortunately, targeted advertising, addition of palatable flavors, and misconceptions about safety has led to a dramatic increase in recreational use of e-cigarettes. Exposure to nicotine injections in rats has been shown to impair decision making; however, the effects of nicotine vapor administration on risky choice remains unknown. The goal of this research is to explore changes in risky decision making following single and repeated exposure to nicotine vapor. Twenty-four male Sprague Dawley rats were trained in the probability discounting task until stable. Following training, rats were exposed to either a control dose of 0 mg/ml nicotine vapor or 24 mg/ml nicotine vapor for 10 consecutive days, with testing in the probability discounting task occurring immediately after daily exposures. Results show that rats receiving single or repeated nicotine vapor exposures show immediate, but not long-term, increases in risky choice. Testing in a response perseveration task further demonstrated that nicotine vapor exposure does not increase perseverative responding. Research investigating the long-term effect of e-cigarette vapor exposure on cost-benefit decision making, such as that described in this proposal, will provide much needed information on the cognitive and behavioral effects of e-cigarettes.

Abstract: In recent years, there has been a dramatic increase in the consumption of nicotine vapor through the use electronic nicotine delivery systems, particularly among adolescents. Pre-clinical studies investigating the rewarding and withdrawal effects of nicotine have primarily used injections to administer nicotine liquid. Currently, there are only a handful of published studies investigating the effects of nicotine vapor inhalation on nicotine reward and withdrawal in rodents. The goal of this study is to explore physical withdrawal signs and anxiety-like behavior following exposure to nicotine vapor in rats. Fifty-six male Sprague Dawley rats were exposed to either 0, 12, or 24 mg/ml nicotine vapor for 9 days. For all groups, blood samples were collected on day 6 of vapor exposure to assess levels of cotinine, a nicotine metabolite. Physical withdrawal signs and anxiety-like behavior, following subcutaneous injections of the nicotinic receptor antagonist mecamylamine, were assessed on day 7 and day 9 of vapor exposure, respectively. Additionally, 30 female Wistar rats were exposed to either 0, 12, or 24 mg/ml nicotine vapor for 14 days, with physical withdrawal signs and anxiety-like behavior following subcutaneous injections of mecamylamine tested on day 14. An increase in cotinine levels, physical withdrawal signs, and anxiety-like behavior was seen in male groups exposed to 12 and 24 mg/ml nicotine vapor, relative to the 0 mg/ml controls. Physical withdrawal signs and anxiety-like behavior was also seen in female groups exposed to 12 mg/ml nicotine vapor, relative to the 0 mg/ml controls. The findings suggest that repeated exposure to nicotine vapor leads to a physical withdrawal syndrome similar to that seen with more traditional routes of administration, in male and female rats. The proposed work will offer a foundation for future pre-clinical studies to identify the neurobiological mechanisms driving dependence following repeated nicotine vapor exposure.

Title: Characterization of the effects of oral nicotine administration and abstinence on anxiety-like behavior and the orexinergic system: role of Chrna4 and Chrna5

Authors: *H. L. MATHEWS[1], J. D. JONES[2], M. KONDRATENKO[2], M. BROWN[2], S. ALLSUP[2], J. A. STITZEL[3];
[1]Inst. for Behavioral Genet., [3]Inst. Behav Genet., [2]Univ. of Colorado Boulder, Boulder, CO

Abstract: Relative to non-smokers, smokers are more likely to report symptoms of anxiety. Although nicotine has been reported to produce anxiolytic effects, smoking may increase the risk for anxiety disorders. Withdrawal from nicotine is also associated with increased anxiety. In this study, we investigated the effect of nicotine consumption and abstinence on anxiety-like behavior and the orexinergic system in C57BLJ/6 mice as well as *Chrna4* and *Chrna5* null mutant mice. Mice were assigned to one of 5 groups: pre-nicotine baseline, nicotine administration day 8, nicotine vehicle day 8, nicotine abstinence day 1, and abstinence vehicle day 1. Mice in nicotine groups received 200ug/ml of nicotine in a 0.2% saccharin drinking solution for 14 days, and nicotine abstinence was initiated by omitting the nicotine from the vehicle solution. Vehicle groups received 0.2% saccharin in water. Anxiety-like behavior data was assessed using an elevated zero maze at either ZT16 or ZT20 (4 and 8 hours into the active phase, respectively). In C57 mice, anxiety-like behavior was not altered by time of day. Relative to C57 mice, α4(-/-) mice displayed increased number of open entries at ZT 20, suggesting decreased anxiety. In α5(-/-) mice, anxiety-like behavior was decreased at ZT16 relative to ZT20. Neither an effect of nicotine administration nor abstinence was seen for anxiety-like behavior in C57, α4(-/-), or α5(-/-) mice. Following behavioral testing, prepro-orexin (PPO) and orexin receptor 2 (OX2R) protein levels were quantified in the hypothalamus. At baseline, PPO expression was reduced at ZT20, relative to ZT16, in C57 mice. The opposite pattern was seen in α4(-/-) mice and there was no time of day effect in α5(-/-) mice. In contrast, no clear effect of nicotine consumption or abstinence on PPO levels were detected for any genotype. Interestingly, the relationship between nicotine intake and PPO levels differed by genotype; in C57 mice, there was a negative correlation, in α4(-/-) mice there was a trend for a positive correlation, and there was no relationship between nicotine intake and PPO levels in α5(-/-) mice. OX2R protein expression at baseline did not differ across timepoints for C57 or α5(-/-) mice. But, similar to the results for PPO, α4(-/-) mice did exhibit increased OX2R expression at ZT16 relative to ZT20. No clear effect of nicotine treatment or abstinence were observed for OX2R expression in any genotype.

Title: Brain activation during self-regulation to smoking cues

Authors: *L. E. MARTIN, M. G. BRUCKS, A. T. FOX, V. B. PAPA;
Hoglund Biomed. Imaging Ctr., Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Nearly 60-80% of smokers who attempt to quit smoking are unable to quit. Difficulty quitting smoking may be due to an imbalance between brain regions that help smokers control their impulses to smoke and brain regions that drive smokers towards rewarding activities like smoking. Therefore interventions used to help smokers quit smoking should aim to strengthen brain regions that help smokers control their impulses to counteract this drive towards smoking reward. The current study examines the impact of practicing skills typically taught to help smokers quit smoking on these key brain regions. In this study, participants are randomized to practice self-regulation by delaying their first cigarette of the day for 2 weeks. The objective of the current analysis, was to identify differences in brain activation when smokers actively regulated their respons to smoking cues compared to not regulating their response. Baseline data for all participants (n = 79) varied in terms of motivation to quit (range = 0 to 10; mean = 4.85; SD = 2.60). During the regulation of craving task participants were asked to regulate their responses to smoking and non-smoking appetitive cues by thinking about negative consequences of consuming the item or not regulate by thinking about positive consequences of consuming the item. Whole brain analysis identified increased activation in the left dlPFC when participants actively regulated their response ($p_{corrected} < .001$). After viewing each image, participants were asked to rate how much they wanted the item on a scale from 1 to 5. Smokers indicated that they wanted smoking items more than non-smoking items ($p < .001$) and that they wanted items less when they were regulating their response ($p < .001$). Future analyses will examine brain changes following a brief intervention during which smokers were asked to delay their first cigarette of the day. These results suggest that effortful regulation when viewing smoking cues results in increased engagement of regulation regions and lower desire for cigarettes. Findings from this study will be used to inform the development of future smoking cessation approaches to help smokers successfully quit smoking by targeting self-regulation brain regions.

Title: Numerosity drives fast saccades in humans

Authors: *E. CASTALDI[1], D. BURR[2,3], M. TURI[4], P. BINDA[1];

Res. Council, Pisa, Italy; [4]Fondazione Stella Maris Mediterraneo, Potenza, Italy

Abstract: Evolution has endowed us with the ability to shift our gaze to faces and animals with exceptional speed. These rapid automatic oculomotor responses are called fast saccades and take only slightly more than a hundred milliseconds. Discriminating the number of foe or prey may also have an evolutionary advantage. In this study fourteen adults (six males, 29 ± 5 yo) were asked to saccade towards the more numerous of two arrays. Saccadic rection-times showed bimodal distributions. In spite of similar and very high accuracy, slow saccades were more frequently elicited in response to very low and very high numerosities; however, fast saccades were more frequent for intermediate numerosities. For the latter, accurate saccades were as fast as 190 ms. Numerosity estimation is thought to rely on a relatively complex neural circuit, comprising several relays of information through parietal and pre-frontal cortex. The short saccadic-reaction times we observe suggest that number is detected by a primitive system that operates on feed-forward signals. In a separate experiment we collected reaction-times for vocal responses using the same task. Vocal responses were slower and homogeneous across numerical ranges. Reaction-times for vocal responses correlated only with the slow, not the fast saccades, suggesting the existence of different systems. Vocal and saccadic responses to very low and intermediate numerosities correlated with arithmetical abilities. This suggests that the saliency of the numerical information may favor numerical operations to be performed on this automatically detected visual feature, setting up the basis for math.

Title: The vast differences between prosaccade and antisaccade performance are largely explained by a sign change in exogenous attention

Authors: *A. T. GOLDSTEIN, E. SALINAS, T. R. STANFORD;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: When we move our eyes, oculomotor circuits weigh both the physical salience of the objects in view and current behavioral goals, but how? The antisaccade task pits these exogenous and endogenous influences against each other, and performance is highly sensitive to cognitive and developmental deficits. Resolving the contributions of these distinct attentional mechanisms is critical, but requires temporal resolution far greater than that of traditional tasks. Here we use novel, urgent variants of classic anti- and prosaccade tasks to uniquely reveal how exogenous and endogenous mechanisms interact in time to dictate performance. In these urgent tasks, the go signal that tells the subject to respond is given before the visual cue that specifies the correct choice. This way, motor plans are initiated early, and time permitting, later arriving perceptual information guides them toward the correct alternative. Thus, subjects guess on some trials and make informed choices on others. Accuracy varies with available processing time to yield a novel psychometric measure — the tachometric curve — with the necessary temporal precision. The behavioral results from 10 human participants are replicated in quantitative detail by a race-to-threshold model in which two opposing motor plans compete to drive the eye movement to the right or the left. Initially, these plans advance at randomly-drawn rates, but later, when perceptual information arrives to the circuit, they are accelerated or decelerated. The exogenous signal arrives earlier (~80 ms after cue onset) and rapidly accelerates the plan toward the cue, regardless of task instructions; the endogenous signal arrives (~40 ms) later to accelerate the correct plan and decelerate the incorrect one as determined by the task. This task dependence is a crucial distinction. By essentially flipping the sign of the exogenous signal, the same mechanisms readily account for the drastically different performance curves in the two tasks. In antisaccade trials, the early exogenous pull opposes the task goal causing performance to drop into a 40 ms attentional "vortex." In prosaccade trials, congruence of exogenous and endogenous influences facilitates performance at precisely the same time point. By imposing urgency, we have effectively resolved the exogenous and endogenous components that drive saccade target selection and have developed a framework for the neural mechanisms responsible for making the choice.

Title: Individual differences in eye movement strategies during a parafoveal attentional task are associated with differences in performance

Authors: *O. KREICHMAN[1], Y. BONNEH[1], S. GILAIE-DOTAN[1,2];
[1]Bar-Ilan Univ., Ramat Gan, Israel; [2]Inst. of Cognitive Neurosci., UCL, London, United Kingdom

Abstract: Attention and eye movements have been shown to rely on joint mechanisms. Shifting attention to a peripheral target could be hidden (covert attention) or precede a saccade (pre-saccadic attention). Pre-saccadic attention was found to enhance performance at the saccade target location just before the eyes move more effectively than covert attention. This was found for low and high-level visual tasks when participants are instructed to perform saccades or to hold fixation. Here we were interested in the individual differences in the tendency to employ either covert or pre-saccadic attentional strategies under uninstructed conditions during a parafoveal attentional task. A group of 31 young adults with normal vision participated in center-periphery discrimination tasks of faces, of inverted faces and of houses, and completed an ADHD-related questionnaire. In each task, participants were instructed to fixate while viewing a central study stimulus which was followed by a target stimulus that briefly appeared (for 200ms) at one of 13 foveal to parafoveal locations (up to 4°). Despite being instructed to fixate, we found that each individual consistently adopted one of two classes of eye-movement patterns, and this individually adopted pattern was consistent across experiments in 24 of 25 participants. One group (n=13) kept central fixation throughout the trial (“fixators”) employing covert attention. The other group (n=18) performed saccades towards the targets (“hoppers”) employing pre-saccadic attention. These post-stimulus saccades in the hoppers group were in the target’s direction and proportional to its distance but were both too short to reach it and too late to land on it (landed after stimulus offset). The “hoppers” showed enhanced performance at parafoveal locations compared to the “fixators” for faces and houses, but not inverted faces, demonstrating a selective gain of pre-saccadic attention. These differences in eye movement patterns across observers were not explained by attention related ADHD measures or by the decline of VA with eccentricity. Our results suggest that individual differences in internally-driven eye movement patterns while attending the visual field may be an active (even if unaware) “choice” related to individual traits.

Title: Visual spatial attention modulations over auditory neural processing emerge with high audiovisual precision and are foreground size dependent

Authors: *F. CERVANTES CONSTANTINO, T. SÁNCHEZ-COSTA, G. A. CIPRIANI, A. CARBONI;
Univ. de la República, Montevideo, Uruguay

Abstract: Synchronization of concurrent auditory and visual events strongly facilitates their integration into unified audiovisual (AV) objects. Further, fully in-sync AV dynamics has been shown to assist bimodal object-based attentional selection. It is unclear how do unimodal selective biases, such as visuospatial attention, transfer cross-modally in AV perception. A possibility is that temporal precision, rather than synchronization, more generally represents a driving factor since perfect temporal matching is often not required for integration. Support for this view may come from proposals that perceptual uncertainty estimation is a relevant computational mechanism for selective attention.
The study addresses whether temporal AV precision but also unimodal sources of uncertainty (e.g. visuospatial) influence the cross-modal transfer of attentional biases. We tested the hypothesis that changes to auditory processing under visuospatial selection are dependent on bimodal but also unimodal uncertainty factors.
Using electroencephalography (EEG), we estimated temporal response function (TRF) models of the auditory processing of tone pips. These sounds were randomly associated to visual contrast changes (‘flips’) spread over a circular dartboard display. Participants (N=30; 9 male; mean age 24; sex differences not addressed) were asked to exclusively attend to visual flips within display subsets (half versus quarter dartboard), while judging for AV precision differences in a two-interval forced choice task. Because pips and flips were never synchronous, the role that presentation order (i.e. pip leads flip and vice versa) has on the timing of cross-modal interactions was further investigated.
TRF estimates show that high AV precision between auditory and visual onset times determines the presence of cross-modal modulations. Visual foreground size additionally determined transfer effects only at low positional uncertainty (quarter dartboard), enabling the visual priming of subsequent tones as relevant for auditory segregation in line with top-down processing timescales. Auditory uncertainty (i.e. when pips lead flips) on the other hand determined susceptibility of early tone encoding to automatic changes by incoming visual update processing. The findings provide a hierarchical account of the role of uni- and cross-modal sources of uncertainty on the neural encoding of sound dynamics in a multimodal attention task.

Title: Attentional demand and consistency of stimuli differentially affect the hierarchical visual processing

Authors: *A. E. RUIZ-CONTRERAS;
Lab. de Neurogenómica Cognitiva, Coordinación de Psicobiología y Neurociencias, Facultad de Psicología, Univ. Nacional Autónoma de México (UNAM), Ciudad de México, Mexico

Abstract: The ability to process the global and local elements of a visualscene might be modulated by attentional demand and consistency of stimuli. Herewe used Event-related potentials to evaluate if the attentional demand andconsistency might modulate the visual hierarchical processing. Thirty-ninehealthy young participants solved the Navon paradigm (i. e., local lettersforming a global one) under two attentional demand conditions (low, i. e.,discriminating between H and S or between 4 and 5; vs. high, i. e., discriminatingbetween H and 4 or between S and 5). Participants answered global (i. e.,identify the global stimulus) and local (i. e., identify the local stimulus)tasks in separate blocks, depending on the demand condition; 50% in each blockwas consistent (i. e., global and local elements coincided). The globalinterference (i. e., larger reaction times for local than for global trials)was higher during the low than the high demand condition. The mean amplitude ofthe P2 component at parieto-occipital sites was higher for local than forglobal processing. At the parietal electrodes, posterior P2 had a more positivemean amplitude, and N2 a less negative mean amplitude, for high demand than forlow demand in the attention task. On the other hand, the P300 latency andreaction times showed that the global processing during the low demand task wasprocessed faster than the global processing during the high demand task,regardless of the consistency of the stimulus. Later, came the processing ofthe local consistent stimulus in the low demand task followed by those in thehigh demand one. Finally, the slowest processing was for local inconsistentstimuli, regardless of the task demand. Our results showed that first, theforest is processed before the trees, followed by a reanalysis of the forestand the trees that depend on the similarity of the trees or the difficulty fordiscriminating the local elements.

Title: Feature-selective modulations of neural priority maps in human cortex

Authors: *D. THAYER, T. SPRAGUE;
Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Priority maps are representations of visual space which determine the relative importance of a given location. Computational priority map models suggest that spatial maps for individual features are integrated into a single map that is modulated by both bottom-up image salience and top-down attention (Itti & Koch, 2001). At the neural level, previous work has identified neural regions that are sensitive to color (hV4/VO1; Brewer et al., 2005) as well as motion (hMT+/TO1/TO2; Amano et al., 2009), making these regions strong candidates for 'feature maps'. Furthermore, when presented with a stimulus consisting of several features, attending to the preferred feature of a region results in a greater fMRI response (McMains et al., 2007; Runeson et al., 2013). In the present study, we hypothesize that multivariate activation patterns across retinotopic feature-selective cortical regions form spatial 'feature dimension maps', which combine to guide attentional priority. If these regions act as feature dimension maps, there will be greater activation corresponding to the location of a stimulus when attending to the preferred feature of a given region (e.g., within color-responsive hV4 when attending color). To test this, participants viewed a peripheral colored moving-dot stimulus presented at a random location. They were precued to attend either the color or motion direction of the stimulus and discriminate which individual feature value was most prevalent (e.g., is red or blue more prevalent when attending color). Additionally, regions of interest were independently defined via retinotopic mapping procedures. We applied a multivariate spatial inverted encoding model to reconstruct spatial maps of the visual field from each retinotopic ROI. Consistent with previous univariate results, we found that stimulus representations within reconstructed priority maps were stronger in color selective regions when color was attended compared to motion, and representations in motion selective regions were stronger when motion was attended compared to color. These findings suggest that feature-selective cortical regions support spatial dimension maps, and that top-down attention can reweight activation profiles across these maps.

Title: Electrophysiological measures reveal distinct contributions of exogenous and endogenous mechanisms of attention in visual working memory

Authors: *A. NOURI[1], E. F. ESTER[2];
[1]Complex Systems and Brain Sci., [2]Psychology, Florida Atlantic Univ., Boca Raton, FL

Abstract: Working memory (WM) performance can be enhanced by an informative cue presented during storage. This effect - termed a retrocue benefit - can be used to explore how participants prioritize information stored in memory for behavioral output. There is general agreement that both voluntary and involuntary attention contribute to retrocue benefits, but it is unclear whether they do so via the same mechanisms. Here we tested this possibility by examining the effects of voluntary and involuntary attention shifts on location-specific working memory representations reconstructed from human brain activity (EEG). 40 human volunteers (both sexes) performed a retrospectively cued spatial WM task requiring them to remember the positions of two stimuli over a delay. To disentangle the effects of voluntary and involuntary attention and retrocue benefits, each participant completed task blocks with cues that identified the to-be-reported location (i.e., pro-cues) and task blocks with cues identified the task-irrelevant location (i.e., anti-cues). Both pro-cues and anti-cues led to improvements in memory performance relative to no-cue blocks. However, EEG recordings revealed noticeable differences in the quality of reconstructed spatial WM representations during pro- and anti-cue blocks. Specifically, during pro-cue blocks, we observed a strengthening of the cue-matching representation coupled with a reduction in the strength of the cue-non-matching representation, replicating earlier findings from our laboratory (e.g., Ester, Nouri, & Rodriguez, J. Neurosci 2018). However, during anti-cue blocks, we observed a transient increase in the strength of the cue-matching representation immediately after cue onset, followed by a rapid reduction in its strength. This effect was coupled with a gradual increase in the strength of the cue-non-matching representation. Collectively, our findings suggest that both voluntary and involuntary attention influence the prioritization of information in WM, but most likely recruit different mechanisms to do so.

Title: Electrophysiological markers of selective attention are affected by the competition of target and distractors in the same visual hemifield

Authors: ***J. A. FRANCO-RODRIGUEZ**[1], T. V. ROMAN-LOPEZ[2], M. MENDEZ DIAZ[3], O. PROSPERO-GARCIA[4], A. E. RUIZ-CONTRERAS[5];
[1]Facultad De Psicología, UNAM, Mexico City, Mexico; [2]Univ. Nacional Autonoma de Mexico, Mexico City, Mexico; [3]Univ. Nacional Autonoma De Mexico, Mexico DF, Mexico; [4]UNAM, Mexico, D. F., Mexico; [5]Lab. Neurogenomica Cognitiva, Fac. Psicologia, UNAM, D.F., Mexico

Abstract: Attentional control is the ability to enhance and suppress information for a goal-directed behaviour. The N2pc and Pd event-related potential components are markers for the

enhancement and suppression of information, respectively. N2pc has a more negative mean amplitude when a target is present than when it is not. Pd has a more positive mean amplitude when a distractor is present than when it is not. We evaluated the competition between a target and a distractor presented in the same or different visual hemifields. Sixty-two healthy young participants indicated the absence or presence of a target stimulus in a visual display. There were four types of trials (each trial consisted in six vertical green rectangles array): Homogeneous (no-singleton), Target, Non-target and Target+Non-Target. These last trials had two singletons: the target and a distractor. In 50% of the trials, they were in different visual hemifields. The mean amplitude difference between the presentation of the target and distractor in the same vs. different hemifield was analysed. No Pd was observed. N2pc was enhanced by the presentation of the singletons in different visual hemifields. This suggests that the attentional system allocates more resources to the target when the distractor is distant because there is an involuntary capture that needs to be overridden; when the singletons are in the same hemifield, the disengagement process is not necessary due to an effect of proximity. Another possibility is that the attentional resources are distributed between the singletons; when they are separate, N2pc is not as prominent because attentional resources are allocated to the non-target in the opposite hemifield. Whereas when target and distractor are in the same hemifield, the prominence of N2pc is given by the addition of the processing of both stimuli. In conclusion, the electrophysiological marker for selective attention modulates the processing of the singletons in the same visual hemifield.

Title: Frontoparietal control of willed attention

Authors: ***Q. YANG**[1], S. MEYYAPPAN[1], J. J. BENGSON[2], G. R. MANGUN[3], M. DING[1]; [1]Univ. of florida, Gainesville, FL; [2]Sonoma State Univ., Rohnert Park, CA; [3]Univ. of California Davis, Davis, CA

Abstract: Cueing paradigms are commonly used to study the neural mechanisms of visual spatial attention control. In these paradigms, each trial starts with an external cue, which instructs the subject to pay covert attention to a spatial location in order to process an impending stimulus. Neuroimaging studies have consistently shown that the dorsal attention network (DAN) is activated following the cue. Recent work has introduced a new form of cueing which asks the subject to spontaneously decide which spatial location to attend (willed attention). We examined the neural substrate of willed attention control by analyzing fMRI data recorded at two

institutions (UF and UC Davis) using the same willed attention paradigm. In addition to instructional cues, a choice cue was included, which prompted the subject to choose the side of the visual field to attend. Applying the general linear model we found that both instructional cues and choice cues activated the DAN. Choice cues additionally activated frontoparietal regions including the dorsal anterior cingulate cortex (dACC), anterior insula (AI), dorsal lateral prefrontal cortex (DLPFC) and inferior parietal lobule (IPL). An MVPA analysis showed that for neural activity evoked by choice cues, decoding accuracy in these frontoparietal regions was significantly above chance level, whereas for instructional cues, decoding accuracy was at chance level. These results, consistent across the two datasets, suggest that willed visual spatial attention is controlled by three major brain networks: the salience network (dACC and AI), the central executive network (DLPFC and IPL), and the DAN.

Title: Patterns of pre-cue alpha power predict the decision about where to attend in willed attention

Authors: *S. KIM[1], S. MEYYAPPAN[1], J. BENGSON[2], G. MANGUN[3], M. DING[1];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL; [2]Dept. of Psychology, Sonoma State Univ., Rohnert Park, CA; [3]Dept. of Psychology and Ctr. for Mind and Brain, Univ. of California Davis, Davis, CA

Abstract: In voluntary cued spatial attention paradigms, each trial starts with a cue instructing the subject to focus attention on a spatial location in order to process an impending stimulus. In contrast to cued attention, attention can also be allocated by purely internal decisions (willed attention), such as when subjects are asked to spontaneously decide where to attend on each trial. Bengson et al. (2014) reported that lateralized alpha power over occipital-parietal cortex immediately before a decision predicted where subjects would attend. Here, we used multivariate pattern analysis (MVPA) of EEG in Bengson's data set and a replication recorded at UF. In addition to instructional cues, 33% of trials had a choice cue that prompted the subject to choose the side of the visual field to attend on that trial; inter-trial intervals varied widely (2-8 s) and unpredictably. To assess the time course of alpha power patterns that predicted where subjects would attend, we performed time window-by-window decoding over the 3000 ms pre-choice cue interval. Above chance (56.42% for UF and 56.57% for UCD datasets) decoding of alpha power prior to the choice cues was observed only immediately prior to the cue, and not earlier in time,

replicating Bengson using decoding. These results demonstrate that decisions about where to attend are influenced by the pattern of alpha power only in the few hundred milliseconds immediately before a decision, supporting the idea that independent of goal-directed or bottom-up sensory factors, spontaneous brain states influence how humans focus attention.

Title: An activation likelihood estimation meta-analysis of attentional bias to emotional information

Authors: *L. FANG, R. SYLVAIN, N. STRAND, J. M. CARLSON;
Dept. of Psychological Sci., Northern Michigan Univ., Marquette, MI

Abstract: When in an environment overwhelmed with information, we tend to allocate our limited cognitive resources to certain objects. In particular, selectively attending to emotional information plays a crucial role in our day-to-day lives. Although there are a number of narrative and systematic reviews on attentional bias to emotional information, meta-analysis concerning its neural correlates is still scarce. The current study aimed to identify brain regions that consistently activate during attentional bias across different paradigms, age groups, and clinical status by using an Activation Likelihood Estimation (ALE) meta-analysis method (Eickhoff et al., 2009; Turkeltaub et al., 2002). Relevant studies were identified by conducting a systematic database search for peer-reviewed articles published between 1994 and 2020 on Google Scholar and PubMed. A total of 98 experiments, 826 foci, and 3090 participants were included in the final meta-analysis. The main ALE-analysis of all studies revealed the regions that are consistently involved in attentional bias to emotional stimuli at an uncorrected $p < .001$ threshold with a minimal cluster size of 100 mm3, such as inferior frontal gyrus, medial frontal gyrus, parietal lobule, temporal gyrus, occipital gyrus, as well as right amygdala, left insula, left precuneus, anterior cingulate cortex and paracingulate gyri, supplementary motor area, right lingual gyrus, and left thalamus. Additional ALE-analyses were also conducted by examining different paradigms (i.e., dot-probe task and emotional stroop task), age groups (adults and non-adults), and clinical status (patients and healthy controls). No significant clusters were found for contrast analyses. However, when the ALE-analyses were conducted separately, some regions were identified as specific to paradigm or group type. Our findings provide empirical support across studies for current theoretical models of attentional bias, which suggest that both subcortical regions that are sensitive to emotional features and cortical regions that associated with cognitive control engage in attentional bias to emotional information. In addition, the identifications on

specific groups also deepen our understanding of the involvement of different regions and corresponding cognitive processes in attentional bias in different assessment paradigms, age groups, and clinical status.

Title: The emotional words temporally capture the spatial attention

Authors: ***H. ONISHI**, R. GUAN, H. NAGAMURA, M. HISHITANI, S. MURAI, K. I. KOBAYASHI;
Doshisha Univ., Kyoto, Japan

Abstract: Our cognitive function was largely modulated by internal emotional factors, which is triggered by external stimuli relevant to specific emotional meaning. Selective attention, for instance, is one of the important functions which is closely affected by the external emotional stimulus. A large number of previous studies revealed that positive emotional stimulus attracted participants' attention to space where the stimulus was presented compared to non-emotional stimulus. These findings were conducted using a visually guided emotional cue. It's important to study other than the visual stimuli for pursuing the generality between modalities. Here we investigated such behavioral mechanisms using auditory emotional stimulus during a Posner cueing task. To understand emotional effects on spatial shift on attention, we used short Japanese spoken words as cue stimuli, each contained positive, neutral, or negative emotional meaning. Reaction time in the trials, which is the target and cue stimulus presented in the same space (valid trial), was significantly faster compared to trials in which the two stimuli were emitted in different space (invalid trial). Moreover, the right stimulus was more attracted to their attention compared to the left stimulus, which is consistent with the notion of right hemispheric involvement specific to language processing. However, there is no apparent difference between emotional cue types in reaction time. To address how long the emotional effect toward sustained attention, we compared the reaction time in each different emotional cue stimulus in previous trials. Our data showed that when a positive stimulus followed a negative stimulus, attention was not directed where the positive stimulus was presented but was sustained where the negative stimulus was presented. The results indicate that negative auditory stimulus sustains their spatial attention in consequent trials compared to the positive or neutral stimulus. This suggests that the emotional effect on our attentional shift is the maintenance of spatial attention, whereas the attentional capturing has no clear difference between emotional types.

Title: Characterizing Physiological Synchrony of the Eyes, Mind and Heart

Authors: ***J. MADSEN**, L. PARRA;
Biomed. Engin., City Col. of New York, New York, NY

Abstract: Movies are known to synchronize physiological signals across viewers. This has been demonstrated for neural signals, eye movements, heart rate, and others. But how exactly does synchronization of different physiological signals relate to one another, and is there a common factor? Here we simultaneously recorded neural signals, heart rate, respiration, eye movements, pupil size and head movements while study participants watched informative videos. The most robust synchronization was found for neural signals, eye movements and pupil size, and to a lesser extent, heart rate and head movements, while respiration did not measurably synchronize in any participant. Synchronous fluctuations of these signals were on a time scale of seconds to minutes, with the exception of neural signals, which synchronized across a broader range of timescales. Subjects with high synchronization in neural signals, eye movements, pupil size, or heart rate also showed high synchrony in the other signals, suggesting that synchronization is modulated by a common underlying factor. The principal component in these data was highly predictive of the ability of participants to recall information presented in the video. Additionally, for all signals, synchronization was modulated by attention, with the strongest effect for eye movement synchronization. Together, these results suggest that cognitive processing of the video mediates physiological responses of the body.

Title: I can see what you are thinking: establishing objective markers for indexing the occurrence of spontaneous involuntary thoughts

Authors: *P. MANGUELE, C. RACEY, C. BIRD, S. FORSTER;
Psychology, Univ. of Sussex, Brighton, United Kingdom

Abstract: Involuntary thoughts are a common feature of daily life and play a key role in many clinical disorders from addiction to ADHD. Here we establish a novel approach for studying the neural mechanisms of such thoughts, using a planted 'marker' thought. Twenty-four subjects (14 females, age range 19-33 years, mean age = 24 years, SD = 4.35 years) were first familiarized with the faces of two characters from the board game 'Clue', during a value-training visual search task in which presentation of the faces was associated with a financial reward. Inside the fMRI scanner, we recorded each participant's fusiform face area (FFA) response while viewing faces. In a separate sustained attention task, participants were instructed to suppress thoughts of the faces. Intermittent thought probes measured whether participants experienced involuntary thoughts about the faces either immediately before the probe, or during the preceding task block (~ 30 seconds). First, a univariate analysis based on an FFA region of interest (obtained while viewing faces), revealed significant group level FFA activation during the two seconds immediately preceding probes at which subjects reported thinking of the faces (M=0.85, SD=0.77) versus being on-task (M=0.21, SD=0.12), $t(13) = -2.98$, $p=.01$. We next employed Representational Similarity Analysis (RSA) analysis to identify the occurrence of spontaneous thoughts across the task block. This analysis compares the multivoxel pattern of activity during face viewing to each timepoint during the sustained attention task. We examined both mean similarity across a block, as well as the number of 'discrete reactivation events' (timepoints showing similarity higher than baseline noise). Mean similarity between the sustained attention blocks and the face templates were significantly higher during blocks where participants reported thinking about a particular face, versus those in which they reported being on task (Face 1, $t(10) = -4.8$, $p = .001$; Face 2, $t(9) = -3.6$, $p=.006$). There were also more reactivation events during blocks in which face thoughts were reported versus on task (Face 1, $t(10) = -6.8$, $p < .001$; Face 2, $t(9) = -3.9$, $p=.004$). We hence demonstrate that spontaneously arising thoughts elicit reliable stimulus-specific patterns of neural activity that resemble those involved in perception, and that can be identified using both univariate and multivariate approaches. Our findings also imply that discrete reactivation events may be used as a 'probe-free' method of identifying when such thoughts occur.

Abstract: Some studies have pointed out the possible adverse neurocognitive effects of exposure to general anesthesia during early childhood. Animal models have shown detrimental effects on brain cell survival and cognitive functions. Human data is not conclusive: some studies have found that anesthesia is related to risk of neurodevelopmental disorders, while other studies showed no difference in cognitive function between exposed and unexposed children. However, as far as we know, there is no study that have addressed the impact of general anesthesia on neurodevelopment by means of brain electrophysiology. The aim of this research was to evaluate the electrical brain activity related to error detection in two groups of preschool children: with and without history of exposure to general anesthesia (n=26). Participants observed animal puzzles being formed either correctly or incorrectly (head of another animal), while their electrical brain activity was recorded. Observation of incorrect configurations produced a significantly larger P3b on the unexposed children, while the anesthesia group showed a difference between correct and incorrect conditions by means of a negative deflection around 450 ms. at central midline. Patterns of brain activity observed on the exposed group are more alike to those observed on toddlers using the same experimental task. From a developmental perspective, our results suggest that exposure to general anesthesia during early childhood could be related to a certain maturation gap in the processing and detection of errors that may be preceded by an attention deficiency. Our results point out the need for more research in this topic, since general anesthesia is in many cases applied to facilitate medical procedures that do not compromise children's life and could be managed using other alternatives to achieve children cooperation.

Title: Spatial characteristics of EEG activities of idiopathic REM sleep behavior disorder patients during visuospatial attention revealed by explainable machine learning

Authors: *H. KIM[1], P. SEO[1], K. CHA[2], J.-I. BYUN[2], J.-S. SUNWOO[2], K.-Y. JUNG[2], K. KIM[1];
[1]Biomed. engineering, Yonsei Univ., Wonju, Korea, Republic of; [2]Neurol., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Introduction: Idiopathic REM sleep behaviour disorder (iRBD) is an early sign of synucleinopathies, including Parkinson's disease, dementia with Lewy bodies, and multiple system atrophy. iRBD is known to be associated with visuospatial impairments. In this study, we tried to reveal spatial the distinctive characteristics of neural activities of iRBD patients based on interpretable machine learning technique. **Methods**: Nineteen healthy subjects (63.47 ± 7.37 years) and 16 drug-naive iRBD patients (64.94 ± 6.92 years) participated in this study. We recorded 60-channel event-related potentials (ERPs) during the Posner task. The ERP amplitudes at 60 channels within 230 ms to 330 ms after probe item were calculated and used as input to a convolutional neural network (CNN) classifier. Layer-wise relevance propagation (LRP) and class activation mapping (CAM) were applied to investigate the relevance of spatial location topographical for distinguishing patients from healthy controls. **Results**: The classification accuracy was 87.81 ± 0.79 % (10-fold cross validation, repeated 10 times). The heatmaps obtained from LRP and CAM showed relevant features for distinguishing iRBD patients, which were mainly located in frontal, centroparietal, occipital regions. **Discussion**: The iRBD patients could be successfully detected based on single trial ERP topographies with high accuracy using a CNN classifier. Furthermore, we could find out disease-specific spatial features of ERP using interpretable machine learning approach which were hardly to be found from statistical modelling. The most relevant features were localized in centroparietal and occipital sites, which may reflect visuospatial attention dysfunction associated with iRBD. Considering that visual dysfunction is regarded as an important diagnostic marker for synucleinopathies including PD, our results support that visual attention problem is pervasive in iRBD which is considered as the prodromal stage of neurodegeneration.

Title: Tagging up! Calibrating a P300-based Home Brain-Computer Interface (BCI) System

Authors: K. M. FITZPATRICK[1], V. GUPTA[1], C. S. CARMACK[1], K. GOSMANOVA[1], D. GOLDBERG[2], G. TOWNSEND[3], *T. M. VAUGHAN[1], J. R. WOLPAW[1];

Abstract: People affected by neuromuscular disorders such as amyotrophic lateral sclerosis (ALS), brainstem stroke, and high-level spinal cord injury need alternative communication and control methods. A brain-computer interface (BCI) using the P300 event-related potential (ERP) allows people with ALS to communicate and control computer applications (Wolpaw et al., Neurology 2018). At present, system calibration requires that the person complete a BCI test session. This pass-fail step relies on day-of candidate readiness, established system parameterization (including a stylized application), and test-set results of $\geq$70%. The present study tests the hypothesis that calibrating the system with data from actual system use, independent of the application, increases the likelihood of success and improves system reliability. Eleven participants (6 men, one with advanced ALS), age 17-60 yr, completed one session with the BCI Home System. We recorded 8 EEG channels from frontal, central, and posterior scalp locations. The person sat in a chair or at a 30^{o} in bed ~100 cm from a 24" monitor for one 1-hr session. A session has 3 stages: a 21-selection training set (S1), a 7-selection test set (S2), and an 81-selection picture-matching set (S3). In S1 and S2, Users viewed a 4x7 (28-item) on-screen keyboard, including all English letters arranged alphabetically, and received visual cues for each selection. For S3, Users viewed a 3X4 (12-item) or a 2X4 (8-item) matrix that included whole words and pictures. At the beginning of S3, the person was instructed how to complete the picture-matching task. Each selection in S1-3 required the person to count up to 14 faces as they flashed over the target item. S1 and S2 selections contained a priori information on the correct selection (AP). S3 data were tagged post hoc (PH). A stepwise linear discriminant function selected and weighted the EEG features to determine the desired selection. Every person completed all stages and averaged >95% accuracy on the Matching Task (S3). Offline analysis (5-fold cross correlation) yielded average accuracies of the 10 people without disability were 92.2$\pm$3.6 and 95.7$\pm$2.8 ($p>.01$) for the AP and PH trials, respectively. The results for the person with were 89.7$\pm$2.2 and 87.0$\pm$5.0 ($p>.21$). These results suggest that an automated calibration routine is an effective alternative for initial assessment of potential BCI Users. This new method could help clinicians, reduce evaluation time, and increase the numbers of people who might benefit from the BCI Home System. We are now automating the method.

Title: The Effects of Methylphenidate on Verbal Creativity, Verbal Fluency, and Convergent Thinking Tasks in Adults with Attention-Deficit/Hyperactivity Disorder

Authors: ***C. APPLING**[1], A. GONZALEZ[2], A. SCHAEFFER[3], A. ZAND[4], D. WANG[7], A. SAM[3], A. TOSH[5], B. FERGUSON[6], D. Q. BEVERSDORF[8];
[1]Interdisciplinary Neurosci., Univ. of Missouri, Columbia, Columbia, MO; [2]California State Univ. San Marcos, San Marcos, CA; [3]MU Sch. of Med., [5]Child Health-Adolescent, [6]SHP/Health Psychology, [4]Univ. of Missouri, Columbia, MO; [7]Emory Univ., Atlanta, GA; [8]Dept Radiol, Neurol, Psychol Sci, DGS of INP, Univ. of Missouri Columbia, Columbia, MO

Abstract: Introduction: A common pharmacological treatment for attention-deficit/hyperactivity disorder (ADHD) is methylphenidate (MPH), which is a psychostimulant that acts as a norepinephrine-dopamine reuptake inhibitor. Both the noradrenergic and dopaminergic systems have been linked to aspects of creativity (Flaherty, 2005; Alexander et al., 2007). Anecdotal reports from patients with ADHD suggest that their creativity is impaired by MPH. MPH does not generally impair creativity among those without ADHD, but effects in those with ADHD is not known. Therefore, this study examined effects of MPH on convergent and divergent tasks associated with creativity in adults with ADHD. **Method:** Seventeen adults aged 18-40 with a diagnosis of ADHD and prescribed MPH participated in the study. Participants attended two sessions in a counterbalanced order, once after taking the prescribed amount of MPH, and once after withholding their MPH. Participants completed problem-solving tasks (anagrams and compound remote associates) and generative tasks (letter fluency, semantic fluency, and Verbal Torrance Test for Creative Thinking, or VTTCT) in a counterbalanced fashion.
Results: There was a significant increase in the number of words generated on the semantic fluency task, $t(16)=3.27$, $p=0.005$ for the MPH session. In addition, there was a significant increase in the MPH session for the originality scores generated on the VTTCT, $t(8) = 1.867$, $p=0.049$, and a trend toward significance was found for the overall VTTCT battery average score, ($p=0.056$). However, there was no effect on problem solving tasks.
Conclusions: In adults with ADHD, MPH enhanced verbal fluency and divergent thinking

abilities, but had no effect on convergent thinking abilities. Furthermore, MPH appeared to enhance the originality aspect of verbal creativity. Therefore, MPH appears to have positive effects on divergent task performance in adults with ADHD. but not convergent tasks. Future studies are needed to understand the roles of norepinephrine and dopamine in this effect.

Title: Disinhibition of frontal cortical circuits underlies inattention and cognitive rigidity associated with Cacna1a loss-of-function mutations

Authors: *A. LUPIEN-MEILLEUR[1], X. JIANG[1,2], M. LACHANCE[1], V. TASCHEREAU-DUMOUCHEL[1], L. GAGNON[1], C. VANASSE[1], J.-C. LACAILLE[2], E. ROSSIGNOL[1]; [1]CHU Sainte-Justine, Montreal, QC, Canada; [2]Neurosciences, Univ. de Montréal, Montreal, QC, Canada

Abstract: Context. Loss-of-function mutations in the *CACNA1A* gene, encoding the α1 subunit of voltage-gated Cav2.1 channels, result in epilepsy and neurocognitive impairments, including attention deficits, intellectual deficiency and autism, as we observed in a cohort of 16 individuals. We showed previously that a homozygous deletion of *Cacna1a* in mice forebrain GABAergic interneurons (IN) leads to epilepsy through disruption of synaptic efficiency from parvalbumin-positive (PV) INs. However, the mechanisms underlying the associated cognitive deficits are unknown, especially in the context of haploinsufficiency.**Hypothesis.** We propose that impaired perisomatic inhibition in frontal circuits underlies the cognitive deficits in *Cacna1a* heterozygous mutants.**Methods.** We generated mutant mice carrying a targeted heterozygous deletion of *Cacna1a* restricted to PV neuronal populations ($PV^{cre};Cacna1a^{c/+}$) or to cortical pyramidal cells (PCs) ($Emx1^{cre}$; $Cacna1a^{c/+}$), which we characterized using patch-clamp electrophysiology, video-EEG and behavioural assays.**Results:** $PV^{cre};Cacna1a^{c/+}$ mutant mice display reduced synaptic efficiency from PV-INs on PCs in both the medial prefrontal (mPFC) and orbitofrontal (OFC) cortices. In addition, they show enhanced seizure susceptibility to PTZ, impulsivity, attention deficits and cognitive rigidity. Interestingly, no change in PC synaptic function or in behaviour were observed in $Emx1^{cre}$; $Cacna1a^{c/+}$ mutants, suggesting

compensation in PCs. To further dissect the contribution of frontal cortical sub-circuits, we injected Cre-expressing AAVs in the mPFC or the OFC. Targeted deletion of *Cacna1a* in the mPFC induces attention deficits, while a deletion in the OFC results in cognitive rigidity. Further, the attention deficits and the cognitive rigidity in $PV^{cre};Cacna1a^{c/+}$ mutants can be rescued by a selective chemogenic activation of PV-INs in the mPFC and the OFC, respectively.**Impact:** In summary, our results demonstrate that haploinsufficiency of *Cacna1a* disrupts perisomatic inhibition in frontal circuits, leading to a range of potentially reversible neurocognitive deficits.

Title: Spatial attention influences bursting in pulvinar subdivisions

Authors: *T. VAN VIEGEN[1], R. LY[2], S. KASTNER[1];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Thalamic neurons are capable of firing single action potentials (tonically) or trains of action potentials that ride atop a calcium influx (bursting). Previous work showed that higher-order thalamic regions, like the pulvinar, have a higher burst-propensity than first-order thalamic regions, like the lateral geniculate nucleus (LGN). The pulvinar, however, is a heterogeneous structure and it is currently unknown whether burst propensity differs across subregions of the pulvinar. Moreover, the pulvinar plays a role in selective spatial attention and it is not known whether spatial attention modulates burst propensity in the pulvinar. We recorded from the pulvinar of two macaques using linear multielectrode arrays and assigned electrodes to dorsal and ventral pulvinar based on receptive field mapping responses. We recorded well-separable single-unit activity (N = 104, 62 in dorsal and 42 in ventral pulvinar) while the animals performed a spatial-attention task. We compared individual units to firing rate matched Poisson simulated data and showed that ~60% of pulvinar units (62 out of 104) show burst percentages more extreme than simulated data. Moreover, this analysis shows that ~53% of dorsal vs. ~69% of ventral pulvinar units burst more than expected under purely Poisson firing. Next, we assessed differences in bursting between attention conditions. We used a burst refractory index in visually responsive cells (N = 24) and found significantly less bursting ($p < .05$ with permutation test) in the attend-in than in the attend-out condition. Importantly, these findings were not caused by differences in firing rate between attention conditions. Taken together, these findings suggest

that pulvinar bursting is more pronounced when spatial attention is directed outside of the receptive field. Decreased bursting under the influence of spatial attention has been previously described in cortical regions such as V4 and MST. Here, we extend these findings to the primate higher-order thalamus.

Title: Functional differentiation in the rat posterior parietal cortex: Implications for controlled and stimulus driven attention

Authors: *F.-C. YANG[1], R. D. BURWELL[1,2];
[1]Dept. of Cognitive, Linguistic & Psychological Sci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The posterior parietal cortex (PPC) in rodents and primates is important for visuospatial attention. The human PPC shows functional differentiation such that dorsal areas are implicated in top-down, controlled attention, and ventral areas are implicated in bottom-up, stimulus driven attention. Whether the rat PPC also shows functional differentiation is unknown. The details of anatomical and functional homology of the PPC across different species is needs to be further examined. In the present study, we provided evidence from functional neuroanatomy and in vivo electrophysiology to address this open question. Using anterograde and retrograde tract-tracing methods, we first examined connectivity with other structures implicated in visuospatial attention including the postrhinal cortex (POR) and the the lateral posterior nucleus of the thalamus (LPn) considered the rodent homolog of the primate pulvinar. We showed that the LPn projects to the entire PPC, preferentially targeting more ventral areas. All parts of the PPC and POR are reciprocally connected with the strongest connections evident between ventral PPC and caudal POR. Next, we simultaneously recorded neuronal activity in several subregions of the PPC as rats performed a visuospatial attention task that engaged in both bottom-up and top-down attention. Our previous study showed that the dorsal PPC is involved in multiple cognitive process in the translation of perception to action. In this study, we showed that ventral PPC cells responded to stimulus onset more rapidly than dorsal PPC cells suggesting involvement in stimulus-driven, bottom-up attention. The slower time course of neuronal response latency in the dorsal PPC might reflect top-down control to guide appropriate actions. These data suggest that the rat PPC, like the primate PPC, is differentiated into at least two functional subregions, which interact closely during visuospatial attention processing.

Title: Post-error Recruitment of Frontal-Sensory Cortical Projections Promotes Attention in Mice

Authors: *K. J. NORMAN[1], H. KOIKE[1], J. S. RICEBERG[1], J. BATEH[1], S. LOPEZ[1], K. CARO[1], A. LIANG[1], K. YAMAMURO[1], M. FLANIGAN[1], Y. GARKUN[1], E. NABEL[1], D. BRADY[1], C. CHO[1], M. Abstract: Goal-directed behavior, such as attention, requires a cognitive control system which not only monitors contextually relevant internal states and external events, but also implements adjustment in informational processing and behavior. Across species, attention is regulated by direct projections from the frontal cortex to sensory areas. Here, we aim to identify the conditions that recruit frontal-sensory projections from the anterior cingulate area to the visual cortex (ACAvis) to influence attentional behavior in mice. We performed circuit-specific fiber photometry and optogenetics to monitor and manipulate ACAvis activity in mice performing freely moving attention behavior during the 5-choice serial reaction time task (5CSRTT) with an automated touchscreen system. The 5CSRTT requires mice to sustain and divide their attention across five response windows during a 5s delay in anticipation of the random presentation of brief stimulus at one of the five locations. First, we sought to characterize the time course and circumstances of ACAvis neuron recruitment during attention. ACAvis neuron activity did not vary depending on whether the current trial was a correct choice, when attention was properly allocated, or an error. Instead, ACAvis neuron recruitment depended on the result of the previous trial as ACAvis neurons demonstrated elevated activity on the trial immediately following error trials compared to correct, suggesting that ACAvis neurons encode an error monitoring signal. The summation of ACAvis neuron activity alone did not fully explain error correction behavior, leading us to examine whether specific patterns of ACAvis neuron activity contribute to post-error performance. We then performed circuit-selective optogenetic modulation of channelrhodopsin-expressing ACAvis neurons while mice performed the 5CSRTT and found temporal-, frequency-, and history-dependent improvement of attention. We then aimed to dissect the temporal requirement of ACAvis projections during error correction behavior in the 5CSRTT independently of local ACA activity. Projection-selective optogenetic suppression of ACAvis terminals in visual cortex using inhibitory opsin halorhodopsin revealed key time points during 5CSRTT showed in which ACAvis circuit plays causal role in post-error attention. Our

data identify prior error history as a key internal condition to recruit top-down frontal-sensory cortical projections and drive post-error attention enhancement. Our findings may provide circuit-based insight into the pathophysiology and intervention strategy for impaired visual attention in neuropsychiatric disorders.

Title: Tms on the inferior frontal cortex (ifc) during standard processing abolished subsequent mismatch negativity (mmn) to deviants: The role of the ifc in establishing a prediction model

Authors: ***C.-Y. TSE**[1], T.-Y. LUI[2], Y.-H. SHUM[2], X.-Z. XIAO[2], Y. WANG[1];
[1]City Univ. of Hong Kong, Hong Kong, Hong Kong; [2]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: The human brain constantly monitors the environment and able to detect unexpected changes even without conscious awareness (i.e., the automatic or pre-attentive change detection). According to the prediction model hypothesis, the inferior frontal cortex (IFC) is involved in extracting and establishing the prediction model from the frequently presented standards, or re-instating the prediction model for detecting deviant. Our previous studies (Tse et al., 2018; Xiao et al., 2020) demonstrated a causal functional connection of IFC and STC in pre-attentive change detection by applying Transcranial Magnetic Stimulation (TMS) to disturb the functioning of IFC while the later STC mismatch response was measured with event-related optical signals. However, evidence supporting the IFC's contribution to the prediction model is typically inferred from studies examining the deviance detection process. The current study examined the functional role of IFC in establishing the prediction model independent of deviance processing by disrupting the functioning of the IFC in processing a train of standard with Transcranial Magnetic Stimulation (TMS) and measuring the subsequent TMS effect on MMN responses to pitch deviants. Specifically, the MMN response preceded by a 3-standard train and with TMS pulses applied to the IFC at the initial 2 standard positions (2W1O; 2 standards with TMS followed by 1 standard without TMS) was compared to that of a 6-standard train with IFC TMS at the initial 2 positions (2W4O), a 6-standard train with IFC TMS at the initial 5 positions

(5W1O), and a 9-standard train with IFC TMS at the initial 5 positions (5W4O). An abolishment of MMN response to deviant was only observed when TMS was delivered to the IFC of the 2W1O condition, while the MMN responses were preserved in other train length conditions with IFC TMS, or in all the train length conditions when TMS at the vertex or TMS pulse sound was presented. These results demonstrated that IFC was involved in processing the standards and critical for pre-attentive detection of subsequent deviants. These results are also consistent with the prediction model hypothesis on the functional role of IFC.

Title: Laterality of individual differences in emotion and cognition networks: Evidence from spontaneous neural activity

Authors: *R. BAKHTIARI[1], A. T. SHAFER[4], I. CRIBBEN[2,3], K. CHEEMA[3], M. MOORE[5], F. DOLCOS[7,6], A. SINGHAL[1,3];
[1]Psychology, [2]Accounting and Business Analytics, [3]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [4]Natl. Inst. on Aging, Baltimore, MD; [5]Beckman Inst. for Advanced Sci. & Technology, Univ. of Illinois at Urbana-Champaign, Urbana–Champaign, IL; [6]Beckman Inst. for Advanced Sci. & Technology, Univ. of Illinois at Urbana-Champaign, Urbana-Champaign, IL; [7]Psychology, Univ. of Illinois at Urbana-Champaign, Urbana–Champaign, IL

Abstract: Objective: Emotion-cognition interactions are mediated through communication between ventral affective emotion processing system (VAS), and dorsal executive system (DES). While each of these networks and their interactions have been studied during task performance, their intrinsic connectivity patterns (resting state functional connectivity between regions of interest [ROIs]) and their association with emotion regulation scores have not been investigated. Graphical models are useful for exploring the complex neural networks as this method is informative about unique functional connectivity between ROIs. **Methods**. Five-minute simultaneous resting state EEG-fMRI recordings were acquired from 19 healthy adults (18-31 years old, 13 females). A set of standard neuropsychological tests in the emotional domain (Scale of Emotional Arousability [SEA], Emotional Contagion Scale [ECS], Emotional Regulation Questionnaire [ERQ]), and attentional domain (Barratt Impulsiveness Scale [BIS]) were collected before the neuroimaging session. Nineteen ROIs that previously have been shown to be

involved in emotion-cognition interactions were chosen. Using the sLORETA toolbox, the scalp EEG activity was transformed to MNI source space, and brain activity was calculated within each ROI. Partial correlation and conditional independence between each ROI pair was calculated to find a sparse network in each hemisphere. **Results:** Although the left and the right hemisphere networks were similar, there were more connections within the DES in the left hemisphere (left dorsolateral prefrontal cortex (dlPFC) and medial prefrontal cortex; and left supramarginal gyrus and insula) and more connections within the VAS in the right hemisphere (amygdala and right fusiform gyrus) supporting brain laterality characteristics. Connectivity within the VAS (left ventrolateral prefrontal cortex (vlPFC) and left amygdala) was significantly correlated with various emotional domains scores from ERQ (expressive suppression), and SEA (general emotionality and timidity scores) scales. Functional connectivity between the left VAS and DES (left vlPFC and the left dlPFC) was significantly correlated with BIS scores in the attentional domain (total score, first and second order attentional score, and cognitive impulsiveness score). **Conclusion:** The findings of this study provide new insights into the lateralization of brain circuitry, namely right-lateralization of connections within the VAS and left-lateralization of connections within the DES. Moreover, they emphasize the importance of integration between these two networks for emotional regulation abilities.

Title: The role of Neurons, Glia, and Synapses in Defining Hierarchical Structure of Resting State Functional Connectivity Networks

Authors: S. KAHALI, M. E. RAICHLE, *D. A. YABLONSKIY;
Mallinckrodt Inst. of Radiology, Saint Louis, MO

Abstract: While significant progress has been achieved in studying resting state functional networks in a healthy human brain and in a wide range of clinical and neurological conditions, many questions related to their relationship to organization brain cellular circuits remain open. In this study we use genetically-enabled quantitative Gradient Recalled Echo MRI (qGRE) technique (Ulrich and Yablonskiy, MRM **75**: 606-615, 2016) for in vivo quantitative mapping of brain cellular circuits and resting state data from Human Connectome Project to explore how components of the human brain cellular circuits relate to the organization of the resting state functional networks. The qGRE data analysis allows in vivo mapping of tissue cellular specific (*R2t**) GRE signal relaxation (here "*t*" means *tissue*) in the human brain cortical GM that is

directly related to the brain tissue cellular composition (Wen, et al, PNAS **115**(41): E9727-E9736, 2018). The functional connectivity data were parcellated to 17 resting-state networks (Yeo, et al, J Neurophysiol **106**(3): 1125-1165, 2011). Our results show that the synchrony of the *short-range* brain connections is mostly governed by the neuron-based circuits while the *long-range* network connectivity is governed not only by the strength of the neuron-neuron connections, but also neuron-glia, and neuron-synapse cross-talk between network regions that are most prominent in the infra-slow frequency range (0.01-0.16Hz) of brain activity. These mechanisms lead to a rather broad distribution of resting state functional networks' properties. We found that the visual networks have the highest neuronal density (but lowest density of glial cells and synapses), the strongest coherence of BOLD signal and the strongest intra-network connectivity (Figure). The Default Mode Network (DMN) that plays a very prominent role in the overall organization of the brain in health and disease is positioned near the opposite part of the spectrum with relatively low coherence of the BOLD signal but a remarkable diversity of cellular circuits.

Title: Image-computable attention model of texture segmentation across the visual field

Authors: ***M. JIGO**[1], D. J. HEEGER[2], M. CARRASCO[2];
[1]Ctr. Neural Sci., [2]Dept Psychol & Ctr. Neural Sci., New York Univ., New York, NY

Abstract: Goal. Attention modulates texture segmentation, our human capacity to isolate objects from their surroundings across the visual field. The cortical computations that underlie their interaction are unknown. We developed a model to explain several signatures of texture segmentation and of its attentional modulation across eccentricity: (i) the central performance

drop, which is the parafoveal advantage for segmentation over foveal locations; (ii) that involuntary attention improves segmentation in the periphery but impairs it at central locations; (iii) that voluntary attention improves segmentation across eccentricity.
Approach. We developed an image-computable model to explain all of these phenomena. The model's components are motivated by canonical motifs that underlie information processing across the visual hierarchy, e.g., normalization and spatial summation. Specifically, segmentation relied on the interaction between normalization and attentional modulation with distinct operating regimes for voluntary and involuntary attention systems. Attention operated before normalization, as per the Reynolds-Heeger (2009) normalization model of attention (NMA), to adjust sensitivity for coarse and/or fine visual details. The model operated on grayscale texture images to reproduce performance across many eccentricities from ten psychophysical experiments—involuntary attention was manipulated in six and voluntary attention in four experiments.
Results. (i) The model generated the central performance drop through spatial summation of normalized sensory inputs, which determined the model's baseline sensitivity to visual detail. (ii) Involuntary attention effects were generated by enhancing sensitivity to a narrow range of visual details (high spatial frequencies), which were too fine to distinguish the textural target at central locations, but progressively overlapped the target toward the periphery. (iii) Voluntary attention effects were mediated by a uniform enhancement of sensitivity to coarse and fine details (broad range of spatial frequencies), which encompassed the target.
Conclusion. Our results highlight and explain how involuntary and voluntary attention differentially shape texture segmentation, and extend NMA to capture attention effects on contrast and texture sensitivity across eccentricity. The model provides a quantitative framework for assessing interactions between attention and perception for complex visual stimuli.

Title: Locus coeruleus modulates perception in the auditory cortex during zebra finch song learning

Authors: *J. KATIC, Y. MOROHASHI, Y. YAZAKI-SUGIYAMA;
Okinawa Inst. of Sci. and Technol. (OIST) Grad. Univ., Okinawa, Japan

Abstract: Juvenile zebra finches learn to sing by vocal communications with adult tutors. While juveniles learn poorly from passive exposure to song playback, song playback paired with task performance causes effective song learning. This suggests that internal states of juveniles, such

as attention or motivation regulate song learning. Here we investigated neuronal activities in the attention control brain region, the nucleus locus coeruleus (LC), when juvenile zebra finches listened to tutor singing via social interaction by using chronic extracellular single-unit recording. LC neurons increased their firing rates in response to tutor song (TUT) playbacks and increased more upon tutor singing. Moreover, LC neurons sustained greater responses to TUT playbacks after hearing hours of tutor singing (mean response strength (RS) before: 1.6±0.4 s, after: 4.5±0.9 (spikes/s), n=16).LC neurons send their axons to the zebra finch higher auditory cortex, the caudomedial nidopallium (NCM), where tutor song memories are thought to form. Previously we showed a fraction of NCM neurons that respond selectively to TUT playback. As seen in LC neurons, TUT selective NCM neurons showed a greater response to tutor singing than to TUT playback and sustained greater responses to TUT playback after hearing hours of tutor singing (mean RS before: 0.4 ± 0.2, after: 4 ± 0.67 (spikes/s), n=24). To ask whether LC neurons directly influence song perception in the NCM, we recorded NCM neuronal activity with optogenetic LC terminal inactivation while juveniles interacted with tutors. We found a subset of silent narrow spiking NCM neurons which showed no auditory responses to TUT playback but responded to LC terminal inactivation (mean RS TUT playback: 0, LC inactivation: 3.8 ± 0.64 (spikes/s), n=10). In contrast, broad spiking NCM neurons, which responded to TUT playbacks, showed reduced responses to tutor singing when paired with LC terminal inactivation (mean RS to TUT playback: 5.6 ± 0.82, tutor singing with LC inactivation: 3.4± 0.73 (spikes/s), n=10). Those neurons showed a reduced response to TUT, but not to the other song playbacks after listening to two hours of tutor singing with LC terminal inactivation. Juveniles, which were tutored for three days with LC terminal inactivation every time a tutor sang, failed to copy tutor songs, while control juveniles that tutored without LC inactivation learned tutor songs well. Taken together, our data suggest that increased attention by social interaction with a tutor modulates song perception in the NCM via LC neuronal activities; this might be an underlying neuronal mechanism for attention control of song learning.

Title: The involvement of glutamate in sustained attention: Effects of the NMDA co-agonist, D-serine, on the skew of initiation time distributions in rats.

Authors: *Z. V. REDDING, K. E. SABOL;
Psychology, Univ. of Mississippi, University, MS

Abstract: Many people live with impaired sustained attention, including individuals with ADHD, schizophrenia, depression, and age-related cognitive decline. The most common treatments for impaired attention include stimulant medications; however, such drugs are

associated with negative side-effects. Stimulant medications improve attention at least partially through effects on the dopamine and norepinephrine (NE) systems. Safer treatments might be developed by targeting other neurotransmitter systems that support sustained attention. For example, glutamate is a major excitatory neurotransmitter that is thought to function in concert with NE to promote cognitive processes like memory and perception (Mather et al., 2016, Behav Brain Sci (39), e200). We tested the involvement of glutamate in sustained attention by administering D-serine, a co-agonist that promotes the activation of NMDA receptor complexes. Male Sprague-Dawley rats (n=16) were tested in a two-choice reaction time task (2CRTT). Power analysis was conducted with an expected effect size from past data. In the 2CRTT, rats nosepoke in a central aperture for 0.3 - 6.0 sec. A stimulus light then comes on above either a left or right aperture. Rats must exit the central aperture and nosepoke beneath the illuminated light. Water is given for a correct response within a performance-based time limit. Each reaction time is broken into initiation time (IT) and movement time (MT) to isolate attentional processes. IT is the time from stimulus presentation until the rat initiates a response. IT mode represents attentive sensorimotor processing speed, while IT distribution skew (devmode; mean – mode) is thought to reflect lapses in attention (Leth-Steensen et al., 2000, Acta Psychologica (104), 167-190; Sabol et al., 2003, Behav Pharm (7), 489-500). All rats received two full dose-response series of six D-serine doses (saline, 10, 50, 100, 150, and 300 mg/kg, i.p.) in a counterbalanced repeated-measures design. Drug was administered 30 minutes before testing. D-serine dose-dependently reduced IT devmode without affecting IT mode. Reduced IT devmode is thought to indicate improved sustained attention, as rats were more able to maintain fast ITs throughout test sessions. The lack of effect on IT mode suggests no effect on sensorimotor processing speed when animals were attentive. D-serine's effects on IT devmode are the first indication from a rat model that sustained attention can be improved by increasing the NMDA-mediated effects of glutamate. This translational work could lead to the development of safer treatments that improve quality of life in a wider range of people living with impaired attention.

Title: Sb-334867, a selective orexin-1 receptor antagonist, alleviates dizocilpine-induced attentional impairments in an nmda receptor hypofunction model of schizophrenia

Authors: *E. B.-L. MANESS[1], J. A. BURK[2];
[1]Applied Sci., [2]Psychological Sci., William & Mary, Williamsburg, VA

Abstract: Schizophrenia is a complex and often-debilitating neuropsychiatric condition that is associated with impaired attentional processing and performance. Failure to maintain attention is thought to result from a hyper-reactive basal forebrain cholinergic system that cannot support increasing attentional load, and available antipsychotics often fail to address this pervasive symptom. Acute systemic administration of psychotomimetic NMDA receptor antagonists, which reproduce the NMDA receptor hypofunction observed in schizophrenia, markedly elevates cortical acetylcholine release and disrupts posterior attention systems. Both orexin (hypocretin) receptor subtypes (orexin-1 and orexin-2) are amply expressed on corticopetal cholinergic neurons, suggesting that their suppression may lessen basal forebrain excitability and reduce attentional deficits stemming from a hypercholinergic state. A previous experiment in our lab showed that rats trained in a sustained attention signal detection task performed worse and responded less when given the NMDA receptor antagonist dizocilpine (MK-801: 0 and 0.1 ip), and these impairments were reversed when dizocilpine was co-administered with the dual orexin receptor antagonist filorexant (MK-6096: 0, 0.1, and 1.0 mM ICV), suggesting orexin receptor antagonism attenuated dizocilpine-induced overstimulation of cortical regions critical for sustained vigilance. To parse the unique role of the orexin-1 receptor, rats in the present experiment received either saline or dizocilpine injections in tandem with the orexin-1 receptor antagonist SB-334867 (0, 3, and 6 µg ICV) prior to attention task performance across six sessions. As was previously found, dizocilpine diminished signal detection accuracy, particularly during and following a flashing visual distracter, and increased the number of omitted trials. Similarly with filorexant, both doses of SB-334867 ameliorated dizocilpine-induced signal detection deficits and significantly reduced errors of omission. Thus, we propose that the orexin-1 receptor is an important target for minimizing the attentional deficits associated with NMDA receptor antagonism.

Title: Evaluating the potential for remediation of attentional deficits in 3xTg-AD mice by 3α-diol

Authors: *J. VISSCHER[1], N. KUWAHARA[1], S. BHULLAR[1], C. CONNERY[1], J. FELIX[1], J. ZAKARIA[1], N. J. MACLUSKY[2], B. D. WINTERS[1];
[2]Biomed. Sci., [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Neurosteroids and their brain-synthesized metabolites have been shown to promote neural cell survival, but their levels are significantly reduced in patients with Alzheimer's disease

(AD). Recent work has suggested that the androgen-derived neurosteroid metabolite 5α-androstane-3α,17ß-diol (3α-diol) may specifically contribute to this neuroprotection, as well as to sex differences in the incidence of AD. This study aimed to determine the effect of long-term 3α-diol treatment on the development of neuropathology and cognitive dysfunction associated with a triple-transgenic mouse model of AD (3xTg-AD). To test the hypothesis that 3α-diol will slow cognitive decline and the progression of the neuropathology of AD in the mouse model used, the 5-Choice Serial Reaction Time Task (5-CSRTT) was utilized. This task is a rodent behavioural paradigm designed to measure the effects of drugs and other manipulations, including genetic, on attentional performance and stimulus control. The following data concerns a cohort of male and female mice aged 6 months implanted with slow release silastic capsules loaded with either 3α-diol or vehicle at 3 months of age. Consistent with our past work, we found that 3xTg-AD mice had significantly lower accuracy than wild-type mice. 3xTg-AD mice also had longer correct response latencies than wild-type mice. In terms of reward collection latency, no genotype or treatment effect was found, but male mice took longer to collect the reward in comparison to their female counterparts. Thus, we confirm the sensitivity of the 5-CSRTT to 3xTg-AD attentional impairment, but provide no evidence to indicate a protective effect of 3α-diol. Further research is required to assess the potential benefits of 3α-diol at later ages and on other cognitive tests. If 3α-diol has significant neuroprotective properties in the central nervous system, in vivo, it could lay the foundation for potential clinical applications as a therapy to slow the progression of AD.

Services, Edward Hines Jr. VA Hosp., Hines, IL; [3]Physical Med. and Rehabil., [4]Radiology, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL; [5]Speech-Language Pathology, Col. of Nursing and Hlth. Sciences, Lewis Univ., Romeoville, IL

Abstract: Background: Disorders of Consciousness (DoC) is a neurological disconnection syndrome, hallmarked by a lack of volitional attention, with few treatment options. Effective treatments are further challenged by heterogeneous lesion profiles associated with severe TBI (sTBI). Familiar Auditory Sensory Training (FAST) was designed to exercise the DoC brain through mechanisms of salience, attention, and the broad cortical activations associated with autobiographical memory recall. To optimize attentional engagement for remaining neurological function, we created FAST-L and FAST-M based on the premise that language/music are comparable in complexity, hierarchical structure, and the type of autobiographical memories they invoke, while engaging a left/right hemisphere processing bias. We compared fMRI volumetric activation to contrasts of FAST-L versus FAST-M in three networks associated with attentional control: the dorsal attention network (DAN), associated with top-down control; the ventral attention salience network (VAN) associated with bottom-up reflexive attention; and the Fronto-Parietal Control Network (FPCN) associated with mediating top-down and bottom-up attention.
Hypothesis: We hypothesized that more left/right diffuse axonal injury (DAI) would predict more attentional engagement to FAST-M/FAST-L, respectively in the VAN, DAN and FPCN.
Methods: In a task-fMRI block design, 3 DoC-sTBI subjects (left DAI, vegetative state: N=2; Right DAI, minimally conscious sate: N=1; 1 Female, 2 Males; mean age = 27, SD = 9.5). Subjects listened to 16 alternating 30s blocks of FAST-L and FAST-M. fMRIprep and AFNI were used to warp, smooth, denoise and censor the data in MNI space. A 40 voxel cluster analysis was run, with a threshold of 3.3, uncorrected p=0.001.
Results: Pilot data analyses supported our hypothesis and revealed that DAI x stimuli-type predicted maximal voxels of activation of VAN, DAN and FPCN, with one caveat. Consistent with our hypotheses, left/right hemisphere DAI was associated with maximal activation of the DAN and FPCN in response to FAST-M/FAST-L respectively. The VAN followed a similar DAI x stimuli-type interaction; however, all 3 subjects showed maximal activation in response to the stimuli-type targeting the damaged hemisphere (e.g., Right DAI showed max VAN response to FAST-M), suggesting the damaged hemisphere may be working harder to reflexively process its optimal stimuli-type.
Conclusions: Pilot data show that both FAST-L/FAST-M can be used to maximize engagement of attention networks in the DoC-sTBI brain, based on DAI profile.

Title: Another dead salmon? The measurement flaw of serial dependence in human perception

Authors: *S. GLASAUER[1], Z. SHI[2];
[1]Computat. Neurosci., Brandenburg Univ. of Technol. Cottbus-Senftenberg, Cottbus, Germany;
[2]Psychology, Ludwig-Maximilians-Universität München, Munich, Germany

Abstract: Human perception is susceptible to various types of contextual biases, such as the range, distribution, and sequential exposure of the stimuli. Recent studies explain those biases as consequences of an optimal estimation process that uses additional contexts and prior knowledge to achieve an overall improvement in estimation reliability (e.g., Jazayeri & Shadlen, 2010, Glasauer & Petzschner 2011). Recently, there is a surge of interest in one type of contextual bias - serial dependence (e.g., Fischer & Whitney 2014, Bliss et al. 2017; Clifford et al. 2018). Serial dependence refers to the current perceptual judgment being influenced by past exposure stimuli. Investigation of serial dependence is not new, it has been shown about a half century ago (e.g., Holland & Lockhead 1968). The novelty is the way of how the serial dependence is measured in recent studies: the perceptual error, measured by the difference between the perceived and the given physical stimulus in the current trial, is then expressed as a function of the stimulus difference between the previous and the current trial (we refer to this as relative measure). This measure, however, is flawed due to mathematical coupling (Archie 1981, Curran-Everett 2010) given that the current stimulus appears in the estimation of both variables - the perceptual error and the stimulus difference. We show that random arbitrary or constant responses can also yield a bogus strong serial dependence in such relative measure - another dead salmon echoing the famous 'dead salmon case' in fMRI analysis (Bennett et al., 2009). Therefore, this relative measure cannot provide a meaningful quantification of serial dependence. Rather, the 'old' measure proposed by early studies (e.g., Holland & Lockhead 1968) - the current error as a function of the stimulus in the previous trial - can reflect a true serial dependence. We further show that iterative updating models (Glasauer & Petzschner 2011; Dyjas et al. 2012; Cicchini et al. 2018), which use past stimulus information for estimating the current stimulus and updating the prior, can make specific and testable predictions about the serial dependence and its relation to the classical central tendency effect, an effect of overestimation of small magnitudes and underestimation of large magnitudes. We reveal that the serial dependence and the central tendency are causally related: if information from previous trials is used as prior for the current perceptual estimate, a central tendency bias will occur as a consequence.

Title: The effect of prior knowledge on visual processing of agents: Time-resolved representational similarity analysis on EEG data

Authors: *S. ER[1,3], H. O. ELMAS[1,3], A. P. SAYGIN[4,5], B. A. URGEN[2,1,3];
[1]Interdisciplinary Neurosci. Program, [2]Dept. of Psychology, Bilkent Univ., Ankara, Turkey; [3]Aysel Sabuncu Brain Res. Ctr. and Natl. Magnetic Resonance Res. Ctr. (UMRAM), Ankara, Turkey; [4]Dept. of Cognitive Sci., UCSD, San Diego, CA; [5]Neurosciences Grad. Program, Univ. of California, San Diego, CA

Abstract: Recognition of agents during action observation is a crucial skill for many species including humans. Visual processing of agents is considered to take place in the pSTS node of the Action Observation Network; however, its temporal course and the factors that affect it still remain unknown. We investigated how prior knowledge about agents affects temporal characteristics of neural processing. We conducted 2 EEG experiments with human subjects. In both experiments (12 female, 15 male in total), subjects were presented videos and still images of 3 agents who performed 8 different actions as EEG was recorded. In the first experiment (Prior experiment), subjects (n=19) were familiarized with the stimuli and informed about the identity of the agents prior to the experiment. In the second experiment (Naive experiment), subjects (n=16) were naive to the identity of the agents. After standard preprocessing, we linked the EEG data in a time-resolved manner to a categorical Agent Model using representational similarity analysis (Kendall Tau correlation). We also used 3 additional models that capture the non-target variables within presented stimuli, a categorical Action model and two low-level visual models: pixel-wise intensity and pixel-wise motion energy. Finally, we did multiple regression analysis at each time point to determine how much each individual model could independently predict the neural data; thus, enabling us to regress out the effect of non-target variables on the correlation between the Agent Representational Dissimilarity Matrix (RDM) and the neural RDM (Bonferroni corrected for all time points and conditions, $p<0.05$). Our results show that the most informative channels about agent information were the ones over the occipital and parietal cortex. In those channels, there was a specific time range when agent information was available but it depended on whether the subjects were naive about the identity of the agents and the presentation mode. The comparison between Prior and Naive experiments showed that when subjects had no prior knowledge about agents, agent information became available for a longer duration during processing of still images (66-418 ms) than videos (90-130 ms). However, when subjects had prior knowledge about the agents, agent information was present for similar durations in both stimulus presentation modes: 82-196 ms for still images or 90-172 ms for videos. We conclude that prior information affects temporal characteristics of visual processing of agent perception by modulating the onset and duration of when agent information is available.

Title: Perceptually biased distance judgments of closer lower visual field information coincide with statistical properties of the visual environment

Authors: *Y. ZILBERTZAN[1], S. GILAIE-DOTAN[1,2];
[1]Bar Ilan Univ., Ramat Gan, Israel; [2]Inst. of Cognitive Neurosci., UCL, London, United Kingdom

Abstract: Human visual perception is often biased and this is sometimes attributed to misinterpretations of visual scenes based on visual priors that may reflect statistical properties of the visual environment. Following a recent model we proposed that suggests differences between the processing of upper and lower visual field information, here we hypothesized that during natural behavior visual inputs from upper and lower visual fields are significantly different and that this difference may bias perceptual decisions. Specifically we assumed that objects in the lower visual field are closer to the eyes than those in the upper visual field, and that distance estimations would therefore be biased for closer distance judgements in the lower visual field. Visual inputs (world and depth videos) were recorded during "in the wild" behavior via Intel Realsense d415 depth and world camera that is mounted on a glasses-like device (PupilLabs eye tracker) such that the camera lenses were right above the eyes. Data was collected during naturalistic behavior in 4 different types of environments (walking in indoor or outdoor environments, passenger in the front seat of a driving car, or while occupied with electronic devices). In all environments we found consistent evidence (across time and space) that lower visual field was closer to the eyes (e.g. in outdoors and car >95%, screens ~80%, and indoors ~75% of the time). We then examined the possibility that perceptual judgments may be biased in accordance with these statistical differences. 190 participants (aged 18-73 with normal vision) were presented with world images with 2 marked points, one in the lower half and one in the upper half of the image, and they were asked to judge which point was closer to the camera that took the picture. The number of pictures with closer upper point was equal to the number of pictures with closer lower point, with the critical condition being the pictures with equidistant points. While there were more errors made towards lower point being closer across all conditions, in the critical equidistant condition, more than half of the decisions (~56%) were of lower point being closer, which was 5 times the amount reported for upper point being closer (~11%). These judgements were not influenced by age, gender, or the height of the participants. Our results reveal a new perceptual bias for distance judgments where objects in the lower visual field are perceived as closer to the eyes than those in the upper visual field. This perceptual distance bias can be explained by our initial finding that in the visual environment objects in the lower visual field are significantly closer to our eyes than those in the upper visual field.

Title: Left inferior parietal cortex represents subjective stimulus visibility

Authors: ***M. HISHITANI**[1], Y. OSAKO[2], S. MURAI[1], H. NAGAMURA[1], H. ONISHI[1], K. I. KOBAYASI[1];
[1]Grad. Sch. of Life and Med. Sci., [2]Grad. Sch. of Brain Sci., Doshisha Univ., Kyotanabe, Japan

Abstract: One of the major debates in neural correlates of visual consciousness concerns which brain regions are the neural bases of the subjective stimulus visibility and how it anatomically relates with visual attention. Stimulus visibility fluctuated even though visual stimulus was physically identical. These dynamics were reported to be involved in the posterior parietal cortex (PPC) in previous studies. Moreover, although visual attention has been believed to be dissociated from subjective visibility, neural substrates of visual attention located in PPC, resulting in the conflation of specific localized regions corresponds to subjective visibility. Here, we investigated which regions in PPC significantly contribute to the representation of subjective visibility independent of visual attention. We used classical Posner cueing task to measure visual attention and applied backward masking to render cue stimulus bedimmed. Participants were instructed to discriminate the location where the tilted target stimulus (in left or right) was presented. They also reported subjective visibility of cue stimulus in four graded scales (invisible to clearly seen). We then constructed four regions of interest (ROIs) in PPC, which is widely covered the PPC to address the information containing subjective visibility, and performed multivariate pattern classification of the BOLD signal to test whether the hemodynamic responses in each ROI represent subjective visibility. Our results demonstrated that only the left inferior parietal lobule (IPL) had the information of subjective visibility. On the other hand, univariate analysis for subjective visibility revealed that the region involved in left IPL was significantly correlated with subjective visibility. Moreover, the hemodynamic responses in the left IPL did not predict the behavioral response latency, indicating that the left IPL response was independent of the visual attentional effect. These results suggest that the left IPL is involved in processing subjective visibility.

Title: The Fronto-occipital Network in Pre-attentive Detection of Visual Changes: An Event-related Optical Signal (EROS) Study

Authors: *Y. SHUM[1], X. XIAO[2], *Y. WANG[3], C. TSE[3];
[1]Dept. of Psychology, The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Sch. of Humanities and Social Sci., The Chinese Univ. of Hong Kong, Shenzhen, Shen Zhen, China; [3]Dept. of Social and Behavioral Sci., The City Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Pre-attentive change detection refers to the ability of human brains to monitor and detect changes in the environment even without attention. Previous studies showed that the Inferior Frontal Cortex (IFC) and the Superior Temporal Cortex (STC) were part of the brain network in pre-attentive detection of auditory changes. Specifically, an early IFC followed by STC then late IFC (i.e., early IFC-STC-late IFC) activation pattern was observed in detecting ambiguous auditory changes. As proposed by the prediction violation framework, the early IFC is related to reinstating the prediction model before the change detection process in the STC; when a prediction violation is detected, STC generates a prediction error that triggers the prediction model updating process which is shown as the late IFC activity. However, it remains unclear whether this fronto-sensory network organization is specific to detecting auditory changes or can also be applied to detecting visual changes. To address this question, the current study investigates the fronto-occipital (OC) network in pre-attentive detection of visual changes by using the Event-related optical signal (EROS). As EROS measures the change in optical properties of the brain associated with neuronal activity, it is able to localize brain activities temporally and spatially in the millisecond and sub-centimeter range. Twenty-four participants were recruited and presented with a visual passive oddball paradigm consisted of a simple physical feature change (i.e., orientation change of a bar array) and an abstract regularity violation (i.e., violating the clockwise rotation pattern among the standard bar arrays). Based on the number of preceding standards, each of the physical and abstract change deviants were further divided into the short train and the long train conditions. A shorter standard train or an abstract regularity among the standard is less likely to provide sufficient information to establish a stable prediction model. In detecting physical changes, the EROS results showed an early IFC-OC pattern to deviant preceded by a short standard train, while an OC-late IFC pattern when preceded by a long train. In detecting abstract changes, no EROS match response was observed for deviant preceded with a short train; however, an early IFC-OC- late IFC pattern was observed for deviant preceded with a long train. These results demonstrated 1) the spatial-temporal dynamics in pre-attentive detection of visual changes is similar to that in detecting auditory changes; and 2) activation patterns that was consistent with the prediction violation framework.

Imaging Res., IBS, Suwon, Korea, Republic of; [5]Wu Tsai Neurosciences Inst., Stanford, CA

Abstract: We experience visual scenes containing objects that change over space and time. To interpret these dynamic changes, our visual system requires representations of both space and time. However, previous population receptive field (pRF) implementations model the spatial aspects of the neural response, but not its temporal aspects. Here, we developed a novel spatiotemporal pRF encoding model that characterizes neural responses to space and time-varying stimuli. The new model predicts fMRI responses to stimuli that vary spatially over the visual field and temporally from milliseconds to seconds. To evaluate if different spatiotemporal models predict different fMRI responses to the same stimulus, we developed a software framework that (i) generates synthetic fMRI data from a stimulus and a spatiotemporal pRF model, (ii) solves spatiotemporal pRF parameters, and (iii) tests the validity of the solution with respect to the ground truth parameters used to synthesize the spatiotemporal pRF. We show that (i) the software accurately solves the parameters of the spatiotemporal pRF validated against the ground-truth data and (ii) both 2-channel (Stigliani et al., 2019) and delayed normalization (Zhou et al., 2019) spatiotemporal pRF models predict stronger responses to traveling wave stimuli using brief (33ms) stimuli compared to the standard pRF model. Then, we tested how well spatiotemporal pRF models predict experimental fMRI data. The fMRI data were collected while participants (n=5) viewed traveling wave stimuli that traversed the visual field, where stimuli within each location varied in their temporal properties from 30 stimuli, each for 33ms to 1 stimulus for 5s. We found that both the 2-channel and delayed normalization spatiotemporal pRF models predict fMRI response better than the standard pRF model for a brief, transient visual stimuli in each of the retinotopic visual areas (V1, V2, V3, V3a, hV4, LO1, LO2, TO1, TO2). Our experiments with synthetic and experimental data suggest that it is important to use spatiotemporal pRF modeling to improve predictions of neural responses in human visual cortex for a wide range of spatial and temporal stimuli.

Title: Posterior parietal cortex neurons distinguish memorised past from what is perceived as reality

Authors: *Y. ZHENG[1], L. WANG[1], L. HUANG[1], H. LAU[2], S. KWOK[3];
[1]Sch. of Psychology and Cognitive Sci., East China Normal Univ., Shanghai, China; [2]Psychology Dept., UCLA, Los Angeles, CA; [3]Div. of Natural and Applied Sci., Duke Kunshan Univ., Kunshan, China

Abstract: Humans can discriminate whether a piece of information is being held internally as memories or externally as coming from the outside world. The posterior parietal cortex (PPC), as an information accumulator for conscious perception, is hypothesized to monitor such distinction between the memorized and perceived information. We recorded electrophysiology data from the dorso-medial posterior parietal cortex on an adult monkey while it performed a temporal-order judgement (TOJ) task. Critically, in the delay/maintenance period of the TOJ task, we presented a congruent image in 1/4 of the trials (i.e., extracted from the video that they had just encoded), in another 1/4 of the trials with an incongruent image (i.e., extracted from other videos), and in 1/2 of the trials without any distractor as baseline (no-picture). We acquired single-unit spike data (66 neurons) from 6 daily sessions (440 trials in total). The monkey's TOJ accuracy was 82.5% ± 38% with RT at 977.9 ms ± 353.5ms. By fitting mixed effect models, RT for TOJ in the congruent condition was longer than that in the no-picture condition ($t(418.34)=2.077$, $p=.038$), and that RT in the incongruent condition was also marginally longer than the no-picture condition ($p = .13$), whereas there was no difference between congruent and incongruent condition ($p = .67$). With the neuronal data, we focused on the 500-ms period in which images were presented during the memory maintenance period. For each neuron, we performed receiver operating characteristic (ROC) analyses to measure how discriminable the distributions of its firing rates to each condition might differ and compared their area under the curve (AROC) with chance level. We found that 16 (~24.2%) of the neurons discriminate congruent and incongruent conditions from no-picture condition. Among them, two-thirds of them (10 neurons, ~15% of total) can further discriminate the incongruent condition from the congruent condition (despite the lack of differences in RT). In addition, another 9 neurons (~13.6%) discriminate the incongruent condition from congruent and no-picture conditions. These results indicate that primate PPC neurons are responsive to the external stimuli while the animal performed a memory task, and more importantly, being able to monitor the congruency of such external stimuli and evaluate them against the memorized content in working memory. We conclude that such neuronal correlates for distinguishing memorized vs. perceived content underline our ability in separating imagined/memorized information from external reality. Our work carries implications for clinical symptoms such as hallucination that is observed in psychosis.

Title: The physics of our perceptual-phenomenal-conscious world can be detected:Replicating for the second time the small impacts of the percepts of a partner on the event-related brain potentials of participants

Authors: J. DEBRUILLE;
Psychiatry, McGill Univ., Montreal, QC, Canada

Abstract: As neuroscientists, we know that we are not seeing stimuli. We know that stimuli trigger outputs from our sensors. We know that these outputs are processed by the brain, which then *creates* percepts. However, these percepts look so real to us that we do as if they were the actual objects we are dealing with. We thus tested whether percepts have their own physics to which we are sensitive to. To achieve that goal, we capitalized on two things: first, on the distance we experience between us and the object-percept that is created by our brain, because this distance suggests that the physics at stake have some nonlocal properties (McFadden, 2020); second, we capitalized on the similarity this physics should have across people. Taken together, these two things mean that, at least in some conditions, the activity of a brain might be sensitive to the percepts of others and could thus include traces of that sensitivity. To look for such traces, we recorded the electrical activity (EEG) of the brains of partners during trials where the photography of a face was presented to participants. Importantly, the design was reciprocal. At each trial, partners were also, and at the same time, presented with a face and having their EEG recorded. These EEGs were used to compute the event-related potentials (ERPs) evoked by those faces in partners and participants. Most importantly, none saw the face presented to the other. Despite this privacy of the presentations, slightly larger late posterior positivities (LPPs) were found in the grand (n = 29) average ERPs when the two face-photographs differed than in the grand average ERPs obtained when they were the same. These slightly larger LPPs seem to be replicable. They appear in each of the two subgroups used. Importantly, it was announced to participants, before the block of trials, that they were about to see images that differ from those simultaneously presented to their partner. The results obtained thus confirm those found by Bouten et al's (2014) and by Haffar et al's (2018) who also observed slightly larger LPPs when the two images of each trial were the same than when these images differed after it had been announced that they will always differ. This is thus the third block-design study that supports the claim that percepts have nonlocal physics, in addition to that of the local neuronal activities responsible for their production. Future studies should thus search for the nature of this physics and test, for instance, McFadden's (2020) electromagnetic hypothesis. In the meantime, cognitive neuroscientists could test whether the sensitivity to percepts of others could be a factor of the similarity of percepts existing across individuals (Hofstadter, 2007).

Title: Identification of perceptual inaccuracy as a source of suboptimal behavior in a mouse foraging task using reinforcement learning

Authors: *B. N. BALLINTYN[1], N. SCHNEIDER[1], H.-J. PI[1], D. B. KATZ[2], P. MILLER[1]; [1]Dept Biol., [2]Dept Psychol, Brandeis Univ., Waltham, MA

Abstract: In the classical view of economic choices, subjects make rational decisions evaluating the costs and benefits of options in order to maximize their overall income. Nonetheless, subjects often fail to reach optimal outcomes. Many studies have shown that the overt values of options drive the direction of decisions, however few have identified sources of suboptimality in animals' decision-making process. Additionally, many questions remain to be answered as to which contexts contribute the most to deviation from an optimal solution and the extent of these effects. In order to tackle these questions, we devised a decision-making task for mice, in which cost and benefit parameters could be independently and flexibly adjusted and for which a tractable optimal solution was known. We then evaluated the optimality of mice in the task and compared their performance across sessions with different cost and benefit parameters finding that the cost parameter had the largest impact on optimality. Lastly, we identify possible sources of suboptimality of mice in the task by comparing their behavior to that of reinforcement learning (RL) agents. We find that only RL models that include a non-linear cost function and take into account estimation error in numerosity (or alternatively time) according to the Weber-Fechner law can reproduce the behavior of the mice. Taken together, our results suggest that although the mouse brain may be employing a normative decision-strategy in this task, perceptual constraints limit the ability of the mice to perform optimally and these constraints affect behavior differentially across sessions with different experimental parameters.

Title: Predicting matching behavior based on the consistency of response to reward feedback

Authors: *E. TREPKA[1], M. SPITMAAN[1], B. A. BARI[2], J. Y. COHEN[2], A. SOLTANI[1]; [1]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Snyder Dept. of Neurosci., Johns Hopkins, Baltimore, MD

Abstract: For decades, behavioral neuroscientists have used the matching law (i.e., choice fractions match reward fractions) to quantify how animals distribute their responses between multiple options in response to reinforcement they receive from the environment. More recently, multiple reinforcement learning (RL) models have been developed to understand how global (in time) matching behavior emerges as a result of local learning rules. Despite reasonable success of these models in capturing choice on a trial-by-trial basis, they are not good predictors of overall matching and its variability. To address this issue, we analyzed data from a probabilistic reversal learning task with a dynamic reward schedule in mice (N = 18 animals, 528 sessions, 3764 blocks) and developed new metrics to capture consistency in response to reward feedback based on the concept of conditional entropy in information theory. In this task, mice chose between licking the left or right tubes that deliver water with certain probabilities. Reward probabilities associated with the two actions changed at random time points without any signal to the animals. Consistent with previous studies, we found that mice exhibit significant and highly variable undermatching behavior. Moreover, we found that our entropy-based metrics could accurately predict deviation from matching on a block-by-block basis, explaining up to 50% and 72% of the variance individually and together. We next used differences between the predictions of existing RL models and observed data in terms of our new metrics to identify missing mechanisms crucial for matching behavior. Using this approach, we developed a new model that combines a slow RL component with a fast win-stay lose-switch (WSLS) component and uses expected uncertainty to arbitrate between the two. The new model improved fit of choice behavior and captured our metrics and undermatching more accurately, whereby revealing new mechanisms for adaptive behavior. Together, our results provide novel entropy-based metrics that can predict one of the most fundamental behavioral laws and can be used to refine reinforcement learning models and reveal neural mechanisms underlying adaptive behavior.

Title: Rat trajectories in 2AFC task endorse parallel processing of motor planning and evidence accumulation

Authors: *J. PASTOR-CIURANA[1], L. HERNÁNDEZ-NAVARRO[1], L. BEKTIC[1], D. DUQUE[1], A. HYAFIL[2], J. DE LA ROCHA[1];
[1]IDIBAPS, Barcelona, Spain; [2]CRM, Bellaterra, Spain

Abstract: Standard decision-making models postulate that a response is triggered once the accumulated evidence reaches a decision bound. We have recently shown that rats in a free reaction time (RT) auditory discrimination task trigger their response before stimulus is processed or even presented in a considerable fraction of trials. However, accuracy in those expressed responses is influenced by stimulus strength, suggesting they are not guesses but sensory informed choices. A new model explained this phenomenon by proposing the parallel processing of response initiation and evidence accumulation processes [1]. Here we expand on this model by characterizing the fine dynamics of the decision making process from the precise response trajectories exhibited by our subjects.

We extracted subject's response orienting trajectories while performing the task and quantified the extent to which they are modulated by stimulus strength, expectations based on trial history and RT. Average trajectories showing the decision coordinate as a function of time exhibit a sigmoidal shape which we quantified by the time at which they crossed a decision threshold right before the side ports and the peak velocity with which they crossed.

Using catch trials with no stimulus we found that prior expectations modulated trajectories in absence of stimulus by reducing the crossing time of the decision thresholds and increasing the peak velocity. This prior effect decreased with RT.

In regular trials, stimulus strength also modulated average trajectories' peak velocity. The point in the trajectory where we could first detect the impact of the stimulus decreased with RT until it plateaued at 80 ms after movement onset, what constitutes an upper bound of the motor efferent latency. For express responses in which the initial trajectory was independent of the stimulus, the modulation onset increased by 40 ms, which set an upper bound of the sensory afferent latency. These results suggest that priors determine an a priori trajectory which is updated en route by the stimulus.

Finally, we explored trials in which expectations were incongruent with the presented stimulus and found a significant fraction of trajectories in which the initial choice was reversed. Several additional analyses indicated that these trajectories may represent changes of mind: their rate increased with prior-stimulus incongruency, decreased with RT and were mostly correcting reversals.

Together, our results illustrate how response trajectories reveal the timely superposition of two processes, prior and sensory evidence, which compete asynchronously to dictate the subject's choices.

Title: Neural signatures of competing proactive and reactive processes during perceptual decisions in dorsomedial striatum

Authors: *L. HERNÁNDEZ-NAVARRO[1], A. HERMOSO-MENDIZABAL[1], D. DUQUE[1], A. HYAFIL[2], J. DE LA ROCHA[1];
[1]IDIBAPS, Barcelona, Spain; [2]CRM, Bellaterra, Spain

Abstract: Standard models of perceptual decision-making postulate that responses are triggered in reaction to the stimulus, when the accumulated evidence reaches a decision threshold[1]. This excludes however informed responses that are generated proactively at a time independent of stimulus[2]. Here we find that, in a free reaction time (RT) auditory discrimination task in rats [Fig. 1a], the timing of the fastest responses does not depend on the stimulus [b], although the choices do [c]. This unveils the coexistence of reactive and proactive responses for all RTs, suggesting that choice selection and motor initiation, commonly viewed as serial processes, are decoupled in general. We capture this behavior by a novel model in which proactive and reactive responses are triggered when either of two competing processes, respectively Action Initiation (AI) or Evidence Accumulation (EA), reaches a bound [d-e]. In all responses, the choice is ultimately informed by the EA. To investigate the neural substrate of the AI, we performed population recordings in the dorsomedial striatum (DMS) of 4 rats (n= 652 single units). Preliminary analysis revealed that a large fraction of neurons (~40%) encoded choice, from response initiation to next trial response. Another subpopulation of neurons (~20%) displayed stimulus-independent ramping activity before response onset whose slope correlated with RT, suggestive of the AI ramping process [f]. Overall, these results fundamentally extend standard models of evidence accumulation in decision making by showing that proactive and reactive processes compete for the generation of responses, and that DMS may play an important role in generating the proactive AI process.

Title: Distinct Social Interactions Elicits Shifts in Functional Connectivity in the Social Decision-Making Network

Authors: *K. R. GOSSMAN, B. DYKSTRA, B. H. GARCIA, A. P. SWOPES, A. S. SMITH; Univ. of Kansas, Lawrence, KS

Abstract: Intimate relationships rely on an individual's ability to display affiliative behaviors toward a partner and rejection of potential partner. It is theorized that these context-appropriate decisions are processed through the Social Decision-Making Network (SDM). Specifically, the SDM hypothesis suggests that the expression of a given social behavior is reflected by the overall activity of a network of brain structures rather than activity of any single structure. While the SDM network was proposed on functional grounds, most of the supporting research is restricted to structural connections and behaviorally-associated regional activity. In the present study, we sought to assess the organization of regions in the SDM network using c-Fos, a neuronal marker for activity, to generate functional connectivity models during specific social interactions in a socially monogamous rodent, prairie voles (*Microtus ochrogaster*). Males from established male-female pairs were exposed to one of four resident interactions: no interaction (control), female partner, novel female, or novel male. Male voles displayed robust partner-directed affiliation and stranger-directed aggression. These social interactions increased levels of the immediate early gene, c-Fos, in select brain regions associated with the SDM network. Pearson's correlation matrices displayed distinct coactivity patterns between individual brain regions based on the social exposure. The correlations presented are exhibited as edges between regions within the network models. Hierarchical clustering was used to group regions with similar c-Fos activity during each social encounter. These clusters of regions form modules that make up separate interrelated units in the functional connectivity models. Our functional connectivity models display unique connectivity and organization based on the social encounter. Our partner functional connectivity model presents similarities to the SDM network, along with connections between regions associated with affiliative behaviors. However, both stranger female and male networks exhibit distinct architecture from one another and the SDM network. Stranger networks demonstrate potential interregional connections that may be associated with threat, aversion, and aggression. This highlights that functional connectivity maps of the SDM network differ during distinct social encounters, which may underlie the display of context-appropriate social behaviors.

Title: B-rats and v-rats: understanding biological rats through a comparison with virtual rats

Authors: *A. KAZAKOV[1], I. NELKEN[2];
[1]ELSC - Edmond & Lily Safra Ctr. For Brain Scienc, Jerusalem, Israel; [2]Dept. of Neurobiology, The Alexander Silberman Inst. of Life Sciences, The Hebrew Univ. of Jerusalem, Hebrew Univ., Jerusalem, Israel

Abstract: Recent neuroscientific approaches suggest ways of generating hypotheses of neural computation in animals, guided by their task-performing models. First, both the animal and its model are trained on the same operant task. Next their performance and learning dynamics are compared. Finally, if they are found to be sufficiently similar, the decision-making module of the artificial agent can be used to generate hypotheses regarding the neural computations in the animal. However, the comparison between the biological and the artificial agents is not thoroughly investigated or standardized.
We analyzed a sound discrimination task in freely behaving rats. The biological data consists of 21,000 trials that spanned the learning process of one rat from its first introduction to the task and up to performance saturation. The virtual rat (V-Rat) is modeled as a point inside the arena, with constraints on its acceleration and turn speed. The V-rats decision-making is performed by an artificial neural network (4-layered multi-layer perceptron, 300 neurons in total) that emits an action based on the observed state. The V-rat was trained through reinforcement learning and converged to a near-optimal policy after few thousands of trials. We quantify V-Rat optimality along the learning process by comparing it with an optimal performer, an exact solution of the optimal control problem.
To compare the two agents, the state of each of them is described at any moment by a behavioral feature vector. Several consecutive feature vectors form a 'behavioral motif' that captures complex temporal dynamic in the agent behavior. We therefore compared corpuses of motives of the two agents. We found that the behavior of both agents is largely shaped by the task constraints. Moreover, we applied motif analysis to phenotype the behavior of individual V-Rats and quantified the population variation, explaining it by the unique realization of the exploration process and the initial network weights.

Title: Monkey See, Monkey Choose: A Nonhuman Primate Model of Gaze Biases in Economic Choice

Authors: *S. M. LUPKIN[1,2], V. B. MCGINTY[1];
[1]Ctr. for Mol. and Behavioral Neurosci., [2]Behavioral and Neural Sci. Grad. Program, Rutgers Univ. - Newark, Newark, NJ

Abstract: In economic decision making individuals must choose between items on the basis of their perceived value. For both human and nonhuman primates, these decisions are typically

carried while the locus of gaze is rapidly shifted between available options. Recent studies in humans have shown that these shifts in gaze actively bias choice. In particular, choices tend to be biased in favor of the items that are viewed first, last, or for the overall longest duration in a given trial. This suggests a possible role for gaze in the value computations that underlie decision making. To date, however, the neural mechanisms that subserve the relationship between gaze and choice are still largely unknown. A critical step towards identifying these mechanisms is the development of a suitable animal model of this behavior. To this end, we have created a novel value-based choice task for macaque monkeys that captures the essential features of the human paradigms in which gaze biases have been observed. Using this task, we observed gaze biases in the monkeys that were both qualitatively and quantitatively similar to those exhibited by humans. In addition, we found that these results are well explained using a computational framework previously used to describe gaze biases in humans—the first time this framework has been used to explore value-based choice in nonhuman primates. Together, these findings suggest that this novel task is ideally suited to study the neural mechanisms underlying the relationship between gaze and value-based choice.

Title: Inferential reasoning in monkeys

Authors: *F. BOUCHACOURT[1], S. TAFAZOLI[1], M. G. MATTAR[2], N. DAW[1], T. BUSCHMAN[3];
[1]Princeton Neurosci. Inst., Princeton, NJ; [2]UCSD, San Diego, CA; [3]Princeton Neurosci. Inst. & Dept of Psychology, Princeton Univ., Princeton, NJ

Abstract: When entering a new restaurant, we use contextual cues to infer whether it is a sit-down or a fast food restaurant. Once this is determined, we can apply previously learned rules for each context to guide our behavior. To understand how the brain infers the current rule, we trained a monkey to perform a task with multiple latent rules. The monkey was trained on three different rules, each requiring to attend and respond to a single feature of a two-dimensional stimulus. Changes in the rule were not cued, forcing the animal to determine which rule was in effect on each block. The animal performed the task well, quickly switching between the rules. However, its performance was reduced for stimuli associated with incongruent responses across the rules. Moreover, the monkey's initial performance improved after a correct response to such an incongruent stimulus, but degraded if the stimulus was instead congruent. To understand the mechanism supporting behavior, we compared two classes of models: an incremental learner, relearning each rule from tabula rasa after a switch, and an inference model inferring the rule in effect through Bayesian update over known latent rules. Only the inference model captured the

key qualitative features of the data, in particular differences in performance and learning following stimuli that either had congruent or incongruent responses across the rules. Together, these results suggest monkeys can use inferential reasoning when determining how to behave.

Title: Expected uncertainty drives phasic and tonic exploration during probabilistic learning.

Authors: *S. R. BINDAS, V. D. COSTA;
Oregon Hlth. and Sci. Univ., Beaverton, OR

Abstract: In changing environments, adaptive decision-making requires balancing when to choose familiar, known options with when to explore new, unknown options. This balancing act, known as the explore-exploit tradeoff, is critical to how we make choices that can maximize reward. Specifically, exploration supports optimal decision-making by reducing the uncertainty associated with certain choices. Exploration is often seen as phasic, where the decision to explore depends on peaks in uncertainty that signal when the benefit of exploring is greatest. However, exploration can also be tonic, occurring more regularly in time. While tonic exploration has been demonstrated in settings where uncertainty is limited to discrete, unexpected rule changes , it is unclear how tonic exploration relates to expected uncertainty from stochastic reward outcomes. Here, we used a Bayesian modeling approach to examine monkeys' choice behavior during a two-arm reversal learning bandit task (Costa et al., 2015) where the monkeys learned to reverse probabilistic reward associations under three different reward schedules: 60/40%, 70/30%, and 80/20%. We found that the monkeys' committed more spontaneous errors (i.e. lapses) during the reversal phase of the task in 60/40% blocks compared to 70/30% or 80/20% blocks. Across all three schedules ($F(2,96)=0.512$, $p=0.601$), however, we found that lapses were negatively correlated with how the monkeys' accuracy in detecting reversals in the reward contingencies. This suggests that a common process contributes to both phasic and tonic exploration (Ebitz et al. 2019). This relationship is not affected by the administration of haloperidol or levodopa ($F(2,16)=3.81$, $p=0.617$). Further, we find that tonic exploration is directed rather than random, as lapses can be accurately predicted by Bayesian estimates of unpredictability ($t(2)=7.66$, $p=0.0166$) and choice consistency ($t(2)=-7.33$, $p=0.0186$). Our results demonstrate how in dynamic learning environments tonic exploration complements phasic exploration to reduce uncertainty and maximize reward.

Title: Past reward biases decision process in auditory detection task

Authors: *H. NAGAMURA, E. SAKAUE, H. ONISHI, M. HISHITANI, S. MURAI, Y. OSAKO, K. I. KOBAYASHI;
Doshisha Univ., Kyoto, Japan

Abstract: The perceptual decision depends not only on sensory input but also on internal factors (e.g., motivation, emotion, and past experience). For example, when we want to play the slot, we tend to choose the same slot machine that we won in the past. Previous studies in visually guided decision task reported that participants showed various reward-history-dependent bias such as win-stay, lose-switch, and lose-stay strategy, even when the optimal decision is independent of their internal history. This indicates that our decision process is largely modulated by reward-associated history. However, how reward history biases the decision process remained unclear. Here, we investigated how reward-associated history modulates behavioral strategies by using an auditory detection task, and we fitted participants' decision to bounded-accumulation decision models to reveal which component of the task and internal factors biases their decision process. In our task, the auditory stimuli were 2300-3000 ms duration sounds consisted of two streams (1000 or 500 Hz) of tone-bursts with background white noise. A 1000 and 500 Hz stream were synthesized by a 155 and 99 ms duration of the tone bursts and a 93 and 74 ms inter-tone interval, respectively. Participants were instructed to detect which of two auditory streams disappeared. In case that they correctly detected the change, they were randomly given 0, 1, or 5 points. They were also instructed to maximize their points and to respond as soon as possible. We found that previous reward, not current reward, significantly slowed reaction time depending on the size of the past trial reward. To obtain the interaction between the past trial reward and the decision process, we then fitted the drift diffusion model to behavioral data. We found that the model with reward-history-dependent drift bias better explained the data than the model without reward-associated history factor and the starting point bias model of reward history. These results indicate that reward history degrades the speed to reach detection threshold rather than shifts the starting point of the perceptual evidence accumulation, suggesting that the reward-associated history affect our decision process as suppressor of accumulating evidence.

Title: Habits can arise from model-based planning due to latent cause inference

Authors: S. M. ALLAN[1], **N. GARRETT**[2,3], *N. D. DAW[2];
[1]Princeton Neurosci. Inst., Princeton Univ., Prinecton, NJ; [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Exptl. Psychology, Oxford Univ., Oxford, United Kingdom

Abstract: Computational models have separately explored two distinct aspects of conditioning. First, findings that instrumental responses are sometimes sensitive-but sometimes insensitive-to reinforcer devaluation have been argued to reflect the use of two learning mechanisms, model-based vs. model-free (Daw et al. 2005). For instance, findings that overtrained animals habitually persist in responding for devalued reinforcers may reflect model-free learning, which is blind to post-training changes in outcome value.
Second, generalization between contexts in classical conditioning has been studied using latent cause inference (LCI) models (Gershman et al. 2010). These theories describe how animals can group experiences into different covert "causes", depending on their overlap, leading to differential generalization across them. For instance, if acquisition and extinction training are attributed to different causes, extinguished conditioned responses reappear when animals reinstate the acquisition cause.
We present a new model combining elements of both lines, to explore the consequences of LCI for instrumental conditioning. The model nests state-action-state model-based instrumental learning under a Dirichlet-process mixture model for trial clustering. Surprisingly, despite omitting model-free learning, this reproduces key aspects of habits: persistent instrumental responding in extinction for a devalued reinforcer, even when a consumption test verifies the efficacy of aversion conditioning. The model is inspired by and captures the patterns of results from recent experiments (Bouton et al. under review) showing that response sensitivity to reinforcer devaluation depends on the similarity between aversion conditioning and acquisition/test contexts. The model captures value-insensitive responding even using model-based evaluation within each cause due to failure to generalize aversion learning to the latent cause where the instrumental test is inferred to occur. Aversion conditioning experience generalizes more readily during the consumption test because of greater feature overlap (e.g. the presence of the outcome itself). Although these results do not rule out a contribution of model-free learning, they point to the importance of state inference in instrumental learning.

Title: A macro-level perspective on evidence accumulation during decision making

Authors: ***M. D. NUNEZ**, J. VANDEKERCKHOVE, R. SRINIVASAN;
Dept. of Cognitive Sci., Univ. of California, Irvine, Irvine, CA

Abstract: Multiple brain areas have been shown to be involved in evidence accumulation during decision making tasks with data from electrophysiological recordings and inactivation studies in animals, including brains areas involved in both perceptual and motor processing. However the whole-brain computational process of decision making remains unclear. We show how simultaneous computational modeling of human behavior and macro-level recordings using human scalp EEG can reveal an individual's cognitive process of evidence accumulation, with measurable cognitive components that include attention, figure-ground segregation, perceptual categorization, motor preparation, and motor execution. In particular, we find that these cognitive components can be measured in a preregistered confirmatory study of 48 human participants. We show how hierarchical Bayesian methods can be used to understand and predict individuals' behavior and EEG potentials during decision making. For example, Hierarchical Neural Drift-Diffusion Models (HNDDMs) with embedded early visual event-related potentials (ERPs; in particular N200 latencies) can not only explain early (e.g. 25th percentile) response times (RTs) well (see Fig. 1a), but also predict, to a certain extent, early response times of completely new participants (see Fig. 1c) when only their ERPs are observed. Prediction of new participants' early RTs are greatly improved by N200 latencies because N200 latencies are confirmed to have a close relationship to non-decision times across experimental conditions (e.g. "Easy", "Medium" and "Difficult" in Fig. 1), replicating our previous study that suggests N200 latencies are a marker of figure-ground segregation and track the onset of evidence accumulation. The results of our work to date suggest a future of studying evidence accumulation using model-based cognitive neuroscience.

Title: A single neural circuit that captures divisive normalization, working memory, and winner-take-all choice

Authors: *B. SHEN, K. LOUIE, P. W. GLIMCHER;
Neurosci. Inst., New York Univ. Sch. of Med., New York, NY

Abstract: Purpose: Circuit models of decision-making utilize two motifs to capture decision-related neural activities. One motif dynamically captures divisively normalized value representation, including value adaptation (Louie et al., 2014; LoFaro et al., 2014; Zimmerman et al., 2018; Padoa-Schioppa, 2009; Cohen & Padoa-Schioppa, 2019). The other motif captures the dynamics of a form of working memory and winner-take-all (WTA) competition (Wang, 2002; Wong & Wang, 2006). However, both motifs are restricted in their explanatory power. Results from fixed-duration tasks exhibit a transition from representation to competition which appears to be under the top-down guidance of action signals (Roitman & Shadlen, 2002; Shadlen & Newsome, 2001). It remains unknown how a single circuit model can capture all of these features. Here we propose a hybrid model that unifies value normalization, working memory, and WTA competition, and test the model in capturing neural and behavioral data across different tasks. Methods: The hybrid model implements recurrent excitation and global inhibition drawn from existing models and incorporates a new element of local disinhibition. The model was implemented as a dynamical system capturing firing rates response to bottom-up signals of stimuli and top-down signals for action execution mediated through local disinhibition. We tested this model in capturing neural dynamics and behavior in a range of empirical paradigms: (1) a classic reaction-time task (Roitman & Shadlen, 2002), (2) fixed-duration tasks (Roitman & Shadlen, 2002; Louie et al., 2011), and (3) a multiple alternative choice task (Churchland et al., 2008). Results: We show that the hybrid model captures the dynamic of WTA competition in the reaction-time task, the phase transition in fixed-duration tasks, and the quantitative effects under multiple inputs. In addition, the model fits well to empirical distributions of reaction time and choice accuracy from the reaction-time task. Finally, the predicted effect of GABAergic manipulation distinguishes models with and without local disinhibition, providing neural and behavioral predictions for pharmacologic/optogenetic experiments. Conclusions: We find that a biologically-plausible decision circuit with recurrent excitation, global inhibition, and local disinhibition easily adapts to the neural dynamics from different paradigms. This model precisely captures empirical psychometric and chronometric data. These results suggest that the specific computations of divisive normalization and WTA competition, under the switch control of local disinhibition, is a core circuit motif in decision-making.

Title: Discovering the correlation between personality determinants & risky choices

Authors: *Z.-Y. YAN[1], P. GLIMCHER[2];
[1]New York Univ., ; [2]New York Univ., New York, NY

Abstract: A variety of personality determinants and emotional states have been linked to the individual differences of the risk preferences. However, most variables reported in the literature were investigated independently and tested without repeated measurements. In order to understand the interaction between these traits and states and risk preferences, we performed longitudinal examinations of emotional states and personality traits from the following domains: attitude toward uncertainty, impulsivity and the level of psychological distresses. All subjects were recruited in the US on CraigsList. We recruited a 50 subject "discovery cohort" and another 50 subjects as the "replication cohort". In the discovery cohort, our goal was to identify the magnitude of the measured traits and states and risk preferences. We employed a mobile smartphone-based experimental platform (Linkt) for gathering daily data from our participants. Each participant was tested with multiple instruments presented over a two-month window. Subjects completed instruments for about 5 minutes per day (one or two tasks and/or questionnaires). We gathered the following instruments at least once every week: a risky choice task (Levy et al. 2010), a delay discounting task (Kable & Glimcher, 2007), the self-report positive and negative affect (Kahneman et al. 2004). Over the course of the study, we gathered a total of 13 personality inventories. We found that our data collection system yielded a high level of compliance, 49 out of 53 subjects finished all instruments. Here we present data showing how the personality traits are correlated with willingness to take risks and its relationship with the parameters estimated with EU (Expected Utility) and ESVT (Expected Subjective Value Theory) models (Glimcher & Tymula, 2016). We found that the ratio of choosing risky option over safe option is positively correlated with the psychological distress as well as the willingness to take financial risk. Parameter governing reward expectation (M) in ESVT model is positively correlated with the willingness to take health and safety risk. M is also positively correlated with the self-reported expected benefit of the financial risk and negatively correlated with the self-reported perceived health and safety risk. Our findings demonstrate that our data collection system is effective in capturing the relationship between the variables. For the next step, we will be testing these effects with our replication cohort.

Title: Decision-making among individuals reporting a COVID-19 infection: Time, probability, and ambiguity preferences

Authors: *A. MELLIS[1], C. M. RAIO[2], A. VINA-ALBARRACIN[1], P. W. GLIMCHER[3], O. OLUFEKO[1];
[1]NYU Langone Hlth., New York, NY; [2]Ctr. for Neural Sci., New York Univ., New York, NY; [3]Ctr. Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Overview: The COVID-19 pandemic imposes a universal threat to individuals' well-being, with individual risks of infection varying based on medical, social, and economic determinants of health. One question that has yet to examined is whether individuals' decision-making may also determine, or be influenced by, infection risk. Based on the previous literature linking economic choice patterns to health-related and clinical outcomes, here we directly test whether preferences for risk and ambiguity, as well as impulsive choice, differ in individuals as a function of COVID-19 infection.
Methods: Between April 8 and July 22, 2020, a total of 232 participants consented to participate in "Our Covid Story" (www.datacubed.com/ourcovidstory). Participants were recruited via Facebook advertising and e-mail listservs, focused on the New York City area. Participation involved downloading a mobile application for administration of tasks and surveys, and completing 5-10 minutes of a rotating battery of assessments. These assessments included a complete demographic battery, self-report instruments, and gamified decision-making tasks, which included the 27-item Monetary Choice Questionnaire to assess temporal discount rate, and an abbreviated (35-item) version of the Levy task which distinguishes between preferences in risk and ambiguity.
Results: Overall, 6% of individuals reported a likely or confirmed case of COVID-19. To assess decision-making, we calculated the proportion of immediate choices in the Monetary Choice Questionnaire to determine degree of impulsive choice; similarly, we calculated percent of lottery choices in the risk and ambiguity trials of the Levy task. In cross-sectional analyses, we observed that individuals who reported a positive history of COVID-19 made fewer risky lottery choices ($t=-2.81$, $p = 0.01$) and made fewer ambiguous lottery choices ($t = -2.22$, $p = 0.04$), suggesting lower risk and ambiguity tolerance in participants reporting COVID-19 infections. We additionally observed a small difference in the proportion of impulsive choices between these groups, with those reporting a history of COVID infection showing higher levels of impulsivity, although this group difference did not reach statistical significance ($t=1.23$, $p = 0.26$) in our initial sample.
Discussion: Our longitudinal data collection is ongoing, to determine whether differences in

decision-making between those who report a history of COVID and those who do not are cause or consequence of the disease. Our preliminary data support the application of econometric approaches to understanding decision-making in COVID.

Title: Information seeking on the horizons task does not predict anxious symptomatology

Authors: I. ZALLER, *S. ZOROWITZ, Y. NIV;
Princeton Univ., Princeton, NJ

Abstract: The explore-exploit dilemma, or the tradeoff between choosing a known reward (exploitation) versus a lesser-known option which might be better (exploration), is a ubiquitous problem in decision making. Excessive information seeking, or exploratory behavior to minimize the uncertainty of unknown options, is a feature of anxiety disorders (Kobori & Salkovskis, 2013). The horizons task (Wilson et al. 2014) is a popular task for measuring exploratory and information-seeking behavior, and has recently been used to identify over-exploitation in psychotic patients (Waltz et al. 2020). The horizons task has not, however, been evaluated as a tool for measuring information seeking symptoms in anxious individuals. We recruited 100 participants from Amazon Mechanical Turk to complete an online version of the horizons task and to complete several self-report symptom measures. Anxiety symptoms were measured with the Penn State Worry Questionnaire (PSWQ), and beliefs and attitudes related to information seeking were measured with the Intolerance of Uncertainty scale (IUS) and the Need for Closure scale (NCS). Information seeking behavior on the horizons task was measured per participant using hierarchical Bayesian modeling. We then correlated each participant's model parameter with their respective total scores on the self-report scales.
We confirmed that behavior on the online version of the horizons task is similar to previously published studies in which participants were tested in person. Contrary to our hypotheses, however, we found no evidence of a relationship between information seeking behavior on the task and anxiety symptoms (condition 1: $r = -0.091$, $p = 0.431$; condition 2: $r = -0.036$, $p = 0.756$) or the information seeking scales (IUS: condition 1: $r = -0.060$, $p=0.602$; condition 2: $r = 0.050$, $p = 0.663$; NCS: condition 1: $r = -0.051$, $p = 0.655$; condition 2: $r = 0.056$, $p = 0.629$). Our results suggest behavior on the horizons task is not predictive of self-report beliefs and

attitudes towards anxious information seeking. We suspect this may reflect design features of the task that reduce the instrumental utility of information seeking behaviors. We conclude by proposing several modifications to the task that may improve its utility as a measure of information seeking behavior in anxiety.

Title: Decision making in the context of multi-attribute options

Authors: *A. PERKINS, E. L. RICH;
Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: When making a decision, there may not be an obvious best choice. Often decisions are made between options that have multiple features, or attributes, that must be considered and integrated before deciding. For example, when deciding between cars to purchase, one might factor the price, miles per gallon, and acceleration into one's selection. The OFC plays an important role in representing associations between stimuli and values, and also may represent the overall option value or that of the stimulus attributes. However, it remains unknown whether options are necessarily evaluated on the basis only of an integrated value, as suboptimal decision-making effects like the attraction effect point to the possibility of within-attribute comparison. In order to investigate how multi-attribute options are represented in neural activity, we trained two rhesus macaques on a multi-attribute decision making task, in which two simultaneously-presented options were represented by stimuli reflecting the sweetness of that option's sucrose reward, and the probability of receiving that reward. These composite stimuli represented information about the attributes of the options with separate bars that either increased *or* decreased with increasing attribute value, allowing us to investigate both free-viewing gaze behavior and changes in choice behavior due to perturbations in attribute presentation. We found that when shared attributes were congruous with each other across option (e.g., both reward bars increased in size with increasing sweetness), choice behavior improved from baseline. However, when shared attributes were not congruous with each other across option (e.g., reward bar A increased in size with increasing sweetness, while reward bar B decreased), choice of the better option became suboptimal, implying a role for within-attribute comparison in the choice process. We will record from OFC using acute electrodes and multi-contact linear probes to determine how complex stimuli are represented in neural code and how

regions related to oculomotor processing and visual attention might contribute to the evaluation of multi-attribute options.

Title: Nonhuman primates use hidden state inference during reversal learning

Authors: *C. F. FORD[1], J. D. WALLIS[2];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Psychology, Univ. of California Berkeley, Berkeley, CA

Abstract: Understanding the world requires making inferences about the hidden causes, or belief states, generating our observations. During value-based decision making, converging evidence from rodent, human, and computational models suggests that the orbitofrontal cortex (OFC) represents these hidden belief states by contextualizing relevant information. The hippocampus (HC) is also implicated in this process by representing a cognitive map, a structural organization of relational information, of the current task environment. Given their strong anatomical and functional connections, OFC and HC likely work together to drive inferential learning and decision-making behavior. However, the neural mechanisms of these processes remain unknown. Here, we trained two male monkeys (*Macaca mulatta*, 6.5 years old, 10.5 and 10.1 kg) on a probabilistic reversal learning task where state inference is required for optimal performance. We analyzed the effect of reward history and task state on subsequent choice behavior, and observed that subjects inferred hidden states to rapidly flip choice preferences at reversal points, even for unexperienced contingencies. This pattern of behavior evolved over time. Early in training, choices were largely influenced by reward history alone. After several training sessions, subjects were able to detect and adapt to state changes, informing decisions on trials where reward contingencies had not yet been directly experienced. These results suggest that subjects acquired a working knowledge of task structure; a cognitive map. Currently, we are simultaneously recording neuronal activity from OFC and HC to investigate how this cognitive map is represented and exploited for behavioral inference.

Title: Circular reasoning: circHomer1 is a molecular modulator of cortical synchrony during visual reversal learning via Homer1b synaptic localization.

Authors: *A. ZIMMERMAN, A. HAFEZ, N. MELLIOS, J. BRIGMAN;
Neurosciences, Univ. of New Mexico HSC, Albuquerque, NM

Abstract: Circular RNAs (circRNAs) are an emerging class of long non-coding RNAs with complex regulatory potential. Some have been shown to impact gene expression and function by sponging microRNAs or RNA binding proteins, while others affect transcription and alternative splicing. However, the vast majority of circRNAs have not been characterized and little is known about their function in the brain despite their abundance in cortical tissue. Recent work has focused on circRNAs as biomarkers for disease and therapeutics due to their increased stability over linear RNA since their biogenesis through backsplicing renders them resistant to exonuclease-mediated RNA degradation. CircRNAs have recently been shown to accumulate in the brain with aging and to be differentially regulated in neurodegenerative and psychiatric disorders including Alzheimer's Disease (AD) and schizophrenia (SCZ). While plasticity-related protein-coding genes have been associated with cognitive dysfunction in these disorders, little is known about the potential for circRNAs in regulating synaptic activity and cognitive ability. A recent paper identified *circHomer1* as a candidate molecule in AD in its correlation with duration and severity of illness. The linear transcript of *Homer1* produces multiple proteins involved in synaptic function and has been implicated in psychiatric disorders including SCZ and major depression. We have previously shown that *circHomer1* is reduced in postmortem orbitofrontal cortex (OFC) samples from patients with SCZ and bipolar disorder (BD) and have shown that reduction of *circHomer1* in rodent OFC is sufficient to produce an OFC-dependent behavioral deficit on a touchscreen visual reversal task. Further, expression level of *circHomer1* is inversely correlated with reversal behavior in a trial type-dependent manner. Our current work demonstrates *circHomer1* is capable of controlling other molecular correlates of behavior including the synaptic localization of *Homer1* linear isoforms, *Homer1a* and *b*. We use long-term *in vivo* electrophysiological recordings from bilateral depth microelectrodes during visual discrimination and reversal learning in twenty adult male C57BL/6J mice to examine changes in excitatory neuronal activity that underlie OFC dysfunction following loss of *circHomer1*. Our results indicate changes in OFC local field activity during impaired reversal stages that closely correlate with those seen in human patients with SCZ. This work is the first to demonstrate a psychiatric-related circRNA is capable of modulating synaptic regulatory processes involved in learning as well as neuronal activity underlying cognitive impairment.

Title: Economic decisions under simultaneous or sequential offers rely on the same neural circuit

Authors: *W. SHI, C. PADOA-SCHIOPPA, S. BALLESTA;
Washington Univ. in St. Louis, St. Louis, MO

Abstract: Economic choices involve assigning values to each option; a decision is then made by comparing values. In a series of studies, monkeys chose between two juices offered in variable amounts. Analyses of spiking activity in orbitofrontal cortex (OFC) revealed that different groups of neurons encode the value of individual options (*offer value*), the binary choice outcome (*chosen juice*) and the *chosen value*. These variables capture both the input and the output of the choice process, suggesting that these groups of cells constitute the building blocks of a decision circuit. A series of experimental and theoretical results support this hypothesis (Padoa-Schioppa and Conen, 2017). Importantly, current notions emerge almost exclusively from studies in which two offers were presented simultaneously. Yet, in most daily circumstances, options available for choice appear or are examined in sequence. Thus an open question is whether choices under sequential or simultaneous offers take place in the same neural circuit. Thus in a recent study we let monkeys choose between different juices offered sequentially. (Ballesta and Padoa-Schioppa, 2019). An analysis of OFC responses across time windows revealed the presence of different cell groups seemingly analogous to those previously found under simultaneous offers. In particular, different groups of neurons encoded individual offer values, the juice identity or the chosen value, with positive or negative slope. The present study was designed to assess whether the cell groups identified in the two choice modalities - under simultaneous or sequential offers - may be identified with each other. Two monkeys chose between different juices offered in variable amounts, and trials with the two task modalities were pseudo-randomly interleaved. We recorded the activity of 1526 from central OFC. Trials from the two choice modalities were analyzed separately, and each neuron was classified in relation to each task using the procedures developed in previous studies. The results obtained for the population were then combined in a 9x9 contingency table (4 variables x 2 signs + untuned cells), which we examined using analyses for categorical data. The correspondence between the two classifications was remarkable. Coincident classification was captured by diagonal entries. We found that 8 of 9 diagonal entries were significantly above chance ($p<0.001$; Fisher's exact test); conversely 70/72 off-diagonal entries were at or significantly below chance ($p<0.001$;

Fisher's exact test). These results indicate that economic decisions under sequential or simultaneous offers rely on the same neural circuit.

Title: The medial orbitofrontal cortex modulates of evoked spiking in nucleus accumbens in an age-dependent manner

Authors: *M. K. LOH, J. A. ROSENKRANZ;
Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. & Sci., North Chicago, IL

Abstract: Appropriate decision-making is evolutionarily important for survival, but is immature in adolescents, who characteristically are risk-takers and reward-centric. The circuits that underlie age-dependent differences in decision-making are not well understood but can further our understanding of high-risk behaviors. The nucleus accumbens (NAc) integrates excitatory inputs from both cortical and limbic structures, which are communicated to downstream motor regions. As inputs from cortical and limbic structures carry goal- and reward-related information, the summation of these signals at the level of the NAc likely combines information about rewards and risks to direct decision-making. Prior experiments suggest that medial orbitofrontal cortex (MO) to NAc inputs are key in integrating risk-based information, as MO-NAc interactions permit risk assessment behaviors. Along these lines, adolescents do not exhibit risk assessment behaviors as frequently as adults, suggesting that MO to NAc inputs may drive age-dependent risk-assessment differences. Here, we used single-unit electrophysiology to identify how MO stimulation modifies reward-seeking pathways, specifically the basolateral amygdala (BLA)-NAc circuit, in both adult and adolescent rats. We hypothesized that MO stimulation diminishes BLA-NAc interactions and that the effect is more robust in adults than in adolescents. We delivered single pulses at increasing interstimulus intervals or frequency-varying trains to the MO and recorded MO's effect on BLA-evoked NAc spike latency and probability. While single-pulse MO stimulation did not affect the strength of BLA-NAc interactions, MO stimulation reduced BLA-evoked NAc spike latencies in both ages. Further, MO train stimulation produced frequency-dependent effect on BLA-evoked NAc spike probability in adults. MO train stimulation delivered at 10 Hz facilitated BLA-evoked NAc spike probability but diminished the interactions at 40 and 60 Hz. These opposing effects by various MO train stimulation frequencies may reflect biases in optimal decision-making, where a subject is inclined towards large-reward/high risk or small-reward/low-risk choices based on previous outcomes and overall long-term benefit. Unlike adults, the adolescent MO failed to produce the bimodal effects on BLA-NAc interactions; MO train stimulation diminished BLA-NAc spiking at all tested frequencies. These results may reflect adolescent suboptimal decision-making. While the adult MO can

regulate the strength of reward-related circuits, the adolescent MO is unable to produce the same bimodal effect to perhaps appropriately guide decision-making.

Title: Subjective Experience and Recruitment of Orbitofrontal Cortex Cell Types during Decision-making

Authors: *C. CAZARES, D. C. SCHREINER, C. M. GREMEL;
UCSD, La Jolla, CA

Abstract: Subjective experience is inherently necessary for adaptive decision-making. However, how subjective experience affects decision-making computations and their neural correlates is not clear. One candidate region is the orbitofrontal cortex (OFC) as it is implicated in decision-making based on prior subjective experience, but little is known about how these computations are instantiated by specific populations in OFC or what influence prior subjective experience may have on that activity. Here, we used an action differentiation task in which mice learn to hold down a lever-press for a minimum duration for food. Our task is self-paced and uncued, such that prior self-initiated actions and their associated consequences provide crucial feedback for future successful performance. Using a linear mixed-effects (LME) modeling approach, we found that current lever press duration depends on prior subjective experience, including a recent and a longer history of past press durations, time passed, and reward checking. Using a genetically engineered caspase-3 Cre-dependent virus to lesion OFC projection neurons in vivo, we found that OFC lesions disrupt the contribution of prior subjective experience to the current lever press. To examine OFC activity during decision-making based on subjective experience, we used virally mediated, genetically encoded fluorescent calcium indicators as proxies for neuronal activity. Activity correlates during action differentiation contrasted between genetically identified OFC populations; for example, excitatory projections decreased, and inhibitory interneurons increased, their calcium activity as animals held down the lever. To investigate whether OFC activity reflects or relies on prior subjective experience, we used LMEs to predict calcium activity across decision-making epochs. Preliminary analyses revealed a predictive relationship between prior subjective experience and population activity correlates in excitatory

projection neurons. Overall, our results suggest that OFC populations have a distinct role in executing decision-making actions that use prior subjective experience.

Title: Sex differences in preference for uncertainty following chronic chemogenetic excitation of dopamine neurons in the substantia nigra

Authors: *B. RUSSELL, M. TREMBLAY, M. SILVEIRA, K. HRELJA, T. HYNES, C. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Parkinson's disease (PD) is characterized by a loss of dopamine neurons in the substantia nigra (SNc) that project to the dorsal striatum, resulting in the hallmark motor symptoms of PD. Dopamine replacement therapies (DRTs) are able to treat these motor symptoms, but they also cause impulse control disorders (ICDs) and gambling disorder in a significant minority of patients. The "overdose" hypothesis suggests that DRTs replenish the lost dopamine in the deteriorated dorsal striatum, producing an improvement in motor symptoms. Meanwhile, the spared mesolimbic reward system is inundated with dopamine, resulting in the development of ICDs or gambling disorder. However, recent studies suggest that the nigrostriatal, rather than the mesolimbic, pathway is involved in the development of gambling disorder. We therefore chronically activated the nigrostriatal pathway by using designer receptors exclusively activated by designer drugs (DREADDS) and measured preference for uncertainty with the rodent Betting Task (rBT), which we have previously shown to be a valid approximation for gambling disorder. The rBT begins with the wager size at play being indicated by the number of holes illuminated at the back of the chamber, corresponding to the number of sugar pellets that can be won. Once the rat nose-pokes in each illuminated hole to extinguish the light, two levers extend, allowing the rat to select either the uncertain lever that delivers double the wager size or nothing at 50:50 odds or the safe lever that guarantees the delivery of the wager size at play. In our first experiment, the excitatory adeno-associated virus AAV-hSyn-DIO-hM3D(Gq)-mCherry was infused into the SNc of 32 female transgenic Long Evans rats (16 TH:cre positive, 16 TH:cre negative). Once trained on the rBT, the rats were administered 1 mg/kg of clozapine N-oxide via intraperitoneal injection twice daily, once 30 minutes prior to rBT testing and again at least 7 hours after the first injection to reflect the chronic administration of DRTs. After 4 weeks, activation of the dopamine neurons in the SNc increased preference for uncertainty on the rBT in wager-sensitive female rats, mimicking the effect of the DRT

ropinirole on the rBT. Following the same procedure, we repeated this experiment with 32 male rats (16 TH:cre positive, 16 TH:cre negative), and there was no significant effect on decision making after 4 weeks of chronically activating the SNc. The findings from these studies suggest that the nigrostriatal pathway may contribute to the development of both iatrogenic and idiopathic gambling disorder in females. The activation of this pathway may also underlie the development of DRT-induced ICDs as well.

Title: Distinct temporal difference error signals in dopamine axons in three regions of the striatum in a decision-making task

Authors: *I. TSUTSUI-KIMURA[1], H. MATSUMOTO[1,2], K. AKITI[1], M. YAMADA[1], N. UCHIDA[1], M. WATABE-UCHIDA[1];

Abstract: It has been postulated that dopamine neurons send reward prediction error (RPE) signals to their target areas to learn reward predictions and to reinforce actions. However, how different brain areas, which have distinct functions, learn from dopamine signals is not fully understood. Here we compared dopamine axon Ca^{2+} activities in the ventral, dorsomedial and dorsolateral parts of the striatum (VS, DMS, and DLS, respectively), while mice performed in a decision task. Specifically, mice were trained in an odor discrimination task with odor mixtures while the reward amounts were biased between the left and right reward ports (BIG side, big or medium rewards; SMALL side, medium or small reward; one of the two sizes was chosen randomly each trial). We found that dopamine axon activities in all three areas were modulated by the amount of received reward as well as the expected reward size both at the onset of cue (big reward predicting cue vs. small reward predicting cue, $p=5.0\times10^{-6}$, t-test, n=22) and reward (big vs. medium water with expectation big, $p=1.2\times10^{-11}$; and medium vs. small water with expectation small, $p=3.8\times10^{-9}$; and medium water with expectation big vs. expectation small, $p=3.9\times10^{-4}$, t-test, n=22), consistent with RPE. However, the overall activity level of reward responses was different between the three regions (p=0.002, ANOVA, n=9, 7, and 6 for VS,

DMS, and DLS). Specifically, reward responses in DLS was positively shifted (VS vs. DLS, p=0.005, t-test, n=9 and 6, respectively); the axonal activity was not inhibited even when the outcome was worse than expected although it was still modulated by reward amounts and expectation. The lack of inhibitory signals in DLS suggests diminished weakening of reward prediction or reinforced actions. On the other hand, reward responses in DMS were shifted negatively (DMS vs. DLS, p=0.003, t-test, n=7, 6, respectively), resulting in large negative dopamine signals even when the outcome was only slightly worse than expected. This suggests a relatively greater sensitivity of DMS to negative RPEs, and a greater requirement to re-learn reward prediction or rewarding actions. These biased dopamine RPE responses provide specific constraints on the behaviors learned through dopamine-mediated reinforcement in these striatal regions.

Title: Neuronal responses track transition evidence in the rat dorsomedial striatum

Authors: *D. DUQUE[1], A. HERMOSO-MENDIZABAL[1], A. HYAFIL[2], L. BEKTIC[1], M. MOLANO-MAZON[1], J. DE LA ROCHA[1];
[1]IDIBAPS, Barcelona, Spain; [2]CRM, Barcelona, Spain

Abstract: To make an adequate perceptual decision, animals need to evaluate not only the current sensory information but also past experiences; indeed, rats performing a perceptual categorization task develop different history choice biases such as the win-stay, the lose-switch, and the transition bias -a tendency to repeat or alternate the previous response (Hermoso-Mendizabal et al., 2020). Previous reports have suggested ventro- and dorso-lateral striatum may be involved in lose-switch responses (Skelin et al., 2014; Thapa et al., 2018), while dorsomedial striatum (DMS) has been shown to encode reward prediction error (Roesch et al., 2009; Stalnaker et al., 2012) and being related with win-stay dynamics (Sakamoto and Okaichi 2001). However, little is known about the possibility that DMS encodes more complex rules such as the transition bias. To investigate if DMS is able to keep track of the sequence of transitions, we first built a theoretical model with a linear-exponential filtering of past transitions. We used this model to obtain an objective measure of the transition evidence (zT), which then will be

correlated with neuronal activity. Next, we recorded from 840 neurons in the DMS of 5 rats while they were performing an auditory two-alternative forced-choice (2AFC) categorization task. As the probability of having the reward on the same side as the previous trial was adjusted to generate serial correlations, the resulting repetitive and alternating blocks could guide the responses of the rats according to the variable zT. We found that most DMS neurons carried task relevant information such as previous choices and outcomes. Moreover, roughly 20% of the neurons recorded in DMS were encoding for the variable zT, thus keeping track of the transition bias. Preliminary data suggests that the activity of these zT neurons -in combination with that of choice neurons- is correlated with animals' choices on a trial-by-trial basis. Finally, to determine if DMS has a causal role encoding the transition bias, we performed bilateral lesions with ibotenic acid to permanently inactivate DMS (n=6). Such inactivation significantly diminished the transition bias, suggesting a key role of DMS in the generation and maintenance of complex expectation biases. Our results suggest that DMS has the capability to encode complex transitions that go beyond the classical model-free reward prediction errors neurons, which only allow for the generation of first-order biases such as the win-stay. Our experiments suggest that DMS has a crucial role in the computation and generation of expectation biases and the potential capability of coding for abstract sequential rules.

Title: Neural correlates of explore-exploit decision-making in alcohol use disorder

Authors: *E. M. CAMPBELL[1], V. D. COSTA[2], J. F. CAVANAGH[1], G. SINGH[1], J. HOGEVEEN[1];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Dept. of Behavioral Neurosci., Costa Lab., Beaverton, OR

Abstract: One crucial component of pathological decision-making in addiction is the explore-exploit tradeoff, wherein individuals choose between exploring options with uncertain outcomes or exploiting options with familiar outcomes. The multi-armed bandit task captures this tradeoff and can dynamically model behavior in response to changing stimulus probabilities. A small number of studies have assayed explore-exploit processes as a potential marker of pathological decision processes in individuals with addiction, but few studies have used drug cues and none have measured task-related neural activity. The present study aims to elucidate neural correlates of disordered decision-making in AUD through EEG recording during bandit task performance.

Individuals with AUD (n = 28) and healthy age and gender-matched controls (n = 16 , data collection ongoing) completed a three-armed bandit task with images of alcoholic beverages and non-alcoholic beverages. The task presents three stimuli for participants to choose from that have particular probabilities of yielding a reward (a display of a green '+1' or a red '~'). A novel stimulus replaces one of these stimuli every 5 to 9 trials with a new reward probability. When individuals continue to choose particular stimuli despite the introduction of new stimuli, they're using an exploit strategy. When individuals choose the novel option in order to earn potentially greater reward, they're using an explore strategy. The BONUS value is a computationally derived parameter which reflects trial-to-trial changes in explore behavior and preliminary results show that it is augmented for alcohol cues in AUD when compared to controls, $t(17)=-2.514$, $p=0.022$. Preliminary time-frequency analysis shows that theta band activity in the frontal cortex scales with surveyed AUD severity when contrasting novel and best choices for alcohol cues, $F(1,16)=4.39$, $p=0.052$. Once data collection of controls has finished, separate multiple linear regression analyses will be used to assess the relationship between frontal theta activity, the P3a component, and computational predictors of explore-exploit behavior between AUD and healthy controls. Both neural responses could reflect an increased recruitment of frontal cortex while making dynamic decisions in response to alcohol imagery. These findings could contribute to the development of biomarkers for AUD that are sensitive to treatment-induced change. Moreover, measurement of EEG response in the present study will lead to a better understanding of the brain dynamics that underlie fundamental cognitive processes and how they're altered in substance use pathology.

Title: A causal role for the dorsal striatum in task-adaptive expectation-based choice biases

Authors: C. SINDREU, Y. FUENTEALBA, R. MARIN, L. JIMENEZ, D. DUQUE, ***J. DE LA ROCHA**;
IDIBAPS, Barcelona, Spain

Abstract: Learned expectations can influence perceptual decisions, but the underlying neural mechanisms have yet to be specified. To promote the use of expectations in adult male rats, we used a two-alternative auditory discrimination task with serial correlations in the stimulus sequence in the form of repeating and alternating trial blocks. Recent work showed that rats

leverage on these correlations to estimate the probability that the previous rewarded side is repeated and bias their choices accordingly, particularly when stimulus evidence is equivocal. A generative model that summed up the stimulus evidence, and the outcome-dependent running estimate of the first- and second-order statistics of the sequence was able to accurately predict such flexible behavior. One brain region that may support the repeating bias is the associative striatum (i.e. dorso-medial division; DMS), as it encodes the value of the different options. However, interventions with high-temporal (millisecond) resolution and a trial-by-trial estimate of the different biases are both required to disentangle to roles of the DMS in expectation-guided choices. Thus, we virally expressed the chloride-conducting opsin stGtACR2 in striatal projection neurons, and implanted fiberoptic cannulae to inhibit their somata. Unilateral illumination during the whole trial generated a strong ipsilateral bias, confirming the role of the DMS in choice selection and the effectiveness of the method. We then hypothesized that silencing the DMS during the inter-trial interval (ITI), i.e. just before stimulus onset, would ablate the repetition bias. We obtained a real-time estimate of the repeating bias and used it to perform closed-loop DMS inhibition while rats performed the task. Bilateral photostimulation occurred in half the trials with a high bias (15% of total trials). Light-on trials showed reduced repetition bias compared with light-off trials, as evidenced by a marked decrease in the separation of the psychometric curves obtained in each of the blocks; no such effect was observed in controls. Moreover, the impact of ITI inhibition on performance depended on the congruency of the trial with the stimulus sequence. We conclude that the dorsal striatum is important to maintain expectation priors that inform perceptual decisions.

Title: Orbitofrontal-accumbens pathway mediates choice behavior guided by an aversive taste memory

Authors: *A. PEÑAS-RINCÓN, L. RAMÍREZ-LUGO, A. MINGUER-URIBE, F. SOTRES-BAYÓN;
Inst. de Fisiología Celular, Mexico City, Mexico

Abstract: The ability to choose what to ingest based on previous experiences is critical for survival. Although much is known about the brain mechanisms that underlie associations with

aversive taste stimuli, little is known about how these stored associations guide choice behavior. By testing aversive memory retrieval during choice versus no-choice conditioned taste aversion (CTA), we previously showed that activity in the lateral orbitofrontal cortex (lOFC) is recruited and necessary during choice behavior guided by an aversive taste memory (Ramirez-Lugo et al., 2016). But which brain structure(s) use(s) such lOFC-mediated choice information to select the appropriate action to execute? The striatum, a brain structure involved in the execution of selected actions, receives strong projections from OFC. Here, we combined immunohistochemical and pharmacological tools with taste-guided tasks to investigate the role of the striatum and its functional connectivity with OFC during choice behavior. c-Fos immunolabeling revealed that ventral, but not dorsal, striatum activity increased in choice CTA compared to no-choice CTA. Interestingly, within the ventral striatum, we identified specific coordinates in the rostro-caudal axis of the nucleus accumbens (NAc) that were highly recruited during choice CTA, compared to no-choice CTA. We used these coordinates to target pharmacological inactivations to determine whether core and shell regions of the NAc were necessary for choice behavior guided by an aversive memory. We found that core, but not shell, inactivations affected choice CTA, as compared to no-choice CTA. Consistent with the notion of opposing roles of NAc along the rostro-caudal axis in motivated behaviors, we found that rostral core inactivations impaired choice CTA, whereas caudal core inactivations facilitated it, as compared to no-choice CTA. Finally, using a pharmacological disconnection strategy, we found that contralateral, but not ipsilateral, inactivations of lOFC and rostral (but not caudal) core impaired choice CTA in contrast to no-choice CTA. Together, our findings reveal that connectivity between lOFC and the rostral region of the NAc core is crucial for animals to make the appropriate decision guided by a previous aversive taste experience.

Title: Reward resonance in amygdala-based circuits

Authors: ***J. K. MORROW**, V. D. COSTA;
Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: The ability to learn from trial and error feedback is dependent on the basolateral amygdala (BLA), ventral striatum (VS), and orbitofrontal cortex (OFC), but how information is communicated between populations of neurons in these interconnected regions is not well understood. Empirical and theoretical work has demonstrated that interactions between low and high frequency oscillations in local field potentials (LFPs), known as cross frequency coupling, may serve as a mechanism to facilitate information transfer between interconnected neuronal

networks by linking system wide inputs and outputs. In particular, coupling between the phase of theta oscillations and the power of gamma oscillations, a phenomenon known as phase-amplitude coupling (PAC), has been linked to a variety of biological functions. Here, we recorded LFPs from the BLA, VS, and OFC while monkeys performed a three-armed bandit task to determine whether PAC within and between these structures is modulated as a function of learning. Specifically, we examined how PAC values were modulated as a function of reward prediction errors (RPEs), a key reinforcement learning signal. In the BLA and VS, large portions of channels showed RPE-related modulation of LFP activity in the theta (5-9 Hz) and gamma (42-55 Hz) bands. Theta encoding in both structures peaked around 1250ms post-outcome (BLA: 97/295 channels, 33%, $p < .001$; VS: 86/291, 30%, $p < .001$). Gamma encoding in both structures peaked around 1100ms post-outcome (BLA: 83/295 channels, 28%, $p < .001$; VS: 63/291, 22%, $p < .001$). No clear peak in theta and gamma encoding in the OFC was present. We next looked at the relationship between the phase of theta oscillations and the power of gamma oscillations between pairs of electrodes that were lowered into the *same* brain region. We found that local PAC values were more robustly modulated by RPE in the BLA (121/295, 41%, $p < .001$) than in the VS (84/291, 29%; BLA > VS, $Z = 3.06$, $p = .0022$) or OFC (19/128, 15%; BLA > OFC, $Z = 5.23$, $p < .001$). We also found that interregional PAC was modulated as a function of RPE in the BLA_{gamma} <-> VS_{theta} (253/666, 38%) and BLA_{gamma} <-> OFC_{theta} (71/191, 37%) pathways. Both local and interregional modulation of PAC by RPE occurred long after the outcome of the trial had been delivered (~800-1100ms post-outcome). Lastly, we found that PAC of gamma power and theta phase was largest when the monkeys' experienced large negative prediction errors and smallest when they experienced positive prediction errors. In conclusion, we found that learning-related information was correlated with changes in local and interregional coupling of fast and slow oscillations in the BLA, VS, and OFC.

Abstract: The diverse temporal and oscillatory dynamics within anterior cingulate (ACC) cortical motor and limbic networks are linked to a wide range activity and behavioral states that function to coordinate and integrate affective and motor signals for flexible, goal-directed behavior. The biophysical and connectional properties of ACC pyramidal neurons that project to motor planning and emotional processing centers, such as the dorsal premotor cortex (PMd) and the amygdala (AMY), are fundamental building blocks of these network interactions. Here, we used a pyramidal-interneuron network model to simulate how single-cell properties can affect oscillatory synchrony in 4 networks consisting of distinct pools of AMY-targeting and PMd-targeting ACC pyramidal (E) neurons in layers 3 (L3) and 5 (L5). Each network included 2 functionally-distinct pools of perisomatic-targeting inhibitory interneurons -- parvalbumin (PV) and cholecystokinin (CCK). We varied the intrinsic membrane and excitatory/inhibitory synaptic properties of pyramidal neurons for each network, based on our empirical data derived from combined tract-tracing and *in vitro* whole-cell patch clamp recording experiments in rhesus monkeys. In all networks, the interplay between inhibitory and excitatory synaptic strength determines the synchrony and frequency of oscillations. The greater the conductance of excitatory recurrent connections, the greater inhibition needed to synchronize activity. Further, the greater the strength of PV to E inhibitory synapses, the more the network synchronizes to fast oscillations driven by high external input currents. Compared to the other networks, the L5 AMY-targeting network, with relatively greater CCK to E inhibition, exhibited oscillations more synchronized and resilient to noise at low input currents and frequencies in the theta-alpha range, consistent with the role of these frequencies in limbic affective and memory processing. This L5 AMY-targeting network can elicit high frequency gamma synchrony only if excitatory connections and CCK inputs to pyramidal neurons are suppressed, elucidating an important role of neuromodulation in shifting cortico-limbic oscillatory states. In contrast, the other ACC networks -with a greater PV to E synapses - are more synchronized at high beta-gamma frequencies, which is implicated in sensorimotor cortico-cortical processing. Our findings predict how single-cell and circuit-specific biophysical synaptic properties confer signaling diversity in ACC networks that control emotional and motor processing and have important implications for understanding mechanisms of flexible goal-directed behavior.

Title: The medial septum enhances strategy switching when cognitive demand is high

Authors: *D. M. BORTZ[1], A. A. GRACE[2];
[1]Neurosci., Univ. of Pittsburgh, pittsburgh, PA; [2]Neuroscience, Psychiatry, and Psychology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cognitive flexibility is the act of adjusting a current behavior or ongoing strategy (cognitive plan to achieve a goal) to account for changing environmental contingencies. Strategies that result in stable reward acquisition, and are repeated over time, eventually become outcome-insensitive. Because a decrease in outcome sensitivity will necessarily lead to a decrease in trial-by-trial flexibility, switching strategies becomes increasingly more difficult and requires more cognitive effort as repetitions increase. Furthermore, deficits in cognitive flexibility are significant in disorders that feature maladaptive habits and compulsions, such as addiction, OCD. Therefore, identifying the circuitry and mechanism that drives the increased cognitive effort required to adjust a well-learned behavior or strategy would both increase our understanding of cognitive flexibility circuitry and reveal novel drug targets to treat several psychiatric illnesses.
Previous studies have hinted at a role for the medial septum (MS), a sub region of the basal forebrain, in cognitive flexibility; however, the extent of this role is unclear. Because the basal forebrain is known to increase cognitive effort under demanding circumstances for other higher order cognitions, such as attention, we hypothesized that the MS may play a similar role in cognitive flexibility. To test this hypothesis, we activated the MS of male and female Sprague-Dawley rats with designer receptors exclusively activated by designer drugs (DREADDs) and measured their performance on an operant-based strategy switching task, following 1, 10, or 15 days of discrimination training. Rats that were tested following 1 day of training were similar across all groups and both sexes, demonstrating no effect of MS activation under these conditions. Following 10 days of training, however, MS activation significantly improved strategy switching, but only in female rats. In female rats, MS activation significantly reduced both the number of trials and number of errors to perform the strategy switch. Following 15 days of training, MS activation improved performance in both male and female rats, demonstrating both a significant reduction in trials and errors to perform the strategy switch. The difference in male and female performance may be explained by learning rate during training as female rats reached an average of >92% correct performance in significantly fewer days than males. As such, our data suggests that MS activation improves strategy switching performance as a function of level of training, suggesting that MS activation increases cognitive effort for strategy switching when cognitive demand is high.

Title: Distributed representation of value and state in reinforcement learning

Authors: *H. TANG[1], V. D. COSTA[2], R. BARTOLO[1], B. B. AVERBECK[1];
[1]NIMH/NIH, Bethesda, MD; [2]Dept. of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Beaverton, OR

Abstract: The amygdala (AMY), ventral striatum (VS), orbitofrontal cortex (OFC), and lateral prefrontal cortex (LPFC) are key brain regions in the neural circuitry that underlies reinforcement learning. Previous studies have shown that these areas all play roles in reinforcement learning. However, responses across these areas to the same task factors from the same task have not been compared previously. To compare how task factors are encoded across these regions, we recorded neural activity from 5 rhesus macaques as they performed a three-armed bandit reinforcement learning task. During the task, novel choice options with unknown values periodically replaced familiar options, and the monkeys had to explore them to choose the options with the highest value. We found that neurons recorded across these regions showed the highest response to visual stimulus and reward information. Spatial information, on the other hand, was only encoded in the LPFC regions. The values of choices were encoded across all regions, although less robustly than the other factors. We also found these regions have different coding properties for the same task factors. At the single-unit level, individual LPFC neurons tended to encode more factors simultaneously, but the effect sizes for each factor were smaller than the AMY, VS, and OFC neurons. However, at the population level, the LPFC regions carried more information than the other regions. Our results revealed the distributed representation of task factors and differences in coding properties among these brain regions relevant to reinforcement learning.

Title: Using neuromodulatory dynamics to arbitrate between distinct behavioral strategies

Authors: *A. MAH[1], Y. LI[2], C. CONSTANTINOPLE[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Peking Univ., Beijing, China

Abstract: A fundamental component of modern decision theories is “reference dependence," in which people evaluate outcomes as gains or losses relative to an internal reference point that likely reflects their expectations. When the reference point is high, an identical reward is viewed less favorably than when the reference point is low. We developed a novel task to study reference dependence in rats, using high-throughput behavioral training. In this task, water-restricted rats are offered a water reward to be delivered after a variable and unpredictable delay. They can either choose to wait or opt out at any time to start a new trial. On a proportion of trials, reward is withheld. The wait time on these trials provides an analog readout of the rat’s subjective value of that offer. By adapting rats to blocks of either the highest or lowest rewards, we can manipulate rats’ reference points. We find that rats wait significantly less time for mid-range offers in high blocks compared to low blocks, which is consistent with reference-dependent valuation. We developed several behavioral models that instantiate different strategies for computing the reference point, including one that uses model-free reinforcement learning, and another that is model-based in that it assumes knowledge of the latent block structure of the task. The models draw from optimal foraging theories, and estimate the trial-by-trial opportunity cost, or the cost of missing out on other potential offers by continuing to wait, in order to determine the optimal wait time on each trial. The models allow us to estimate latent cognitive variables driving behavior, including the reward prediction error (RPE), or the difference between expected and experienced rewards. In reinforcement learning, the RPE acts as a teaching signal; in our task, it is used to update the reference point, or the rat’s estimate of the opportunity cost of time. We used fiber photometry with fluorescent dopamine (DA) sensors in rats performing the task, and found that DA release in the nucleus accumbens core encodes the RPE several seconds after the cue that indicates the rat can receive its reward. Because our behavioral models made distinct predictions about the trial-by-trial RPE, we used these in vivo measurements of DA release to determine which strategy was most consistent with each individual rats’ neurobiological data. Here, we report rats’ strategies for computing an economic reference point, using measurements of neuromodulation to arbitrate between competing behavioral models. We view this as a promising avenue for performing model comparison of behavior in complex tasks.

Title: The effect of Re suppression on Vicarious Trial-and-Error events

Authors: *J. J. STOUT, Jr.[1], H. L. HALLOCK[2], A. L. GRIFFIN[3];
[1]Grad. Student, Newark, DE; [2]The Johns Hopkins Med. Campus, The Lieber Inst. for Brain Develop., Baltimore, MD; [3]Univ. Delaware, Newark, DE

Abstract: During decision making tasks, rats sometimes pause and look around their environment, as if they are contemplating a future choice. These behaviors are commonly referred to as vicarious trial-and-error (VTE) events and are hypothesized to be a behavioral manifestation of deliberation (Redish, 2016). Recent work suggests that medial prefrontal cortex (mPFC) ensemble activity may guide dorsal hippocampal (dHPC) representations of future information during VTE's (Hasz and Redish, 2020). In line with these results, it has recently been hypothesized that mPFC-dHPC interactions may directly inform VTE behavior (Redish, 2016). The nucleus reuniens (Re) is critical for mPFC and dHPC-dependent tasks, as well as mPFC-dHPC communication (Ito et al., 2015; Layfield et al., 2015; Hallock et al., 2016; Maisson et al., 2018). It is therefore possible that the Re is also implicated in deliberation, which would be reflected in VTE behavior. To this end, we analyzed VTE events in a previously-published dataset from our lab (Hallock et al., 2016). In this experiment, rats were trained to perform a spatial working memory T-maze task that required them to alternate between left and right trajectories at a choice-point, with each traversal being separated by 30 seconds. Male rats (n = 6) were implanted with cannulae targeting the Re and/or rhomboid nuclei (Rh). Each rat underwent 3 manipulations on separate sessions: a baseline day (no manipulation), a saline infusion day (manipulation control), and a muscimol infusion day (neuronal suppression). Per day, rats completed a set of baseline trials, underwent a manipulation, then performed a second set of trials 30 minutes later. Using IdPhi to identify VTE's (code from David Redish), we find that inactivating Re/Rh results in variable effects on VTE expression across rats, with 4/6 animals exhibiting a significant increase in IdPhi scores. By looking across trials, we further show that Re/Rh inactivation coincides with an increased chance of observing deliberative-like behaviors ($D = .44$, $p = 6.1e\text{-}09$, 2-sample KS-test). Thus, Re/Rh functionality is not critical for the behavioral manifestation of VTEs. Interestingly, however, we observed a negative correlation between the proportion of VTE's per session and choice accuracy ($R = -.58$, $p < .001$) that was entirely driven by muscimol sessions. Thus, Re/Rh inactivation resulted in poor choice accuracy and an increase in deliberative-like behavior. Moreover, we found that rats exhibiting perseverative dominant strategies during Re/Rh inactivation also exhibited consistent VTE's. These results may implicate the Re/Rh nuclei in the physiological 'content' associated with VTE events.

Title: Optimal prestimulus cortical state predicts response outcome in a selective detection task

Authors: *K. MARRERO[1], K. ARULJOTHI[2], C. GAO[3], B. ZAREIAN[2], Z. ZHANG[1], D. B. SALKOFF[2], E. ZAGHA[1,2];

Abstract: In the field of sensory detection, most studies focus on sensorimotor processing after a stimulus arrives (post-stimulus). However, the prestimulus neural activity can strongly alter stimulus encoding and behavioral outcomes. We sought to determine the impacts of prestimulus activity throughout neocortex on stimulus detection, for both target and distractor stimuli. We trained mice in a selective whisker detection task, in which they learned to respond to target stimuli in one whisker field and ignore distractor stimuli in the contralateral whisker field. During expert task performance, we used widefield Ca^{2+} imaging to assess prestimulus and post-stimulus neural activity broadly across frontal and parietal cortices. We find, indeed, that prestimulus activity strongly predicts trial outcome, with lower activity preceding response trials (hits and false alarms). Interestingly, the activity predictive of trial outcome does not localize to whisker regions but globally distributes throughout dorsal neocortex. The global activity is not reflected in whisker movement energy and therefore may reflect internal changes in task engagement. Using principal component analysis, we demonstrate that response trials are associated with a distinct and less variable prestimulus neural state. We interpret these findings as supporting an optimal prestimulus neural state for task performance that presents globally and affects responses to both target and distractor stimuli.

Title: Mixed representations in a visual-parietal-retrosplenial network for flexible navigation decisions

Authors: *S. KIRA[1], H. SAFAAI[1,2], A. MORCOS[1], G. PICA[2], S. PANZERI[2], C. D. HARVEY[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Istituto Italiano di Tecnologia, Rovereto, Italy

Abstract: The survival of many animals requires the ability to navigate to goal locations by making decisions based on sensory inputs and past experience. These navigation decisions arise from the flexibility to respond to the same sensory input with distinct motor outputs depending on recent memories. However, navigation decisions have often been studied in tasks that require a stereotyped motor output in response to a given sensory stimulus, precluding investigation into the flexibility of decision-making. Here, we studied which brain areas are essential for flexible navigation decisions and how their neural activity endows such flexibility.
We trained mice to perform a delayed match-to-sample task in a virtual reality T-maze. As a mouse ran through the maze, it sequentially observed two cues separated by a short delay (1-2 s). The mouse was required to combine the short-term memory of the first cue and visual information of the second cue to choose an appropriate turn direction at the T-intersection. For a given visual stimulus in the second cue, the mouse responded flexibly with a different turn direction based on the memory of the first cue.
We used an optogenetic screen to identify areas that are involved in flexible navigation decisions. We bilaterally inhibited different sites across the dorsal cortical surface by optogenetically activating inhibitory neurons in VGAT-ChR2 mice. Inhibition of V1, posterior parietal cortex, or retrosplenial cortex (RSC) induced a large decrease in task performance, suggesting that these areas were critical for mice to perform the task.
Two-photon calcium imaging revealed distributed representations of task-related events across areas. Notably, a large number of individual neurons were selectively active for a particular combination of the first cue's memory and the second cue's sensory signal. Such mixed representations encoded information about a correct choice direction in a format useful for guiding navigation, and appeared critical for accurate decision-making because they were prominent on correct trials but weak on error trials. The analysis of activity in populations of neurons revealed that these mixed selectivity neurons efficiently encoded a correct choice direction, compared to populations of neurons selective only to the first or second cue. Although mixed selectivity neurons were found across all areas studied, they existed most densely in RSC, and had a strong correlation with the mouse's choices. Together, we propose a mechanism for flexible navigation decisions based on mixing memory and visual signals primarily in RSC neurons to guide choices, within a visual-parietal-retrosplenial network.

Title: Ineffective affective processing: neural correlates of cognitive control in young urban women with a history of sexual violence

Authors: L. SINKO[1], P. REGIER[2], A. M. TEITELMAN[3], J. ELKIND[3], S. ARYAL[3], A. CURTIN[4], H. AYAZ[4,5,6,7], A. R. CHILDRESS[2];

Engineering, Sci. and Hlth. Systems, [5]Dept. of Psychology, Col. of Arts and Sci., [6]Drexel Solutions Inst., Drexel Univ., Philadelphia, PA; [7]Ctr. for Injury Res. and Prevention, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: MOTIVATION / PROBLEM STATEMENT: Women's experiences of sexual violence (SV) are not only often psychologically and physically traumatizing, but may also have lasting effects on brain functions, including cognitive control relating to the inhibition and processing of emotion. Despite this, few studies have explored underlying neural correlates of SV's impact on cognitive control in women. The purpose of this study was to understand cognitive control differences between women who have a history of SV vs. those who do not using functional near-infrared spectroscopy (fNIRS), a portable neuroimaging technology used to characterize inhibitory control at the level of the brain. We hypothesized that prior SV might be linked to poor inhibition, and to lower recruitment of cognitive control circuitry.
METHODS / APPROACH: Thirty women (ages 21-30) were recruited from an urban setting in the northeastern United States. Surveys assessed demographic and mental health characteristics including SV history (i.e. childhood and adult SV). All participants underwent an affect-congruent Go-NoGo task, using positively-valenced (baby animal) pictures as "Go" stimuli , and negatively-valenced (spiders, scorpions) pictures as NoGo stimuli, while prefrontal activity was monitored by 16 optodes via fNIRS. An ANOVA tested for main effects of the condition (Go vs. No-Go), group (SV vs. no prior SV), and potential interactions.
RESULTS: Fifteen of 30 women reported a history of childhood (n=6) and/or adult (n=12) SV. Those with SV histories reported higher levels of depression ($p<0.01$), anxiety ($p<0.01$), and posttraumatic stress ($p<0.01$) symptoms, as well as increased impulsivity ($p=0.02$). Behavioral performance (errors of commission) did not differ between the groups, however, fNIRS data revealed a significant (group x condition) interaction in optodes 13 ($p=0.001$) and 16 ($p = 0.008$). Women with a history of SV had significantly different cognitive control responses compared to their peers, with lower recruitment in the right dorsolateral prefrontal cortex (e.g., optodes 13, 16) during the "NoGo" condition, but heightened recruitment during the "Go" condition.
CONCLUSION / IMPLICATIONS: These results suggest altered prefrontal cortical activity during cognitive processing in women with a history of SV, showing hypoactivity in regions

important to response inhibition and hyperactivity to the positive/approach stimuli. These findings highlight a significant link between SV and critical brain functions, demonstrating a strong translational promise for innovative assessment and prevention of untoward effects (impaired affective processing) among women with SV.

Title: Investigating obesity-linked cortico-accumbal plasticity mechanisms underlying enhanced hedonic feeding

Authors: B. A. MATIKAINEN-ANKNEY, A. V. KRAVITZ;
Psychiatry, Washington Univ. in St. Louis, St Louis, MO

Abstract: Obesity is a leading cause of preventable death in this country. However, despite widespread knowledge of the prevalence and health disparities linked to chronic obesity, effective treatments remain elusive - most people who lose weight will re-gain it. Though prior research has often explored metabolic or energy adaptations to explain weight re-gain, this does not address the proven contribution of hedonic feeding mechanisms to weight re-gain after obesity. Human and rodent studies show that weight loss after obesity causes increased motivation to consume palatable foods, and that activity in brain areas involved in food motivation - namely the medial prefrontal cortex (mPFC) and the nucleus accumbens (NAc) - is altered with obesity. Yet the neural mechanism underlying enhanced motivation for palatable food following weight loss is unknown. Using in vivo fiber photometry recordings on a novel assay measuring motivation for palatable foods, our data shows that a subpopulation of NAc neuronal activity is enhanced following obesity and subsequent weight loss. We hypothesized this reflected increased input from mPFC to NAc, and used in vivo electrophysiology and optogenetic stimulation to reveal that long-term synaptic depression (LTD) was occluded in obese mice. This reveals a mechanism likely underlying sustained NAc activity during and after obesity and potentially leading to obesity-linked persistent increases in hedonic feeding. These

experiments may contribute to obesity treatments, potentially helping to hone current initiatives such as deep brain stimulation in the NAc.

Title: Optogenetic and pharmacological investigation of prelimbic cortex involvement in strategy set-shifting

Authors: *V. M. LO, D. A. BERCOVICI, S. B. FLORESCO;
Psychology, Univ. British Columbia, Vancouver, BC, Canada

Abstract: Behavioral flexibility is an adaptive behavior entailing altering actions in response to environmental changes. Strategy set-shifting is a form of flexibility where animals learn to use one rule to receive reward (e.g. select the lever denoted by a cue light) but after a switch in reward contingencies, a different strategy must be used (e.g always select the left/right lever for reward). Pharmacological inactivation studies have shown that set-shifting is facilitated in part by the prelimbic (PL) subregion of the medial prefrontal cortex (mPFC). Additionally, neurophysiological findings have shown that mPFC activity is correlated with different task events. However, it is unclear whether the PL is important for performing more than 1 rule shift and how phasic PL activity during discrete periods of the choice sequence contributes to flexibility. Here we used pharmacological inactivations to determine how PL is involved in multiple shifts between cue and response rules and optogenetic inhibition to address whether PL activity during cue presentation is important for set-shifting. In one study, rats were trained to learn an initial discrimination and then perform 3 rule-shifts within a session. PL inactivation early in training (~8 days) increased perseverative and non-perseverative errors made during rule shifts. Inactivation of PL after extended training (~30 days) resulted in perseveration of the previous rule. These results suggest PL is necessary to keep track of changing contingencies and remember which rules have already been performed in a given day. In contrast, PL inactivation did not impair shifting in rats trained for ~8 days to perform a single shift each day, suggesting that PL is not necessary when rats perform an easier task of 1 rule-shift per day. Finally, we used optogenetic suppression of neural activity in the PL to probe how phasic firing of PL neurons prior to choice influences the ability to perform 3 within-session set-shifts. During testing, PL neural activity was inhibited 3-5s prior to each choice trial. Compared to baseline, inhibition of pre-choice PL activity impaired performance when shifting from the response to cue rule but not from the cue to response rule, suggesting that PL activity prior to choice is important for flexibility when it involves a shift to a more attentionally demanding rule. Together, these

findings indicate that the PL does not play a role in mediating a single shift in well-trained animals but does play a role when task difficulty is increased, and rats must perform multiple shifts within a session. Furthermore, PL activity prior to action selection facilitates shifts under conditions where attentional demands are high.

Abstract: Within the frontal executive network, the anterior cingulate cortex (ACC) is a strategic hub for synthesizing and coordinating motivational and motor signals to guide flexible, goal-directed behavior. The dynamics of this cortical processing likely depend on the signaling properties of lamina-specific pyramidal neurons in the ACC that send coordinated output to dorsal premotor cortex (PMd) for motor planning and to emotional processing centers in the amygdala (AMY). We combined tract-tracing with *in vitro* whole-cell patch clamp recording in rhesus monkeys to assess the detailed biophysical and structural properties of neurons targeting AMY or PMd in ACC layers 3 (L3) and 5 (L5). Results demonstrate significant differences in the biophysical properties of ACC pyramidal neurons that are lamina and pathway specific (Two-way ANOVA with post-hoc comparisons, $p < 0.05$). Hence, pyramidal neurons targeting AMY in L5 are significantly more excitable, exhibiting higher input resistance and action potential (AP) firing rates, then those in L3. Further, pathway diversity was found specifically for L5 pyramidal neurons, with L5 AMY-targeting neurons exhibiting significantly less firing frequency adaptation, more complex apical dendritic tufts, and greater densities of dendritic spines and non-parvalbumin perisomatic inhibitory inputs than PMd-targeting neurons. Simulations using a pyramidal-interneuron network model predict that these differences in AMY versus PMd targeting neurons at the single-cell level contribute to distinct network temporal and

oscillatory dynamics. Compared to other simulated networks, the network model comprised of L5 AMY-targeting neurons is more robustly synchronized to slow theta/alpha frequencies, supporting the important role of these frequencies in affective and memory processing in limbic structures. In contrast, network models of L3 neurons and L5 neurons targeting PMd are more tuned to beta/gamma synchrony, which is implicated in perceptual motor decision making and cortico-cortical processing. Our data demonstrate the relevance of laminar location as strong predictors of cortical pathway functional diversity. The lamina-specific properties of ACC projection neurons directed to AMY and PMd enable diverse control of emotional and motor processing and provide the building blocks to understand the networks mediating motivational and affective aspects of flexible decision-making.

Title: Distribution of inhibitory synapses on amygdala targeting projection neurons in dorsal and ventral monkey anterior cingulate cortex

Authors: *A. KAPITONAVA[1], M. MEDALLA[2];
[1]Anat. & Neurobio. and Ctr. for Systems Neurosci., [2]Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: The anterior cingulate cortex (ACC) sends robust output to the amygdala (AMY) forming a key cortico-limbic pathway critical for regulating emotions and stress. The dorsal (area 24) and ventral (area 25) subdivisions of ACC are thought to have distinct roles in affective processing, likely conferred by the properties of lamina-specific AMY-targeting pyramidal neurons from these areas. Unique to the primate is the strong bilaminar origin patten of these ACC projections to the amygdala, with AMY-targeting pyramidal neurons located in both layers 3 (L3) and 5 (L5). Laminar location influences the extent and nature of excitatory and inhibitory inputs that these projection neurons receive, which, in turn, shapes signal integration and firing activity. The current study focuses on comparing the distribution of perisomatic and proximal dendritic inhibitory inputs onto AMY-targeting projection neurons in L3 and L5 of ACC areas 24 (A24) and 25 (A25) in rhesus monkey (*Macaca mulatta*). Using retrograde neuronal tract-tracing and high-resolution confocal imaging, tracer-labeled cell bodies and dendrites were reconstructed in 3D, and appositions with inhibitory nerve terminals immuno-labeled with

vesicular-GABAergic transporter (VGAT) were quantified. We found that the density and neurochemical nature of VGAT+ inhibitory inputs on AMY-targeting pyramidal neurons within each layer differed between the two ACC areas (Two-way ANOVA with post-hoc comparisons, $p < 0.05$). Both L3 and L5 AMY-targeting neurons in the dorsal A24 receive significantly more inhibitory inputs on somata and proximal dendritic compartments compared to those in A25. This regional difference was mainly due to a significantly lower density of inhibitory inputs from parvalbumin-expressing neurons that mediate strong and rapid inhibition on AMY-targeting neurons in ventral A25. Thus, compared to dorsal ACC A24, the projection neurons from the ventral A25 directed to the amygdala are subject to less inhibition. These findings may help explain the specific susceptibility of the ventral subgenual ACC to pathologic hyperexcitability, excitatory: inhibitory imbalance, and excitotoxicity associated with affective disorders such as depression.

Title: An fmri study on the encoding of political fake news

Authors: *B. L. GONZALEZ, Y.-W. CHEN, T. CANLI;
Psychology, State Univ. of New York at Stony Brook, Stony Brook, NY

Abstract: The concept of “fake news” has gained increasing attention in the past few years, but much is still unknown about the neural processes underlying the encoding of false news stories in the political context. We used functional magnetic resonance imaging (fMRI) to investigate the effect of congruency, when participants believed a political news statement was “real” or “fake” and were then shown a news label that was either congruent (i.e., matched) or incongruent with their beliefs. In this pilot study, human participants (N=14; mean age: 25.14; 57.14% female) were shown negative news statements in the form of a Twitter ‘tweet’ from two hypothetical political opponents in the scanner. Participants were asked to initially rate the news as probably real or fake, and then shown whether the news was in fact “real” or “fake”. They were asked to remember the news label given for an immediate memory task. After the scan session, participants completed a set of questionnaires to assess their political orientation, attitudes, and beliefs, and were then debriefed. Preliminary results suggest that participants recruit different areas of the brain depending on whether the news label was congruent with their initial judgement of the news statement compared to when the label and judgement were incongruent. This can be broken down even further into conditions when the news was judged as real and labeled as real, compared to when it was judged as fake and labeled as fake. Activation in these congruency conditions were found in areas such as the posterior cingulate, precuneus, supramarginal gyrus, and superior medial frontal cortex. These areas have been shown to be

implicated in cognitive processes such as decision confidence, emotional responses, and memory retrieval. Understanding how people process political fake news can lead to more insight on political cognition and decision-making. Bridging this gap between psychology, neuroscience, and political science can better help understand issues that are important to society but subject to partisanship.

Title: Dorsomedial frontal cortex participates in both evidence accumulation and trial history-based updating during perceptual decision-making

Authors: *T. Z. LUO[1], T. D. HANKS[2], D. GUPTA[1], A. G. BONDY[1], C. D. BRODY[1]; [1]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Univ. of California, Davis, Davis, CA

Abstract: When making a decision based on noisy sensory stimuli, integration over time mitigates the impact of noise and is therefore a core component of many types of decisions. In trial-based perceptual tasks, the decision process is learned and continually updated through the evaluation of actions in past trials and their outcomes. The neural mechanisms underlying evidence accumulation and the updating of the decision process by trial history remain poorly understood. It is unknown whether the same brain region that mediates evidence integration in expert observers is also involved in updating the process of choice formation. To identify a candidate brain region, we first examined whether changes in history-dependent updating can be detected after the pharmacological inactivation of five separate sensorimotor brain regions in rats accumulating noisy auditory evidence. Only the perturbation of dorsomedial frontal cortex (dmFC) resulted in both an impairment in behavioral sensitivity to the sensory stimulus and also a change in trial history-dependent updating. Chronic lesion of dmFC similarly changed both behavioral sensitivity and history-dependent updating. Three separate experiments indicate that dmFC is causally involved in the gradual accumulation of evidence. Recordings from Neuropixels probes indicate that the encoding of accumulated sensory evidence is more robust and emerges more rapidly in neural populations in dmFC than in four other anterior brain regions. Optogenetic inactivation of dmFC specifically during trial epochs when evidence was accumulated impaired behavioral sensitivity. Lastly, either optogenetic or chronic inactivation of dmFC resulted in an impaired representation of sensory evidence in anterior brain regions interconnected with dmFC. These results indicate the rat dorsomedial frontal cortex is a shared

node in the circuits that mediate the gradual accumulation of evidence and history-dependent updating and suggests that activity in dmFC encodes action values that are used for both choice formation and modification of subsequent decisions.

Title: Certainty and uncertainty of the future changes planning and sunk costs

Authors: ***A. A. DUIN**[1], L. AMAN[2], B. SCHMIDT[1], A. D. REDISH[1];
[1]Dept. Neurosci., [2]Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Many foraging experiments have found that subjects are suboptimal in foraging tasks, waiting out delays longer than they should given the reward structure of the environment. Additionally, theories of decision-making suggest that actions arise from interactions between multiple decision-making systems and that these systems should depend on the availability of information about the future. To explore suboptimal behavior on foraging tasks and how varying the amount of future information changed behavior, we ran rats (4M, 4F) on two matching neuroeconomic foraging tasks, Known Delay (KD) and Randomized Delay (RD), with the only difference between them being the certainty of the cost of future opportunities. On these tasks, rats foraged for food by encountering reward sites that provided the opportunity of reward after delay. On KD, delays remained constant at each individual reward site throughout the session; on RD, delays were random (1-30s) and were revealed on each encounter. We found that when rats were given knowledge of the future, they were able to plan their actions. The behavior of rats on the task providing known outcomes indicated that they understood the future offers before encountering them. Rats on both tasks exhibited suboptimal behavior, and when we explored hypotheses to explain these suboptimalities, we found that the rats more heavily accounted for pre-reward foraging times than post-reward lingering or traveling times. Additionally, we found that rats on both tasks showed a sensitivity to sunk costs; however, sunk cost susceptibility was diminished in the task enabling planning (KD). These results suggest that while future certainty reduced decision-making errors, more complex decision-making processes unaffected by future certainty were involved and likely produced these decision-making errors within subjects on these foraging tasks. These results led us to a hypothesis that there was an inverse relationship between planning and sunk costs. To test this hypothesis, we re-analyzed data in rats from a similar foraging task with medial prefrontal disruption (using h4MDi DREADDS) and found that

mPFC disruption, which has been previously shown to decrease planning, led to increased sunk cost behavior.

Title: Cognitive implications of brain structural connectivity alterations between nodes of the Default Mode Network related to cannabis use and HIV infection

Authors: ***P. M. VIERA PEREZ**[1], J. S. FLANNERY[1], R. GONZLEZ, Jr[2], A. R. LAIRD[3], M. T. SUTHERLAND[1];
[1]Cognitive Neurosci., [2]Psychology, [3]Physics, Florida Intl. Univ., Miami, FL

Abstract: The default mode network (DMN) is a large-scale functional brain network composed of brain regions that show greater activity in the absence of explicit task demands relative to when engaged in a task. Emerging evidence suggests that human immunodeficiency virus (HIV) infection and chronic cannabis use are both separately linked with alterations in DMN functional connectivity. People living with HIV (PLWH) infection often report using cannabis to alleviate HIV-related symptoms (e.g., pain, nausea, loss of appetite). Of the 38 million PLWH, nearly half demonstrate neurocognitive impairments highlighting a need to clarify the brain-based manifestations of such impairments. Using diffusion weighted imaging (DWI) data, we characterized the structural connectivity profiles of DMN regions among 100 participants stratified by HIV serostatus (+ vs. -) and cannabis use (+ vs. -). A deterministic fiber tractography algorithm was used to track cingulum tracts (CT), the fronto-occipital fasciculus (FOF), and the genu of the corpus callosum (CC). A general linear model was then used to compare the effects of both HIV and cannabis on tract length (mm) and tract volume (mm^3) averaged across all tracts of interest. A second general linear model analysis was used to characterize the effect of HIV and cannabis on cognitive control in the Error Awareness Task (EAT), a response-inhibition task in which participants make errors of which they are either aware or unaware. We detected a significant HIV x cannabis interaction when considering error awareness in the EAT, ($F(5,94)=1.5$, $p<.05$). However, we did not detect a significant interaction when considering the average tract length of all tracts ($F(3,96)=0.7$, $p=0.8$) or the average volume of all tracts ($F(3,96)=0.9$, $p=0.4$). These outcomes indicate that chronic cannabis use by PLWH was linked with a reduced ability to self-detect performance errors. A compromised ability to self-monitor one's errors may lead to the continuation of sub-optimal behaviors in the real-world (e.g., HIV-medication management). The null structural connectivity results suggest that consideration of individual tract analysis (as opposed to the average of multiple) is warranted.

Title: Cognitive fatigue induces changes in resting-state functional connectivity

Authors: ***S. IWAKI**[1,2], T. FUJIWARA[1,2];
[1]Natl. Inst. Adv Indust Sci. & Tech. (AIST), Tsukuba, Japan; [2]Univ. of Tsukuba, Tsukuba, Japan

Abstract: Sustained cognitive demands cause a decline of cognitive resources accompanied by subjective feeling of mental exhaustion, which is called "cognitive fatigue (CF)" (Pattyn, 2018). The purpose of this study is to elucidate the CF-related changes in brain state. The current study employs functional MRI to evaluate resting-state functional connectivity between brain regions to investigate changes in brain networks under CF. Eighteen young adults (22.8 ± 1.8 years of age, all right-handed) participated in the study which includes two days of lab visits, separated by more than a week. On each visit, the participants conducted two sessions of MRI data acquisition separated by either cognitive task sessions for fatigue loading (CF condition) or passive environmental video viewing sessions as control. The order of CF and control conditions was randomized between participants. The fatigue loading in the CF condition consisted of 4 sessions of 30-minutes continuous simple mental arithmetic task with 5 minutes of interval. MRI scans were conducted before and after the fatigue loading/control sessions, which include T1 structural scans and 12-minutes resting-state fMRI (rsfMRI) scans (TR=2,000 ms, TE=35 ms, FA=90 deg, 31 slices with 3.7 mm thickness) using 3 T scanner (Philips Ingenia 3.0T). CONN software (Whitfield-Gabrieli, 2012) was used to analyze the effective connectivity between brain regions. This study was approved by the internal review board of AIST. The flicker perception threshold (FPT) after the fatigue loading session in the CF condition decreased significantly compared to the FPT measured before the session ($p < 0.05$) while FPT did not changed significantly in the control condition. Results of the connectivity analysis of the rsfMRI data showed that (a) significant increase in effective connectivity between the posterior cingulate cortex (PCC), which is a part of the default mode network (DMN), and the bilateral inferior occipital gyrus (IOG), and (b) decrease in connectivity between the frontal eye field (FEF), one of the nodes included in the dorsal attention network (DAN), and the anterior cingulate cortex (ACC), in the CF condition compared to the control condition ($p<0.05$; FDR corrected). The current results indicate the changes in resting-state brain network after the CF loading which might reflect the difficulty in allocating attentional resources to specific task performance under CF (Esterman, 2013).

Title: Resting state functional connectivity networks associated with cognitive flexibility in rhesus monkey

Authors: ***T. SHNITKO**, C. KROENKE, K. GRANT;
Oregon Natl. Primate Res. Center, OHSU, Beaverton, OR

Abstract: Cognitive flexibility is an essential component of behavioral control related to variety of psychiatric disorders. In rhesus monkeys, cognitive flexibility shows individual differences in rates of task learning when assessed with a set-shifting procedure. This study used resting state functional connectivity (rsfcMRI) to identify brain regions associated with cognitive flexibility in monkeys. We hypothesized that the functional connectivity of brain regions involved in executive control network in human subjects will be predictive of learning a set-shifting task in rhesus monkeys. Rhesus monkeys (N=35, 18 females) were housed individually with computer-controlled touch-screens imbedded in their cage wall. The set-shifting procedure employed serial discriminations between two 2D stimuli (geometric shape and color) and included shape- or color-based discrimination and their reversals. Animals were given 30 sessions to assess rate of task acquisition, which resulted in distinguishing two groups with high (n=17) and low (n=18) learners using *k*-mean clustering. Animals with low learning rates had a higher perseverative response and short latencies to respond during task performance. rsfcMRI data were obtained in anaesthetized monkeys (1% isoflurane) prior to cognitive testing and resting state networks (RSNs) were identified using independent component analysis. The MRI data revealed 4 RSNs showing visual similarity to known RSNs identified in human and nonhuman primates. A dual regression analysis based on the high and low group-dependent differences was preformed using the 4 RSNs. The two groups of learners exhibited differences in functional connectivity related to one of the RSNs termed the Prefrontal-Orbitofrontal Network (PON), due to its overlap with brain regions included in the human executive control and default mode network. Functional connectivity of putamen, caudate, orbitofrontal and ventrolateral prefrontal cortices with the PON were stronger in the group of monkeys that exhibited high rates of learning. Higher levels of coactivation of caudate and putamen with the PON were predictive of low perseverative responding. Higher levels of coactivation of ventrolateral and ventromedial prefrontal cortex with the PON were predictive of greater response inhibition. Thus, connectivity within the PON that is involved in executive control over human cognition is also associated with the rhesus monkey's ability to learn a task that requires high levels of cognitive flexibility.

Title: Clustering of excitatory neurons and slow synaptic dynamics lead to longer autocorrelation timescales and slow ignitions in spiking networks

Authors: ***J. C. GAVENAS**[1], U. RUTISHAUSER[2,3], A. SCHURGER[1], U. MAOZ[1,3,4]; [1]Chapman Univ., Orange, CA; [2]Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Caltech, Pasadena, CA; [4]UCLA, Los Angeles, CA

Abstract: Spontaneous voluntary actions are canonically preceded by anticipatory signals that "ramp up" before the time of action, such as the canonical EEG Readiness Potential (RP), which begins around 0.5-1.5 seconds before movement (e.g. Libet et al., 1983). These anticipatory buildups also emerge when backwards-averaging an autocorrelated stochastic process (e.g. drift-diffusion) aligned to a threshold-crossing (Schurger et al., 2012). However, anticipatory ramping in single-neuron firing rates begins even earlier, up to 4 seconds before movement (Fried et al., 2011), even though the autocorrelation timescales of single neurons are only on the order of hundreds of milliseconds (e.g. Cavanagh et al., 2016)—far too short to explain such early ramp ups, if the underlying dynamics are those of a stochastic accumulator. In an exploratory study of a network of leaky integrate-and-fire neurons, we demonstrate 1) that clustering groups of excitatory neurons in a balanced network leads to slow fluctuations (Litwin-Kumar & Doiron, 2012), spontaneous ignitions (rate models: Moutard et al., 2015), and increased autocorrelation timescales in a critical range of clustering (in-between homogenous and WTA); 2) aligning to upswings in a cluster's firing rates results in exponential ramping in cluster firing rates, as well as a counter-intuitive negative ramping of post-synaptic potentials on excitatory neurons owing to overall increased inhibition; and 3) the dynamics and critical clustering range differ markedly for fast and slow synapses, with more gradual ramping present in networks with slower synapses. These results suggest the pre-movement buildups seen in voluntary action and possibly other spontaneous cognitive events (e.g. Broday-Dvir & Malach, 2020) are reliant on slow synaptic signaling (NMDA, GABA-B) and fluctuations in a clustered network architecture.

Title: Diverse cortical responses to claustrum perturbation

Authors: *E. G. MCBRIDE, S. R. GANDHI, J. R. KUYAT, A. ARKHIPOV, S. R. OLSEN, C. KOCH;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The claustrum is a small and thin structure between cortex and basal ganglia whose function remains elusive. It primarily receives inputs from cortical regions and projects back to most, in particular midline and frontal structures. Hypotheses of claustrum function include cortical coordination, salience detection, allocation of selective attention, and consciousness. A recent study demonstrated a feedforward inhibitory effect of claustrum on neurons in the medial prefrontal cortex of mice (Jackson et al. 2018), but it is unknown to what extent this generalizes across claustrum's many projection targets in the cortex.

To characterize the effect of claustrum activity on its projection targets across cortical areas, we employed the transgenic line Gnb4-IRES2-CreERT2;Ai32 to largely limit expression of opsin to the claustrum. Previous work at the Allen Institute characterized the Gnb4 driver line (Wang et al. 2017) and demonstrated single claustrum Gnb4+ neurons send axonal projections to a median of 21 cortical areas (Wang et al. 2019). In these mice, we implanted an optic fiber cannula above the claustrum and recorded with multiple Neuropixels probes across many cortical areas during optogenetic stimulation with both short (5ms) and long (500ms) pulses. Six female and four male mice aged 5-10 months were used for these experiments, though sex differences were not directly assessed.

We found, both within and across cortical areas, a diversity of responses including both inhibition and excitation following optical perturbation of claustrum. 500ms pulses elicited robust, largely excitatory responses, and the proportion of neurons recruited differed across cortical areas. In anterior cingulate cortex (ACA), more fast-spiking (FS; putative inhibitory) neurons were recruited than regular-spiking (RS; putative excitatory) neurons, which is consistent with the idea of a feedforward inhibition mechanism. However, in retrosplenial cortex (RSP), roughly equal proportions of RS and FS neurons were recruited, despite the fact that many Gnb4+ claustrum neurons project to both ACA and RSP. Single 5ms pulses elicited a mix of excitation and inhibition, though inhibition was not as potent or widespread as in the previous study (Jackson et al. 2018). The difference could be explained by a different method for opsin expression or the Neuropixels probes detecting and differentiating more neurons. Additionally, in some neurons we observe trial-trial variation of both the magnitude and the sign of responses to claustrum perturbation. Our findings thus far suggest that the effect of claustrum on its cortical projection targets is more complex than previously thought.

Title: Detecting consciousness in mice using perturbational complexity

Authors: *L. D. CLAAR, I. REMBADO, S. R. GANDHI, J. R. KUYAT, A. ARKHIPOV, S. R. OLSEN, C. KOCH;
Allen Inst., Seattle, WA

Abstract: Currently, the clinical evaluation of consciousness relies on a patient's ability to interact with the surrounding environment. However, under certain circumstances, such as in locked-in syndrome, during dissociative anesthesia, or after severe brain injury, a person can be conscious but disconnected from the external environment. In these situations, the current clinical practice fails to reliably access the level of consciousness of a patient.
To overcome this limitation Casali et al. (Casali, et al. 2013) developed a procedure that discriminated between the presence and absence of consciousness in human subjects. They used transcranial magnetic stimulation to evoke neural responses, measured using electroencephalography (EEG), and quantified the spatio-temporal complexity of the responses using a novel scalar measure called perturbational complexity index (PCI). They showed that a single threshold, PCI*, across subjects, discriminated with 100% specificity and 100% sensitivity conscious from unconscious states in a variety of subjects - wakefulness, sleep, anesthesia, neurological patients, etc. Although very promising, these results do not address the mechanisms underlying the differential complexity in different states of consciousness.
We aim to extend the technique to mice so we can use invasive tools to reveal the circuits and mechanisms underlying the change in PCI as it relates to presence or absence of consciousness. We record EEG-like activity using a flexible 30-electrode surface array on the skull and multiple Neuropixels (NPX) probes in cortical and subcortical areas. While the animal is awake and head-fixed on a wheel, we use a bipolar electrode in the secondary motor cortex to deliver a single, biphasic electrical pulse (100 trials) to evoke cortical responses recorded simultaneously by the EEG and NPX electrodes. The same procedure is repeated after inducing an anesthetized state.
During the awake state, we observe robust evoked responses in the EEG signals across many cortical regions. These responses are also reflected in the neural responses recorded on NPX probes up to 4 mm away from the stimulation site. During the anesthetized state, the responses in the EEG signals lack the spatial diversity seen in the awake responses, as expected based on the previous work. Our preliminary results show that we can discriminate between conscious and unconscious states by calculating PCI-st (Comolatti, et al. 2019) on the EEG evoked responses. With this work, we aim to investigate whether the complexity

differences are purely a cortico-cortical phenomenon or rely on cortical and subcortical, in particular, cortico-thalamic interactions.

Title: The role of maternal education on executive functions and attention system networks for school-age children

Authors: *P. B. GREENWOOD[1,2], E. SCOTT[2], J. DUDLEY[2], J. HUTTON[2], M. DIFRANCESCO[2], R. FARAH[3], T. HOROWITZ-KRAUS[4,2];
[1]Univ. of Cincinnati Col. of Med., Cincinnati, OH; [2]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [4]Educational Neuroimaging Ctr., [3]Technion Israel Inst. of Technol., Haifa, Israel

Abstract: Reading difficulties (RD, or dyslexia) affect 5-15% of school-age children with deficits in phonological processing, fluency, and executive functions (EFs). Children with RD have decreased abilities in EFs such as working memory, inhibition, and self-monitoring compared to typically developing readers (TRs). Although RD can be genetically inherited, many children have RD due to environmental variables with a lack of exposure to literacy materials and parental involvement during emergent literacy. Maternal education is a construct of socioeconomic status (SES) which has been shown to be a strong predictor of language development, reading acquisition, and educational outcomes for their children compared to household income and occupation. The goal of the current study was to relate maternal education to EFs and reading in children with RD compared to TRs using behavioral and neurobiological resting state fMRI data. The results show that higher maternal education is related to better EFs for children with RD and TRs. Additionally, higher maternal education is associated with decreased connectivity between attention system networks and regions related to visual word recognition and planning behaviors for children with RD greater than TRs (*P<0.05, FDR-corrected) . Our results suggest maternal education may have different roles in EFs for children with varying reading profiles. We conclude that higher maternal education may be associated with differences in the synchronization of attention system networks for better abilities related to reading for children with RD compared to TR's.

Title: Latent factor analysis of the neurocognitive assessments of executive function in the Addictions Neuroclinical Assessment battery.

Authors: *T. GUNAWAN[1], K. PARIDA[1], E. L. VOGT[1], B. MANOR[1], M. L. SCHWANDT[1], L. E. KWAKO[1], T. VINSON[1], Y. HORNEFFER[1], D. T. GEORGE[1], G. F. KOOB[1], N. DIAZGRANADOS[1], D. GOLDMAN[2], V. A. RAMCHANDANI[1];
[1]Natl. Inst. On Alcohol Abuse And Alcoholism, Bethesda, MD; [2]Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: RATIONALE: The Addictions Neuroclinical Assessment (ANA) is a clinical framework that encompasses three neurofunctional domains, executive function, incentive salience, and negative emotionality, that are hypothesized to underlie the etiology and heterogeneity of alcohol use disorder (AUD). The ANA battery consists of self-reports and neurocognitive assessments. The present report focuses on the characterization of the executive function domain of the ANA battery. **METHODS:** Participants (n = 251; 43% female) completed a series of questionnaires and neurocognitive behavioral tasks assessing the executive function domain of the ANA. Behavioral tasks consisted of the Digit Span Task - Backwards (DST-B), Continuous Performance Task (CPT), Paced Auditory Serial Addition Test (PASAT), Stop Signal Reaction Time Task (SSRT), Manikin Mental Rotation Task (MAN), Approach Avoidance Task (AAT), and the Trail Making Task (TMT). A three-factor model of Executive Function (Updating, Shifting, Inhibition) was used to fit the data using confirmatory factor analysis. Latent factors were then used to evaluate for associations with demographic variables, drinking-related outcomes, and the self-reported impulsivity measures (UPPS-P). **RESULTS:** The three-factor model provided excellent fit to the data (CFI = .99, TLI = .99, RMSEA = .01). Indicators of the Updating factor consisted of performance on the DST-B, CPT, and PASAT, Shifting was indicated by performance on the MAN, AAT, and TMT, and Inhibition was indicated performance on the SSRT. Age and race were associated with all three latent factors (p's < 0.005). Sex was associated with Inhibition (p = 0.04), but not Updating or Shifting. Current AUD diagnosis was negatively associated with Updating and Shifting (p's < 0.005), but not Inhibition. Updating and Inhibition, but not Shifting, were associated with number of heavy drinking days (p's < 0.05). Finally, self-reported sensation seeking was associated with all three latent factors (p's < 0.014). Positive urgency was associated with Updating and Shifting (p's < 0.002), but not Inhibition. Negative urgency, premeditation, and perseverance was not significantly associated with any of the latent factors. **CONCLUSIONS:** Latent factor structure of the neurocognitive tasks in the ANA battery is consistent with a three-factor model of

Executive Function. Associations between the three factors and demographic variables, alcohol-related outcomes, and self-reported impulsivity were found. Together with the Incentive Salience and Negative Emotionality domains, the ANA battery can provide a framework for an improved understanding of the neurobiology of addiction.

Title: Related Neural Networks Underlie Suppression of Emotion, Memory, Motor Processes as Identified by Data-Driven Analysis

Authors: *K. J. HUNT, L. KNIGHT, B. DEPUE;
Univ. of Louisville, Louisville, KY

Abstract: Goal-directed behavior benefits from self-regulation of cognitive and affective processes, such as emotional reactivity, memory retrieval, and prepotent motor response. Dysfunction in self-regulation is a common characteristic of many psychiatric disorders, such as PTSD and ADHD. This study sought to determine whether common neural regions are involved in the regulation of emotion, motor, and memory, and if a data-driven approach using independent components analysis (ICA) would successfully identify intrinsic connectivity networks (ICNs) that contribute to inhibitory regulation. Eighteen participants underwent neuroimaging while completing an emotion regulation (ER) task, a memory suppression (think/no-think; TNT) task, and a motor inhibition (stop signal; SS) task. In the ER task, participants were presented with negatively valenced pictures and instructed to either feel or inhibit their emotions. In the TNT task, participants received training to remember face-picture (cue-target) pairs. Participants were then presented with only the cue and told to either recall the picture or try to block its retrieval. In the SS task, participants were presented with either a stop- or go-signal and instructed to press a button only at the go-signal - not before the go-signal or at the stop-signal. ICA (CONN; MATLAB) was conducted on the neuroimaging data. Corresponding components were selected across task based on interrelated patterns of activation. Subsequently, ICNs were correlated with behavioral variables. ICA indicated a common medial prefrontal network, striatal network, and frontoparietal executive control network, as well as down-regulation in task-specific ROIs. These results illustrate that overlapping ICNs were exhibited across three distinct inhibitory regulation tasks as successfully identified through a data-driven approach (ICA).

Title: The effect of transcranial direct current stimulation of the pre-supplementary motor area on the imitation-inhibition task depends on the autism spectrum traits

Authors: ***N. MATSUDA**, M. O. ABE;
Grad. Sch. of Educ., Hokkaido Univ., Sapporo, Japan

Abstract: Adequate inhibition of automatic imitative tendencies is crucial in our daily lives. Many studies have investigated the neural mechanism of control over automatic imitation and suggested two brain networks as the neural basis of imitation control; one is the theory-of-mind (ToM) network, and the other is that of multiple-demand (MD) network. However, evidence supporting the MD network theory, with intervention to modulate network activity, is scarce. In addition, an individual difference in the engagement of the two networks has been little considered, which is one possible reason that the previous findings about the neural basis of imitation control were not consistent. Thus, we investigated the engagement of the MD network in imitation inhibition using transcranial direct current stimulation (tDCS). Twenty-four right-handed human subjects (20 men, mean age 21.44 ± 1.25 years) participated in the study. We employed a single-blind and within-subject study design. Each participant underwent all three conditions (anodal, cathodal, and sham stimulation) on different days in a randomized order, counterbalanced across participation. Transcranial direct current stimulation was applied to the pre-supplementary motor area (pre-SMA), which is a node of the MD network, at 2mA, for 15 min. Following the stimulation, participants performed the imitation-inhibition task, which required them to lift either their index or middle finger in response to a number cue presented on the screen. We analyzed only the trials where the number cue was “1” and the index required to be lifted, because of the apparatus’s accuracy of measurement. As a result, tDCS on the pre-SMA did not significantly affect the performance of the imitation-inhibition task. However, Pearson’s correlation analysis revealed a significant negative correlation between the Autism-Spectrum Quotient (AQ) score, which is a measure of autism spectrum traits, and reaction time (RT) on incongruent trials, which requires the inhibition of the automatic imitative tendency under the anodal condition ($r = -0.49$, $n = 24$, $p = 0.01$). The AQ score significantly correlated neither with RT on the other trials under the anodal condition nor with RT on incongruent trials under the other conditions. Assuming that people with higher autism spectrum traits tend to engage the pre-SMA in the imitation-inhibition task, the anodal tDCS in this study could enhance the ability to inhibit automatic imitation of the participants with such traits. Therefore, our findings suggest that the brain regions involved in the imitation-inhibition task differ depending on autism spectrum traits.

Title: Cortico-subcortical beta burst dynamics underlying action stopping in humans

Authors: ***D. A. DIESBURG**[1], J. D. W. GREENLEE[2], J. R. WESSEL[3];
[1]Psychological and Brain Sci., [2]Neurosurg., [3]Psychological and Brain Sciences/Neurology, Univ. of Iowa, Iowa City, IA

Abstract: Beta band activity in the neural field potential in both subcortical and cortical motor regions indexes net-inhibition of the motor system. This beta-band activity is typically studied as an average of many trials. However, recent work has demonstrated that motoric beta is in fact not a sustained but a transient, burst-like signal. During movement initiation and cancellation in tasks like the stop-signal task, these beta bursts reveal fine-grained dynamics that are lost when averaged over trials. During movement initiation, decreases in beta burst rates are observed over contralateral motor cortex. During movement cancellation, increases in bursting are observable over frontocentral regions, which are followed shortly by a surge in bursts over motor cortex (a purported signature of rapid re-instantiation of inhibition after a signal to cancel an action; Wessel 2020, *J Neurosci*). Furthermore, beta bursts are also known to exist in key subcortical motor regions such as the subthalamic nucleus (STN) and thalamus, but how these bursts relate to inhibitory processes and motor output is unclear. Here, we investigated the role of subcortical beta bursts during stopping, namely: a) whether bursts in the subcortex relate to movement cancellation, and b) how beta bursts in the subcortex influence burst rates, and thereby motor output, in the motor cortex. To address these aims, we collected a unique sample of data from surgical patients undergoing deep brain stimulator (DBS) implantation in the STN (N = 9), the ventral intermediate nucleus (VIM, N = 11) of the thalamus, or in both STN and VIM (N = 1). Patients completed an auditory stop-signal task peri-operatively while we recorded from bilateral DBS leads and subgaleal strips over primary motor cortices (M1). In the STN, we observed an increase in beta bursts within 100ms of the stop signal, which suggests beta bursts in the STN indeed relate to rapid deployment of motor inhibition during stopping. Moreover, our results seem to indicate this early deployment of inhibition in the STN produces downstream effects in M1. On average, bursts in STN following the stop signal were more likely to be followed within 25ms by a burst in M1. On the other hand, thalamic bursts were observed 25ms *after* M1 bursts

in stop trials, suggesting that the earliest stages of inhibition might not rely on the thalamus. Finally, we observed earlier beta bursting in STN than in VIM following stop signals in the overall sample and in a rare patient with implants in both regions, which supports existing network models of stopping and the theory that inhibitory control is ultimately accomplished via inhibition of motoric signaling in recurrent thalamocortical pathways.

Title: Precision mapping of the right inferior frontal cortex of human brains and its function for response inhibition at the single-subject level

Authors: *A. SUDA[1,2], T. OSADA[1], A. OGAWA[1], M. TANAKA[1], K. KAMAGATA[3], S. AOKI[3], N. HATTORI[2], S. KONISHI[1];

Abstract: The right inferior frontal cortex (IFC) is critical to response inhibition. The right IFC referred in the human studies of response inhibition is located in the posterior part of the inferior frontal gyrus and the surrounding regions, and consists of multiple areas that implement distinct functions. Recent studies using resting-state functional connectivity have parcellated the cerebral cortex and revealed across-subject variability of parcel-based cerebrocortical networks. However, how the right IFC of individual brains is functionally organized and what functional properties the IFC parcels possess regarding response inhibition remain elusive. In the present functional MRI study, precision functional mapping of individual human brains was adopted to the parcels in the right IFC to evaluate their functional properties related to response inhibition. Twenty right-handed subjects (10 men and 10 women, age: 26.6 ± 9.2 years (mean ± SD)) participated in the experiments. Based on group data of resting-state fMRI, six parcels were identified in the right IFC (vpIFC, dpIFC, IFJ, mIFC, vPCS, dPCS). Parcels in the right IFC of individual subjects were classified into the six “modules” or subsets of parcels, which were defined by the spatial pattern of the group-level parcel-cortex functional connectivity. The functional properties of each module were then evaluated in terms of the brain activation and its correlation with stop signal reaction time (SSRT) during the performance of the stop-signal task at the single-subject level. Each module revealed unique characteristics of brain activity and its correlation to behavior related to response inhibition. The brain activation was prominent in the parcels near the anterior bank of the precentral sulcus, the vpIFC module ($t(19) = 4.0$, $p < 0.001$,

one sample t-test), dpIFC module ($t(19) = 5.6$, $p < 0.001$, one sample t-test), IFJ module ($t(19) = 7.2$, $p < 0.001$, one sample t-test), and dPCS module ($t(19) = 7.8$, $p < 0.001$, one sample t-test). On the other hand, the correlation between the brain activity and SSRT was significant in the vpIFC module ($r = -0.53$, $p = 0.02$), mIFC module ($r = -0.49$, $p = 0.04$), and vPCS module ($r = -0.69$, $p = 0.004$). These results provide updated functional features of the IFC and demonstrate the importance of individual-focused approaches in studying response inhibition in the right IFC.

Title: The executive demand of response suppression is related to a preparatory hemodynamic response: Evidence from fTCD

Authors: ***B. TARI**[1], M. SHIRZAD[1], N. A. BADCOCK[2], G. R. BELFRY[1], K. SHOEMAKER[1], M. HEATH[1];
[1]Sch. of Kinesiology, Univ. of Western Ontario, London, ON, Canada; [2]Sch. of Psychological Sci., Univ. of Western Australia, Perth, Australia

Abstract: Executive function represents a constellation of higher order processes composed of three core components: inhibitory control, working memory and cognitive flexibility. Antisaccades are goal directed eye movements mirror-symmetrical to a presented target that engage all three components of executive function. Notably, antisaccades result in longer and more variable reaction times (RTs) than their prosaccade (i.e., saccade to target location) counterparts. These deficits in antisaccade planning and control are related to the executive demands of withholding a prepotent response (i.e., response suppression) and inverting a target's coordinates (i.e., vector inversion). Additionally, previous literature has demonstrated that antisaccades produce a larger hemodynamic response when compared to their prosaccade counterparts. It is however, unclear whether response suppression and/or vector inversion contribute to this hemodynamic effect. Here, Experiment 1 required participants (N=22) complete blocks of stimulus-driven (SD) prosaccades and antisaccades. In Experiment 2, the same participants performed blocks of SD and minimally delayed (MD) prosaccades. MD prosaccades require participants look toward a target only after target offset, and therefore require the same response suppression demands as those present during antisaccades. However, MD prosaccades are performed independent of the executive demand of vector inversion. During Experiments 1 and 2, blood flow velocity in the middle cerebral artery was measured via functional transcranial Doppler ultrasound (fTCD) in order to provide an estimate of cerebral

blood flow. Experiment 1 demonstrated that RTs for antisaccades were reliably longer than those of SD prosaccades ($p<0.001$); however, there was no reliable difference between their respective hemodynamic responses ($p=0.59$). Experiment 2 showed that MD prosaccades produced longer RTs ($p<0.001$), and a reliably larger hemodynamic response ($p=0.01$) than SD prosaccades. Accordingly, our results provide evidence that response suppression, independent of the executive demand of vector inversion, is related to a reliably larger hemodynamic response when compared to a non-executive task.

Title: A potential neural signature of impaired self-control pertinent to excessive asset trading: Low functional connectivity between dorsolateral and ventromedial prefrontal cortex

Authors: *J. L. HARACZ;
Indiana Univ., Bloomington, IN

Abstract: Objective: Neuroeconomic studies have begun to examine heuristics (i.e., simple rules that guide behavior while minimizing effort) and biases (i.e., systematic behavioral deviations from rational-choice models [Mobbs et al., 2018]). Haracz (2020) proposed that inadequate deliberation could bias traders toward simply using asset-price changes as guides, or heuristics, to popular or unpopular assets, thereby letting investors fall under the spell of a bubble or crash bias, respectively. These biases may promote trend-following investment strategies that yield price bubbles and crashes. Ogawa et al. (2014) used functional magnetic resonance imaging (fMRI) to study neural mechanisms of a bias to buy stocks (i.e., a bubble bias) while subjects traded in lab markets with stock-price bubbles. In the studied lab-market conditions, a bubble bias was found only during the bubble period of exposure to historical 2003-2008 Lehman Brothers stock-price changes. However, Ogawa et al. (2014) failed to discern evidence from their data suggesting that the bubble bias was associated with a neural signature of impaired self-control. Therefore, their findings are presently re-examined.Methods: In Figs. 2C and 2D of Ogawa et al. (2014), fMRI functional-connectivity data were examined to determine whether a bubble bias was associated with the previously reported neural signature of decreased self-control (Hare et al., 2014; Maier et al., 2015).Results: Among all lab-market conditions (Ogawa et al., 2014), low dorsolateral prefrontal cortex (DLPFC)-ventromedial PFC (VMPFC) connectivity was specific to the bubble period of Lehman Brothers stock prices. Among all conditions, the finding of a bubble bias was specific to the bubble period of Lehman Brothers stock prices.Conclusions: The low DLPFC-VMPFC connectivity associated with a bubble bias (Ogawa et al., 2014) resembles findings of low DLPFC-VMPFC connectivity linked to impaired

self-control when subjects were exposed to a food reward (Maier et al., 2015). Low DLPFC-VMPFC connectivity also was found when subjects failed to resist readily available monetary rewards in an intertemporal choice task (Hare et al., 2014). Therefore, subjects with a bubble bias show connectivity changes that may represent the neural signature of impaired self-control. Neuroimaging studies should determine whether less-profitable investors who trade stocks excessively (Barber and Odean, 2000, 2001, 2002) may show similarly decreased DLPFC-VMPFC connectivity.These results encourage further research on neural mechanisms underlying the bubble bias and traders' self-control problems that may promote asset-price bubbles.

Los Angeles, Los Angeles, CA; [8]Office of Scientific Res., United States Air Force, Springfield, VA

Abstract: Cognitive fatigue (CF) is an important factor in the efficiency and safety of performance-dependent tasks. It is postulated that the degree of CF experienced by an individual may be reflected by biomarkers in biofluids, such as saliva. Neuronal innervation of the salivary gland provides a mechanism through which neuron-derived exosomes are secreted into saliva, while harboring signals (proteins, lipids, mRNA, miRNA, DNA) that are indicative of changes in the cellular and molecular landscape of the central nervous system. The overall objective of this study was to elucidate protein and microRNA (miR) biomarkers of CF in salivary neuronal exosomes. Subjects were medical residents who underwent a cognitively-fatiguing 12-hour work shift. Before and after the work shift, CF was measured by the POMS questionnaire and saliva samples were obtained. Total exosomes and neuronal exosomes were isolated from saliva using magnetic beads coupled to antibodies against CD9+CD63+CD81 (markers for exosomes), or CD56 (NCAM, a neuronal surface marker), respectively. Total protein and miR were purified and subjected to proteomic (using mass spectrometry) or miR-omic (using Nanostring panel of 800 curated miRs) analysis. We identified many proteins and miRs that change (increase or decrease) significantly with CF in neuronal exosomes. Several of these proteins, AMY1A,

CSTB, and 14-3-3 protein zeta/delta, have been shown to be discordant between monozygotic twins discordant for chronic fatigue syndrome (Ceriga 2013). Many miRs change (increase or decrease) significantly with CF, including miR29a-3p, miR519, miR24-3p, and miR1296-3p. Additionally, several miRs known to regulate the expression of genes encoding three proteins were changed with CF (in the opposite direction to the direction that the protein changed with CF), namely the protein gene/miR pairs *PGK1*/miR3185, *PIGR*/miR642a-5p, and *YWHAZ*(14-3-3 protein zeta/delta)/miR134-3p. Bioinformatics identified several protein interaction networks and molecular pathways associated with the CF-changing proteins. These results identify potential biomarkers of CF in saliva exosomes and provide intracellular signaling (protein-protein and miR-gene/protein) pathways that may underly the effects of CF on the homeostatic physiology of neurons that innervate the salivary gland.

Title: Episodic Memory Training Induces Functional Plasticity in PFC - Hippocampal Neural Circuitry

Authors: *J. M. KANE, O. COOK, K. HUNT, B. DEPUE;
Univ. of Louisville, Louisville, KY

Abstract: Episodic Memory Training Induces Functional Plasticity in PFC – Hippocampal Neural Circuitry Kane, J., Cook, O., Hunt, K., Naaz, F. & Depue, B.University of Louisville Training programs for cognition are becoming more ubiquitous in mainstream society. However, there are relatively few studies exploring whether specific task related training leads to functional plasticity in the brain. Furthermore, understanding which neural regions show changes across training highlights important areas underlying the putative neural networks under investigation. We explored this question using fMRI before and after episodic memory training. Eighteen undergraduate students were recruited in a 5-day training study. Participants were scanned on day 1 and day 5. The episodic memory task and training consisted of mnemonic practice of cue-target paired associates (scenes and objects) or a single scene presented in isolation. A cued recall task (approximately 30 minutes later) required participants to either recall the name of the object when presented with the scene, or indicate if the scene was presented alone. Behaviorally, a significant increase in recall accuracy on day 5 compared to day 1 was found (Day 1= 67%; Day 5=75%). Functional analyses revealed greater activation in left ventral lateral prefrontal cortex (VLPFC), bilateral hippocampus (HC), bilateral inferior parietal

sulcus (IPS), and ventral visual processing stream (VVPS) during the task (Paired > Single) on day 5 compared to day 1. Using accuracy as a regressor in functional analyses revealed positive relationships with the same regions mentioned above, but also included the dorsal attentional network. The results indicate that training leads to increased activation of the neural regions associated with encoding/retrieval, attention, and visual processing.

Title: The recovery of directional relationships between brain nodes in schizophrenia by dynamic graphical models

Authors: *T. ATTISHA, S. BAAJOUR, M. GAPPY, A. CHOWDURY, J. STANLEY, V. A. DIWADKAR;
Psychiatry & Behavioral Neurosci., Wayne State Univ., Detroit, MI

Abstract: Schizophrenia (SCZ) is characterized by cognitive impairments relating to associative memory and learning and to brain networks that sub serve these processes. Here we co-opted a recently proposed method, Dynamic Graphical Models (DGM) (Schwab et al., 2018) to estimate directional network interactions induced during an associative learning paradigm (Stanley et al., 2017). DGMs can recover instantaneous directed "parent-child" relationships between nodes in a network (Smith et al., 2011) and unlike methods like granger causality, are less vulnerable to variations in hemodynamic lag. Here we applied DGM to a) estimate parent-child relationships between brain network nodes induced during a learning paradigm and b) summarized these relationships using graph theoretic measures.
fMRI data were collected for 79 subjects (46 SCZ; $18 \leq Age \leq 50$). The paradigm oscillated between Encoding, Passive Consolidation and Cued Retrieval Epochs (27 s), and participants were required to learn nine object - location association pairs. A conjunction analysis (across conditions and groups) was used to identify a commonly activated substrate of twelve bilateral nodes in hetero- and uni-modal cortex (Frontal-Hippocampal: hippocampus, DLPFC, dACC; Uni-Modal: SPC, ITG and FG). Time series for each participant and condition were averaged and submitted for DGM using publicly available code (in *R*)(Schwab et al., 2018). The directional relationships recovered using DGM were summarized using graph theoretic analyses

(Rubinov and Sporns, 2010).
DGM recovered a common set of directional relations in both HC and SCZ, most notably across hemispheric pairs (e.g., $dACC_L \leftarrow \rightarrow dACC_R$). High levels of complementarity (relationships in one group, but not the other) were observed between nodes in hetero-modal and unimodal regions. When the large swathes of binarized relationships across the network were summarized using graph theoretic measures, the following trend emerged. During Encoding, SCZ were characterized by lower outdegree centrality of the HPC, and the ITG, and lower indegree centrality of the dPFC and ITG. During Retrieval, SCZ were characterized by lower out-degree centrality of the dACC, but greater out-degree centrality of the dPFC.
A disruption of parent-child relationships within and across frontal and hippocampal networks, render our results consistent with previously hypothesized deficits in schizophrenia (Stephan et al., 2006) and complement recent investigations using granger causality (Baajour et al., 2020). These analyses reinforce the notion that the flow of information in brain networks is disrupted in schizophrenia, particularly during learning and memory.

Title: Multiple memory systems contribute to one-shot reinforcement learning

Authors: *A. R. ZOU[1], A. G. E. COLLINS[1,2];
[1]Dept. of Psychology, [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA

Abstract: Human learning recruits multiple cognitive processes like reinforcement learning (RL), episodic memory (EM), and working memory (WM). How can we disentangle their contributions? In the context of learning reward-driven stimulus-action associations, RL represents values of action choices relevant for future reward-driven decisions, EM stores information for long-term retrieval, and WM serves as temporary, capacity limited storage. However, what information is gated in WM's limited store remains unclear. To clarify WM's role and disentangle it from RL and EM, we designed a new one-shot reinforcement learning task. We manipulated the information seen before and after encoding to identify the relevant features of a stimulus-action association (e.g. feedback received, delay between stimulus presentations) for WM input and output gating. We used a test phase to parse out EM and RL contributions from WM's. In 16 training phase blocks, subjects used one-shot reward to learn new stimulus-action associations. In each independent block of 8 trials, they pressed one of two keys for each of 4 images shown sequentially, and received a pre-determined pseudo-randomized

positive (+1) or negative feedback (0) for each choice. The 4 images were shown again in a different order, and subjects had to press the correct key for the image based on the feedback received during the first presentation; they received no feedback on these trials (5-8). After the training phase, we assessed long-term retention in a test phase where all 64 stimuli were shown in randomized order; subjects were asked to press the correct key learned previously, and received no feedback. We analyzed 81 human adult subjects (48 female) who used the optimal choice policy during training. We found signatures of both RL and EM in test phase choices, where performance was dependent on training phase presentation order (primacy effect) interacting with feedback, indicating storage of both stimulus-choice and stimulus-choice-outcome associations. Trials 5-8 showed evidence of additional WM contributions in training, with high but delay-dependent performance. We found that feedback affected WM gating: subjects performed better for trials where they received +1, even though with only two keys, 0 provided the same correct key information. Furthermore, WM retrieval in training impacted RL/EM-dependent performance in the test phase. Our results show that our new protocol successfully parses out three memory systems contributing to reward-based learning. This opens the possibility to better understand each system's exact contributions, and particularly, what information WM prioritizes during learning.

Title: The effects of resistance exercise on cognition and hippocampal volume in older adults at-risk for diabetes

Authors: *J. FURLANO, L. NAGAMATSU;
Western Univ., London, ON, Canada

Abstract: Background: Older adults with type 2 diabetes experience cognitive and brain decline beyond normative aging, including deficits in memory and executive function, and reduced hippocampal volume. Studies show that those at-risk for type 2 diabetes (based on high body mass index (BMI) and blood glucose levels) already experience some neurocognitive deficits. One lifestyle intervention that may improve these deficits is exercise. Six months of aerobic training has been found to improve cognitive and brain function in overweight and prediabetic older adults, however whether resistance training (RT) can produce comparable results in this population is unknown. **Methods:** We conducted a 26-week, thrice-weekly randomized controlled trial of RT in older adults at-risk for type 2 diabetes to assess the effects of RT on cognitive function and hippocampal volume. Participants (n = 24, mean age 68.7 ± 5.7

years; 50% female) were older adults with BMI ≥ 25 and/or fasting blood glucose in the prediabetic range (6.0-6.9 mmol/L). Participants were randomized into a progressive RT (weight training) group or a balance and tone (BAT) control group consisting of stretching and balance exercises. All participants were blinded to group allocation. At pre- and post-intervention (0 and 26 weeks, respectively), we measured cognitive performance via standardized neuropsychological tests and hippocampal volume via T1 weighted structural images from a 3T MRI scanner. **Results:** Compared to BAT training, 26 weeks of RT led to significant improvements in task switching and item memory. Both groups improved in conflict resolution and short-term verbal memory, but showed a decrease in hippocampal volume overtime. **Conclusions:** Findings from our exploratory study suggest that RT may improve specific cognitive functions in older adults at-risk for type 2 diabetes, however more research is needed on whether RT leads to structural brain changes. Unexpected improvements with BAT training suggests that stretching and balance exercises may also improve cognitive function in this population of older adults. This study was funded through Western Strategies Support for CIHR Success, and the authors have no competing interests to declare.

Title: Functional cortical activation changes and working memory loss in postmenopausal women with Type II Diabetes

Authors: *S. L. GORNIAK[1], A. E. HERNANDEZ[2], S. A. MONTERO HERNANDEZ[3], L. POLLONINI[3];
[1]Hlth. and Human Performance, [2]Psychology, [3]Engin. Technol., Univ. of Houston, Houston, TX

Abstract: The overall aim of this project was to evaluate the relationship between deficits in working memory and functional cortical activation in postmenopausal females with Type II Diabetes (DM). Our recent studies have shown that adults with DM experience undiagnosed mild cognitive impairment, specifically in the domain of recall/working memory. Currently, no specific consistent structural deficits have been identified as a cause of such deficits in persons with DM. The reported behavioral deficits may be exacerbated in older adult females, who are at the highest risk of cardiovascular decline as DM is considered a cardiovascular disease. Twenty-one (21) community-dwelling DM patients (age = 65 ± 6 years, A1c = 7.5 ± 1.1) and twenty-one (21) age- and sex-matched healthy controls (age = 66 ± 6 years, A1c = 5.4 ± 0.3) were recruited and evaluated in this cross-sectional study. Working memory performance (via N-back) was evaluated while study participants donned cortical functional near-infrared spectroscopy devices

(fNIRS) in one testing session. Bilateral cortical regions of interest (ROIs) included: PFC, SMA, M1, S1, and Brodmann area 40. Health state, metabolic (e.g. glycated hemoglobin values, A_{1c}), and menopausal status data were collected. Deficits in working memory response accuracy ($p < 0.001$) and response time ($p < 0.05$) were found in the DM group as compared to controls. DM differences in HbO ($p < 0.05$) and HbR ($p < 0.05$) measures were found across all ROIs, such that the DM group exhibited significantly larger HbO and HbR values across all tasks. Increased HbO and HbR responses in the DM group were not associated with worsened health state measures (e.g. lipidemia, increased adiposity, etc). These data are the first to indicate functional cortical activation changes during cognitive tasks in postmenopausal females with DM, particularly in the performance of working memory tasks. These data indicate increased cortical activation across the entire cortex during memory tasks in persons with DM while simultaneously exhibiting symptoms of memory loss, suggesting neuronal dedifferentiation in postmenopausal women with DM.

Abstract Working memory (WM) engagement produces pain inhibition. However, it remains

unclear whether higher WM load increases this effect. The aim of this study was to investigate the interaction between WM load and pain inhibition by WM and examine the contribution of descending inhibition. Thirty-eight healthy volunteers were assigned to one of two n-back groups for which WM load was different (2-back or 3-back). The experimental protocol comprised five counterbalanced conditions (0-back, n-back, pain, 0-back with pain, and n-back with pain). Pain and the nociceptive flexion reflex (NFR) were evoked by transcutaneous electrical stimulation of the sural nerve. Pain was significantly different between conditions, but not between n-back groups. Both the 0-back and n-back tasks reduced pain compared with pain alone, but the n-back task produced stronger pain inhibition compared with the 0-back task. NFR amplitude was significantly different between conditions but not between n-back groups. NFR was inhibited by the 0-back and n-back tasks, with no difference between the two tasks. These findings indicate that pain inhibition by WM is increased by WM load, but only to a certain point. NFR inhibition by WM suggests that inhibition of pain by WM depends, at least in part, on descending inhibition.

Abstract: Working memory (WM) is the ability to maintain (Mt) and manipulate (Mp) information in goal-directed behavior. WM performance is associated with the rs2180619 of CNR1 (the gene which encodes for cannabinoid receptor 1): GG genotype had lower accuracy (vs. AA genotype) as task difficulty increases; we hypothesized this effect could be due to the Mt or Mp processes. This study evaluated if the accuracy in Mt and Mp is associated with rs2180619 genotypes. Eighty-six healthy young volunteers responded to a delay-match to sample task with two conditions (Mt vs. Mp) and two types of trials (target and non-target). For the percentage of correct responses (%CR), no evidence of a genotype effect were found. However, for the type of trial: the %CR was significantly higher for the target than for non-target, suggesting this latter type were more difficult to discriminate than targets. For reaction times (RT), AG and GG genotypes, but not AA, had longer RT for non-target than for target trials. These results indicate that the effect in WM previously observed might not be related to a particular process in WM (i.e., Mt or Mp), but with the task demand, in which AG and GG genotypes are more prone to decrease the accuracy as difficulty rises.

Title: Forced alternation in an air-lifted T maze for assessing spatial working memory in head-fixed mice

Authors: *Y. LI[1], J. SONG[2], M. A. GO[1], S. R. SCHULTZ[1];
[1]Imperial Col. London, London, United Kingdom; [2]Albert Ludwig Univ. of Freiburg, Freiburg, Germany

Abstract: Head-fixation of awake mice provides for behavioral testing and neural recording *in vivo*. While mouse navigation and choice-based discrimination tasks under head-fixation have been demonstrated, forced alternation tasks (widely used for assessing short-term spatial working memory in rodents) using a T maze have not been demonstrated in head-fixed animals. Here we present the assessment of spatial working memory used a novel modified T maze based on an

air-lifted platform in head-fixed mice. Methods: We implanted mice (C57BL/6J, male, 2 months, N=5) with metal head plates. Animals were under recovery at least one week after head plate implantation surgeries. For this reinforced T maze task, water restriction was used to motivate maze traversal and learning motivation. After habituation to head-fixation in the apparatus (Mobile HomeCage Large, Neurotar Ltd) and the air-lifted T maze cage with phosphorescent visual cues and tactile cues, mice were trained for 45 min sessions twice daily for 11-16 consecutive days. Animals were transferred to the start arm for the first trial running and they were given one reward (4 µl 1% sucrose water) after either a right or left choice. They then ran back to the start arm, pushing through a one-way door. After the first trial choice, rewards were only given when animals entered the goal arm opposite to the arm visited on the previous trial. Using a magnetic position tracking system, we recorded rewards, movements and locations with real-time velocity; data were analyzed using MATLAB. Results: Head-fixed mice performed habituated to navigation behaviour after training day 6 and significantly improved alternation behaviour from training day 10. With further extension of training they were able to reach a 70% correct alternation score, a typical criterion for freely-moving rodents in traditional T maze. We found that the number of left and right turn trials were not significantly different, indicating the lack of direction preference by head-fixed mice in this T maze, as desired. We also found that the altered velocity patterns in the choice point, start and stem arm can predict the next trial decision. Our results suggest that the forced alternation T maze task in head-fixed mice may be useful for assessing spatial working memory. Our novel behavioral paradigm for spatial working memory shows promise for combination with longitudinal cellular resolution imaging *in vivo.*

Abstract: Oxidative stress generated by sub-chronic hyperglycemia impairs spatial memory in CD-1mice

AbstractDiabetes mellitus (DM) is a metabolic disorder that induces serious micro and macrovascular consequences, affecting several organs and tissues. Increasing evidence suggests that cognitive dysfunction is an important comorbidity of DM, that correlate with abnormal structural and functional brain magnetic resonance imaging in diabetic patients. Oxidative stress has been pointed out as one of the neurodegenerative processes implicated in cognitive loss caused by DM, since the CNS is characterized by an elevated production of free radicals (FR), due of the high consumption of O2 and glucose, making it vulnerable to the harmful effects of reactive oxygen species. Several mechanisms of neuronal damage induced by hyperglycemia like redox imbalance, mitochondrial dysfunction, brain insulin resistance, β-amyloid accumulation, as well as neuronal apoptosis has been described. There is a wide variation in the results reported in this field, mainly because of methodological differences between studies (e.g., DM model employed, the time lapse between hyperglycemia induction and behavioral evaluation, and the learning paradigms used). The aim of this study was to evaluate the effects of sub chronic hyperglycemia induced by systemic STZ administration on spatial and recognition memory, and to analyze its correlation with oxidative stress markers. Fifteen days after STZ-induced hyperglycemia, mice were evaluated for learning, short-term and long-term memory capabilities in three explicit memory tasks: 1) eight-arm radial maze, 2) buried food location test, or 3) novel object recognition task. Lipoperoxidation and antioxidant enzymes activity of superoxide dismutase (SOD) and catalase (CAT) were measured in brain regions primarily related to explicit memory. The results showed spatial memory deficits and short-term recognition memory impairment in diabetic mice. Moreover, an increased free radicals' level as well as a decreased enzymatic activity of both SOD and CAT in diabetic animal's hippocampus was observed. We conclude that hyperglycemia-induced free radicals increase, probably due to antioxidant enzymatic activity decline in key brain regions, contributed to the cognitive impairment observed in diabetic mice, however, biochemical and molecular studies are needed to understand the pathophysiological mechanisms underlaying these findings.

Title: Investigating spatial working memory deficits in a rodent model of Fetal Alcohol Spectrum Disorder

Authors: *S. KIM, A. Y. KLINTSOVA, A. L. GRIFFIN;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Fetal Alcohol Spectrum Disorder (FASD) is estimated to affect 1-5% of live births in the United States. FASD patients may show cognitive impairments such as working memory deficits. Alcohol exposure (AE) during the 3rd trimester of human pregnancies results in underdevelopment of key brain regions critical for working memory, specifically medial prefrontal cortex (mPFC) and hippocampus (HC). We have shown that there is damage to the thalamic nucleus reuniens (Re) in the rodent model of 3rd trimester AE. Re functions as a key intermediary node in the mPFC - HC circuit. Our lab has also demonstrated that Re is critical for mPFC - HC oscillatory synchrony and spatial working memory (SWM). From these findings, we hypothesized that AE during the brain growth spurt (BGS) in rats would result in SWM deficits that would be more pronounced with higher SWM demand. We compared choice accuracy between AE and sham intubated (SI) groups on a SWM-dependent delayed alternation (DA) task with different delay lengths in both male and female rats. The AE pups were given 5.25 g/kg/day ethanol in milk formula via intragastric intubations on postnatal days (PD) 4-9. The SI group received the same intubation as the AE but without any liquid. The handling and pre- training began on PD90 followed by a continuous alternation (CA) T-maze task. Upon reaching a choice accuracy criterion of 80% for two consecutive days on CA, the rats underwent 6 DA sessions, consisting of 12 each of 10-second (s), 30 s, and 60 s delay trials in a pseudorandom sequence. There were no significant differences in performance of the CA task between AE and SI groups for both sexes, which suggest the ability to learn tasks with a low SWM demand is not impaired by AE. Choice accuracy on the DA task was assessed using a mixed factor 2(sex) x 2(postnatal treatment) x 3 (delay) x 6 (day) ANOVA, with subsequent posthoc tests as appropriate. We find a trending sex x delay x postnatal treatment interaction ($F(1.63, 40.85)=1.71$, $p =.198$), which is driven by the fact that the AE group performed uniformly poorly on all delays, whereas SI group showed the expected delay-dependent decrease in choice accuracy. Interestingly, this trending pattern was observed in males ($n(AE) = 7$, $n(SI) =11$, $F(1.38, 22)=1.80$, $p =.194$), but not female groups ($n(AE) = 6$, $n(SI) =5$, $F(2, 18)=.43$, $p=.660$). These preliminary findings support the hypothesis that AE during the BGS leads to SWM deficits with increasing SWM demand, and our data suggest that males and females show different vulnerability. This study will lead to a better understanding of how damage to HC-Re-mPFC circuitry resulting from early AE impacts cognitive function later in life.

Title: The Role of the MCH system in Regulation of the Length of Primary Neuronal Cilia

Authors: *W. S. ALHASSEN, B. ROBBINS, H. NGUYEN, T. MYINT, A. ALACHKAR; Univ. of California Irvine, Irvine, CA

Abstract: The MCH system has been implicated as a regulator of energy homeostasis and food intake, sleep, stress, mood, aggression, reward and cognition. MCH works by interacting with a G protein-coupled receptor, MCHR1, which has widespread distributions in the brain, particularly in the frontal cortex, amygdala, nucleus accumbens, septum and hippocampus providing an anatomical basis for an MCH role in the modulation of social, emotional, and cognitive functions. MCHR1 localizes to primary neuronal cilia, small microtubule backbones that protrude from the plasma membrane of almost every cell including neurons. Cilia act as cells' antennas and play crucial roles in cell signaling through detecting and transducing external stimuli, and regulating the proper cell differentiation and migration. Specifically, 77 cilia genes have been associated with neurological deficits. We asked whether the MCHR1 localization on cilia membranes is the basis of the uniqueness of these receptors in the ciliary signaling, through converging different sensory signals in the extracellular environment, and transmitting these signals into the cell. This is supported by the fact that the activation of MCHR1 causes shortening of the cilia length in *in vitro* experiments through cytoskeleton-related regulation. We aim to establish study the effect of the activation and inhibition of MCH system on cilia length in the brain. This study is one of the first to show *in vivo* manipulation of the MCH system regulates the length of primary neuronal cilia. This was done via pharmacological techniques in mice, including intracerebroventricular infusions of the MCH peptide and intraperitoneal injection of an MCHR1 antagonist, and MCHR1 knockout and MCH conditional knockout. We found that ex vivo MCH exposure shortens cilia length. We also found that cilia length is increased in MCH and MCHR1 deficit mice in the brain, including the prefrontal cortex, striatum, nucleus accumbens, and hippocampus. Infusions of MCH via i.c.v displayed a decrease in cilia length while administering an MCHR1 antagonist resulted in an increase in cilia length. In this study we were able to uncover the role between the MCH system in regulation of the length of primary neuronal cilia in mice and an *ex vivo* setting and concluding that the activation of MCH reduces cilia length while inhibition increases cilia length.

Title: History biases and working memory mechanisms alternate but do not interact in a rodent 2AFC task

Authors: T. ONA-JODAR[1], G. PRAT-ORTEGA[1], C.-Y. LI[2], J. DALMAU[3], J. DE LA ROCHA[1], *A. COMPTE[1];

Abstract: Working memory (WM) is an essential brain function, which is central for cognition and severely impaired in multiple brain disorders. To investigate the underlying mechanisms limiting WM we developed a two-alternative delayed response task in which head-fixed mice are presented with an acoustic stimulus coming from either a left or a right side speaker. Animals had to remember the prospective response during a variable delay (duration D=0, 1, 3 and 10s) after which, they had to lick the corresponding side port (Fig. 1a).To understand how the length of the delay period affected the mice accuracy, we fitted a Generalized Linear Model that quantified the impact of the different factors on choice (Fig. 1b). The fitted model captured the forgetting process that took place during the delay as a reduction of stimulus impact on choice as D increased. Mice also showed (1) an idiosyncratic fixed bias showing a preference for one choice that was affected by the delay and (2) a delay-independent history bias favoring the previously rewarded side and opting away the previously unrewarded side. To recapitulate these two biases and their dependence (or lack of) on memory, we propose a two state hidden Markov Model in which animals switch between a WM and a reinforcement learning module (RL) (Fig. 1c). The WM module is a double well potential where the information about the planned response is degraded during the delay. Since the double well is asymmetric, this introduces a modulation of the side bias with the delay. The RL one is a logistic function that only depends on previous response and outcomes and is thus unaffected by the delay. Also, we observed an increase in the weights of history regressors with trial index within a session and a reduction of stimulus importance. This suggests that the transitions to the RL module are more frequent towards the end of the session. Lastly, we performed pharmacological manipulations where we inhibited NMDA receptors using NR2B antagonists. These animals showed a decrease of stimulus relevance that was taken over by a more prevalent presence of reinforcement learning strategies.

Title: Superior effect of a dopamine D_1 agonist compared with methylphenidate on prefrontal cortical modulated working memory

Authors: *Y. YANG[1], R. B. MAILMAN[2];
[1]Pharmacol., Penn State Univ. Col. of Med., Hershey, PA; [2]Pharmacol., Penn State Col. of Med., Hershey, PA

Abstract: Methylphenidate (MPH) is used widely to treat symptoms of attention-deficit/hyperactivity disorder (ADHD), but like other stimulants, has significant side effects. This study utilized a rodent model of spatial working memory (sWM) to compare the effects of MPH with a novel dopamine $D_{1/5}$ receptor (D_1R) agonist, 2-methyldihydrexidine (2MDHX). Administration of MPH caused a complex result in which 50% of the rats had improved sWM, whereas the other half showed impairment. Both improvement and impairment on sWM induced by MPH were eliminated when the D_1 antagonist SCH39266 was administered directly into the prefrontal cortex (PFC). The MPH-induced improvement in sWM was correlated negatively with sWM capacity, indicating rats with lower sWM capacity tended to improve more. Compared to MPH, 2MDHX showed greater improvement in sWM without significant impairment in any subject. These behavioral effects were reflected in firing rates of PFC neurons leading to alterations in both single neuron sensitivity to correct or error behavioral responses and in the power of local field potentials. Overall, 2MDHX was superior to MPH in decreasing the strength of neural sensitivity prospectively and increasing it retrospectively, and also in decreasing the oscillation power at alpha and beta bands. These results suggest that a $D_{1/5}$ agonist is more effective than MPH in regulating WM-related behavior and neural activities in the PFC, supporting the hypothesis that $D_{1/5}$ agonists would be superior to MPH or other stimulants as a treatment for ADHD.

Title: Pathway-specific chemogenetic neuromodulation enhances working memory in rhesus monkeys

Authors: ***N. A. UPRIGHT**, C. ELORETTE, A. FUJIMOTO, P. L. CROXSON, B. E. RUSS, P. H. RUDEBECK, M. G. BAXTER;
Nash Family Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Acetylcholine plays a critical role in promoting neuronal plasticity and shaping synaptic connections throughout the brain, largely by projections from the basal forebrain

cholinergic system. Deficits in cholinergic neurotransmission impair cognitive performance and stimulation of cholinergic receptors in prefrontal cortex enhances task-related firing in working memory tasks. Although systemic pro-cholinergic drugs and electrical deep brain stimulation of the basal forebrain have shown to improve memory performance in nonhuman primates and humans, it has yet to be determined whether circuit-specific activation of a cholinergic neuromodulatory system can affect memory performance. Using a dual-viral intersectional approach, we transduced excitatory hM3D-Gq-coupled DREADDs (designer receptors exclusively activated by designer drugs) into the basal forebrain to reversibly activate projections from the nucleus basalis of Meynert to the dorsolateral prefrontal cortex. We tested whether circuit activation could overcome cognitive deficits caused by the muscarinic antagonist scopolamine (SCOP) in two young male rhesus monkeys. Monkeys were trained on the spatial-delayed response task to assess working memory performance after combined intramuscular injections of either SCOP and vehicle, the DREADD actuator deschloroclozapine (DCZ) and vehicle, or a combination of SCOP and DCZ. Working memory performance after DCZ did not differ from performance after vehicle in either monkey, and working memory was impaired in both monkeys after combined SCOP and vehicle injection. Notably, working memory was significantly improved after SCOP plus DCZ injection compared to performance after SCOP alone, indicating that the activation of the nucleus basalis to dorsolateral prefrontal circuit could offset working memory impairment caused by the cholinergic antagonist. These findings may provide a novel potential neurotherapeutic method for circuit-specific treatment of cognitive impairments seen in aging and disease that result from deficits in cholinergic neuromodulation.

Title: Distinct types of cortical projection neurons for working memory and timing

Authors: J. BAE[1], H. JEONG[2], C. BAE[2], H. LEE[3], S.-B. PAIK[3], M. JUNG[1];
[1]KAIST/Institute for Basic Science/CSBD, Yuseong-gu, Korea, Republic of; [2]Inst. for Basic Science/CSBD, Yuseong-gu, Korea, Republic of; [3]Dept. of Bio and Brain Engineering, Korea Advanced Inst. of Sci. and Technol., Yuseong-gu, Korea, Republic of

Abstract: Intratelencephalic (IT) and pyramidal tract (PT) projection neurons, which project primarily to cortical and subcortical structures, respectively, represent two major types of cortical excitatory neurons. Currently, little is known about the division of labor between these different types of cortical projection neurons that allows them to support diverse cortical functions. Here,

we show that IT and PT neurons in the prefrontal cortex are differentially engaged in the maintenance of working memory and tracking the passage of time. We examined the discharge characteristics and inactivation effects of IT and PT neurons in the medial prefrontal cortex of mice performing a delayed response task. We found that IT, but not PT, neurons convey significant working memory-related signals during the delay period. We also found that the inactivation of IT, but not PT, neurons impairs behavioral performance. In contrast, PT neurons conveyed far more temporal information than IT neurons during the delay period. Our results indicate differential contributions of IT and PT neurons to the maintenance of working memory and the tracking of the passage of the delay period. These differences may reflect a more generalized functional segregation between neural networks involving IT and PT neurons. For example, the prefrontal cortex may contribute to high-order cognitive functions by sharing working memory-related signals with other cortical areas (IT neuronal network) and to the temporal organization of behavior by sending temporal information to its downstream subcortical structures (PT neuronal network).

Title: Distributed representations in primate DLPFC with strategy use in a self-ordered working memory task

Authors: *F.-K. CHIANG[1], J. D. WALLIS[2], E. RICH[1];
[1]Nash Dept. of Neurosci. and The Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept. of psychology and Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: The limited capacity of working memory (WM) can be improved by implementing cognitive strategies. For instance, our previous work showed that incorrect responses decreased when monkeys adopted more routine selection patterns in a spatial self-ordered search task (Chiang and Wallis 2018). At the same time, the spatial tuning in neurons recorded in the dorsolateral prefrontal cortex (DLPFC) decreased with more stereotyped behavior. Here, we assessed how the same WM task is represented at the ensemble level, under these different self-generated behaviors. We re-analyzed data from two monkeys performing the self-ordered WM task with six identical visual targets. Subjects made a saccade to each target, one at a time in any

order, returning their eyes to the center after each selection. Reward was delivered only after the first visit to each target within a trial. When all targets had been visited, the reward contingency was reset and a new trial began. Therefore, monkeys had to use WM to track which targets had been visited and prepare for the next target selection. Blocks of 40 trials with the same target configuration enabled us to quantify selection patterns. We found that two task-relevant variables, target identity and saccade number, could be decoded from ensembles of simultaneously recorded DLPFC neurons. However, decoding performance was similar or better on trial blocks when monkeys used more stereotyped selection strategies, seemingly contradicting single unit results that found less spatial tuning. To investigate this further, we used multiple approaches to determine how much the single-unit information contributed to the neural ensembles under the self-generated behaviors. We found that single units contributed less and the size of optimal neural ensembles for decoding increased with stereotyped strategies, suggestive of a more distributed but less efficient neural code. Lastly, the unique design of resetting target-reward contingency in this self-ordered task allowed us to explore changes in dimensionality of neural ensembles with strategy use in a single trial. We found that the informative dimensionality was significant positively correlated to the WM loads, and negatively correlated to the levels of stereotyped strategy. In sum, our data indicate that a change in the local distribution of WM representations could parsimoniously explain how single unit and ensemble representations are manipulated by behavioral strategies. This model may also shed light on how locally distributed representations may overcome the limited capacity of WM.

Title: A spiking neuron model of encoding in working memory without gating

Authors: *J. K. KROGER;
Psychology, New Mexico State Univ., Las Cruces, NM

Abstract: I describe a realistic network of integrate-and-fire neurons, simulating those found in connected neural structures, that addresses questions about how information is “loaded” or encoded into working memory, how salience signals that information be loaded, how the frontal cortex controls retention of salient information, which is stored in the parietal association cortex. This information is learned, such that when encountered again, it is reinstituted. The current model implements striatal-thalamo-cortical interactions resulting in a sustained dynamical state that permits maintenance of information in working memory. The current model achieves greater verisimilitude by virtue of more accurate modeling of neurons comprising the networks. Further,

it demonstrates how these operations may be the “control” portion of information maintenance and processing, while the information itself is represented in other association brain regions.

Title: Optogenetic investigation of medial prefrontal cortex contributions to delayed response working memory performance in young and aged rats

Authors: M. FARAJI[1], C. M. HERNANDEZ, III[2], A.-R. WHEELER[1], K. M. GONZALEZ[1], C. J. FRAZIER[1], *B. SETLOW[1], J. L. BIZON[3];
[1]Univ. of Florida, Gainesville, FL; [2]Cellular, Developmental, and Integrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL; [3]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL

Abstract: Aging is associated with deficits in multiple forms of cognition, including working memory mediated by the prefrontal cortex (PFC). Working memory refers to the maintenance of information over short delays, and studies employing lesion and intracerebral pharmacological approaches have identified a critical role for PFC. Working memory involves multiple phases, however, including acquisition, maintenance, and retrieval of information, and lesion and pharmacological approaches lack the temporal resolution to differentiate the role of PFC across these stages. Moreover, emerging evidence indicates that aging is associated with shifts in the neural substrates supporting specific cognitive functions, such that brain regions critical for a particular aspect of cognition in young adults may be less involved in older subjects. To determine how the PFC is engaged in distinct phases of working memory, and to determine whether its engagement differs across the lifespan, we used an optogenetic approach to selectively activate or inactivate pyramidal neurons in the medial PFC (mPFC) in young adult and aged rats. Young adult (6 mo.) and aged (24 mo.) male Fischer 344 x Brown Norway F1 hybrid rats were surgically implanted with bilateral guide cannulae targeting mPFC, through which AAVs bearing halorhodopsin, channelrhodopsin, or a control construct were delivered and optic fibers were implanted. Rats were subsequently trained in operant chambers in a three-stage delayed response working memory task. On each trial in this task, rats were presented with a sample lever (either left or right), a press on which initiated a delay phase ranging from 0-24 s. After the delay expired, both levers were extended and rats had to choose the same lever pressed during the sample phase. Rats were trained until reaching stable baseline performance, at which point they received laser light of the appropriate wavelength delivered to the mPFC. Aged rats showed impaired task accuracy relative to young under baseline conditions. Inactivation of

mPFC during the sample phase impaired accuracy in both age groups, particularly at longer delays. In contrast (and somewhat surprisingly), mPFC inactivation during the choice phase enhanced accuracy at the longest delay, particularly in aged rats. Experiments with mPFC activation and the control construct are currently ongoing. Considered together, the results suggest a complex role for mPFC in working memory that varies across both age and task phase.

Title: Eeg connectivity signatures of load-dependent scene memory maintenance

Authors: *C. REICHERT PLASKA[1,2], B. A. GOMES[3], J. ORTEGA[1], T. M. ELLMORE[1,2,3]; [1]Psychology, City Univ. of New York, New York, NY; [2]Behavioral and Cognitive Neurosci. Program, [3]Cognitive Neurosci. Program, The CUNY Grad. Ctr., New York, NY

Abstract: Changes in load-dependent working memory (WM) activity have been studied in animals and humans using simple stimuli, such as shapes, but few studies have examined the neural connectivity changes that support maintenance for complex visual stimuli, such as scenes. We examined this question in an exploratory EEG analysis employing a within-subjects design with a WM load manipulation. Twenty-two participants completed a modified Sternberg WM task with either 5 (high-load) or 2 (low-load) color scene stimuli presented at encoding during 32-channel EEG recording. They were told to remember the scenes during a 6 sec delay period during which phase-scrambled scenes (PS) with similar color and spatial frequencies were presented as a perceptual baseline. Participants viewed the PS but were not required to remember them, so they served as interference. Since sensor-level estimates of connectivity are confounded by volume conduction, a time-frequency analysis (TSA) of delay period data was computed using a source montage (15 brain regions) with phase-locking value (PVL) as the connectivity measure. Performance was better for the low- compared to high-load condition (90.64% correct vs. 78.27%, Wilcoxon Signed Rank Test $p = .002$). Inspection of TSA absolute amplitudes during the delay period showed greater reductions in the alpha and beta across frontal, central, and parietal regions for the high- compared to the low-load condition (5 clusters, $p < 0.05$, permutation testing with a cluster-level multiple comparison correction). There were no significant differences in TSA in these oscillation bands. Analysis of the PVL revealed 3 significant clusters: 1) Increased PVL between left frontal and right temporoparietal regions in the theta and alpha bands for the low- compared to high-load condition, 2) increased PVL

between the right anterior temporal and the left central region in the alpha and lower beta bands, and 3) an increased PVL between the left anterior temporal and left temporoparietal regions in the theta, alpha, and lower beta bands. Low-load scene maintenance was better compared to high-load in terms of performance. Connectivity increased during low-load in frontoparietal regions implicated in top-down control of maintenance and in anterior temporal-temporoparietal regions implicated in semantic and language-based maintenance. The pattern of findings for the low-load could be explained by the availability of attentional resources to filter the PS with fewer stimuli being maintained. Additionally, some subjects may have employed a covert rehearsal strategy that is easier to implement during the delay in the low- compared to high-load condition.

Title: Performance in a working memory task is predicted by delay period blink rate and changes in neural activity

Authors: *J. ORTEGA[1], C. REICHERT PLASKA[1,2], B. A. GOMES[3], T. M. ELLMORE[1,2,3]; [1]Psychology, The City Col. of New York, New York, NY; [2]Behavioral and Cognitive Neurosci. Program, [3]Cognitive Neurosci. Program, CUNY Grad. Ctr., New York, NY

Abstract: Blink rate (BR) is found to be predictive of performance in incentive-based, spatial WM, and IQ based tasks; however few studies have looked at BR across the delay period of a WM paradigm. In the present study, we observed BR at different times during the delay period while participants maintained novel visual stimuli. Nineteen participants completed a modified Sternberg WM task while having their eyes tracked. Seven participants also had 32-channel scalp EEG recorded. EEG artifacts were removed by visual inspection and by using defined topographies. Participants completed three runs of the task, each consisting of 3 novel scenes during encoding, followed by a varied (2, 5, or 9 sec) delay period where participants maintained the scenes in memory. After the delay, a probe was presented and participants had to identify whether it was a new or previously presented image. Task performance was measured by the number of correct trials across all runs. BR was measured by rate of eye closure throughout the entire delay period. The first 2 seconds of all delay periods were used in the analysis and divided into four 500ms periods (0-500ms; 500-1000ms; 1000-1500ms; 1500-2000ms). Time frequency analysis (TFC) was run on EEG data collected during the entire 2-sec delay period. When BR

was examined as a factor of period, BR during the last 500ms of the delay and performance was found to be negatively correlated $r(13) = -.575$, $p = .025$. A polynomial regression model was computed with BR squared as the quadratic term and BR as the linear term. The results revealed BR during the last 500ms and performance had a significant non-linear correlation, $R^2 = .547$, $F(2,12) = 7.251$, $p = .009$. Examining individual TFC for lower performers (high and low BR) revealed an early (first 500ms) period of desynchronous and a later (last 500ms) alpha-theta band activity in the Parietal electrode (Pz), whereas for higher performers there was strong, early synchronous (first 500ms) alpha and lower beta band activity. High BR during later periods (last 500ms) of the delay in a WM task was correlated with low performance. The relationship between BR and performance was also found to be non-linear, where low and high BR during the later period of the delay was predictive of low performance. These results suggest that blinking is predictive of performance with higher and lower BRs leading to lower performance in a WM task. Additionally, results from TFC analysis suggest that early desynchronous alpha activity is related to worse WM performance and earlier synchronous alpha and lower beta is related to better performance.

Title: A simultaneous eeg-fmri study of thalamic load-dependent working memory delay period activity

Authors: *B. A. GOMES[1], C. REICHERT PLASKA[2], J. ORTEGA[3], T. M. ELLMORE[4]; [1]Cognitive Neurosci., CUNY Grad. Ctr., New York, NY; [2]City Univ. of New York, Ramsey, NJ; [3]City Col. of New York, New York, NY; [4]Psychology, The City Col. of New York, New York, NY

Abstract: Working memory (WM) is an essential component of executive functions that depend on maintaining task-related information online for brief periods in both the presence and absence of interfering stimuli. Active maintenance occurs during the WM delay period. Previous studies have extensively documented prefrontal and posterior parietal cortex activity during the WM delay period, but the role of subcortical structures, including the thalamus, remains to be fully elucidated.
32-channel EEG data were acquired simultaneously with BOLD-fMRI in 24 participants during a variant of the Sternberg WM paradigm. Participants viewed novel outdoor scenes during an

encoding period followed by Fourier phase-scrambled stimuli with similar color and spatial frequency during a delay period. Scrambled scenes served as a perceptual baseline and interference during delay that participants were instructed to view while maintaining in memory the scenes presented at encoding. Event-related potentials (ERPs) were computed for scene onset at encoding (time window: 0-1000 msec) and for scrambled scenes during the 6 sec delay period (time window: 0-1000 msec). Bilateral dipoles were seeded during source analysis with solutions weighted by the simultaneously-acquired individual fMRI maps.
Each participant completed 50 low- and 50 high-load trials presented in separate runs with order randomized and counterbalanced. A related-samples Wilcoxon Signed Rank test showed a difference in accuracy between low-load (Mean = 90.6% correct, SD = 19.4) and high-load (78.3% correct, SD = 25.9) performance ($p=.002$).
Group analysis of individual dipole source estimates weighted by fMRI activation maps showed greater ERP amplitude in bilateral thalamus during the low- compared to high-load delay condition between 160 msecs and 390 msecs ($p = .003$) after delay period onset.
Group paired t-test difference maps between delay conditions were computed from fMRI data in AFNI. Among other regions, the left thalamus showed higher activation during low- compared to high-load ($t>3.67$, $p<.001$), consistent with the group ERP source results.
We found that thalamic activation was attenuated during high- compared to low-load memory maintenance, suggesting a sensory filtering role for thalamus during consolidation of stimuli in WM. The highest evoked activity occurred during the delay when fewer stimuli were maintained in the presence of interfering perceptual stimuli. The results support the idea that the thalamus plays a role in short-term memory maintenance by regulating processing of interfering stimuli.

Title: Brain-state dependent neural mechanisms of transcranial alternating current stimulation in humans

Authors: *I. ALEKSEICHUK[1], C. SAIOTE[2], A. HERMAN[3], D. DARROW[2], R. MCGOVERN[2], M. PARK[2], A. OPITZ[1];
[1]Dept of Biomed. Engin., [2]Dept of Neurosurg., [3]Dept of Psychiatry, Univ. of Minnesota, Minneapolis, MN

Abstract: Transcranial alternating current stimulation (TACS) targets electrophysiological activity in the human brain by applying weak time-varying electric currents in a safe, non-invasive manner through the scalp. Medical and cognitive scientists increasingly explore TACS as a possible tool to investigate the causal role of brain oscillations and normalize them in patients with cognitive deficits. However, progress is slowed down by an incomplete understanding of the fundamental mechanisms of TACS. The non-invasive nature of the intervention prevents direct neural recording in humans, while non-invasive human brain activity recordings, like electroencephalography, suffer from large TACS-induced artifacts. On the other hand, translational research in laboratory animals allows for direct invasive exploration; however, it provides little insights into the role of the neural state and cognitive load on the sensitivity of the brain to the external perturbations, such as TACS. Here we aim to answer this question by recording direct human brain activity in surgical epilepsy patients. Patients who met clinical guidelines and provided informed consent were implanted with a combination of intracranial subdural grids, strips, and depth electrodes according to medical needs (100-200 contacts). Intracranial recordings were acquired with a 256-channel amplifier, sampling at 40 kHz with a high dynamic range and 24-bit resolution. The patients performed a classical 2-back verbal working memory task to create the cognitive load condition or remained at rest while being subjected to TACS for 10 min at an average intensity of 1 mA and frequency in either the theta or beta range. The study is conducted in accordance with the Declaration of Helsinki and IRB regulations (University of Minnesota, MN). At this stage, three patients (one female, age range 30-40 y.o.) successfully performed all research procedures and were analyzed. Preliminary analysis using generalized linear mixed effect model with stimulation condition as a fixed effect (theta TACS, beta TACS, or sham) and patient's id as a random effect indicated a significant improvement in memory performance (d-prime metric) during the stimulation (glmm $F = 4.6$, $p = 0.02$). The positive effect emerged specifically in the beta range, known to be involved in working memory processes, which indicate its frequency-specific nature. The present preliminary findings highlight TACS potential in the study of brain oscillations and support continuing research to determine individual brain state-dependent sensitivity to the applied stimulation.

Title: Common neural substrate for Working Memory maintenance and Long-Term Memory formation in humans

Authors: *J. KAMINSKI[1], N. CHANDRAVADIA[1], A. G. P. SCHJETNAN[2], Y. SALIMPOUR[3], I. REUCROFT[4], C. REED[1], J. M. CHUNG[1], S. KALIA[2], W. ANDERSON[3], T. A. VALIANTE[2], A. N. MAMELAK[1], U. RUTISHAUSER[1];
[1]Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Krembil Res. Inst., Toronto, ON, Canada; [3]Johns Hopkins Sch. of Med., Baltimore, MD; [4]Johns Hopkins Univ., Baltimore, MD

Abstract: Long-Term Memory (LTM) and Working memory (WM) interact closely, but the neuronal basis of this interaction between declarative memories and WM remains poorly understood. As part of a BRAIN initiative consortium, we performed single-neuron recordings in the Medial Temporal Lobe (MTL) and the Medial Frontal cortex (MFC) in neurosurgical patients undergoing depth electrode implantation for localization of epileptic seizures. Patients performed a WM task followed by a LTM recognition memory task. During the WM task, we asked subjects to maintain novel images in memory for a few seconds, followed by a probe. Recognition of these images was then subsequently tested in the LTM task. Out of 35 sessions acquired, we analyzed 26 of these sessions; behavioral accuracy was 93% and 72% for the WM and LTM task, respectively. In the MTL, 16.3% of cells were selective for the category of the item(s) held in WM during maintenance. The strength of the category-selective activity during maintenance predicted whether an item was subsequently remembered or forgotten in the LTM recognition task, thereby linking persistent activity during WM maintenance to LTM formation. Further supporting this result, the extent of persistent activity predicted the strength of the response of memory-selective old-new cells during the recognition task. Single-trial decoding showed that it was possible to predict whether a given image will be later remembered based on the activity of category-selective neurons during WM maintenance (accuracy 57.6%, p=0.013). Analysis of a SVM decoder trained to read-out the category currently held in WM revealed that neural activity in trials that were later remembered was located further away from the decoder hyperplane compared to neural activity in trials later forgotten (SVM geometric margin for later remembered trials was 0.43 vs. forgotten 0.1; p=0.0005). Together, these results show a direct link between the activity of neurons in the MTL during WM and the subsequent strength of declarative memories and demonstrate that category-selective neuronal activity acts as a common neural substrate for both WM maintenance and LTM formation.

Title: Long-term learning transforms prefrontal cortex selectivity during working memory

Authors: *J. A. MILLER[1], A. TAMBINI[2], A. KIYONAGA[3], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [2]Dept. of Neurobio. and Behavior, UC Irvine, Irvine, CA; [3]Dept. of Cognitive Sci., UC San Diego, San Diego, CA

Abstract: The neural representations supporting goal-directed behavior may change with learning. However, uncovering how long-term memory influences working memory (WM) is difficult because of inconsistencies across studies, species, and recording techniques. For instance, non-human primate (NHP) electrophysiology research finds that lateral prefrontal cortex (lPFC) circuitry maintains WM representations, while human neuroimaging suggests that such content is instead stored in sensory cortices. To bridge between these findings, we implemented a unique, longitudinal functional MRI (fMRI) protocol to test the influence of long-term learning on WM processes in each of three human participants. Across three months, each participant was trained on (1) a serial reaction time (SRT) task, wherein complex fractal stimuli were associated with arbitrary response mappings and embedded within probabilistic sequences, and (2) a delayed recognition task that probed WM for trained or novel stimuli. Participants showed a stimulus learning benefit, as they became increasingly faster and more accurate in the WM task for trained, but not novel, fractals. Neurally, long-term learning influenced the activity patterns associated with WM maintenance. Across training, voxelwise WM delay period activity became more distributed throughout lPFC, paralleling a recent finding that spiking activity across NHP lPFC also becomes more distributed with training (Qi et al., 2019). Individual voxels in lPFC also showed increases in stimulus selectivity among the trained fractals. Pattern similarity analyses of WM delay activity demonstrate that across learning, item-level representations emerged within lPFC but not in sensory cortices. Representations of stimulus sequences that were learned over time in the SRT task, but unrelated to the goals of the WM task, also emerged in lPFC during WM. This work helps reconcile disparate findings across species and scales, showing that with learning, human prefrontal areas change their selectivity during WM to develop stimulus-selective properties most commonly found at the neuronal scale in NHP recordings. Further, this dense sampling of changing memory substrates establishes novel evidence for the influence of long-term memory on WM maintenance processes.

Abstract: Objective: Characterize the organization and connectivity of the default mode neural network (DMN) in a sample of spider monkeys. **Background:** The DMN consists of an aggregate of dynamic centers and subsystems that play an important role in cognitive processes of “internal mentalization”. Increases its activity during cognitive tasks directed towards objectives and require forms of self-generated thought. We measure the blood oxygenation-dependent (BOLD) contrast signal to register the functional connectivity among different brain regions. Research on the underlying mechanisms, organization and alteration of brain neural networks requires homologous animal models that allow neurophysiological and phylogenetic records. **Desing/Methods:** Whole brain images were obtained from three healthy adult spider monkeys *(Ateles geoffroyi),* followed by resting state sequences. The fMRI data was processed first and then an independent component analysis (ICA) grouped was performed to identify the DMN. The results were compared with those of human studies and the group-level ICA yielded two bilateral and symetrical default-mode networks. **Results:** The group-level ICA yielded two bilateral and symmetrical DMN. Components of the networks were found to be extending into ventral medial prefrontal cortex (*vmPFC*) and posterior cingulate cortex (*PCC*), as well as precuneus and parts of the parietal cortex. The correlated areas suggest that some elements of network may be conserved across primate species. **Conclusions:** The animal studies, although still incipient, are fundamental instruments that have contributed to the understanding of the neural basis underlying the evolution and function of this complex system. The study of the neural networks in vmPFC and PCC, precuneus and parietal cortex, they can provide basic information for the investigation of neurological and psychiatric disorders associated with their cognitive processes. Re-evaluation of these disorders from an evolutionary perspective would generate insights into our comprehension, and open new line of research unveiling the biological mechanisms and thereby prevention and treatments.

Abstract: The Buridan's paradigm is widely used for testing visual spatial orientation and spatial learning of fruit fly. In this study, we firstly explored the mechanism of such fixation performance. Meanwhile, we proved that the wing-shortened fly prefers dark objects instead of salient objects or high-contrast of strips and screen. Then we tested flies' spatial orientation and memory. The results revealed that for the naïve fruit fly, after stimulus exposed for over 60 s, the fly maintained fixation performance for a short time, and such fixation period was positively correlated with the stimulus exposure duration. In the next step, we discussed neural functions in fly ellipsoid body (EB) and protocerebral bridge (PB). The EB is a ring-shaped region contained several sub-ring. In our theoretical model, the C circuit and P circuit play important roles in navigation. The C circuit stabilizes the orientation signal in EB region, while P circuit updates neural activity when rotating. The alternative work of such two circuits maintains neural activity in fly brain. Our results showed that manipulating either of such region produces distinct behavioral deficits, which also consisted with the theoretical model.

Title: Interplay between estrogen & oxytocin receptors on rapid social recognition

Authors: *P. PALETTA[1], G. DHUGA[2], E. WATSON[1], E. CHOLERIS[1];
[1]Psychology and Neurosci., [2]Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: Estrogens and oxytocin (OT) play important roles in mediating social recognition (SR). For example, when the genes for the estrogen receptors, OT, or the OT receptor are "knocked out", SR is impaired. From these experiments showing that both estrogens and OT are needed for SR, it was proposed that they could be interacting to mediate it. A model of this

interaction has been proposed, where estrogens bind to the estrogen receptors located in the paraventricular nucleus of the hypothalamus (PVN) to facilitate OT production and/or release. This OT then acts in the medial amygdala (MeA), a region important for SR since it receives direct projections from the olfactory bulbs. The OT will bind to the OT receptor in the MeA and allow the incoming olfactory information to be used to recognize a familiar conspecific, thus mediating SR. We have previously tested this model and found that administering 17b-estradiol (E2) into the PVN can rapidly facilitate SR, and that administering an OT receptor antagonist into the MeA can block the rapid facilitation of SR by E2 in the PVN. These results showed support for the proposed model of an interplay between estrogens and OT in the mediation of SR. Our current experiments are determining which estrogen receptor (ER) is mediating this interplay. Two of the ERs are highly expressed in the PVN: ER beta (ERb) and the G-protein coupled ER (GPER). We have found that the administration of agonists for either ERβ or GPER (DPN and G1 respectively) into the PVN can rapidly facilitate SR. Our current experiment is investigating if the OT receptor antagonist in the MeA can also block the rapid facilitation of SR by the ER agonists in the PVN. Preliminary results have shown that the OT receptor antagonist in the MeA can block the rapid facilitation of SR by the GPER agonist G1 in the PVN, but not the ERb agonist DPN. These results suggest that in the PVN, GPER, but not ERb, is mediating the interplay between estrogens and OT on SR.

Title: Autonomic state predicts baseline firing rates and response properties of neurons in the amygdala and somatosensory cortex

Authors: ***A. B. MARTIN**[1], R. ANDERSEN[2], L. HILLIER[1], G. SOMASEKHAR[1], M. CARDENAS[1], N. N. JACOBSON[1], S. J. BENSMAIA[3], A. J. FUGLEVAND[1], K. M. GOTHARD[1];
[1]Dept. of Physiol., [2]Col. of Med., Univ. of Arizona, Tucson, AZ; [3]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Neural responses to environmental stimuli depend not only on the specific features of the stimulus but also on the behavioral state of the organism. With this in mind, we explored the potential role of autonomic state in modulating the neuronal representations of discriminative vs affective elements of touch. To this end, we simultaneously monitored heart rate and single unit activity from the primary somatosensory cortex (SI), which carries discriminative tactile

representations, and the amygdala, which carries affective tactile representations, under varying levels of autonomic arousal. To manipulate arousal, we delivered to regions of the monkey's face and head either gentle, non-aversive puffs of air or sweeping touches from a human handler meant to mimic social grooming. Heart rate was significantly lower when the monkeys received social touch (puff median = 119, touch = 116 BPM, Wilcoxon signed rank $p < 2e-7$, N = 26 sessions), indicative of a decreased autonomic response. Surprisingly, changes in heart rate resulted in concomitant changes in baseline firing rate in both SI and the amygdala but the directionality of these relationships was reversed between the two areas. Across the population of SI neurons, lower heart rate was associated with lower baseline activity (linear regression median slope = 0.21, $p < 4e-17$, N = 135 cells) whereas in the amygdala lower heart rate was associated with higher baseline activity (median slope = -0.05, $p < 0.0003$, N = 430). Next, we examined the relationship between heart rate and stimulus-evoked responses in SI and the amygdala. In both brain areas, we found that the fidelity of the stimulus-evoked responses was inversely related to baseline activity, where lower baselines were associated with more reliable stimulus responses (SI median slope = -0.85, $p < 3e-32$, N = 195; amygdala median slope = -0.95, $p < 8e-89$, N = 633). Thus, sensory representations were enhanced in SI and suppressed in the amygdala when the monkey was in an autonomic state characterized by a lower heart rate. In fact, at low arousal, neurons in the amygdala showed prolonged tonic elevation in firing rates that spanned multiple stimulus events rather than responding phasically to individual tactile stimuli ($p < 0.02$). We hypothesize that responses in the amygdala encode the overall affective state of the animal and not the individual stimuli that induce the state whereas responses in SI encode individual stimuli and these stimulus representations are enhanced in low arousal states.

Title: The effects of testosterone on pro-social and pro-aggressive behaviours in male mice

Authors: ***D. ASPESI**, Z. R. BRILL, G. GUILLAUME, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Exhibiting successfully behavioural plasticity for appropriate responses to dynamic social environments is crucial to the survival of the individuals of social species. Among the social skills required for living in groups, social recognition (SR) is one of particular interest because it allows to identify previous investigated individuals and to emit appropriate pro-social

or -aggressive behaviours. Several studies highlighted the role of vasopressin (AVP) in aggressive and social behaviours, including SR. The vasopressinergic circuit includes highly sexually differentiated brain regions, such as the bed nucleus of the stria terminalis (BNST) and the lateral septum (LS), which show more AVP neurons and fibers in males than in females. Androgens play a key role in the organization and activation of this system. Furthermore, brain levels of sex hormones are rapidly impacted by social interactions, quickly regulating behaviours. The androgens/AVP interplay impact social and aggressive behaviours, even if the mechanisms involved are currently poorly understood. To elucidate testosterone (T)'s rapid effects on AVP neurons in the BNST of male mice, adult castrated male mice were intracerebrally infused with one of 4 doses of T (0.25, 0.5, 0.75, 1µg of T in 0.5µl of DMSO/side) in the BNST. They were then tested in a 'difficult' SR paradigm, in which castrated mice are impaired, and in a resident-intruder (RI) paradigm to assess aggressive behaviours. The 'difficult' version of the SR paradigm consisted in the exposure, 15 min after the infusion, to two 5-min sample phases with the same 2 stimulus mice and one 5-min test, whereas one of the stimuli was exchanged with a novel one. Each phase was separated by 5-min rests. For the RI paradigm, the focal animal was exposed to a castrated mouse for 5 min at 2 different time points (35 and 120 min) to evaluate rapid and genomic effects of T. Results revealed that T in the BNST rapidly facilitates SR, with male mice preferentially investigating a novel over a familiar castrated mouse with an inverted U-shaped dose-response. Moreover, even if T infusions did not elicit overt aggression towards the intruders, the highest doses altered the emission of dominants and submissive behaviours. The mice receiving 0.75 or 1µg of T increased their dominance score, with long-lasting effects in the 1µg group. Further investigations will determine the potential mechanisms, by evaluating the role of T metabolites and whether T modulates AVP release in the LS, potentially identifying a BNST-LS brain circuit of T/AVP interplay in the regulation of male social cognition.

Title: Longer looking time at high-ranking individuals depicted in videos of virtual social interactions

Authors: ***S. LEE**, T. M. CHAMP, B. T. SEATON, L. HILLIER, D. O'NEILL, A. B. MARTIN, K. M. GOTHARD;
The Univ. of Arizona, Tucson, AZ

Abstract: The status of interacting partners is a key determinant of social behavior, yet how the brain extracts this information from the behavior of others is unknown. The study of the neural representation of social status requires experimental manipulations that are seldomly possible under naturalistic conditions. To generate an adequate stimulus set we selected from videos of natural macaques' behavior segments that could be juxtaposed to mimic dominant-subordinate interaction between pairs of monkeys. In these videos (of 15-second duration), dominant animals threaten subordinates, who then react to these threats with appeasing displays. We generated one female and two male hierarchies with four members in each, allowing for six pairwise interactions. In these videos, the highest and lowest status individuals show only threatening and appeasing facial expressions, but the mid-ranking individuals show both dominant and submissive behaviors. Based on previous work in monkeys (Deaner *et al.*, 2005) we expected that the higher the social status of an individual, the more time the viewer monkey would spend looking at them. Indeed, a one-way ANOVA of looking time data from one male viewer monkey showed a significant difference in looking time with respect to hierarchy position ($F_{3,2624}$ = 152.9, $p < 0.0001$, n = 657 videos; Bonferroni post-hoc tests: $p < 0.001$ for all comparisons). We verified that the longer looking times elicited by dominant individuals are not explained by facial expressions, left-right side bias, or overall motion in the video. Ongoing experiments are expected to confirm these results in additional male and female monkeys. Furthermore, based on previous attempts to identify the neural corelates of social status (Munuera *et al.,* 2018) we expect neural activity in the amygdala to vary as we manipulate the perceived status of each individual.

Abstract: Cerebellar alterations are among the most replicated neuropathological findings in postmortem brain samples of individuals with autism. Besides, the cerebellum has been shown to

be involved in several non-motor related behaviors, such as sensory processing, which is usually affected in autism. However, how these alterations contribute to the autism spectrum phenotype remains unknown. In this study, we performed an electrophysiological characterization of the cortical cerebellar circuit in relation to sensory processing in the Cntnap2 Knock-out mouse model of autism, a model previously reported to have cerebellar-learning dysfunction. We performed local field potentials (LFP) and extracellular unitary recordings of identified Purkinje cells (PC) in the cerebellar area Crus I/II of alert mice during spontaneous activity and in response to whisker stimulation. Our results show striking differences in Cntnap2-KO mouse compared to wild type both in LFP and in extracellular PC recording. The components of sensory evoked potentials were altered in KO mice, showing aberrant components across time compared to WT. These aberrant components seem to have correlations with PC simple spikes. Further, a thorough analysis of PC activity reveals a higher variability in the firing pattern in mutant mice. We conclude that Cntnap2 mice show dysfunctional cerebellar sensory processing due to asynchronous response of PC to sensory inputs.

Group, KBRI, Daegu, Korea, Republic of; [5]Dept. of Brain and Cognitive Sci., DGIST, Daegu, Korea, Republic of; [6]Psychology and Program in Neurosci., Univ. of Washington, Seattle, WA

Abstract: We studied the brain mechanisms underlying action selection in a social dilemma setting where individuals' credits are unfairly distributed among group members. A stable 'worker-parasite' relationship developed when three individually operant-conditioned rats were placed together in a Skinner box equipped with response lever and food dispenser on opposite sides. Specifically, one rat, the 'worker,' engaged in lever-pressing while the other 'parasitic'

rats profited by crowding the feeder in anticipation. Anatomically, c-Fos expression in the anterior cingulate cortex (ACC) was significantly higher in worker rats than in parasite rats. Functionally, ACC inactivation suppressed the worker's lever press behavior under social, but not individual, settings. Genetically, $GABA_A$ receptor- and potassium channel-related mRNA expressions decreased in the worker's ACC. These findings indicate the requirement of ACC activation for the expression of exploitable effortful behavior in a social dilemma setting, which could be mediated by molecular pathways involving $GABA_A$ receptor/potassium channel proteins.

Title: Dorsal hippocampal D2-type dopamine facilitated social learning in male mice regulated by estrogenic mechanisms

Authors: ***N. BASS**[1], M. HICKEY[2], S. VAN DEN BERGHE[2], E. CHOLERIS[2];
[2]Psychology, [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Social learning is one of the most common forms of learning in almost all species and can be defined as learning that occurs via social interaction and/or social observation (Galef, 1988). The social transmission of food preference (STFP) paradigm is commonly used to test social learning in animals. During the STFP, intra-dorsal hippocampal (HPC) infusions of the D2-type dopamine (DA) receptor antagonist raclopride blocked social learning in female but not male mice, suggesting an interaction with sex hormones (Matta et al., 2017). Notably, later studies revealed that intra-HPC infusions of raclopride blocked social learning in gonadectomized male and female mice but not in gonadally intact male or female mice, suggesting a direct interaction between gonadal sex hormones and dorsal HPC D2-type DA receptors in social learning (Bass et al., 2019). However, the question of which specific sex hormone(s) are involved remains unanswered. The present study focused on the hormonal regulation of DA facilitated social learning in males because the previous findings were more robust in male mice. In the male brain testicular hormones may act via either androgenic or estrogenic mechanisms. In this study, we implanted castrated (CAS) “observer” (OBS) mice with subcutaneous slow releasing silastic capsules filled with either 1) the estrogen estradiol benzoate or a sesame oil control, or 2) the potent androgen dihydrotestosterone (DHT) or a cholesterol control. 10 days later (is this correct?) OBSs received bilateral intra-HPC infusions of raclopride (20 μg/μL) or a saline control 10-minutes prior to a 30-minute social interaction with a recently

fed, same sex, CAS "demonstrator" (DEM). Lastly, OBSs underwent an 8-hour choice test with free access to two novel flavored food diets, one of which their respective DEMs consumed before their social interaction. If social learning occurs, OBSs will prefer the DEM diet. Preliminary findings revealed that social learning was blocked following intra-HPC infusions of raclopride in CAS mice treated with the sesame oil control but not in CAS mice treated with estradiol. These findings appear to confirm the hypothesis that dorsal HPC D2-type DA receptors are interacting with estrogen receptors to regulate social learning in mice. Thus, D2-type DA-facilitated social learning appears to be regulated by estrogenic mechanisms in the male brain. However, these findings should be interpreted with caution until the DHT portion of the study is completed. This study was funded by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Title: Automatic tracking of mouse social posture dynamics by 3D videography, deep learning and GPU-accelerated robust optimization

Authors: *C. L. EBBESEN[1], R. C. FROEMKE[2];
[1]New York Univ. Sch. of Med., New York, NY; [2]Otolaryngology, NYU Med., New York, NY

Abstract: Social interactions powerfully impact both the brain and the body, but high-resolution descriptions of these important physical interactions are lacking. Currently, most studies of social behavior rely on labor-intensive methods such as manual annotation of individual video frames. These methods are susceptible to experimenter bias and have limited throughput. To understand the neural circuits underlying social behavior, scalable and objective tracking methods are needed. We present a hardware/software system that combines 3D videography, deep learning, physical modeling and GPU-accelerated robust optimization. Our system is capable of fully automatic multi-animal tracking during naturalistic social interactions and allows for simultaneous electro-physiological recordings. We capture the posture dynamics of multiple unmarked mice with high spatial (~2 mm) and temporal precision (60 frames/s). This method is based on inexpensive consumer cameras and is implemented in python, making our method cheap and straightforward to adopt and customize for studies of neurobiology and animal behavior.

Title: Eye-gaze dynamics using nonsocial and social visual guides for decision-making

Authors: ***J. SIMON, IV**[1,2], E. L. RICH[1,2];
[1]Nash Family Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY;
[2]Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: There has been increased interest in the neural dynamics underlying social cognition in recent years. In conjunction, research in rhesus monkeys has mainly focused on aspects of social perception, reasoning, and social valuation of rewards. While experimental designs have looked at how agents make decisions for or with others, it remains unclear how social information coming from others impact the agent's choices with respect to nonsocial rewards. To address this question, we have developed a reward localization task (RLT) that incorporates visual guides in the form of social (eye-gaze) and nonsocial (arrows) cues. The RLT experimental design has monkeys deciding between two identical squares representing a potential fruit juice reward. Each visual cue provides contextual information about the location of the rewarded target. Preliminary results show that monkeys are able to learn to use both types of visual cues and perform above chance-level of 50%. Interestingly, the viewing duration was longer for nonsocial cues compared to social cues. Gaze data also revealed the monkey spent more time looking at the visual cue during correct trials compared to incorrect trials. This

behavioral design sets the foundation for future neurophysiological studies on how the brain incorporates social information with non-social decision processes.

Title: Therapeutic benefits of vitamin D3 supplementation to rescue motor and cognitive disability in mouse model of Huntington's disease

Authors: *V. SRIMATH KOIL KANDADAI;
Dept. of Biol. Sci., Birla Inst. of Technol. and Sci. - Pilan, Telangana, India

Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder which leads to massive loss of neurons in the striatum. The onset of the disease is due to the presence of the mutation in the Huntingtin (HTT) gene present on the chromosome 4p16.3, where the number of CAG repeats present in HD affected patient is more than 40. Vitamin D3 (VD, cholecalciferol) is a known neurosteroid and affect myriad number of physiological processes. The present study was designed to explore neuroprotective role of VD supplementation in 3-nitropropionic acid (3-NP)induced mouse model of HD. 3-4 months old male C57BL/6 mice were divided into four groups based on their treatment i.e., Group I: Saline treated animals; Group II: 75mg/kg of 3-NP treated animals; Group III (HD): animals supplemented with 500IU/kg of VD for 15 days and GroupIV (HD + VD): animals supplemented with 500IU/kg of VD for 15 days’ post 3-NP treatment. Various behavioural tasks were undertaken to explore the effect of VD on movement, motor and memory like locomotion, stride length, rotarod and morris water maze. Thereby, striatal brain tissue was isolated from all the 4 groups on 30th day and mRNA expression of Vitamin D receptor(VDR), nerve growth factor (NGF) and brain derived neurotrophic factor (BDNF) were assessed. We found that Vitamin D3 (Cholecalciferol) intake significantly rescued striatal functions like motor activity, locomotion and spatial memory in HD animals with a significant enhancement in the expression of key neurotrophic factors like brain-derived neurotrophic factor (BDNF) and nerve-growth factor (NGF) together with increased Vitamin D receptor (VDR) mRNA expression. Altogether, our finding suggests that VD shows a therapeutic effect on motor dysfunction in HDv is a downstream neuroprotective pathway which involves a cross-talk between VDR and neurotrophic family of receptors. Key words: Huntington’s disease, 3-nitropropionic acid, vitamin D, behaviour, vitamin D receptor, nerve growth factor, brain derived neurotrophic factor.

Title: 'nothing to see here': no structural brain differences as a function of neuroticism and extraversion from a systematic review and meta-analysis of gray matter volume studies

Authors: *Y.-W. CHEN[1], T. CANLI[2];
[1]State Univ. of New York At Stony Brook, Stony Brooke, NY; [2]State Univ. of New York At Stony Brook, Stony Brook, NY

Abstract: Personality reflects social, affective, and cognitive predispositions that emerge from genetic and environmental influences. Contemporary personality theories conceptualize five traits: Neuroticism, Extraversion, Agreeableness, Conscientiousness, and Openness to Experience. Starting around the turn of the millennium, neuroimaging studies have begun to investigate functional and structural features in the brain of these traits. Here, we present the first study to systematically investigate the association between Neuroticism and Extraversion, the two most commonly studied personality traits, and gray matter volumes, analyzing the literature of studies in a systematic review and meta-analysis. We observed some consistent results (e.g., Neuroticism and frontal regions; Extraversion and temporal regions) as well as some inconsistent results (e.g., Neuroticism and temporal, subcortical regions; Extraversion and frontal, subcortical regions) from the systematic review. These findings failed to be confirmed when we used a quantitative meta-analytic approach. Potential explanations to account for these discrepancies were discussed, including sample heterogeneity, five-factor trait measurements, structural image data acquisition, processing, and analytic strategies, statistical approach and statistical significance threshold, and complex nature and individual differences of personality construct and brain structures. Our conclusions will help to guide future research by adopting more rigorous designs and analytic approaches.

Title: The dorsolateral prefrontal cortex presents structural variations associated with empathic capacity in psychotherapists

Authors: *M. E. DOMÍNGUEZ-ARRIOLA, V. E. OLALDE-MATHIEU, E. A. GARZA-VILLARREAL, F. A. BARRIOS;
Inst. of Neurobio. (INB - UNAM), Querétaro, Mexico

Abstract: Empathic capacity has been shown to be correlated with brain structural variations. This study investigates how this is the case in a group of psychotherapists who have a constant demand to modulate their empathic response. Eighteen professionally active psychotherapists and eighteen healthy controls underwent 3-Tesla MRI scanning and completed empathy-related psychometric assessments. Cortical thickness (CT) measures were estimated for each participant using the CIVET 2.1.0 pipeline. We evaluated how these measures differed between groups, and if they were associated with individual empathy scores at a series of regions of interest. Our analysis shows that psychotherapists display a significantly greater CT at the left dorsolateral prefrontal cortex (dlPFC; p < 0.05, FDR corrected). Moreover, psychotherapists' CT in this region is correlated with the tendency to feel empathically concerned for others (p < 0.01, FDR corrected). Finally, psychometric scores show that psychotherapists have a higher tendency to adopt the other's perspective to understand how they feel, and a lower tendency to use expressive suppression as an emotion regulation strategy. These findings are relevant because this dlPFC region participates importantly in emotion regulation and perspective taking processes. Thus, our findings support the idea that empathic capacity is reflected by brain structural variations, recruiting for the first time a sample of subjects for whom empathic responding is crucial in their profession.

Title: Neural differentiation of self vs. other trait judgments by timing and magnitude of processing stages: implications for a theory of mind model of self-referencing

Authors: *M. REESE[1], L. E. ETHRIDGE[2,1];
[1]Psychology, Univ. of Oklahoma, Norman, OK; [2]Pediatrics, Univ. of Oklahoma Hlth. Sci. Ctr., Norman, OK

Abstract: Simulation theory (ST) states that people understand others through simulation, which counters the probabilistic reasoning view of theory theory (TT). When thinking about traits of a close other, people use self-referential thought (Mitchell et al., 2006; Moran et al., 2011). It is

unclear which theory—ST or TT best describes the method by which self-referential thoughts occur. A combination of event-related potential (ERP), event-related spectral perturbation (ERSP), source localization, and hidden semi-Markov model multivariate pattern analysis (HSMM-MVPA) techniques are hypothesized to disentangle the neural underpinnings of self-versus-other information processing and distinguish competing theory of mind theories during a trait judgment task. EEG was recorded for 45 participants (30 females) ages 18-24 (M = 19.4) on resting and task measures, in which participants determined whether a series of character and appearance words match characteristics of the self and a close and distant other. Data analysis included repeated measures MANOVAs of reaction times, ERP amplitudes and latencies for the P300 generated from the parietal lobe (PCC/precuneus) and latter components of the frontal (mPFC) and parietal LSW. Time-frequency analysis included evoked and induced power through 100 Hz. ERP amplitudes were localized using minimum norm estimation to verify location and timing assumptions made for P300 and LSW. Lastly, an HSMM-MVPA approach provided an alternative look at differences in number and timing of processing stages. Results for the P300/LSW and source localization showed no differences between self, mother, and Fallon, which did not reflect prior BOLD activation (Moran et al., 2011). Overall, the ERP data did not have enough power or specificity to detect changes amid highly variable trials. Differences in self and mother were predicted by induced gamma power, suggesting the role of high frequency oscillations in information integration and categorization in the frontal and centroparietal regions. HSMM-MVPA models fit TT predictions and showed significant self-other differences in both duration of processing stages and magnitude of peaks. Findings suggest a timing and amplitude difference in self-other processing that parallels the TT probabilistic reasoning model of self-referencing. Future research should clarify the role of the mPFC in self-referential thought and its relation to ST and TT with simultaneous fMRI and EEG and populations with impaired self-recognition such as ASD and schizophrenia.

Title: Decoding communicative intentions using real-time brain activity

Authors: *A. E. HADJINICOLAOU[1], Y. AMIDI[1], G. BELOK[1], A. C. PAULK[1], Z. W. WILLIAMS[2], A. YOUSEFI[3], S. S. CASH[1];
[1]Neurol., Massachusetts Gen. Hosp., Boston, MA; [2]Neurosurg., Harvard Med. Sch., Boston, MA; [3]Computer Science/Neuroscience, Worcester Polytechnic Inst., Worcester, MA

Abstract: Humans constantly shift their goals and intentions. This is perhaps most pronounced during the act of conversation, in which the words of a companion change our thoughts and ultimately lead to the genesis of communicative intentions that unfold over a wide range of time scales. The study of intentions, as with many other high-level cognitive objects, is challenging as they are thought to arise from the activity of a distributed network of regions throughout the brain and are therefore difficult to measure directly. To examine such systems under natural conditions, we analyzed intracranial brain activity from N=6 epileptic study participants (implanted with electrodes for clinical purposes) who participated in recorded conversations with family, friends, and hospital staff. After transcribing spoken dialog to yield individual word timings for each participant and their companions, we modeled intent state as a latent variable whose dynamics were inferred from the onset of spoken words. We then built neural decoders for speech intent using spectral power estimates (theta, alpha, beta, gamma bands) of the recording channels as predictors. This was a two-stage process, in which we first determined the most informative predictors for intent state by fitting lasso-regularized maximum-likelihood coefficients for generalized linear models (GLMs) and standardizing these coefficients to account for their relative variance. In the final stage, GLM decoders were constructed for multiple predictor sets defined by a selection of (a) up to three different frequency bands, and (b) the best-p predictors for the selected frequency bands. Our results demonstrate that unexpected and widespread brain structures are predictive of speech intent. More specifically, spectral power predictors in theta (4-8 Hz) and gamma (30-50 Hz, 70-115 Hz, 125-200 Hz) bands were found to be most useful in decoding speech intent in the amygdala and hippocampus. To our knowledge, this study is the first to investigate the dynamics of communicative intent using ordinary human conversations and couple these dynamics with intracranial brain recordings.

Title: Inter-brain electroencephalography synchronization during joint tapping: A comparison between stranger pairs and acquainted pairs

Authors: *Y. KURIHARA[1], T. TAKAHASHI[1,2], R. OSU[2];
[1]Grad. Sch. of Human Sci., [2]Fac. of Human Sci., Waseda Univ., Tokorozawa, Japan

Abstract: Inter-brain synchronization (IBS) provides information on interpersonal relationships. For example, romantic couples showed higher IBS than pairs of individuals not familiar with one another (Kinreich et al., 2017). However, the identification of the brain regions whose IBS

correlates more with interpersonal relationships is still unknown. We simultaneously recorded electroencephalography (EEGs) from two individuals during the joint tapping task and compared IBS between strangers who meet for the first time and acquaintances who already knew each other. Seven stranger pairs (male pairs: four, female pairs: three, mean age:23.64, SD age: 4.31) and nine acquainted pairs (male pairs: four, female pairs: five, mean age:20.85, SD age: 1.27) volunteered for this study. IBS was evaluated using the Circular Correlation Coefficient (CCorr). For each pair of EEG electrodes between two participants, CCorr was measured. The average was calculated through the electrodes within each of the six regions of interest (ROIs; frontal, central, right-temporal, left-temporal, parietal, and occipital regions). The task comprised two resting conditions (Pre and Post) and four tapping conditions (Slow; 2 Hz, Fast; 4 Hz, Free; no reference of Hz, and Pseudo; tap to 2 Hz metronome). We conducted a two-way analysis of variance (ANOVA) considering the interpersonal relationship conditions (stranger pairs or acquainted pairs) and tapping conditions for each ROI. In the central region, significant differences in alpha IBS were observed between the interpersonal relationship conditions ($F_{1,14}$=7.39 ,p=.017,η_p^2=.346). However, tapping conditions and interaction of the two factors were not significant. ANOVA demonstrated the stranger pairs displayed higher IBS than the acquainted pairs in contrast with the earlier finding (Kinreich et al., 2017). The interpersonal interaction did not significantly affect the theta (4-7Hz) or beta (13-30 Hz). In the other five ROIs, there was no significant influence on interpersonal relationships. The central region with substantial IBS in the alpha included the motor area (C3, C4), where the alpha EEG was synchronized during joint tapping in Kawasaki et al. (2018). The observed significantly larger IBS in the stranger pairs than in the acquainted pairs may be explained by the possibility that the participants in the former pairing were more polite with each other. However, IBS depends on the type of behavioral task (Kingsbury and Hong, 2020), such as cooperation and competition. Therefore, future studies should examine the effect of interpersonal relationships on IBS during other behavioral tasks.

Title: Modality-specific opioidergic modulation of empathy for pain

Authors: *M. RÜTGEN[1], E.-M. WIRTH[1], I. RIECANSKY[1], M. WOLETZ[2], C. WINDISCHBERGER[2], G. SILANI[1], P. PETROVIC[3], C. LAMM[1];

Abstract: The shared representations account of empathy proposes that similar mechanisms underlie pain and its empathic experience. Previously, we found supportive evidence for this account, demonstrating that causal experimental manipulations of first-hand pain affect empathy for pain in a similar way. In a functional magnetic resonance imaging experiment (N = 102), placebo analgesia modulated both experiences, as indicated by decreases in subjective pain ratings and activity in brain regions that are part of a shared network of pain and empathy for pain. In a follow-up psychopharmacological behavioral experiment (N = 50), we then successfully blocked placebo effects for pain and its empathic experience using an opioid receptor antagonist (naltrexone). In the present study, we aimed at assessing whether these previously observed effects were specific for pain or a domain-general effect of placebo analgesia on affective processing. To this end, we analyzed imaging and self-report data of an empathy for affective touch paradigm, which participants of the aforementioned experiments performed immediately after the empathy for pain task. Placebo analgesia significantly reduced empathy for unpleasant touch and its first-hand experience, but did not affect pleasant touch. We found both overlapping and modality-specific neural placebo effects for pain and unpleasant touch in the bilateral anterior insula. Conversely, activity in the anterior midcingulate cortex was only modulated during experiences of pain. In contrast to previously observed effects on pain, naltrexone had no significant effects on any kind of affective touch. Our findings suggest a modality-specific involvement of opioidergic mechanisms in pain empathy and shed light on the neuro-chemical underpinnings of empathy.

Title: In amygdala we trust: different contributions of the basolateral and central amygdala in social experiential learning

Authors: *R. SLADKY, F. RIVA, L. ROSENBERGER, C. LAMM;
Univ. of Vienna, Vienna, Austria

Abstract: Human societies are built on cooperation and mutual trust. Yet, not everybody is trustworthy. Through repeated interactions, we learn to adapt our social behavior accordingly. The amygdala, in general, is widely regarded as paramount for social cognition (Adolphs, 2010). Human patients with acquired BLA damage with acquired BLA damage failed to adapt their trust behavior towards trustworthy vs. untrustworthy interaction partners in a repeated trust game (Rosenberger et al., 2019). However, functional reorganizations and comorbidities might limit

the generalizability of these findings to neurotypical populations. Neuroimaging studies in neurotypical human samples indeed do not consistently report involvement of the amygdala in trusting others. This may be due to a lack of differentiation between subnuclei and their different functions in the development of trust. Here we used the same repeated trust game previously used in patients (Figure A) in neurotypical volunteers (age=23.83±3.15 years, f/m=31/31) while undergoing functional MRI (3 T Siemens Skyra, MB-EPI factor=4, TR/TE = 704/34 ms, $2.2\times2.2\times3.5$ mm^3, $96\times92\times32$ voxels). We observed that both the BLA and the central amygdala (CeA) played a role, but they were relevant for different aspects (Figure B). While the BLA was most active when obtaining feedback on whether invested trust had been reciprocated (or not), the CeA was most active when participants were anticipating their trust decisions (Figure C,D). Only in those who learned to differentiate between the trustees (measured by a difference in their investments and their subjective ratings), BLA and CeA were significantly more active for untrustworthy trustees before choosing whether to trust or mistrust this trustee (Figure C,D boxplots). In sum, we show that the amygdala is highly relevant for learning about the trustworthiness of an interaction partner, also in neurotypical subjects. However, its involvement is heterogeneous with respect to anatomical (BLA vs. CeA), functional (introduction vs. outcome), and individual factors (learners vs. non-learners).

Title: Electroencephalography (EEG) hyperscanning measurements in children with neurodevelopmental disorders, their mothers, and music therapists

Authors: *K. KANG[1,2], S. ORLANDI[2], N. LORENZEN[3], T. CHAU[2,1], M. H. THAUT[1]; [1]Univ. of Toronto, Toronto, ON, Canada; [2]Holland Bloorview Kids Rehabil. Hosp., Toronto, ON, Canada; [3]Univ. of Guelph, Guelph, ON, Canada

Abstract: Music arouses emotions and is also one of the most powerful tools to bring people together. Previous findings showed that physiological indicators can align spontaneously and contemporaneously between people during social interaction. Electroencephalography (EEG) research has shown this also for music-based interaction, how interbrain synchronization emerges while performers in music ensembles interact musically with each other. In such context music drives a mutually calibrated state of emotional and physiological 'synchronization'. However, this interbrain synchronization in clinical settings has less been studied. Thus, we investigated interbrain synchronization in the child with disabilities-mother (CM) dyads and the child with disabilities-music therapist (CT) dyads during a music session. A total of seven dyads participated in a 15-minute-long music session (Table 1). During the music session, the music therapist played the guitar and sang the child's favorite songs. The parent observed their child's responses through the screen in a partitioned area. Interestingly, the results showed a significantly higher interbrain synchronization in CM dyads (M = .24, SD = .02) compared to CT dyads (M = .17, SD = .001), $p < .001$, possibly due to music familiarity, and maternal cognitive-empathy and emotional predisposition. In addition, higher interbrain synchronization occurred in empathy-related frequency bands (delta: 0-3 Hz) in CM and in cognition-related frequency bands (alpha: 8-15 Hz) in CT. Both dyads also experienced higher synchronization in the frontal and temporal lobes which are associated with socio-emotional responses. These findings opened the possibility of using interbrain synchronization as an objective measurement of socio-emotional responses in children with neurodevelopmental disorders. For example, if there is less synchrony in CM and/or CT dyads than expected, a therapist or parent may alter their approach to engage with the child.

Title: The Role of Autobiographical Memory in Empathy. An EEG and fMRI investigation.

Authors: *F. MECONI[1], C. FERREIRA[1], J. LINDE-DOMINGO[2], S. MICHELMANN[3], B. STARESINA[1], I. A. APPERLY[1], S. HANSLMAYR[4];

Abstract: Empathy is the ability to feel and understand others' inner states at the basis of any social interaction. Theoretical accounts suggest that past experiences play a role in empathy but direct evidence of a reactivation of autobiographical memories (AM) in empathy is yet to be shown. We addressed this question in two experiments. In experiment 1, electrophysiological activity (EEG) was recorded from 28 healthy students who were required to judge their empathy for individuals depicted in contexts for which participants either did or did not have an AM. This empathy task was followed by a task that explicitly required memory retrieval of the AM and non-AM contexts. The retrieval task acted as a localizer aimed to extract the neural fingerprints of the mental representation of AM and non-AM contexts, which were then used to probe data from the empathy task. An EEG pattern classifier was trained and tested across tasks and showed evidence for AM reactivation when participants were preparing their judgement in the empathy task. Participants self-reported higher empathy for people depicted in situations they had experienced themselves as compared to situations they had not experienced. This behavioural finding was replicated in experiment 2 in which hemodynamic activity was recorded from an independent sample of 28 participants performing the same empathy task as in experiment 1. Consistently with previous neuroimaging studies showing brain activations underlying empathic processes, we observed greater activation in precuneus, posterior parietal cortex, superior and inferior parietal lobule and superior frontal gyrus when targets of empathy were depicted in AM as compared to non-AM contexts. Taken together, our findings show evidence for the reactivation of AMs in empathy that magnifies self-perception of empathic feelings.

Title: Social isolation impairs the prefrontal-nucleus accumbens circuit responsible for social recognition in mice

Authors: G. PARK, C. RYU, S. KIM, S. KIM, *Y.-S. LEE;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Social isolation impairs the prefrontal-nucleus accumbens circuitresponsible for social recognition in mice
It is well known that social experience in early life causes prolonged deficits in cognitivefunctions. Previously, social isolation in the postnatal critical period has been shown to affect variousmedial prefrontal cortical (mPFC) functions including social preference in mice. However, it is stillelusive how other aspects of social functions and which downstream targets for the mPFC areaffected by the insubstantial social experience in young age. In this study, we observed that sociallyisolated mice in their postnatal developmental period show an impairment in social recognitionwhich was not rescued by following re-socialization period. Interestingly, we found that thefunctional connectivity between mPFC and the shell part of nucleus accumbens (NAc shell) is alteredafter the social isolation. Monitoring neural activity either by c-fos staining or by in vivo fiberphotometry revealed that mPFC neurons projecting to NAcSh selectively activated whenencountered by familiar conspecifics, suggesting that this circuit may encode social familiarity.Chemogenetic inhibition of mPFC to NAc shell projecting neuron showed a significant impairmentin the social recognition without affecting social preference while activation of such neuron insocially isolated mice exhibited a rescued social behavior. This result suggests that early socialexperience of mice can have a lifelong-lasting impact on their social behavior, which phenomenoncritically involved by mPFC-NAc shell circuit.

Title: Prefrontal thalamocortical and corticothalamic networks in mouse social behavior

Authors: *C. HABERL[1], A. C. BRUMBACK[2];
[1]Neurol., [2]Neurology, Pediatrics, Neurosci. and The Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX

Abstract: The medial prefrontal cortex (mPFC) reciprocally connects with the mediodorsal nucleus of the thalamus (MD). This bidirectional circuit has been implicated in a range of cognitive and social / emotional behaviors. Here, we tested the hypothesis that the mPFC⇄MD circuitry is required for novel social exploration behavior in mice. To do this, we optogenetically activated mPFC→MD and MD→mPFC projection neuron terminals in wildtype mice in the following behavioral assays: novel mouse exploration, novel object exploration, open field, olfactory habituation / dishabituation. We observed that optogenetic activation of the mPFC→MD or MD→mPFC axon terminals decreased social exploration behavior. Notably, the other behaviors tested were largely unaffected. These results imply that the bidirectional MD⇄mPFC circuit is required for social exploration behavior.

Title: Role of Hypothalamic Paraventricular Oxytocin Neurons in Social Recognition Memory

Authors: *K. THIRTAMARA RAJAMANI[1], K. NIBLO[1], V. GRINEVICH[2], H. HARONY-NICOLAS[1];
[1]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Univ. of Heidelberg, Heidelberg, Germany

Abstract: TitleRole of Hypothalamic Paraventricular Oxytocin Neurons in Social Recognition MemoryAuthorsKeerthi Thirtamara Rajamani, Kristi Niblo, Valery Grinevich, Hala Harony-NicolasAbstractOxytocin is a nine amino acid neuropeptide that is synthesized and released by neurons in the paraventricular (PVN), supraoptic and accessory nuclei of the hypothalamus. It is implicated in social behaviors including maternal care, social bonding, and social recognition memory. Social recognition memory (SRM) in mammals is a corner stone for several behaviors which together contribute to their evolutionary fitness, starting from being able to distinguish prey from conspecifics to reproductive behaviors and kinship. Despite the clear role of oxytocin in SRM, it is still unclear which of the three nuclei within the hypothalamus is necessary for the formation of this form of memory. We hypothesized that oxytocin neurons within the PVN of the hypothalamus are necessary for both short- and long-term SRM. Using designer receptors activated by design drugs (DREADDS), we specifically silenced oxytocin neurons (OT-hM4DGi) in the PVN of wild type Sprague Dawley rats and assessed their performance on both

short and long term SRM.We found that following saline injection, rats exhibited normal short and long-term SRM. However, upon clozapine N oxide (CNO) injection and, via silencing of OXT neurons in the PVN, the same animals failed to exhibit either forms of memory. In order to account for nonspecific effects of CNO, we performed the same behavior in a different cohort of rats that were injected with a control virus (OT-mcherry), which lacks the DREADD. We found that CNO does not have a nonspecific effect, suggesting that the behavioral effects observed in the DREADD injected animals are a result of silencing of oxytocin neurons in the PVN.Taken, together these findings attribute a novel role for PVN oxytocin neurons in social recognition memory. Future studies are aimed at identifying the downstream targets of these OXT projections neurons that originate in the PVN and their ability to modulate OXT dependent social recognition memory.

Title: Anterior insula-associated social novelty recognition: orchestrated regulation by a local retinoic acid cascade and disynaptic oxytocin-serotonin signaling

Authors: *K. AN[1], S.-H. KIM[1], H. NAMKUNG[1], M. MIHALJEVIC[1], K. YANG[1], B. MAHER[2], M. NIWA[1], A. SAWA[1,3];
[1]Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Lieber Inst. for Brain Development, Johns Hopkins Med. Campus, Baltimore, MD; [3]Johns Hopkins Univ. Bloomberg Sch. of Publ. Hlth., Baltimore, MD

Abstract: Social cognition is critical for human behavior in complex social environments, and deficits in social cognition consistently underlie functional disabilities in individuals with a wide range of psychiatric disorders. Neuroimaging studies have suggested that the anterior insula (AI) is a ‘common core’ brain region that is impaired across neurological and psychiatric disorders, which include deficits in social cognition. Nevertheless, neurobiological mechanisms of the AI for social cognition remain elusive. Here we demonstrate that the AI is a crucial center for social novelty recognition and decipher its regulatory mechanisms at both cell-autonomous and cell non-autonomous levels. At the molecular and cellular level, AI-associated social novelty recognition is maintained by proper activity of AI layer 5 pyramidal neurons, for which retinoic acid (RA)-mediated gene transcription, regulated by an AI-enriched RA-degrading enzyme

Cyp26B1, plays a pivotal role. At the circuitry level, social novelty recognition is regulated by 5-HT2C receptor-mediated serotonergic inputs from the dorsal raphe nucleus (DRN) to the AI. Furthermore, we demonstrate that oxytocin (OT) influences the AI-mediated social cognition not by a direct projection of OT neurons, nor by direct diffusion of OT in the AI, but instead, by influencing the serotonergic projections in the DRN. Together, we demonstrate an orchestrated regulation of AI-mediated social novelty recognition by a local RA cascade and disynaptic OT-serotonin signaling.

Title: The left temporoparietal junction causally supports goal emulation in human observational learning

Authors: ***L. ZHANG**[1], F. I. KANDIL[2], C. C. HILGETAG[2], C. LAMM[1], J. GLÄSCHER[3]; [1]Fac. of Psychology, Univ. of Vienna, Vienna, Austria; [2]Inst. of Computat. Neurosci., [3]Inst. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Humans learn from their own trial-and-error experience and observing others by inferring their goals (i.e., goal emulation) in order to guide future decisions. Previous studies have established a comprehensive neurocomputational account of the integrated value computation between directly earning and social observational learning (e.g., Zhang & Gläscher, 2020, Science Advances). Crucially, these studies have identified that bilateral temporoparietal junction (TPJ) is functionally associated with goal emulation. To date, however, the causal role of bilateral TPJ in such observational learning processes remains unclear. Here, employing a within-subject double-blind continuous theta-burst stimulation (cTBS; Huang et al., 2005) over bilateral TPJ as well as vertex (control), we tested how the (bilateral) TPJ supports goal emulation in observational leaning, with a probabilistic reversal learning task (N = 31, female: 17). Participants on each trial were first required to choose between two stimuli, after they have seen the choices from four other co-players, they had the opportunity to adjust their choices. A probabilistic reward was then delivered given their second choice. Notably, the four co-players were instructed to the participants as “intelligent computers,” and choices from those computers were in fact generated from our computational algorithm model (Zhang & Gläscher, 2020), such

that they matched with actual human behavior. To increase ecological validity, we used human faces to indicate each computer. Behavioral results indicate that disrupting activity in the left TPJ resulted in reduced choice switch probability paired with longer response time when confronted with opposing social information, as opposed to the right TPJ and vertex conditions. In addition, choice accuracy was declined when participants actually switched their choices in the left TPJ condition, showing opposite pattern relative to right TPJ and vertex conditions. Computational modeling with the hierarchical Bayesian approach suggests that the corresponding parameter quantifying social information significantly decreased in the left TPJ condition, as compared to the right TPJ and vertex conditions. And the associated between this model parameter and behavioral performance is the weakest in the left TPJ condition. Together, our results provide evidence for the causal role of left TPJ in supporting goal emulation in human observational learning.

Title: Brain networks for self-recognition from whole-body movements

Authors: *A. KADAMBI, G. ERLIKHMAN, M. JOHNSON, M. MONTI, H. LU;
UCLA, Los Angeles, CA

Abstract: Humans can identify own-body movements presented in whole body point-light actions despite little visual experience of seeing themselves from third person. Though this ability taps into the core of dynamic self-awareness, the neural mechanisms remain unknown. In the present study, we utilized functional neuroimaging to examine which brain networks may support self-recognition from whole-body movements. Twelve right-handed participants (males = 6, females = 6, M_{age} = 20.00) performed six visually instructed actions (e.g., "perform *argue"*) and six verbally instructed actions ("*imitate* the movements in the video"), which were recorded by a motion capture system. One of each participant's friends (gender-matched) was also recruited to record motion capture data for performing the same actions. After a delay period of 12 - 20 days, the participants ran a fMRI session in which they viewed point-light actions either performed by the participant self, gender-matched friend or stranger. Participants were asked to make a self-recognition judgment among three choices (i.e., self, friend, or stranger). Each point-light action was presented for five seconds. The experiment consisted of four runs of 36 trials each. Behavioral accuracy in self-recognition from point-light displays (0.48) was significantly

above-chance (0.33). Brain activity was first compared between self-action and stranger-actions. Perception of own-body movements activated bilateral inferior parietal lobule (IPL; supramarginal gyrus), left inferior frontal gyrus (IFG; pars opercularis), posterior superior temporal sulcus (pSTS; input to the mirror neuron system), as well as the prefrontal cortex (dlPFC; dorsolateral). Self-specific activity controlling for familiarity (i.e., self-action versus friend-action) similarly showed involvement of bilateral IPL and left IFG activity. Greater engagement of lower-level visual (extrastriate body area), and primary motor (M1) and somatosensory (S1) regions was found during processing of stranger and friend-actions versus self-actions. These results extend theories of visuomotor recruitment during domain-general action processing, and highlight a possible self-specific action circuitry, consisting of fronto-parietal mirroring (pSTS, IFG, IPL) and control network (dlPFC) regions recruited during dynamic movements.

Title: An Ensemble Classifier for Decoding Hippocampal Spike Patterns During a Delayed Match-to-Sample Task in Human

Authors: *X. SHE[1], B. MOORE[1], B. M. ROEDER[3], G. NUNE[1], B. LEE[1], S. SHAW[5], A. NGUYEN[5], C. HECK[1], C. LIU[1], S. A. DEADWYLER[4], R. E. HAMPSON[4], T. W. BERGER[2], D. SONG[2];
[2]Biomed. Engin., [1]USC, Los Angeles, CA; [3]Neurosci., [4]Wake Forest Sch. of Med., Winston Salem, NC; [5]Rancho Los Amigos Rehabil. Ctr., Downey, CA

Abstract: To understand how visual memories are encoded in the hippocampal spiking activities in human, an ensemble memory decoding model is developed to classify spike patterns into memory labels on a single trial basis. Model inputs are spatio-temporal patterns of spikes recorded in the hippocampal CA3 and CA1 regions of epilepsy patients performing a delayed match-to-sample (DMS) task. Each DMS trial is initiated by touching the screen within the focus ring on the computer screen. The “Sample” phase starts after the focus ring clicks, and a sample image shows up at a random location on the touch screen. Once subjects touch the sample image, a random delay occurs, and then the “Match” phase starts. In the “Match” phase, the same sample image is displayed with four other non-match distracter images. Subjects are required to touch the correct sample image to achieve a successful trial. Sample images shown in the task are categorized with binary memory labels indicating their categories and features. Such memory

labels are used as outputs of the decoding model. The ensemble memory decoding model consists of two layers. In the first layer, to solve the underdetermined problem resulting from small sample size and the very high dimensional input and output signals, B-spline basis functions are applied to reduce dimensionality; L1-regularized logistic regression (LASSO) classifiers are used to achieve sparse model estimation. Multiple classifiers with different B-spline resolutions are employed to include a wide range of temporal resolutions of neural signals. Each classifier serves as a base-learner to classify spatio-temporal patterns with a given temporal resolution. A bagging-based sampling strategy is used to further reduce the estimation variances of these classifiers. In the second layer, another LASSO classifier takes outputs of first-layer classifiers as inputs to make the final output prediction. This ensemble classifier serves as a meta-learner that combines multiple temporal resolutions to classify the spatio-temporal patterns of spikes. Results show that this method can effectively avoid overfitting and yield significant prediction of memory labels. The ensemble classifier consistently outperforms the best single-layer classifier by utilizing multi-resolution spatio-temporal features of spike patterns in classification. In addition to decoding memory contents, the proposed model can also be used to design optimal stimulation patterns for eliciting specific memories in the hippocampus and thus has important implications for the development of hippocampal memory prostheses.

Title: Size matters: larger images are better remembered during free viewing

Authors: *S. MASARWA, O. KREICHMAN, S. GILAIE-DOTAN;
Sch. of Optometry and Vision Science, Fac. of Life Sci., Bar Ilan Univ., Ramat Gan, Israel

Abstract: We are constantly exposed to multiple visual scenes, and while freely viewing them without an intentional effort to memorize or encode them, only some are eventually remembered. It has been suggested that image memorability is influenced by multiple factors as depth of processing, familiarity, and visual category. However, this is typically investigated with intentional or unintentional encoding tasks. Furthermore, since visual memory relies on size-invariant high-level visual perception that is less sensitive to image size, image size is not typically considered a contributing factor. Here we reasoned that during naturalistic visual behavior of free viewing, of images without an encoding task, bigger images would be better remembered due to multiple factors (as vaster expanse of activated visual cortex, deeper

processing and others). In an extensive set of experiments participants (n=117) freely viewed small to large images (3-24 vis. deg.) without any encoding task or knowledge about a memory test that may follow. Subsequently, they were presented with mid-sized images (50% already seen) and were asked to report if they recall seeing them or not. Larger images were better remembered (~23% more than smaller images), image memorability was proportional to image size, faces were better remembered, and outdoors the least. These were independent of image set, presentation order, or screen resolution. Furthermore, when the amount of information in the images and its world size were kept constant but viewed from different distances (changing the retinal image size), memory performance was influenced by the retinal image size and not by the other factors. While multiple factors affect image memorability, here we show that during free viewing with no encoding task, a basic physical image dimension influences its memorability.

Title: Investigating the neural correlates of retroactive interference at encoding: an EEG study

Authors: *M. MUNSEN, J. D. KOEN;
Psychology, Univ. of Notre Dame, Notre Dame, IN

Abstract: It is well established that encountering a new, but similar, experience can induce retroactive interference that results in forgetting a previous experience. Evidence from multivariate analyses of fMRI data suggests that reactivating a previous experience during potentially interfering experience might protect against retroactive interference. However, little is known about if the time course of memory reactivation differentially predicts resistance to retroactive interference. The present study addressed this question by leveraging the temporal resolution of EEG with an AB/AC interference paradigm. We recorded EEG from 32 participants during a task where they encoded a series of words while performing one of four judgment tasks. Words in the Interference (AB/AC) condition were presented twice (associated with two different encoding judgments) whereas words in the Control (DE) condition were presented only once. Following encoding, participants completed a source memory test where they were required to recall the judgment(s) that were performed with each word seen during the encoding phase. As expected, source memory accuracy was lower for both tasks on Interference trials relative to the Control trials. The main analysis of the EEG data focused on two putative correlates of episodic memory retrieval—the FN400 and LPC - because, if the AB task is being reactivated during AC learning, we should see differences in the amplitude in one or both of these components during AC trials as a function of subsequent AB source memory. However, a one-way repeated measures ANOVA on AC trials with a within-subjects factor of AB subsequent memory showed no significant AB memory effects for the FN400 nor LPC.

Moreover, a similar analysis using a scalp-wide cluster mass test did not identify any AB subsequent memory effects during AC trials. Furthermore, a scalp-wide within-subjects cluster mass test performed showed only canonical front-central subsequent memory effects that were similar for AB, AC, and DE trial types. The present results suggest that the electrophysiological correlates of memory encoding do not differ with retroactive interference. Future analyses will employ multivariate classification of the EEG data to further address the question of reactivation.

Title: Replicability of fMRI Subsequent Memory Effects in Children and Adults

Authors: *L. TANG, Q. YU, P. J. PRUITT, Q. YIN, R. HOMAYOUNI, J. DAMOISEAUX, N. OFEN;
Wayne State Univ., Detroit, MI

Abstract: With the advent of neuroimaging techniques such as functional MRI (fMRI), scientists have been able to characterize the neural correlates of memory functions and investigate the neural basis underlying changes in memory function across development. However, in recent years, the replicability and consistency of task-based fMRI effects have been broadly questioned, and specifically, the replicability of memory-related fMRI effects such as those obtained by the commonly used subsequent memory paradigm remains unknown. Consistency and replicability are particularly important in developmental studies in which interpretations are often based on the assessment of age-related individual differences in observed fMRI effects.
In this study, we investigated the reliability of behavioral and brain measures observed using a subsequent memory paradigm in a sample of children, adolescents, and adults (n = 85; ages 8 to 25, 16.51 ± 4.73). We found excellent replicability for contrasts related to general task performance (all encoding trials vs. implicit baseline; ICC = .94) and reduced but good replicability for a specific contrast targeting subsequent memory (Hit trials vs. Miss trials; ICC = .73). Better replicability was found in cortical regions, including frontal, parietal, and occipital cortex, but reduced in subcortical regions, including the hippocampus.
We argue that the group-level subsequent memory effects are replicable for children and adults, although the level of confidence varies by the choice of contrast and brain regions.

Title: Cortical signal at major boundaries between internally-generated mental contexts during narrative recall

Authors: *H. LEE, J. CHEN;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Growing evidence suggests that humans identify boundaries between events in a continuous stream of stimuli based on the mismatch between predicted and actual sensory inputs, and that boundary detection is associated with transient cortical and subcortical responses. However, little is known about neural responses at transitions between mental contexts during experiences that are internally rather than externally driven. Here, boundaries cannot be based on mismatches between predictions and sensory inputs, but are instead self-generated. To test whether internally-driven boundaries produce neural responses comparable to those observed during stimulus-driven experience, we conducted an fMRI experiment. Subjects watched a series of short movies and then verbally recalled the movie plots regardless of the order of presentation. During recall, transitions between movies were considered major event boundaries, determined purely by subjects' internal mentation; no external stimulus was presented to prompt the onset/offset of the recall of each movie. We observed activity changes at boundaries between movies during recall, as well as during movie watching, across widespread brain areas. We focused our analyses on the posterior medial cortex (PMC), a brain area thought to be involved in representing 'situation models' of events, and also reported to show boundary-related responses in prior studies. At between-movie boundaries during recall, PMC showed a transient increase in activation followed by decreased activation. This signal was present even when there was little or no pause between the recall of two different movies, suggesting that it was not mainly caused by a break in the speech. PMC multi-voxel patterns at recall boundaries were positively correlated with each other and less distinctive across different movies compared to non-boundary patterns, suggesting that the boundary response was insensitive to the specific content of each movie. Boundary-related PMC patterns were also task-general, as the patterns at between-movie boundaries during recall were highly similar to those measured during movie watching. Early sensory control regions showed a transient change in overall activation similar to PMC, but their patterns at recall boundaries showed neither decreased movie-level distinctiveness nor a positive correlation with the movie watching phase. Together, our results demonstrate that internally-driven boundaries between self-generated mental contexts evoke task- and content-general neural responses in higher associative areas, potentially reflecting a cognitive state related to the flushing and updating of situation models.

Title: Neural Representation of Long-term Value Memory in Human Ventral Striatum

Authors: ***J. KANG**[1,2], H. KIM[3], S. HWANG[4], H. F. KIM[4], S.-H. LEE[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain and Cognitive Engin., KAIST, Daejeon, Korea, Republic of; [3]Ctr. for Neurosci. Imaging Res., Inst. for Basic Sci., Suwon, Korea, Republic of; [4]Sch. of Biol. Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Learning object values is essential in dealing with environmental problems and increasing our benefits through better decisions. While the ventral striatum in the basal ganglia is thought to be critical to the learning process of object values, recent studies of addiction suggest that activation of the ventral striatum is related to memory of addicted objects, indicating that the ventral striatum may be involved in the long-term maintenance of object value memory. To investigate whether the ventral striatum is involved in long-term value memory processing, we performed an event-related functional magnetic resonance imaging (fMRI) experiment, comprising separate pre-learning, learning, and post-learning sessions. Both during the pre-learning and the post-learning sessions, participants were scanned while they passively viewed fractal object images. During the learning session, which took place between the pre-learning and post-learning sessions for five days outside the scanner, participants were trained to associate each object image with monetary gain, no gain, or loss. Focusing on the responses in the ventral striatum, we found that the neural responses to the objects associated with monetary gain increased significantly after learning. Moreover, the responses were greater than those for objects paired with monetary loss after learning. Furthermore, using multi-voxel pattern analysis, we revealed that the similarity of neural response patterns for individual objects associated with monetary gain increased significantly after learning compared to the similarity before learning, and that this increase in neural pattern similarity was positively correlated with the memory performance after learning. Taken together, our data suggest that the ventral striatum contains long-term memory that underlies evaluations of learned values of objects.

Title: The anterior temporal lobe retains shared semantic representations of distinct verbal information during successful memory retrieval

Authors: ***S. BHASIN**[1], W. XIE[1], A. VAZ[3], J. H. WITTIG, Jr.[1], S. INATI[2], K. A. ZAGHLOUL[4];
[1]Surgical Neurol. Br., [2]Electroencephalography (EEG) Section, Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD; [3]Duke Univ. Sch. of Med., Durham, NC; [4]Surgical Neurol. Br., Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: When an observer retrieves a word from memory, the anterior temporal lobe (ATL) reinstates patterns of neural activity present when the word was first encountered. While these patterns have been associated with item-specific information represented in the ATL, they only account for a small amount of variance in the ATL activity during memory retrieval. It remains unclear whether these ATL retrieval patterns also reflect other aspects of retained memory contents. We hypothesize that ATL retrieval patterns also contain the activation of a gist representation shared across items in addition to item-specific information. To test this hypothesis, we asked a group of participants (n = 19) to perform a paired associates verbal memory task while they were undergoing intracranial electroencephalogram (iEEG) monitoring. In this task, participants studied word pairs from a pre-selected word pool and were later cued with a single word from each pair. We extracted spectral power from the iEEG signal using Morlet wavelets between 3-150 Hz and developed a trial-by-trial neural similarity matrix for every participant over the time course of retrieval. Next, using the semantic features as quantified by their co-occurrence statistics in natural language, we quantified the similarity among the to-be-retrieved words across trials. We used this word similarity pattern across trials to quantify the gist representation of these words. We found that ATL retrieval pattern similarity was strongly correlated with the similarity among words. As the words were more related to other words on average, namely more centrally situated within the semantic space, they triggered more similar ATL retrieval patterns. We ruled out several alternative interpretations of these observations, including attention, motor response, and lower-level word features at the single-item level. Collectively, our findings suggest that ATL retrieval patterns contain not only item-specific information, but also a gist representation that is shared across items in memory.

Title: Semantic knowledge of famous people and places is represented in hippocampus and distinct cortical networks

Authors: *N. W. MORTON[1], E. L. ZIPPI[2], S. M. NOH[3], A. R. PRESTON[3];
[1]Ctr. for Learning and Memory, The Univ. of Texas at Austin, Austin, TX; [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Ctr. for Learning and Memory, The Univ. of Texas At Austin, Austin, TX

Abstract: Studies have found that anterior temporal lobe is critical for detailed knowledge of object categories, suggesting that it has an important role in semantic memory. However, in addition to information about entities, such as people and objects, semantic memory also encompasses information about places. We tested predictions stemming from the PMAT model, which proposes there are distinct systems that support different kinds of semantic knowledge: an anterior temporal (AT) network that represents information about entities and a posterior medial (PM) network that represents information about places. We used representational similarity analysis to test for activation of semantic features when human participants viewed pictures of famous people and places, while controlling for visual similarity. We used machine learning techniques to quantify the semantic similarity of items based on encyclopedic knowledge in the Wikipedia page for each item and found that these similarity models accurately predict human similarity judgments. We found that regions within the AT network, including anterior temporal lobe and inferior frontal gyrus, represented detailed semantic knowledge of people. In contrast, semantic knowledge of places was represented within PM network areas including precuneus, posterior cingulate cortex, angular gyrus, and parahippocampal cortex. Finally, we found that hippocampus, which has been proposed to serve as an interface between the AT and PM networks, represented fine-grained semantic similarity for both individual people and places. Our results provide evidence that semantic knowledge of people and places is represented separately in anterior temporal and posterior medial areas, while hippocampus represents semantic knowledge of both categories.

Title: Effects of chronic low and high blood pressure on source memory and working memory

Authors: *S. CANSINO[1], F. TORRES-TREJO[1], C. ESTRADA-MANILLA[1], A. MERCADO-CANALES[1], D. MEDINA-VELÁZQUEZ[1], R. ESQUIVEL-GARCÍA[1], S. RUIZ-VELASCO[2]; [1]Lab. NeuroCognition, Nat Autonomous Univ. of Mexico, Mexico City, Mexico; [2]Dep Probability and Statistics, IIMAS, Nat. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: The effects of chronic low (hypotension) and high blood pressure (hypertension) on memory are unclear due to divergent results, originating in part, due to participant misclassifications. The aim of this study was to compare source memory and working memory performance in individuals diagnosed as hypotensive or hypertensive receiving medical treatment with the source and working memory performance in normotensive participants. From a sample of 1656 participants, 219 were identified as hypertensive and 37 were identified as hypotensive. Each of these two groups was compared with normotensive individuals matched by age, education and sex. Individuals who were diagnosed with diabetes mellitus, hypercholesterolemia or hypertriglyceridemia were excluded from all groups. Source memory performance and working memory performance were assessed through computerized tasks. Source memory accuracy was lower in hypotensive and hypertensive individuals than in normotensive individuals, and spatial working memory discrimination was inferior in hypertensive participants compared to that of normotensive individuals. Moreover, the more time that has passed since hypertension or hypotension was formally diagnosed, the worse recognition and source memory accuracy were. Blood pressure impairment should be considered a major concern not only because it is linked to severe cardiovascular and cerebrovascular diseases but also because of its negative effects on the two types of memory that are the most essential for preserving a self-sufficient lifestyle.

Title: The effects of a mindfulness intervention on the neural activity of musicians with musical performance anxiety during a working memory task

Authors: *K. BOILEAU[1], U. HANSEN[1], N. STANSON[1,2], G. COMEAU[1,2], L. FANG[1], A. SMITH[1];
[2]Piano Pedagogy Res. Lab., [1]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Rationale and Objective: Studies have shown that music performance anxiety (MPA) impacts all types of musicians, affecting their personal and/or professional functioning. Anxiety in general has also been shown to affect cognitive functioning, such as working memory, which is critical to musicians' performances. Mindfulness, an effective treatment for those with general anxiety, has been used as a potential treatment for MPA, while the efficacy of mindfulness on working memory has shown mixed results. The objective of this study was to determine the effectiveness of a short mindfulness intervention on musicians' neural activity during a working memory task. **Methods:** Twenty participants (10 participants who underwent a mindfulness intervention and 10 control participants) were recruited for this exploratory study. All participants were young adult musicians who experienced MPA. Ten participants identified as female and 10 identified as male, and the age range for this sample was 18 to 35 years. For this study, participants were allocated to either a mindfulness condition where they practiced structured mindfulness for six to nine sessions over a course of two weeks or a control group where they did not practice mindfulness. At time one, participants underwent a one-hour MRI scan that included a letter N-Back task, a common task used to measure participants' working memory. Participants also completed the same scan sequence two weeks later (time two). **Results:** When examining neural activity in the mindfulness group pre- and post-intervention, a repeated measures t-test showed that there was significantly less activity post-intervention in the bilateral dorsolateral prefrontal cortex and in the left supplementary motor area, regions required for successful working memory. More activity pre-intervention might suggest more effort required to accomplish the task. When examining the difference in neural activity between the mindfulness and control groups at time two, a two-sample t-test showed that there was significantly less activity in the visual cortex bilaterally, including in the cuneus and the lingual gyrus in the mindfulness group compared to controls. **Conclusions:** These findings demonstrate that mindfulness interventions have efficacious results on working memory in those who experience MPA. Musicians who incorporate mindfulness into their daily lives may benefit from potentially lessened effort required during working memory tasks, allowing for more neural resources to focus on their music.

Title: Tradeoff between hippocampal learning and numerical processing in young children

Authors: *M. ZAFAR, S. SELVAM, K. K. NAIDOO, R. NARAHARISETTY, C. K. MATTINGLY, T. E. PILGER, N. C. HINDY;
Dept. of Psychological and Brain Sci., Univ. of Louisville, Louisville, KY

Abstract: Children can perceive the number of objects in a configuration in different ways: either through numerical processing or pattern recognition. An example of numerical processing is a child counting or subitizing a small number of disorganized blocks. Numerical cognition is related to neural processes in the intraparietal sulcus (IPS). On the other hand, a child might instantly know the number of blocks stacked in a familiar configuration. Remembering previously seen patterns is related to neural processes in the hippocampus. Using fMRI and an at-home training program on an iPad, we examined how these neural mechanisms are affected in young children through repeated exposure to particular patterns. A multi-touch iPad game, Fingu, was used for at-home training; players see configurations of 1-10 fruits moving on the screen and have to indicate the number of fruits by pressing down the correct number of fingers. Before and after at-home training, participants completed tasks similar to those in Fingu in an fMRI scanner. Half of the fMRI tasks contained configurations that were repeatedly viewed during iPad training with Fingu, while the other half contained configurations that were not seen in Fingu. Prior to training, we observed greater functional connectivity between the IPS and visual cortex than between the hippocampus and visual cortex. However, after a week of training on the iPad, functional connectivity was enhanced between the hippocampus and visual cortex, and diminished between the IPS and visual cortex. This trend remained consistent across Fingu and novel configurations. Thus, while perception of spatial configurations appeared to rely on numerical processing in the IPS before training, perception of the same configurations after a week of training may have primarily relied on pattern recognition by the hippocampus. These findings suggest an inverse relationship between the hippocampus and IPS in perception as a function of repeated exposure to visuospatial patterns. As children learn patterns around them, visual perception may become increasingly mediated by mnemonic processes in the hippocampus.

Title: Effects of multiday repetitive transcranial magnetic stimulation of functional brain networks supporting memory in healthy young adults.

Authors: *C. J. PHIPPS, A. RANGEL, A. M. HELLER, V. S. PHATAK, D. L. MURMAN, D. E. WARREN;
Neurolog. Sci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Declarative memory has been associated with a network of brain regions including the hippocampus. Investigations suggest that non-invasive brain stimulation (NBS) applied to components of this network may affect memory performance. For example, repetitive transcranial magnetic stimulation (rTMS) applied to lateral parietal regions has been shown to enhance declarative memory performance in young adults by up to 20% (Wang et al., 2014). To test generalizability of this approach, we are administering a clinical trial (ClinicalTrials.gov #NCT03574207) applying NBS to healthy young adults, healthy older adults, and patients with amnestic mild cognitive impairment (aMCI). Here, we report preliminary findings from the trial arm studying young adults. Our approach replicates methods from Wang et al. (2014). Young adults (N=15, age=18-35 years) completed two rounds of participation combining pre/post-NBS brain and cognitive measurement with stimulation (treatment or sham for five consecutive days) in the form of rTMS. Interventions were identical except for stimulation intensity. Pre-/post-NBS, brain measures included structural and resting-state functional MRI data; cognitive measures included cognitive abilities (e.g., hippocampal-dependent memory). Interventions applied a β-frequency pulse alternating 2-sec. 20 Hz stimulation with 28-sec. rest for 20 min; stimulation location was constant between conditions (left lateral parietal cortex coactive with a hippocampus-centered network). Intensity was tailored to participants' resting motor threshold (RMT) and varied by condition: treatment, 100% RMT; sham, 10% RMT. Conditions were completed in a counterbalanced order, with at least two weeks between conditions. Using rs-fMRI data from each participant, we mapped a hippocampal functional networks and identified individualized left lateral parietal targets for rTMS. Changes were observed in brain and cognitive measures related to the stimulation condition. Brain measures revealed changes in patterns of RSFC between several areas of the hippocampus-centered network targeted with rTMS in the treatment condition. Our ongoing clinical trial measures changes in brain and cognitive variables associated with NBS of a functional brain network supporting memory. The current trial arm, focused on healthy young adults, found evidence consistent with plasticity in the intrinsic brain network supporting memory. Findings from the remaining arms (older adults, healthy or aMCI) will inform the generalizability and translational potential of our observations to populations with clinical impairments of memory.

Title: The effect of hippocampal damage on integrating information across time

Authors: *Z. BELCHEV[1], **H. MARLATTE**[1], M. FRASER[2], A. GILBOA[1];
[1]Univ. of Toronto, Rotman Res. Inst., Toronto, ON, Canada; [2]York University, Rotman Res. Inst., Toronto, ON, Canada

Abstract: Introduction: The hippocampus (HPC) supports some forms of integration of information across time. Two tasks prominently used to test temporal integration are i) associative inference (AI) tasks, which require inferring an association between stimuli that are indirectly related but were never presented together, and ii) statistical learning (SL) tasks, which involve learning item relationships by extracting regularities across many experiences. There is general agreement that the HPC is required for AI, and recent studies also argue it is required for SL- contrary to longstanding theories. **Methods:** We tested four patients with varying degrees of bilateral HPC damage and their matched healthy controls. During AI, participants studied overlapping paired associates (AB, BC) then were tested on premise pairs (AB, BC) and indirect associations (inferred AC). Past research predicts deficits to both direct and indirect pairs in patients with any degree of HPC damage. During SL, participants passively viewed continuous picture sequences that contained an underlying structure of triplets to later be recognized. Based on a recent model we predicted that an intact CA1 field of the HPC would be sufficient to support SL, even with damage to the dentate gyrus (DG) and CA3. **Results:** Unexpectedly for AI, patients with more localized HPC damage could infer the indirect associations as well as controls when performance for the premise pairs was equated. Thus, HPC damage alone does not impair inference as long as the direct associations are acquired. For SL, binomial tests were used to determine above chance performance. None of the patients exhibited above chance statistical learning, including patient BL with focal DG damage. Notably, however, neither did many of the controls. **Conclusions:** Temporal integration of indirect relationships through AI can be intact even with damaged HPC so long as the premise pairs are available. This may indicate that extra-HPC structures support inference at retrieval, or that residual HPC tissue that is insufficient for normal acquisition of the premise pairs is sufficient for normal inference. For SL, we believe it is premature to draw any conclusion about either impairment or preservation of function with intact CA1. Our data of presumed impairment in SL are consistent with previous studies that used the same task, however many controls in previous research also show chance performance, complicating the interpretation of deficits in individuals with HPC damage. A more reliable task should be developed before conclusions about SL ability can be made in a small group of patients.

Title: Disordered network topology during associative learning in schizophrenia

Authors: *E. D. MERAM, S. BAAJOUR, A. CHOWDURY, J. STANLEY, V. A. DIWADKAR;
Psychiatry & Behavioral Neurosci., Wayne State Univ., Detroit, MI

Abstract: Schizophrenia (SCZ) is characterized by impairments in associative learning (Diwadkar et al., 2008) but differences from controls in brain network topology *during* phases of learning have not been investigated. We used the graph theoretic measure of betweenness centrality (BC) to summarize network topology in 4 different conditions of an object-location associative learning task: Memory Formation (MF), Post-Encoding Consolidation (PEC), Retrieval (MR), and Post-Retrieval Consolidation (PRC) (Baajour et al., 2020). BC estimates the number of "shortest functional paths" traversing through a node and thus indexes a node's hubness or "integrative value" (Sporns et al., 2010). fMRI data were collected from 59 subjects (32 SCZ, 18<Age<50, 3T Siemens Verio). During MF, 9 objects were presented in associated locations (3x3 spatial grid) for naming. During PEC, participants covertly rehearsed memoranda as they fixated on a marker. During MR, locations were cued, & participants were required to name the associated object. PRC was identical to PEC. The sequence cycled eight times. fMRI data were processed in SPM12. For each condition, time series were extracted from 90 cerebral parcels (Tzourio-Mazoyer et al., 2001). BC was estimated for each node in each participant's network. Inter-group differences in BC were estimated for each node in each condition.
During MF, SCZ had *decreased* BC in the thalamus, putamen, precuneus, & frontal nodes, but increased BC across visual, temporal, parietal, & frontal lobe nodes. During PEC, differences in the superior frontal, precuneus, thalamus, and putamen were identical to those in MF with additional decreases in posterior cingulate and Heschl's Gyrus, & increases in frontal-hippocampal nodes. During MR, decreased BC was observed in multiple nodes, & increases in parietal, frontal, and visual nodes. During PRC, decreased BC was in frontal & striatal nodes, with increased BC observed in frontal, temporal & parietal nodes. Ranking nodes by BC within groups revealed that generally, significantly reduced BC in SCZ was observed for highly ranked nodes. Increased BC was observed for lowly ranked nodes.
We observed a disordered network topology in every condition, emphasizing the global nature of network deficits in SCZ during associative learning. Second, in all conditions, decreases

occurred in nodes more central to the network whereas increases were present in nodes less central to the network, suggesting a predictable pattern of network dysfunction. Third, disordered topology was observed even in conditions devoid of overt sensori-motor processing, suggesting a crucial role of these refractory periods in associative learning.

Title: Brain-wide quantitative analysis reveals complementary patterns of parvalbumin and calbindin neurons in executive and modulatory regions of the mouse brain

Authors: I. E. BJERKE[1], S. C. YATES[1], A. LAJA[2], M. P. WITTER[2], M. A. PUCHADES[1], J. G. BJAALIE[1], *T. B. LEERGAARD[1];

Abstract: The calcium-binding proteins parvalbumin and calbindin are expressed in largely non-overlapping types of neurons across the murine brain. These cell types are known to play important roles in neural networks involved in sensorimotor processing, spatial navigation, and fear memory. Knowledge about the number and spatial distribution of these cell types within and across brain regions will be important to understand their contributions in functional networks, but such data are so far only available for a few regions. To amend this we performed a brain-wide quantification of immunohistochemically stained parvalbumin and calbindin neurons across

the adult mouse brain. We used the QUINT workflow, which combines anatomical information from the Allen Mouse brain Common Coordinate Framework with machine-learning based segmentation of cells. Our results indicate that these two neuron types distribute in complementary patterns. Parvalbumin neurons are more prevalent in sensorimotor cortices, hippocampal and parahippocampal areas, and in the brainstem, while calbindin neurons are relatively more dominant in olfactory and amygdalar areas, as well as in the thalamus and hypothalamus. These results point to interesting differences in the relative importance of these cell types in different brain regions. We share all raw data and analytic results via EBRAINS.eu to facilitate further exploration and re-use of the data.

Title: Perirhinal and postrhinal cortices contribute to the configural process of contextual learning

Authors: *X. PENG, D. L. POETA, R. D. BURWELL;
Dept. of Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Behaviors do not occur in a vacuum: many paradigms in humans and animals have shown that behaviors are often critically dependent on the physical context. The medial temporal lobe (MTL) is an important structure underlying context-dependent behavior. Within the MTL, a preponderance of the literature has targeted the role of the hippocampus. In addition to the hippocampus proper, the MTL also comprises parahippocampal areas including the perirhinal (PER) and postrhinal cortices (POR). These areas, however, have received less attention regarding their contribution to context-dependent behavior. It has been proposed that the hippocampus supports the configural approach of contextual processing, in which elements of the environment are first combined into a unitary representation before being associated with other stimuli. It is unknown whether the PER and POR are necessary for this process. In this study, bilateral excitotoxic lesions of the PER or POR were created in adult male rats, and their performances in two context-dependent procedures were compared with sham-lesioned rats. One procedure is a fear conditioning variant that specifically demonstrates the context pre-exposure facilitation effect (CPFE), which results from the configural process of context learning and critically depends on the hippocampus. Preliminary data indicates that either PER or POR lesions impaired CPFE when compared to shams. The second procedure is contextual spontaneous object recognition (SOR). Normal rats show increased exploration when encountering a familiar object but in a different context, because the rats not only encode the object but also bind it with the context where it previously appeared. PER and POR lesioned rats also displayed deficits in this procedure. These results suggest that both the PER and POR are necessary for forming a configural representation of the context for both fear learning and spontaneous exploratory behavior. This finding will compliment our existing knowledge of the hippocampus and provide a fuller picture of how the medial temporal lobe functions to support contextual learning.

Abstract: Serotonin is implicated in aversive processing and updating responses to changing environmental circumstances. Optimising behaviour to maximise reward and minimise punishment may require shifting strategies upon encountering new situations. Likewise, emotional reactions to threats are critical for survival yet must be modified as danger shifts from one source to another. Whilst numerous psychiatric disorders are characterised by behavioural and emotional inflexibility, few studies have examined the contribution of serotonin in humans. We modelled both processes in two independent experiments (N = 97; 50 females, mean age 24), using instrumental and aversive Pavlovian reversal learning paradigms, respectively. Upon depleting the serotonin precursor tryptophan - in a double-blind randomised placebo-controlled design - healthy volunteers showed impairments in updating both behaviour and emotion to reflect changing contingencies. Reversal deficits in each domain, furthermore, were correlated with the extent of tryptophan depletion. These results translate findings in experimental animals to humans and have implications for the neurochemical basis of cognitive inflexibility.

Title: Behavioral and neural substrates of learning attentional rules

Authors: *C. I. JAHN, N. MARKOV, B. MOREA, T. BUSCHMAN;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: We must constantly adapt the rules we use to guide our attention. To understand how the brain learns attentional rules, we trained two monkeys to perform a novel task, which required them to learn which color is the most rewarded at a given time (the current 'attentional rule'). However, just as in real life, monkeys were never explicitly told the rule. Instead, they had to learn it through trial and error by choosing one of three presented colors, receiving feedback (amount of reward), and then updating their internal attentional rule. Then, after the monkeys reached a behavioral criterion, the rule changed, and they had to re-learn the new rule. This change was not cued but could be inferred based on reward feedback. Behavioral modeling found that monkeys used rewards to learn attentional rules. After the rule changed, animals adopted one of two strategies. If the change in the rule was small, reflected in a small reward prediction error, the animals continuously updated their rule. However, for large changes in the rule (large reward prediction errors), monkeys 'reset' their belief about the rule and re-learned the rule from scratch. To understand the neural correlates of learning new attentional rules, we simultaneously recorded single units in the lateral prefrontal cortex (lPFC, 402 neurons), frontal eye fields (FEF, 300 neurons) and lateral intraparietal cortex (LIP, 185 neurons). Preliminary results suggest that lPFC neurons encode the rule, developing stable rule representations early in learning and maintaining them throughout the block of trials. This representation was lost immediately after the rule switch, reflecting the reset seen in behavior. In contrast, LIP neurons encoded the rule only once the rule was well-known and behavioral accuracy was high. This suggests that attentional rules are learned first in lPFC and then passed to LIP. Together, our results provide insight into the behavioral and neural basis of learning new abstract rules.

Title: Differential influence of ventromedial prefrontal cortex lesions on neural representations of schema and category knowledge

Authors: *A. E. GIULIANO[1,2], K. BONASIA[2], V. E. GHOSH[2], M. MOSCOVITCH[1,2], A. GILBOA[2,1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Rotman Res. Inst., North York, ON, Canada

Abstract: This project investigated the oscillatory dynamics of prior knowledge (PK)-mediated processing, whether or not we can differentiate kinds of PK, and how these processes are altered by ventromedial prefrontal cortex (vmPFC) damage. PK influences how we perceive and interpret information. For this to transpire, PK must first be reinstated (i.e. activating PK templates) and instantiated (i.e. using the activated template to interact with incoming information). We focused on two kinds of PK: schemas and categories. Schemas are flexible networks of PK that represent information gathered over multiple similar experiences (e.g. going to the doctor); schema knowledge is presumed to be mediated by the vmPFC. Categories are groups of concepts that are related based on certain characteristics (e.g. bugs) and are mediated by the anterior and lateral temporal lobes (ATL/LTL). While two separate systems are proposed to underlie each respective PK type, there is evidence of overlap. While electroencephalography was recorded, patients with vmPFC damage (n = 11) and matched controls (n = 13) brought to mind a schema or category (reinstatement) and were asked to decide whether words appearing on the screen were related to the schema or category (instantiation). We predicted reinstatement would be supported by low-frequency oscillatory activity between the vmPFC and angular gyrus for schemas, and between the ATL/LTL and inferotemporal cortex for categories. For instantiation, we expected focal, high-frequency oscillatory activity in the vmPFC for schemas, and ATL/LTL for categories. Of particular interest was whether or not vmPFC patients performed poorly for both knowledge types, which would indicate system overlap. Reinstating PK was associated with pre-stimulus theta and alpha desynchronization; for schemas, this involved communication between the vmPFC and posterior parietal lobe, including the angular gyrus, whereas category reinstatement was associated with LTL and inferotemporal cortex desynchrony. In both conditions, patients showed reduced desynchrony. Instantiating PK was indexed by post-stimulus low and high-frequency desynchrony between the same respective regions for schemas and categories. While some differences emerged between schemas and categories, desynchrony between the regions above often predicted performance on trials of both knowledge types. Notably, however, certain patients showed deficits specific to schematic processing: those with damage to the subcallosal vmPFC. We conclude that damage to vmPFC

influences processing of both schemas and categories, but the underlying network-level mechanisms of this disruption differ.

Title: The role of mPFC projecting sub-populations in recent and remote expression of memories

Authors: *A. GOLBABAEI[1,2], S. A. JOSSELYN[1], P. W. FRANKLAND[1];
[1]Neurosci. & Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: As memories age, they undergo reorganization at the systems level. In particular, memories are known to initially depend on the hippocampus for expression, but become more dependent on the medial prefrontal cortex (mPFC) at remote time-points. Although retrieval-induced activity of mPFC neurons increases with time, it is unclear whether mPFC projecting subpopulations contribute to retrieval in distinct ways at different time points. mPFC has many different projection targets in the brain, including the basolateral amygdala (BLA), nucleus reunion (NRe), and nucleus accumbens (NAc). Using a contextual fear conditioning paradigm in mice, we aimed to delineate how these distinct projection-specific sub-populations of mPFC neurons contribute to memory expression at recent vs. remote time-points. To examine this, we used retrograde viral vectors to label projection-specific sub-populations in the mPFC. First, we examined the extent to which these distinct mPFC sub-populations are activated during contextual fear learning (i.e. encoding), and subsequently reactivated during recent vs. remote recall. Second, we used an activity-dependent tagging method to express excitatory and inhibitory opsins in these projection-specific mPFC sub-populations during learning. We then asked whether reactivating these sub-populations is sufficient for memory expression at recent and remote time-points in a novel context. Our results provide evidence that different mPFC projection-specific sub-populations differentially contribute to recent vs remote recall. In particular, BLA projecting mPFC neurons are reactivated at both recent and remote time-points, while NRe and NAc projecting populations exhibited increased reactivation at the remote compared to recent time-point. Consistent with this, photo-stimulation of BLA projecting cells induced freezing at both recent and remote time points, whereas photo-stimulation of NRe and NAc projecting neurons only induced freezing at the remote time point. The involvement of BLA projecting sub-population at both recent and remote time-points suggests that mPFC-BLA circuit contributes to the fear memory recall independent of memory age. However, mPFC-NRe and mPFC-NAc contribute only at the remote time-point. The differential dependency of these

three circuits to memory age may relate to the role of their down-stream targets in regulating fear memories. BLA is well-known for the encoding and expression of emotional memories regardless of the memory age. On the other hand, NRe and NAc are, respectively, related to the generalization and extinction, properties of memories which may change as a function of memory age.

Title: Differential engagement of prefrontal and medial temporal lobe cortex during memory formation under semantic versus perceptual attention conditions

Authors: *S. VIJAYARAJAH, M. L. SCHLICHTING;
Univ. of Toronto, Toronto, ON, Canada

Abstract: Although it is known that learning new information in relation to prior knowledge can promote successful remembering, the mechanisms that support this memory benefit remain unclear. Recent work suggests the integration of new information into one's existing knowledge engages ventromedial prefrontal cortex (PFC) networks. However, most work examining the mechanisms that facilitate integration have focused on the presence versus absence of a relationship to prior knowledge. Within experiences that do contain features related to prior knowledge, it is unclear how attending to such features might impact medial PFC network engagement. Here, we used functional magnetic resonance imaging (fMRI) to ask whether attending to semantic features related to prior knowledge (i.e., well-known stories) recruits medial PFC memory networks more so than attention to perceptual features unrelated to prior knowledge (i.e., artist style). We manipulated participants' (N=42 adults) attention to the semantic (story) or perceptual (artist style) features of storybook illustrations during incidental encoding by asking them to search for consecutive feature repeats along the cued dimension. Participants then completed an old/new recognition memory test for the studied illustrations. To assess whether semantic versus perceptual attention recruited different regions to support

remembering, we compared univariate activation at encoding for subsequently remembered versus forgotten illustrations. We found that a number of regions throughout the brain showed greater activation for subsequently remembered than forgotten trials across both attention conditions, including both lateral and medial PFC; medial temporal lobe cortex (parahippocampal cortex, PHC); and ventral visual stream (inferior temporal gyrus and fusiform). When interrogating activation as a function of the attentional encoding state, PHC as well as both lateral and medial PFC showed greater activation for semantic versus perceptual attention overall, with a significantly greater attention-related difference in medial than in lateral PFC. Our results demonstrate common neural substrates for successful memory formation when attending to either semantic or perceptual features of experiences, with increased activation in a subset of these regions (i.e., PHC; medial and lateral PFC) when attending to meaning—a dimension that would enable connections to be formed with prior knowledge. These findings suggest that the *availability* of information consistent with prior knowledge may be sufficient to engage PFC and medial temporal lobe, with *attention towards* such features amplifying this engagement.

Title: Cocaine-sensitive orbitofrontal circuits encode action variables for flexible decision making

Authors: *D. LI, E. PITTS, N. DIGHE, B. BARBEE, B. KOCHOIAN, S. GOURLEY; Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Goal-directed decision making is critically important for navigating dynamic environments, and requires the flexible encoding, representation, and retrieval of learned action-outcome associations (contingencies) in order to guide future choices. Meanwhile, failures of flexible contingency-guided action represent a core feature of many neuropsychiatric disorders including drug addiction. First, we find that individual differences in cocaine-induced decision-making deficits are associated with post-synaptic protein and dendritic spine alterations in the orbitofrontal cortex (OFC). We thus sought to identify specific OFC circuits that underlie flexible goal-directed action. Using projection-selective chemogenetic manipulations, we reveal that basolateral amygdala (BLA)>OFC projections are necessary for the encoding, but not

retrieval, of contingency memories, and that these connections bidirectionally modulate contingency encoding across multiple environmental domains. Meanwhile, we also find that OFC>dorsomedial striatum (DMS) projections are necessary during choice epochs themselves to facilitate "online" contingency memory retrieval. Thus, we demonstrate that learned contingency information is transmitted in a directionally defined manner across a discrete BLA>OFC>DMS circuit, which functions in concert across temporal scales to enable flexible choice behavior. We then utilized activity-dependent genetic tools to demonstrate that a memory trace for learned contingency information is stably represented by encoding-activated neuronal ensembles within the OFC, whose reactivation is necessary for subsequent memory retrieval. We then sought to identify potential cellular plasticity mechanisms which are necessary for long-term storage of contingency information by OFC neurons. Accordingly, we employed di-synaptic circuit mapping and connection-selective gene silencing to show that contingency learning is associated with both dendritic spine plasticity and neurotrophin signaling specifically within a BLA>OFC>DMS circuit. Our findings therefore suggest that the OFC is indispensable for flexible decision making by serving as the critical locus within an extended amygdalo-fronto-striatal network, providing the temporal link between memory encoding and retrieval, thus bridging the initial learning of new contingency information with its future application.

Title: The orbitofrontal cortex is necessary for learning to ignore irrelevant cues

Authors: *K. M. COSTA, G. SCHOENBAUM;
NIDA IRP / NIH, Baltimore, MD

Abstract: We learn not only what is potentially useful, but also what is meaningless and should be ignored. Failures in this ability have been associated with psychosis and attentional disorders, yet how it is accomplished is a seldom explored question in neuroscience. Learning to ignore irrelevant cues is evident in latent inhibition - where presenting a cue several times without consequences leads to retardation of subsequent conditioning to that cue. Importantly, this pre-exposure learning is a form of learning that requires the recognition of hidden task states (contingencies not directly distinguishable by external events). We hypothesized that this should depend on the orbitofrontal cortex (OFC), since this region has been implicated in such processing. We tested this by using chemogenetics to selectively inactivate the OFC in rats during the pre-exposure phase of a within-subjects latent inhibition task. Adult male rats were

transfected with either hM4d (a Gi-coupled DREADD; N=16) or mCherry (control; N=15) in the OFC; after recovery, they experienced four pre-exposure sessions in which an auditory cue was presented 12 times without any consequences, after injection of 0.2 mg/kg of the high-potency DREADD agonist JHU37160 (JH60) to inactivate OFC principal neurons. Rats then underwent six conditioning sessions in which the pre-exposed auditory cue (PE) and a novel, non-pre-exposed cue (NPE) were presented, each immediately followed by the delivery of three sucrose pellets. Control rats showed latent inhibition, developing stronger conditioned responding to the NPE than to the PE. In contrast, hM4d rats did not show latent inhibition, but developed strong conditioning to both cues at a similar rate. We also tested if OFC inactivation affected what was learned about the PE cue. Rats received additional conditioning to equalize responding to the PE and NPE cues, then they underwent extinction and satiety-based devaluation tests. The effects of extinction and devaluation did not differ between cues or groups, suggesting that the impact of OFC inactivation during pre-exposure was limited to the latent inhibition effect, at least as assessed by these tests. Our findings implicate the OFC in learning that a given cue is irrelevant, a cardinal form of latent learning. Inactivation during pre-exposure ensured that the observed effects are restricted to the integration of information prior to its use in any sort of behavior, which is congruent with the concept that the OFC supports this critical aspect of learning.

Title: Inactivation of the nucleus reuniens impairs spatial memory in mice

Authors: *M. R. SCHWABE, C. M. LINCOLN, L. TAXIER, K. M. FRICK;
Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Coordinated activity between the hippocampus and medial prefrontal cortex (mPFC) is required for memory encoding and retrieval. Our laboratory demonstrated that simultaneous subthreshold chemogenetic inactivation of the dorsal hippocampus (DH) and medial prefrontal cortex (mPFC) impairs the consolidation of object placement (OP) memory in female mice (Tuscher et al., 2018), suggesting that these two brain regions work in concert to promote memory consolidation. However, mechanisms through which these brain regions interact to promote memory consolidation remains poorly understood. A small cluster of cells in the midline thalamus known as the nucleus reuniens (RE) facilitates communication between the

hippocampus and mPFC through bidirectional excitatory projections. Furthermore, recent work from other labs indicates that the RE is necessary for spatial working memory and fear extinction learning. The goal of this study was to determine whether activity in the RE is necessary for OP memory. Kappa-opioid receptor DREADD (KORD) virus activated by salvinorin B was used to inactivate excitatory neurons in the RE. Mice infused with GFP virus or saline were used as controls. During training, mice were allowed to explore 2 identical objects placed near the corners of a large white box, and received a 10 mg/kg injection of salvinorin B either 10 minutes prior to training or immediately after training to target effects to the encoding and consolidation phases of memory, respectively. Testing was conducted 4h after training, a timepoint at which control mice remember the location of training objects. During testing, one object was moved to a different quadrant of the testing box. Activation of the KORD prior to or immediately after training blocked OP memory relative to chance and controls, supporting a key role for the RE in spatial memory consolidation. Current work is investigating the roles of specific projections among DH, mPFC, and RE. We include preliminary findings from retrograde labeling work using AAV-Cre-eGFP in a retrograde-specific serotype.

Title: Role of the Nucleus Reuniens in Long Term Memory Consolidation

Authors: ***K. CALVIN**[1], R. A. WIRT[2], E. FLORES[1], B. UDIN[1], J. M. HYMAN[3];
[1]Univ. of Nevada, Las Vegas, Las Vegas, NV; [3]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Anterior cingulate cortex (ACC) and hippocampal interactions are well characterized in episodic memory. The dorsal hippocampus is critical for memory-guided behavior, but experimental evidence suggests that spatial and contextual memories depend not only on the hippocampus itself, but the ACC and hippocampal circuit. Investigations disrupting the hippocampal and medial prefrontal cortex (mPFC) circuit have shown a failure to transfer spatial and contextual information that is processed by the hippocampus to mPFC circuitry responsible for goal-directed behavior and decision making. In spatial and contextual memory tests, oscillatory synchrony between these regions has been show to increase. However, very little is known about how this synchrony arises. The nucleus reuniens (RE) of the thalamus has reciprocal connections to hippocampus as well as ACC and has been shown to be vital to a variety of episodic and contextual memory tasks. This suggests that the hippocampus and mPFC oscillatory synchrony noted above may be modulated by activity in the RE. Prior findings have demonstrated that this circuit between mPFC, RE, and the hippocampus is necessary for

processing and regulating fear memory generalization. Additional research has shown that neurons in the RE provide trajectory-specific coding during a continuous alternation T-maze task, similar to coding observed in the dorsal hippocampus. There have also been recent findings of head direction cells in the RE. Recent research has also shown an essential role of the RE in coordinating slow oscillatory activity between hippocampus and neocortex, suggesting a role for slow-wave sleep-related episodic memory consolidation. RE has also demonstrated a role in suppressing the retrieval of memories, and inhibiting the activity of the reuniens has a significant effect on the retrieval of remote contextual memories. These mechanisms of control seem like a rich area for further research, especially considering somewhat analagous mechanisms in anterior cingulate cortex (ACC). Similar to hippocampus and prefrontal cortex, the RE may participate in a variety of memory-related behaviors, and may act to coordinate hippocampal-mPFC interactions. To investigate this role of the RE further, we recorded from ACC, RE and hippocampus while animals performed a simple place preference task. In preliminary findings, animals that received a chemogenic block of the reuniens immediately following behavior and prior to memory consolidation showed a marked deficit in their ability to recall remote memories of place preference, while they demonstrated a clear bias from preference memory in all control conditions.

Abstract: Brain processes underlying encoding and recall of verbal memory can be probed by intracranial electroencephalography (iEEG) during the presentation of words in a free recall task. The purpose of this study was to investigate the spectral and temporal properties of brain activity underlying human verbal memory encoding with recordings from bilateral hippocampus and

anterior nucleus of the thalamus (ANT). Recordings were obtained during the encoding of words from a patient with drug resistant epilepsy implanted with an investigational Medtronic Summit RC+S^{TM} sensing and stimulation device. The patient was able to complete verbal memory tasks in their home environment with iEEG and behavioral data streamed to a handheld device and cloud repository. The participant was presented with lists of words on a handheld tablet screen for a delayed test of free recall. Lists were composed of 12 randomly chosen nouns. After a distractor task, the participant was asked to recall as many of the words as possible. The participant completed 8 independent sessions over several weeks with 15 lists per session for 1440 total word epochs recorded. Epochs with interictal epileptiform spikes were removed from analysis. For each electrode, we determined the average power spectral density at each time point across all word presentation epochs and found the overall induced power during word presentation. We then calculated the average subsequent memory effect (SME) per trial in each frequency band. Frequency bands analyzed were low theta (2-4 Hz), high theta (4-8 Hz), alpha (8-12 Hz), beta (13-25 Hz), low gamma (25-55 Hz), and high gamma (65-115 Hz). The SME was found to have a dependence on the frequency band analyzed (ANOVA, $F=3.87$, $p<0.01$), and post-hoc group analysis (Tukey-Kramer, $p<0.05$) showed that SME was higher in the low gamma band than in alpha or beta bands. SME was dependent on brain area (repeated measures ANOVA, $F=20.72$, $p<0.05$). SME also had an event related dependence (repeated measures ANOVA, $F = 515.39$, $p<0.001$) with SME being higher during word presentation than both before or after presentation. The spectral, spatial, and temporal patterns identified in the human iEEG recordings from this preliminary study are consistent with previous studies of large-scale, distributed dynamics of verbal memory encoding, and are the first to investigate the effects in the ANT. Emerging devices for electrical stimulation of the brain enabling smart sensing and continuous streaming of the iEEG data are crucial for long-term studying of underlying brain dynamics during cognitive tasks.

Title: Age-associated alterations in locus coeruleus neuronal, glial cell, and vascular elements in cognitively assessed aged macaque monkeys

Authors: *K. MCDERMOTT[1,2], I. SINAKEVITCH[1,2], D. T. GRAY[1,2], S. O. KHATTAB[1,2], W. S. PYON[4], C. A. BARNES[1,2,3];

Abstract: The Locus Coeruleus (LC) is a brainstem nucleus best known for being the primary central nervous system site of noradrenaline production and is involved in the modulation and optimization of behavioral performance in mammals. The LC is a molecularly and anatomically heterogeneous region that is densely innervated by blood vessels and glial cells. The LC appears to be especially vulnerable to age-related neurodegeneration and is one of the first regions to show evidence of pathological changes associated with Alzheimer's disease (Mather & Harley 2016). While previous work has investigated age-related changes in neurochemical markers in the LC, the impacts of normative aging on LC neuron, glial cell, and vascular characteristics in non-human primates remains an open question. Our research utilizes coronal brainstem sections from a colony of 30 cognitively assessed rhesus macaque monkeys ranging in age from 7 to 32 years (human equivalent ~21 - 96 years). All monkeys underwent tests of spatial short-term memory (delayed response), object recognition memory (delayed nonmatching-to-sample), and object discrimination. We used immunofluorescence techniques to identify neuronal nuclei (NeuN), catecholaminergic neurons (TH), vasculature (STL), and astrocytes (GFAP). The entirety of the locus coeruleus region for each immunolabeled section was imaged bilaterally at 40X on a high-resolution confocal microscope to obtain 3-dimensional volumes of the LC for the quantification of neuron, glial cell, and vascular densities using unbiased stereological techniques. These data were assessed with respect to the age and cognitive status of the monkeys. Preliminary results indicate that overall TH+ density and total neuron density remain stable in the older monkeys compared to the adults. Furthermore, vascular and reactive astrocyte density was not different between the adult and aged animals. No anatomical variable has shown a relationship with any of the three behaviors used to assess cognition in these animals. If these results hold it would indicate that cell loss, changes in vascular innervation, and increases in astrocyte reactivity do not occur in the LC region in normative aging. These results support the hypothesis that LC degradation is a key component of pathological aging but is not compromised in healthy normative aging.

Abstract: The Locus Coeruleus (LC) is a brainstem nucleus best known for being the primary central nervous system site of noradrenaline production. Dysregulation of LC systems contribute to cognitive dysfunctions in both healthy aged brains and brains that succumb to Alzheimer's disease. Importantly, the LC is heterogeneous along both the rostral-caudal and dorsal-ventral axes with respect to neuron morphology, projection targets, and vulnerability to the impacts of normative brain aging and neurodegenerative disease. In particular, the rostral LC projects to cortical and hippocampal brain regions critical to cognition. The aim of the present study is to examine the LC in a nonhuman primate model of aging, using a system that standardizes the 3D morphology of the LC nucleus to enable precise comparisons of neuronal morphology and densities in immunolabelled brain sections from individual monkeys. To this end, coronal brainstem sections were examined every 240 microns along the rostral-caudal axis of the LC from a colony of 30 cognitively assessed rhesus macaque monkeys ranging in age from 7 to 32 years (human equivalent ~21 - 96 years) were used. Three young and three aged monkeys from this sample were used in the present study. To create the 3-dimensional volume, digitized Nissl-stained images of 30 micron thick frozen brain sections at the level of the pons were first collected. High-resolution 5x microscopy images of each LC that had been immunolabeled with a fluorescent morphological marker of catecholaminergic neurons (tyrosine hydroxylase) were then acquired, followed by a 40x high-resolution confocal stack of the LC on the same section. AMIRA software was employed to reconstruct the LC. The volume of the nucleus was delineated using cell bodies positive for TH and large cell bodies in Nissl stains characteristic of this nucleus as boundaries. Preliminary data from these animals indicate that the macaque LC extends approximately 2000 um along the rostro-caudal axis. We observed a core LC nucleus with high TH+ cell densities that became more scattered in more rostral brain sections. Overall volumes varied between 1 and 2.2 mm^3, and the older monkeys tended to have smaller LC volumes compared to the younger individuals, but this will need to be replicated in the full sample of 30 animals. This analysis pipeline will allow specific sites of vulnerability along the rostral-caudal axis of the LC to be identified for further molecular analyses aimed at understanding the mechanisms responsible for LC vulnerability and its impacts of cognition in normative aging and disease.

Title: Temporal dynamics of locus coeruleus norepinephrine during a learned behavior

Authors: *V. BRETON-PROVENCHER, G. T. DRUMMOND, M. SUR;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: Neurons in the locus coeruleus (LC) are the main source of the neuromodulator, norepinephrine (NE), in the forebrain. Despite the brain-wide effects of LC-NE release, the conditions under which LC-NE neurons are activated and the modes of NE action during learned behavior are poorly understood. Previous reports on LC-NE have sought to explain its role in gain control or network reset, yet how these two functions get integrated at the level of LC dynamics remain unknown. Here, we recorded and manipulated genetically identified LC-NE neurons in mice trained on an instrumental learning behavior incorporating stimulus-reward uncertainty. In this auditory detection task, head-fixed mice have to press a lever to a go tone to obtain a water reward, and refrain from pressing the lever to a no-go tone to avoid an air puff punishment. We modulated task difficulty by using tones of four intensities within the two frequencies. Targeted recordings of LC-NE neurons with opto-tagging, or with calcium imaging via two-photon microendoscopy, show that the majority of LC-NE neurons responds before execution - the lever press - and after punishment, and a smaller fraction responds to reward. The amplitude of the execution and reward response of LC-NE neurons varies with tone intensity: the execution signal increases with tone intensity, while the reward signal decreases with tone intensity (lower uncertainty of reward). LC-NE transient activity peaks following a punishment regardless of tone intensity to signal greater uncertainty or surprise. The effect of photo-inactivation of LC-NE activity during selected trials is twofold. First, inactivating LC-NE produces a decrease in lever presses during go trials with low tone intensity, suggesting a role for LC-NE activity during behavioral response in high uncertainty conditions. Second, inactivating LC-NE impairs active reinforcement learning, or the ability of the mice to optimize its task strategy following a punishment trial. Together, our results suggest that distinct temporal dynamics enable the simultaneous regulation of execution and active learning by LC-NE during learned behavior.

Title: Modular projections and engagement of locus coeruleus norepinephrine in a learned behavior

Authors: *G. DRUMMOND, V. BRETON-PROVENCHER, M. SUR;
Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: The locus coeruleus (LC) is a small brainstem nucleus and the primary source of the neuromodulator norepinephrine (NE) in the brain. Receiving diverse, widespread inputs, while also projecting throughout the brain, LC-NE is thought to signal global brain states such as arousal and attention. However, LC-NE is implicated in more precise roles such as mediating learning, promoting task execution, and signaling unexpected uncertainty. In our own lab, we have found that in mice performing an instrumentally conditioned auditory go/no-go task with rewards, punishments, and varying tone intensities to modulate trial difficulty, LC-NE neurons are active pre-lever press and post-reinforcement, with responses scaling with the degree of uncertainty. LC-NE activity affects task execution on the current trial, as well as performance on the following trial. How these execution and reinforcement signals are used to facilitate different aspects of behavior—task execution and active learning—remains unknown. Here, we explore the idea that modular projections and spatiotemporal targeting of LC-NE release enable modulation of multiple aspects of a learned behavior. Using retrograde tracing, we examine whether LC-NE neurons exhibit a modular organization, such that subsets of LC-NE neurons selectively project to specific cortical outputs, the motor or dorsomedial prefrontal cortex. Further, we assess how the activity of LC-NE neurons projecting to the motor or dorsomedial prefrontal cortex can promote different aspects of behavior. To do so, we use two-photon calcium imaging of LC-NE axons and imaging of NE release using the genetically encoded fluorescent sensor, GRAB-NE, while the mice perform the auditory go/no-go task. Our preliminary results show that though there is evidence for some degree of modularity at the anatomical level, both prefrontal cortex and motor cortex may receive similar LC-NE activity. Hence, functional modularity of LC-NE action may be limited to differential integration of NE in subcortical targets, or require selective, dynamic engagement of task-specific NE signals in specific cortical areas.

Title: Neural activity quickly and accurately differentiates iron deficient from iron sufficient women early in visual category learning

Authors: *M. J. WENGER, L. A. DE STEFANO, S. E. RHOTEN, L. BOOZARY, A. BARNETT;
The Univ. of Oklahoma, Norman, OK

Abstract: Iron deficiency is prevalent in both developed and developing environments and is typically ignored medically until it reaches the point of anemia. However, iron deficiency can lead to negative consequences before it reaches anemia, including negative impacts on measures of work productivity; measures of perception, attention, and memory; and measures of academic success. We have documented that the negative relationship between iron deficiency and cognition is mediated by negative changes in electroencephalography (EEG). These results suggest that iron deficiency changes brain function in ways that are manifest in behavior, which implies that brain function in the subclinical condition of iron deficiency without anemia is affected. The present study sought to determine the possibility of identifying someone as either iron deficient or sufficient based solely on brain activity, and, if possible, how quickly (based on processing time on a cognitive task) this could be done. Both iron sufficient and deficient (non-anemic) women learned two visual categorization tasks while concurrent EEG was acquired. Both tasks involved classifying gray-scale gabor patches on the basis of spatial frequency and orientation; one task used an easily-verbalized rule, the other required complex integration of the information. Moving windows (20 ms width) of EEG data from 100 electrodes were used to predict the participant's iron status using logistic regression; model form was determined using stepwise variable selection. Results show that iron status can be predicted with more than 90% accuracy in less than 150 ms of processing time, within the first 200 trials of learning, with fewer than 12 electrodes. This suggests that iron deficiency, before it becomes a medical problem (anemia), produces measurable changes in brain function, highlighting the need to consider interventions earlier than standard practice. We discuss the implications with respect to the role that the visual system plays in understanding the mechanisms by which iron deficiency exerts negative influences on perception and cognition.

Title: Striatal melanocortin-4 receptor controls behavioral flexibility in mice

Authors: *E. C. HEATON[1], S. T. YOUNT[2], S. L. GOURLEY[1];
[1]Pediatrics, Neurosci. Program, [2]Pediatrics, Pharmacol. Program, Emory Univ., Atlanta, GA

Abstract: Goal-directed action refers to behaviors that are dynamic, sensitive to unexpected events, and require the dorsomedial striatum (DMS). Meanwhile, habitual behaviors are reflexive and unchanging and rely on the dorsolateral striatum (DLS). Molecular factors underlying an organism's ability to flexibly shift between goal-directed and habitual behavior are incompletely understood. We recently discovered that striatal melanocortin-4 receptor (*Mc4r)* expression correlates with this behavioral flexibility in adult male and female mice. To identify functional consequences, we used viral-mediated gene silencing to reduce *Mc4r*. *Mc4r* knockdown in the DMS enhanced the ability of mice to select actions based on reward likelihood and value, while reduction in the DLS facilitated habit formation. Thus, inhibiting MC4R appears to enhance the functions of distinct striatal subregions. Changes in *Mc4r* expression are thought to modulate activity of medium spiny neurons, leading to the hypothesis that chemogenetic manipulation of *Mc4r*+ DMS neurons will impact expression of behavioral flexibility. Stimulation of *Mc4r*+ DMS neurons via Gq-coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) facilitated animals' ability to select actions based on reward likelihood. Meanwhile, inhibition via Gi-DREADDs rendered animals insensitive to changes in reward likelihood, promoting habits. Finally, we discovered using trans-synaptic tracing that several brain regions necessary for goal-directed action synapse onto *Mc4r*+ neurons in the DMS, and we confirmed using combinatorial viral vector strategies that inputs from one such region, the orbitofrontal cortex, are necessary for MC4R-related behavioral flexibility.

Title: Dopamine release patterns in the nucleus accumbens core are influenced by novelty detected in environment

Authors: *M. G. KUTLU[1], P. MELUGIN[1], J. E. ZACHRY[1], G. SCHOENBAUM[2], M. J. SHARPE[3], E. S. CALIPARI[1];
[1]Pharmacol. Dept., Vanderbilt Univ., Nashville, TN; [2]Intramural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD; [3]Psychology Dept., UCLA, Los Angeles, CA

Abstract: Dopamine in the nucleus accumbens (NAc) is critically involved in signaling prediction error; however, findings indicate that attention-related constructs such as novelty are also involved in associative learning and suggest that NAc dopamine may play an important role in mediating this relationship. Prior investigations of dopamine's involvement in associative learning have often been constrained by the use of traditional techniques that preclude the ability to precisely examine dopamine's role in associative processes. Here we use fiber photometry in conjunction with a fluorescent dopamine sensor with high temporal resolution to examine novelty-induced dopamine responses in the NAc core. Using a "latent inhibition" design, we first showed that repeated exposure to a stimulus decreased the peak dopamine response to that stimulus progressively. The preexposed conditioned stimuli (CS) elicited a weaker dopamine response than the non-preexposed CS, which was also associated with a decreased learning rate for the preexposed CS when paired with a footshock. We further demonstrated that both the presentation of unexpected and the omission of expected stimuli produced a similar protracted increase in dopamine baseline. Consistent with the observation of external inhibition, we also showed that presentation of an unexpected stimulus resulted in a decreased conditioned response to the predictive stimulus. Finally, we found that the presentation of an unexpected stimulus reversed the decreased dopamine response caused by repeated stimulus presentation, an effect known as "dishabituation". While our findings are largely consistent with prevailing theories of dopamine's role in signaling prediction error, the data presented here highlight the importance of attention and novelty in dopamine's involvement in associative learning.

Title: Human brain activity and functional connectivity as memories age from one hour to one month

Authors: C. W. TALLMAN[1,2], *C. N. SMITH[1,3,4];
[1]Res. Service, Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [2]Psychology, [3]Psychiatry, Univ. of California San Diego, San Diego, CA; [4]Ctr. for the Neurobio. of Learning and Memory, Univ. of California Irvine, Irvine, CA

Abstract: Theories of memory consolidation describe changes in the role of brain regions and changes in connectivity between brain regions as memories age. Human lesion studies suggest memories become hippocampus-independent over years, whereas animal studies suggest this process occurs across relatively short intervals, from weeks to months. Recent human neuroimaging studies provide evidence that changes in hippocampal and cortical activity and connectivity can be detected over these short intervals, but many of these studies examined only two time periods. We assessed brain activity and brain connectivity over four time periods to allow for increased temporal resolution of these neural changes. Memory and whole-brain FMRI activity was measured for unique sets of photos of indoor and outdoor scenes studied 1 hour, 1 day, 1 week, and 1 month prior to scanning. During scanning, participants (N=21 young adults) viewed scenes, made old/new recognition judgments, and gave confidence ratings. Memory accuracy, confidence ratings, and response times changed with memory age. We examined brain activity associated with scenes to identify regions where activity changed with the age of memory (following a power function). A widespread cortical network was observed where activity either increased or decreased with memory age [prefrontal cortices (PFC), anterior cingulate, sensorimotor cortices, posterior parietal cortices (PPC), and middle occipital gyrus; $p < 0.001$]. Hippocampal activity was not related to memory age. These findings were almost identical when we minimized the effect of behavioral changes across time periods. Whole-brain connectivity associated with the bilateral ventromedial PFC (ROI-based, generalized psychophysiological interaction analysis associated with memory age [following a power function]) revealed a significant increase in connectivity with the left PPC ($p < 0.001$). Connectivity analysis for the bilateral hippocampus revealed decreasing connectivity with the hippocampus, parahippocampal gyrus, lateral temporal cortex, and PPC ($p < 0.02$). In sum, we detected changes in cortical activity and changes in hippocampal and cortical connectivity with memory age across short intervals. These findings provide support for the predictions of systems consolidation and suggest that these changes begin soon after memories are formed.

Title: Retrieval Spikes: A dendritic mechanism for retrieval-dependent memory consolidation

Authors: *E. GERON, W. GAN;
NYU, New York, NY

Abstract: Retrieval of a new memory can improve its long-term retention. We investigated neuronal mechanisms underlying this phenomenon, by training mice with the classical fear conditioning paradigm under two-photon imaging. We used a protocol in which cued retrieval during training improved fear learning, and imaging focused on the primary motor cortex (M1), a region that is essential for conditioned freezing. We found that cued retrieval elicited strong calcium spikes in apical dendrites of layer 5 pyramidal neurons (L5 PNs), the principal cortical output cells. Dendritic spines that were very active shortly before, and during, these retrieval spikes underwent persistent depotentiation: becoming smaller, and less active at later presentations of the tone. Transient optogenetic inhibition of CaMKII, a calcium-dependent master regulator of plasticity, abrogated the depotentiation of active spines, only if applied shortly after retrieval spikes. Retrieval spikes activity correlated negatively with dendritic and somatic activities at later recalls. These inverse relationships were not observed in L5 PNs whose plasticity was disrupted by optogenetic inhibition of CaMKII. We further show that the generation of retrieval spikes coincides with reduced activity of dendritic-targeting inhibitory neurons (SST^+, $NDNF^+$) during retrieval, suggesting that the local inhibitory circuit is poised for retrieval-dependent spike formation. Collectively, these findings indicate that retrieval evokes dendritic spikes that weaken the synaptic inputs that were active during spiking. This negative feedback leads to a reduced representation of the conditioned stimulus in M1, which supports stillness during freezing. We describe a dendritic consolidatory mechanism in which retrieval of a new memory increases its strength.

Title: What is the spatial scale of sleep oscillations in cortex?

Authors: *M. HASANZADEH MOFRAD[1,2], A. SULLER MARTI[2,3], L. MULLER[1,2];
[1]Dept. of Applied Mathematics, [2]Brain and Mind Inst., [3]Dept. of Clin. Neurolog. Sci., Western Univ., London, ON, Canada

Abstract: In the two-stage model of memory consolidation, memories are first formed in the hippocampus and then transferred to neocortex for long-term storage (McClelland et al.,

Psychological Review, 1995; Rasch and Born, Curr Opin Neurobiol, 2007). This transfer is mediated by synaptic plasticity, for which co-occurrence of pre- and post-synaptic activity plays a critical role (Bi and Poo, J Neurosci, 1998). While it has become increasingly clear that sleep oscillations actively and causally contribute to this process, it remains unclear to what extent these oscillations coordinate activity across areas in neocortex. Based on early recordings in animals under anesthesia, sleep rhythms were generally considered to occur across a wide range of cortex, creating a state of large-scale synchrony (Andersen et al., J Physiol, 1967; Contreras et al., J Neurosci, 1997; Achermann and Borbély, Neuroscience, 1998).Recent work, however, has challenged this idea by reporting isolated sleep rhythms such as slow-oscillations and spindles. What is the spatial scale of sleep rhythms in cortex? To answer this question, we adapted deep learning algorithms initially developed for detecting earthquakes and gravitational waves in high-noise settings to analysis of neural recordings in sleep (Perol et al., Science Advances, 2018; George and Huerta, Physics Letters, 2018). We studied sleep spindles in non-human primate electrocorticogram (ECoG), human electroencephalogram (EEG), and clinical intracranial electroencephalogram (iEEG) recordings. Our approach, which detects a range of clearly formed large- and small-amplitude spindles during sleep, reveals that sleep spindles co-occur over a broad range of cortex. In particular, multi-area spindles, where more than 10 electrode sites exhibit this rhythm simultaneously, are much more frequent than previously estimated by amplitude-thresholding approaches, which tend to select only the highest-amplitude spindles and can miss events that temporarily fall below threshold. Because spindles are intrinsically related to sleep-dependent consolidation of long-term memories, these results have important implications for the distribution of engrams in cortex of primate and humans.We next hypothesized that, if spindles are actively involved in consolidating distributed networks in cortex, they may exhibit an increased prevalence across areas following a memory task. To address this additional hypothesis, we analyzed human EEG recordings following a low- and high-load visual working memory task. Consistent with this hypothesis, we find our method detects an increase in multi-area spindles in the high-load memory condition.

Title: Tracking the emergence of novel memory representations across hippocampal-cortical networks

Authors: ***A. TAMBINI**[1], J. MILLER[2], L. EHLERT[1], A. KIYONAGA[3], M. D'ESPOSITO[2]; [1]Univ. of California Irvine, Irvine, CA; [2]Univ. of California Berkeley, Berkeley, CA; [3]Univ. of California San Diego, San Diego, CA

Abstract: While the hippocampus is necessary for associative memory formation, extensive evidence indicates that memory representations become distributed across hippocampal-cortical networks over time. Memory reorganization across hippocampal-cortical networks is thought to be accompanied by a change in the nature of memory representations, including the extraction of structured knowledge across experiences. Most studies typically probe memory representations at a few timepoints, with some studies reporting immediate changes after learning, while others find changes across days to weeks. Here, we characterized the development of de novo memory representations by performing longitudinal fMRI on the same individuals across three months. Three human participants were repeatedly exposed to abstract fractal images (referred to as trained stimuli) in the context of a serial reaction time (SRT) task. A subset of fractals was presented in temporal sequences during the SRT task. Sequence learning was reflected in reduced response time for intact sequences that emerged over time. Neural representations were characterized in fMRI scans while individual stimuli were presented in isolation. A set of brain regions became increasingly responsive to trained fractals over time, including the hippocampus, medial prefrontal cortex (mPFC), medial parietal cortex, angular gyrus, and anterior temporal cortex. This set of brain regions significantly overlapped with large-scale cortical networks implicated in memory retrieval ('core' and 'dorsomedial' subsystems of the 'default network'). Moreover, shared sequence-level representations (greater pattern similarity for stimuli within versus between sequences) emerged over time in the hippocampus, mPFC, and medial parietal cortex, providing evidence for integration across items within sequences. Evidence for sequence representations persisted in the hippocampus over months, in contrast to the notion that memories are 'transferred' from the hippocampus to neocortical sites as posited by some theoretical accounts of memory consolidation. These findings provide novel evidence for the formation of de novo associative memory representations over the course of months across hippocampal-cortical networks.

Abstract: Exposure to a novel context induces the immediate-early gene expression in a subset of neurons that constitute neuronal networks for memory trace. These neural ensembles may be modulated by memory updating such as fear association through synaptic reorganization. However, the steps of the circuit modulation have yet to be visualized at the level of individual synapses. Contextual fear conditioning is a behavioral paradigm in which an aversive stimulus is associated with a neutral context. To visualize and manipulate neural circuits activated during behaviors by recombinant adeno-associated virus vectors, we developed a doxycycline-inducible reporter expression system (Tet-ON) under the control of enhanced synaptic activity response elements (E-SARE) from the *Arc* promoter. By using this method, we first expressed channelrodopsin-2 (ChR2) into neuronal ensembles in the retrosplenial cortex (RSC) of the mouse brain activated during exposure to a neutral context, and then tested whether light-induced activation of these ensembles could elicit fear responses 1 day after the fear conditioning. We found that ensembles recruited by a preceding exposure to the same context with the fear conditioning could induce fear responses (*P = 0.013, paired t-test, n = 8) whereas neurons recruited by a distinct context exposure could not (P = 0.49, paired t-test, n = 8). Next, by using 2-photon microscopy, we visualized and monitored dendritic spines of the context-activated RSC neurons that were labeled with enhanced green fluorescent protein using the E-SARE Tet On system. We detected dendritic spines newly formed after the fear conditioning in the neuronal ensembles recruited by the preceding exposure to the same context rather than by the exposure to a distinct context (**P < 0.01, one-way ANOVA post hoc turkey's test, n = 6). Finally, we explored brain regions projecting to the RSC by a retrograde viral injection (AAV2 retro) into the RSC. We found several brain regions projecting to the RSC including claustrum, subiculum, frontal association cortex, anterior cingulate cortex, parietal association cortex, and basolateral amygdala. These results suggest that, accompanied with synapse formation, the RSC neuronal ensembles responding to the neutral context are incorporated into fear memory traces after subsequent fear conditioning training in the same context.

Title: Feed-forward inhibition in Dentate Gyrus-CA3 drives time-dependent re-organization of memory ensembles in prefrontal cortex

Authors: *H. TWARKOWSKI[1,2,3], V. STEININGER[1,2,3,4], M. KIM[1,2,3,5], A. SAHAY[1,2,3,6]; [1]Ctr. for Regenerative Med., Massachusetts Gen. Hosp. Abstract: Hippocampal-cortical communication is thought to determine the extent to which memories generalize over time, but the underlying circuit mechanisms are poorly understood. By identifying Ablim3, a cytoskeletal F-actin binding protein that is exclusively localized to dentate granule cell (DGC) mossy fiber terminals, as a molecular brake of DGC connectivity with parvalbumin inhibitory neurons (PV-INs), we demonstrated a critical role for DGC recruitment of feed-forward inhibition (FFI) onto CA3 in time-dependent memory generalization. Viral downregulation of *Ablim*3 in DGCs enhanced excitatory drive onto stratum lucidum PV INs, elaborated PV IN synaptic contacts with CA3 neurons and increased FFI in DG-CA3. Mice with increased FFI in DG-CA3 exhibited reduced remote memory generalization. These observations motivated investigation of how FFI in DG-CA3 affects neuronal ensemble dynamics in hippocampal-prefrontal cortical networks over time. Towards this goal, we performed single-photon calcium imaging in hippocampal CA1 and the anterior cingulate cortex (ACC) of awake, behaving mice - in which we increased FFI in DG-CA3 - to longitudinally track neuronal ensembles during encoding and recall of contextual fear memory in the fear conditioned and neutral contexts at recent and remote timepoints. We first developed a Matlab-based automated workflow to standardize the extraction and sorting of temporal and spatial information from both CA1 and ACC datasets to allow for comparison between these two brain regions. Consistent with the notion that memory traces re-organize during consolidation in hippocampal-cortical networks, we directly observed time-dependent refinement of context-associated ensembles in ACC over time. Importantly, increasing FFI in DG-CA3 potentiated this refinement and we observed a decrease in the overlap between ensembles of the fear-conditioned and neutral contexts in CA1 and ACC at remote timepoints. Analysis of active neurons revealed that FFI reduced numbers of correlated pairs of active neurons in ACC, but not CA1, following context exposure. Together, these findings provide direct evidence for time-dependent evolution of memory ensembles and identify FFI in DG-CA3 as a neural substrate for memory consolidation in hippocampal-cortical networks. Targeting Ablim3 may represent a strategy to promote hippocampal inhibition, dampen hippocampal hyperactivity and promote memory consolidation in aging and Alzheimer's disease.

Abstract: The occurrence of dreaming during rapid eye movement (REM) sleep prompts interest in the role of REM sleep in hippocampal-dependent episodic memory. Within the mammalian hippocampus, the dentate gyrus (DG) has the unique characteristic of exhibiting neurogenesis persisting into adulthood. Despite their small numbers and sparse activity, adult-born neurons (ABNs) in the DG play critical roles in memory; however, their memory function during sleep is unknown. Here, we investigate whether young ABN activity contributes to memory consolidation during sleep using Ca^{2+} imaging in freely moving mice. We found that contextual fear learning recruits a population of young ABNs that are reactivated during subsequent REM sleep against a backdrop of overall reduced ABN activity. Optogenetic silencing of this sparse ABN activity during REM sleep alters the structural remodeling of spines on ABN dendrites and impairs memory consolidation.

These findings provide a causal link between ABN activity during REM sleep and memory consolidation.

Title: Dietary fibre attenuates novel object impairment resulting from high fat/sucrose diet and increases hippocampal DeltaFosB

Authors: *E. W. TUPLIN, E. ALUKIC, D. E. LOWRY, F. CHLEILAT, W. WANG, N. A. CHO, R. A. REIMER;
Kinesiology, Univ. of Calgary, Calgary, AB, Canada

Abstract: A high fat/sucrose diet (HFS), one of the most important risk factors for the development of metabolic diseases such as type 2 diabetes, has also been shown to affect cognitive performance. A HFS diet can trigger a cascade of inflammatory responses which may be a factor in triggering neuroinflammation and associated cognitive decline. The hippocampus, which is paramount for memory consolidation and retention, shows increased neuroinflammatory markers and decreased neurogenesis following a HFS diet. The stability of hippocampal memories requires changes in transcription factors that are involved in synaptic plasticity/function. DeltaFosB is a stable transcription factor that is involved in forming associations between stimuli and the environment and a decrease in DeltaFosB, such as in depression, is associated with cognitive decline. In rodents, a high fibre diet has been shown to attenuate HFS-induced cognitive decline in hippocampal-dependent tasks, but the mechanisms by which this occurs remains elusive. The current study examined the effects of HFS and high fibre diets on novel object recognition (NOR), a hippocampal-dependent task, and explored associated relative DeltaFosB expression in the hippocampus using western blotting. 100 male Sprague-Dawley rats underwent obesity induction with a HFS diet for 8-weeks. The top 50% of weight gainers were allocated to the following groups (n=10/group) for an 8-week fibre intervention: chow-fed control, HFS, HFS+oligofructose (HF/O), HF/O+beta-glucan (HF/OB), HF/O+resistant starch (HF/OR), or HF/OB + resistant starch (HF/OBR). During week 6 rats

underwent NOR procedures consisting of habituation, familiarization, and testing, each occurring for 5-min over three days. Insulin tolerance testing occurred during week 7 to determine the effects of the diets on metabolic function. The HFS diet group was unable to distinguish between the novel or familiar objects suggesting impaired memory consolidation or retention, these rats also showed impaired insulin sensitivity confirming the presence of metabolic dysfunction. Dietary fibre groups significantly distinguished the novel from familiar objects and had improved insulin sensitivity. Relative DeltaFosB expression was increased in the HF/OB and HF/OR fibre groups which positively correlated with time spent exploring the novel object, alluding to increased hippocampal activity. These results suggest that not only can a high fibre diet attenuate metabolic outcomes associated with a HFS diet, a diet high in fibre has the potential to attenuate HFS-induced cognitive dysfunction possibly via increased neuronal activity within the hippocampus.

Title: Intermittent fasting alters cognition, anxiety-like behavior, and hippocampal norepinephrine content in aged mice

Authors: *K. WIERSIELIS, A. YASREBI, K. CONDE, T. ROEPKE;
Rutgers Univ., New Brunswick, NJ

Abstract: Intermittent fasting (IMF) is associated with many health benefits in animal models and humans. Yet, little is known if an IMF diet affects mood and cognitive processing. We have previously identified that IMF in diet-induced obese males increases norepinephrine content in the hypothalamus and increase arcuate neuropeptide Y (NPY) gene expression more than in *ad libitum* males. This suggests that IMF may improve cognition through activation of the hindbrain norepinephrine neuronal network and reverse the age-dependent decline in NPY expression. Less is known about the association between anxiety and IMF. In humans, IMF during Ramadan may alleviate anxiety. Here, we address the impact of IMF on hippocampal-dependent memory using the Y-maze and spatial object recognition (SOR), hippocampal-independent memory using novel object recognition (NOR), and anxiety-like behavior using the open field task (OFT) in middle-aged male (12 mo) and aged female (18 mo) mice. Y-maze data indicate that IMF males perform worse in the identification of the unknown arm than same-sex controls, suggesting an IMF-

induced deficit in interpreting spatial navigation routes. Conversely, no difference was detected in females on this task. In the SOR task, which evaluates hippocampal-dependent object orientation, IMF males were not affected; however, IMF females exhibited a decrease in performance. This suggests that, in females, IMF impairs spatial information about the arrangement of objects. In the NOR, which detect differences in hippocampal-independent memory, IMF males performed better than their same-sex counterparts; however, we did not detect an effect in females. IMF treated males displayed and increase in hippocampal norepinephrine content, suggesting IMF may alter hindbrain norepinephrine signaling. Our overall cognitive results suggest that, in males, IMF results in deficits only in hippocampal-dependent tasks, yet an enhancement in performance when hippocampal-independent tasks are conducted. In females, only the hippocampal-dependent task of SOR was affected by IMF, suggesting IMF disrupts spatial object configuration. In the OFT, IMF male and female mice spent more time in the center zone, indicative of an anxiolytic phenotype. Collectively our research suggests that IMF is enough to produce both an impairment and enhancement in memory dependent upon age, sex, and hippocampal involvement, as well as an anxiolytic phenotype in both male and female aged mice.

Title: Mapping glutamatergic projections from the median raphe to the hippocampus in mice

Authors: *J. FORTIN-HOUDE[1,2], F. HENDERSON[1,2], G. DUCHARME[2], B. AMILHON[1,2]; [1]Univ. de Montréal, Montreal, QC, Canada; [2]Ctr. de recherche du CHU Sainte-Justine, Montreal, QC, Canada

Abstract: The raphe nuclei contain a vast diversity of neuronal populations, including glutamatergic neurons characterized by the expression of the vesicular glutamate transporter type 3 (VGLUT3). VGLUT3-positive neurons project to many areas of the brain, including the hippocampus (HP). The aim of our study was to reveal the topography of glutamatergic projections from the raphe to the HP. We performed anterograde and retrograde tracing studies in male and female VGLUT3-Cre mice (n=12), using Cre-dependent viral vectors expressing fluorescent proteins. Local injection of an anterograde viral tracer in the median raphe, but not in the dorsal raphe, revealed VGLUT3 positive fibers in all subfields of the HP (CA1, CA2, CA3 and dentate gyrus). A high density of glutamatergic fibers was observed at the junction between

stratum radiatum and stratum lacunosum-moleculare. Next, we used retrograde viral vector injections to map the position of HP-projecting glutamatergic neurons within the different raphe sub-nuclei. VGLUT3 neurons projecting to the HP were predominantly found in the median raphe region (paramedian and median raphe) and the B9 nuclei. A large majority of VGLUT3-positive neurons were situated in the rostral parts of these nuclei and their number decreased caudally. Finally, we sought to determine if distinct glutamatergic pathways projected to the dorsal and ventral parts of the HP, known to have different roles. We found that most VGLUT3-positive neurons projected to either dorsal of ventral HP. In addition, a medio-lateral gradient was observed with ventral HP-targeting neurons located close to the midline whereas dorsal HP targeting neurons were found more laterally. Our results uncovered a clear segregation of inputs from raphe VGLUT3 neurons to the dorsal and ventral parts of the HP, suggesting roles for raphe glutamatergic projections in the modulation of functions such as spatial learning and memory or anxiety.

Title: Spatial working memory can be supported by differential firing of medial entorhinal cortex cells in the delay zone

Authors: *L. YUAN[1], M. SABARIEGO[1], T. TANG[1], J. LEUTGEB[1], S. LEUTGEB[1,2];
[1]Neurobio. Section, UCSD, San Diego, CA; [2]Kavli Inst. for Brain and Mind, San Diego, CA

Abstract: The ability to retain information in working memory (WM) over periods of seconds is central to numerous cognitive tasks. Included in the large brain network that is necessary for encoding and maintaining spatial WM are the medial entorhinal cortex (MEC) and the hippocampus. Even though both brain regions contribute to WM, we have previously shown that an intact MEC can at least partially compensate for the loss of hippocampal function and vice versa. Such compensation raises the question which aspects of neuronal coding remain intact after partial damage to the entorhinal-hippocampal circuit. For example, we have shown that hippocampal spatial firing patterns during spatial WM are partially preserved without MEC. To determine to what extent MEC depends on hippocampal input to represent task-related information we recorded neuronal activity patterns in MEC with and without hippocampal input while rats performed a spatial alternation task on a figure-8 maze. As previously described, WM over delays of 10 s and 60 s was partially impaired by the loss of hippocampal neurons, while

behavioral performance without a delay remained intact. To describe the entorhinal contribution to spatial WM, we first examined the firing patterns in the memory task in control rats (n = 3 rats, n = 147 cells). Similar to the open field, the majority of MEC neurons showed spatial selectivity on the maze with their firing preference distributed across different maze zones, such as delay zone, stem, and return arms. Of the cells that were active during the delay and on the stem, ~20 % were differentially active between trials when animals were turning either right or left at the choice point, although the proportion was lower with 60 s delays. Large hippocampal lesions (n = 4 rats) did not abolish either spatial selectivity or left/right choice selectivity, but altered the firing patterns of MEC cells (n = 79). Spatial selectivity was reduced in layer II cells and occurred preferentially in the delay zone or the stem. When cells were active in these zones, they surprisingly showed increased differences between left and right choice trials, but only during trials without delay. In trials with either 10 s delay or 60 s delay, differential activity was retained in < 10 % of MEC cells. Taken together, MEC efficiently codes for memory-related information, and such information is reduced but not abolished by removing hippocampal feedback. The physiological patterns thus resemble the effects of the lesion on memory performance, which supports the possibility that task-relevant information in MEC does not depend on an intact hippocampus and can directly support spatial WM.

Title: Modulation of cortical sensory processing by direct hippocampal feedback

Authors: *T. BUTOLA, L. PENG, J. BASU;
NYU Langone Hlth., New York, NY

Abstract: Our brains constantly extract salient information from the environment and compare it to our experiences. The modulation of ongoing sensory processing in the context of prior experiences helps us to perceive an environment and experiences within it as rewarding or harmful; novel or familiar. This interplay between stored representations and sensory processing

relies on the functional interaction between the hippocampus (HC), critical for learning and memory, and its neighboring entorhinal cortex (EC), a hub of multi-sensory information processing. The canonical circuit posits that HC receives sensory information from superficial layers of EC for long-term memory representation but does not send direct hippocampal feedback to these cortical layers. Instead, HC is believed to project to the deep layers of EC, which then relay the information back to the superficial layers of EC forming an indirect feedback loop. Our study aims to elucidate the true direct reciprocal circuit between the HC and the EC to explore how 'memory' inputs from the hippocampus modulate 'real-time' cortical sensory processing allowing the animal to adapt to its changing environment. Using virus-based anatomical mapping and optogenetic functional dissection of hippocampal-EC inputs, we demonstrate the presence of monosynaptic hippocampal connections to both deep and superficial layers of EC. We find that the hippocampal inputs to EC deep layers are more extensive in terms of innervation surface area, have higher probability of monosynaptic connections and significantly greater connection strength than the HC inputs to EC superficial layers. To understand the circuit mechanism underlying the EC layer specific differences in synaptic strength of the HC input, we are characterizing the dynamics of excitation-inhibition balance and short-term plasticity of the hippocampal inputs onto cortical neurons. Using paired stimulation of hippocampal and sensory inputs converging on to EC neurons, we will further identify the mechanism by which hippocampus modulates cortical sensory processing. Our findings suggest anatomically and functionally segregated feedback from hippocampus to EC resulting in a reciprocal circuit architecture for parallel information processing.

Title: Lateral entorhinal cortex: a distal input that drives strong inhibition and dendritic excitation onto CA1 pyramidal neurons

Authors: *O. BILASH, J. BASU;
Neurosci. Inst., NYU Sch. of Med., New York, NY

Abstract: The functional interaction between the entorhinal cortex (EC) and hippocampus (HC) is critical for episodic memory formation. Direct projections from the medial and lateral entorhinal cortex (MEC and LEC) provide the hippocampus with spatial and non-spatial (contextual) sensory information, respectively. Previous studies have largely focused on MEC-HC interactions, and only recently have behavioral studies started to demonstrate that LEC is involved in olfactory learning, novelty and object-related learning, and contextual learning. Still, the circuit-level functional interactions between LEC and the hippocampus remains underexplored. LEC inputs synapse onto the distal dendrites of CA1 pyramidal neurons (PNs), where they are poised to integrate with other extra- and intra-hippocampal inputs, likely influencing compartment-specific hippocampal learning rules. Our study examines how distal dendritic input from LEC modulates hippocampal information flow through specific GABAergic microcircuits, short-term plasticity rules, and non-linear dendritic computations. Using slice electrophysiology and optogenetics, we demonstrate that glutamatergic LEC projections drive excitation onto CA1 PNs, while simultaneously recruiting strong feed-forward inhibition (FFI). LEC inputs elicit subthreshold post-synaptic potentials, but are not strong enough to elicit action potentials in CA1 PNs. However, using dendritic recordings, we find that optogenetic stimulation of LEC axons in CA1 can drive dendritic spikes in CA1 PN distal dendrites. To better understand the mechanism underlying the LEC-driven dendritic spikes, we began to probe the GABAergic microcircuit elements recruited by LEC inputs. We performed targeted recordings from GABAergic neuron-specific transgenic mouse lines and found that LEC inputs directly recruit specific inhibitory neurons (INs) in area CA1, notably vasoactive intestinal peptide (VIP)-expressing INs. VIP INs are known to be disinhibitory in the hippocampus and neocortex, so we propose that LEC inputs gate dendritic spikes in CA1 PNs by engaging local disinhibitory VIP INs. Given that *in vitro* and *in vivo* studies have previously demonstrated the role of dendritic spikes in hippocampal plasticity, our findings suggest that LEC plays an important role in promoting supralinear dendritic computations, thus enabling it to influence long-term representation in the hippocampus.

Title: Lateral entorhinal cortex modulates contextual and spatial memory processing in CA1 hippocampal area through long range circuitry

Authors: *M. HERNANDEZ FRAUSTO, L. PENG, J. BASU;
Neurosci. and Physiol., New York Univ., New York, NY

Abstract: The entorhinal cortex (EC) and Hippocampus (HC) are crucial structures for episodic memory, and spatial and contextual dependent learning. Lateral entorhinal cortex (LEC) conveys contextual features of the environment, related to objects, novelty, fear, and rewards, while the medial entorhinal cortex (MEC) conveys spatial information, encoding an animal position in space[1,2]. LEC sends both long range excitatory and inhibitory[3] projections to hippocampal CA1 area through direct pathways. While indirect excitatory pathway has been implicated in memory storage, direct pathway from LEC to CA1 area functions remains unclear. Here, we propose that LEC long range projections in CA1, modulates contextual non-spatial and spatial representations while the animal is executing different cognitive tests. To address the role of long excitatory projections (LREP) we use a chemogenetic silencing in CA1 during contextual Novel Object Recognition test (NOR), Novel Object Location test (NOL) and the natural tendency of the mouse to escape from open environments and hide in a safe area through association of spatial external cues in a Barnes maze. Our results suggest an important role of excitatory projections from LEC in CA1 in discrimination of objects as well as spatial memory recall.We are currently exploring the contribution of each of the GABAergic projection neuron subtypes, as we found that long range inhibitory projections (LRIP) comprise of parvalbumin (PV), somatostatin (SOM) and vasoactive intestinal peptide (VIP) expressing GABAergic neuron subtypes.1. P331. Modulations in Hippocampal Spatial Representations

Program #/Poster #: P331.01

Topic: H.09. Spatial Navigation

Title: Natural switches in attention and active-sensing rapidly modulate hippocampal spatial codes

Authors: *A. SAREL[1], S. PALGI[1], D. BLUM[1], J. ALJADEFF[1,2], L. LAS[1], N. ULANOVSKY[1];
[1]Weizmann Inst. of Sceince, Rehovot, Israel; [2]Univ. of California, San Diego, CA

Abstract: Navigation is a rich and dynamic behavior. It requires the animal to know its own location within the environment, while also paying attention to incoming sudden events such as

obstacles, other conspecific or predators that may appear along the way. Most studies on the neurobiology of navigation focus on the representation of the animal's current position in small, empty and static setups that do not imitate well the complexity and rich dynamism of real-world navigation. Here we set out to test how brief attentional switches to 'things out-there' affect the representation of space in the hippocampus. To this end, we designed a task in which two bats flew together in a 120-meter flight tunnel, and had to be attentive both to the environment and to the position of the other bat, in order to avoid collisions during events of 'cross-over' between the bats. We recorded the neural activity in hippocampal area CA1 and tracked the positions of the bats in the tunnel using wireless-electrophysiology and custom tracking devices. We recorded the bats' echolocation calls and found that bats increased their call rate and amplitude ~20 meters before a cross-over event, indicating that the bats were attentive during these events. Our neural recordings showed that during cross-overs, CA1 neurons encode the distance to the other bat. Thus, as the bats approached each other, the neurons switched from an allocentric coding of the tunnel (place tuning) to egocentric × allocentric coding (inter-bat distance × place tuning) – and then switched back to allocentric coding after the bats passed each other. These neuronal switches were very rapid, as fast as 100 ms. This switching to a neuronal representation of the other bat was correlated on a trial-by-trial basis with the attention signal, as indexed by the bat's echolocation calls – suggesting that spatial attention and active-sensing are controlling these major switches in neural coding. Interestingly, we found that in place-cells, the different place-fields of the same neuron could exhibit very different tuning to inter-bat distance – creating a non-separable coding of allocentric position × egocentric distance. Theoretical analysis demonstrated that such a non-separable code leads to better decoding. Together, our results suggest that attentional switches during navigation – which in bats can be measured directly based on their echolocation signals – elicit rapid dynamics of hippocampal spatial coding. More broadly, this study demonstrates that during natural behavior, when animals often switch between different behaviors, neural circuits can rapidly and flexibly switch their core computations.

Title: Hippocampal cells encode time or distance, depending on the rat's prior expectation

Authors: *S. ABRAMSON[1], B. KRAUS[2], J. A. WHITE[3], M. E. HASSELMO[2], G. MORRIS[1], D. DERDIKMAN[1];
[1]Rappaport Fac. of Med. and Res. Inst., Technion – Israel Inst. of Technol., Haifa, Israel; [2]Ctr. for Systems Neurosci., [3]Biomed. Engin., Boston Univ., Boston, MA

Abstract: The hippocampus is known since the 1970ies for playing an important role in spatial processing and in episodic memory. The discovery of place cells within the hippocampus has pointed to the importance of these cells for navigation. The more recent discovery of hippocampal time cells has broadened the perspective of encoding in the hippocampus. One hypothesis is based on the notion that hippocampal cells deduce location by integrating travelled distance ("path integration"). According to this hypothesis, time cells, which fire at particular times when animals are running on a treadmill without changing location, actually encode accumulated distance on the treadmill. To examine this hypothesis, Kraus et al.[1] performed treadmill experiments in which animals either ran for a fixed-time or a fixed-distance with varying velocities. The two distinct coding modes of that hippocampal principle cells, whereby some cells encoded travelled distance and others elapsed time, thus excluding the notion that all hippocampal cells were performing path integration. Using the data from these experiments, we asked whether the two populations depended on the type of task the rats were engaged in. We show that indeed the type of experiment determined the cells' encoding: In experiments in which the rat ran for a fixed time interval with varying distance, the cells tended to encode a fixed time. In contrast, in the experiments in which the rat ran for a fixed distance with varying time intervals, the cells tended to encode a fixed distance. These results demonstrate that the specific response of the cells depends on the rat's expectation of the rules determining its behavior

Title: Multi-scale representation of very large environments in the hippocampus of flying bats

Authors: ***T. ELIAV**, S. R. MAIMON, J. ALJADEFF, M. TSODYKS, G. GINOSAR, L. LAS, N. ULANOVSKY;
Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Most animals navigate daily over distances spanning from hundreds of meters to many kilometers. However, over the last fifty years, hippocampal research focused on spatial representations in small laboratory environments. Nothing is known about hippocampal neural codes for large spatial scales - the scales of natural navigation of rodents, bats and other mammals. Here we addressed this question for the first time, by developing a unique setup - including a very large environment with an ethologically-relevant spatial scale. We studied Egyptian fruit bats - flying mammals that are excellent navigators over large scales, and which have rodent-like hippocampal spatial representations in small laboratory environments. We

developed an on-board wireless neural-logger, which allows recording single-units over unlimited distances. We built a 200-meter long tunnel where bats can fly freely; bat's position was tracked using an RF localization device that measures distances to a ground-based antenna array - yielding high accuracy of ~9-cm, much better than GPS. Bats flew back-and-forth along the tunnel, more than 100 laps per-session (over 20-km total distance). Recordings from dorsal hippocampal area CA1 of 10 bats in the long tunnel showed spatial firing that was very different from findings in small-scale laboratory environments: Across neurons, the size of place-fields ranged from 0.6 m to 32 m. Single-neurons exhibited multiple fields, and a multi-scale representation of space - whereby place-fields of the same neuron differed up to 20-fold in size. These large variations in scale were unrelated to local landmarks, and could not be explained by the animal's flight speed, which was extremely stable along the tunnel - suggesting that dorsal CA1 neurons have a genuine multi-scale representation of space. This coding scheme was observed from the first exposure to the environment, and was similar between lab-born and wild-born bats, suggesting the multi-scale code is a very robust phenomenon, which does not require neither recent experience nor early experience with large environments. Theoretical decoding analysis showed that this multi-scale code enables representing very large environments with extremely low decoding-errors. We modeled these results using a set of overlapping continuous attractors of different scales that randomly share neurons between them - which created a continuum of field-sizes, and recapitulated the multi-field multi-scale code observed in the data. Together, the experiments and theory suggest that in large environments, the hippocampus exhibits an efficient coding scheme that is radically different from small environments.

Title: Local field potential theta, spike-theta phase modulation and precession along the CA1 transverse axis

Authors: *A. BISHNOI, S. S. DESHMUKH;
Ctr. for Neurosci., Indian Inst. Of Sci., Bangalore, India

Abstract: Brain rhythms help coordinate neural activity to support cognitive functions. Theta oscillations (5-10Hz) in the rodent hippocampus have been hypothesized to facilitate learning and spatial memory. Theta mediated coordination of neural activity can allow effective communication between different spatially tuned populations for processing spatial information

and context. Pyramidal cells in the hippocampus can use rate and temporal codes to convey spatial information. Hippocampal neurons exhibit temporal codes through theta phase precession: the preferred phase of firing advances as the animal progresses through the neuron's place field. Along the CA1 transverse axis, distal CA1 (dCA1) has been shown to be less spatially selective, and exhibit weaker theta modulation and phase precession than proximal CA1 (pCA1) (Henriksen et al., 2010, Oliva et al., 2016). In contrast, we recently reported that spatial selectivity is comparable along the CA1 transverse axis when the animals run on a circular track with distinct local texture cues and global visual cues in a circular arena (Deshmukh, 2020, bioRxiv). In the current study, we sought to compare theta oscillatory dynamics in pCA1 and dCA1 in the same environment by studying theta power in the local field potentials (LFP), theta modulation of neural spiking, and phase precession along the CA1 transverse axis in 10 male Long Evans rats. We find that a similar proportion of neurons are theta modulated (pCA1: 62/83 cells, dCA1: 79/115 cells, Chi-square, $p = 0.357$) and show phase precession (pCA1: 81/83 cells, dCA1: 112/115 cells, Chi-square, $p = 0.929$) between pCA1 and dCA1. The strength of modulation (median: pCA1 = 0.73, dCA1 = 0.67, Wilcoxon rank-sum, $p = 0.087$) and phase precession (median: pCA1 = 0.28, dCA1= 0.27, Wilcoxon rank-sum, $p = 0.205$) is also comparable between the two CA1 sub-regions. This trend does not change when the local and global cues are mismatched by rotating local cues counterclockwise and global cues clockwise by equal amounts. We also demonstrate that absolute theta power in LFP is higher in dCA1 than in pCA1 (Wilcoxon Sign rank, $p=0.02$). These findings challenge the established notion of dCA1 being inherently less spatially selective than pCA1. The combination of higher theta amplitude in LFPs in dCA1 than pCA1 and the presence of theta phase precession in almost all neurons indicates that theta mediated spatial information processing in the two areas is comparable in our experimental paradigm.

Title: Dorsal and ventral CA1 representations of space and reward during spatial learning

Authors: *P. JARZEBOWSKI, O. PAULSEN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Dorsal CA1 (dCA1) place cells accumulate at rewarded locations. Because the ventral CA1 (vCA1) projects to the amygdala and the nucleus accumbens — brain regions canonically involved in reward learning — we hypothesized that the reward would also modulate vCA1 activity. We asked how the learned reward location shapes the dCA1 and vCA1 activity, and if the cells active at the reward location change their place fields to track the reward after translocation. Such representation could provide a stable representation for navigational goals in a malleable representation of space in the hippocampus.
We imaged calcium fluorescence from the dCA1 and vCA1 of freely-moving mice performing a spatial reward learning task using a miniaturized microscope (miniscope). Mice navigated on a circular maze with holes that were baited with rewards (cheeseboard maze) where the reward locations were initially fixed. Following the acquisition, we moved the reward location to test which spatially modulated cells in the dCA1 and vCA1 tracked the reward locations.
We present a comparison of spatial representations in the dCA1 and vCA1 and how they changed in the same cells over learning that spanned three sets of reward locations. We found that place cells accumulate at rewarded locations in the dCA1 but not in the vCA1. On individual runs towards the reward, the dCA1 cells organized their firing into a sequence that progressed faster at the reward location. We also report how the place fields remapped to follow the translocated reward.

A vast amount of research has shown that numerous species, including young children and

rodents, rely primarily on the geometric shape of navigable space to regain their sense of direction after disorientation, often ignoring non-geometric cues even when they are informative. Notably, these experiments have almost always been performed in single-chamber environments in which there is no ambiguity about place identity. In real life scenarios, lost navigators must identify their current location and recover their facing direction in order to restore their bearings. In previous work we tested the idea that these two tasks - place recognition and heading retrieval - might be mediated by distinct cognitive systems. We found that mice used non-geometric features to identify the chamber in which they were located, but failed to use those same features to recover their facing direction, instead relying exclusively on spatial geometry. These results suggested the existence of separate systems for place recognition and heading retrieval that are differentially sensitive to geometric and non-geometric cues, respectively. In this study we investigated the neuronal correlates of these processes using single unit and calcium imaging recordings in disoriented mice trained a two-chamber reorientation task. We found that the hippocampal map aligned to the geometry of each chamber and changes in firing rate served to disambiguate the contexts. These results were corroborated with calcium imaging in freely moving mice. Together these data indicated that the alignment of the hippocampal map serves to recover heading, while changes in firing rate underlie place recognition. Interestingly, while the overall spatial information content of the cells was the same in both contexts, distinct subpopulations had higher information in one context than the other, suggesting that accurate prediction of location in each environment was achieved by distinct subpopulations. These results suggest that heading retrieval and context recognition are distinctively coded at the hippocampal level.

Title: Investigating in vivo hippocampal activity over long timescales reveals predictive nature of CA1 place cell representations in complex behavioral tasks

Authors: *K. FINKE[1], G. STRAUS[1], C. ALVARADO[1], E. HAPGOOD[1], E. KAROLCZAK[1], A. METOYER[1], C. RICHMOND[1], T. BOYD-MEREDITH[2], D. TANK[2], J. GAUTHIER[1]; [1]Swarthmore Col., Swarthmore, PA; [2]Princeton Univ., Princeton, NJ

Abstract: The hippocampus plays a vital role in navigation. It is unclear, however, how the hippocampus supports spatial learning over long timescales in complex tasks. One limitation has been the ability to track neural activity for more than a few days or weeks. Even with two-photon imaging, which allows precise anatomical localization of recorded cells, brain deformations make it difficult or impossible to repeatedly image the same plane. Here, we introduce an analysis technique to track calcium activity in large populations at cellular resolution over months of training despite substantial deformations. In our experiments, mice learned to associate reward with several locations in a virtual reality environment over the course of three calendar months. Within each cell, our analysis could follow how multiple place fields formed, drifted, and dissolved. We also identified discrete behavioral strategies that gradually evolved from the first trials through expert performance. When we compared neural activity to the trajectory of behavioral learning, unexpected patterns emerged. When a new task was introduced, place fields underwent significant changes prior to behavioral improvement. In addition, predictive representations tended to form more often in complex tasks than simple ones. Together, these findings suggest that the hippocampus does not form a general-purpose map of space, but instead that spatial representations must be suited to support the unique demands of each task. We anticipate our technique for tracking large populations could allow for recording longer timescales of activity in other brain areas.

Title: Animal-to-animal variability in hippocampal remapping

Authors: P. NILCHIAN[1], M. WILSON[2], ***H. SANDERS**[2];
[1]Florida Intl. Univ., University Park, FL; [2]MIT, Cambridge, MA

Abstract: Hippocampal place cells map an animals' environment. Remapping describes changes in place field locations and firing rates and occurs when animals' context changes. However, the variability across animals in remapping behavior is not well understood, and its characteristics have only been studied sporadically. In this work, we analyzed electrophysiological recordings from Alme et al., 2014, in which five rats were exposed to 11 different environments. To compare the hippocampal maps in two rooms, we computed average rate map correlation coefficients. We discovered that the heterogeneity in animals' remapping behavior is structured: animals' remapping behavior is consistent across a range of independent comparisons. Our

findings highlight that remapping behavior between repeated environments depends on animal-specific factors.

Title: Behaviorally-driven divergence and stabilization of place cell maps during episodic memory formation and consolidation

Authors: *R. ZEMLA[1,2], J. MOORE[3,4], J. BASU[1,2];
[1]New York Univ. Sch. of Med., New York City, NY; [2]NYU Neurosci. Inst., New York City, NY; [3]NYU Neurosci. Inst., New York, NY; [4]Flatiron Inst., New York City, NY

Abstract: The hippocampus is critical for the formation and recall of episodic memories which store past experience of events ('what') occurring at particular locations ('where') in time ('when'). Place cells, hippocampal pyramidal neurons which show location-specific activity during navigation, form a spatial map of the environment and are hypothesized to be the neural substrate of the 'where' of episodic memory. Previous experiments suggested that place cells should retain stable spatial tuning activity following learning to facilitate future memory recall. While long-term imaging studies in CA1 demonstrated limited reactivation of place maps upon repeated exposure to a familiar environment, these studies examined place map stability in the absence of memory and attentional demand. Thus, the relationship between episodic learning and long-term place map stability remains unanswered. To examine the relationship between long-term place map stability and episodic memory, we developed an operant, head-fixed, odor-cued, spatial navigation task and used 2-photon calcium imaging to track CA1 pyramidal neuron activity during task learning and recall. We found that existing place cells are rapidly recruited into task-dependent spatial maps and that place cells use a diverse set of remapping strategies to represent changing task goals. Furthermore, we observed the stabilization of learned place cell maps following memory consolidation and a performance dependent divergence of spatial maps between trial types. Our findings suggest that a subset of place cells is recruited by episodic

spatial learning, actively reconfigured to represent task-relevant spatial relationships, and stabilized following successful learning and consolidation.

Title: Inhibitory feedback control of behavioral time scale plasticity induction in CA1

Authors: ***S. V. ROLOTTI**, M. S. AHMED, M. SZOBOSZLAY, H. BLOCKUS, K. C. GONZALEZ, F. T. SPARKS, A. SOLIS CANALES, D. S. PETERKA, A. LOSONCZY; Dept. of Neurosci., Columbia Univ., New York, NY

Abstract: Pyramidal cells in area CA1 (CA1PCs) of the mammalian hippocampus develop spatially restricted firing fields as the organism explores an environment, forming a cognitive map. Clarifying the circuit mechanisms by which a given CA1PC forms a ‘place field' (PF) or otherwise develops de novo feature selectivity is critical to a broader understanding of memory formation, and has been a topic of considerable interest.
Recent work has revealed that PF formation occurs through a novel form of plasticity, behavioral time scale synaptic plasticity (BTSP). Importantly, BTSP can be experimentally induced in individual CA1PCs via repeated current injection at a fixed location, allowing experimenters to probe PF dynamics and representational content. To date, the limitations of intracellular electrophysiology have constrained this avenue of inquiry to single cells over short timescales, leaving the relationship of BTSP to population coding and memory behavior undetermined. The induction and subsequent longitudinal tracking of PFs in arbitrary numbers of cells would therefore represent a major advance, clarifying the circuit mechanisms regulating BTSP and the relationship of PF formation in neural ensembles to learning and behavior.
Here we argue that recurrent inhibition in CA1 represents a circuit mechanism for limiting arbitrary scaling of BTSP across the population. We present sparse-labeling and targeted-stimulation approaches that enable the first demonstrations of optogenetic PF induction in single cells. Pairing these optogenetic approaches with 2-photon calcium imaging, we characterize longer timescale dynamics of induced PFs to show that they are functionally indistinguishable from spontaneously formed PFs. We find that these approaches scale to small numbers of stimulated cells but fail to induce PFs at higher densities. Importantly, we further show that local

interneuron (IN) activity scales with stimulation density, and that manipulation of local INs to suppress recurrent inhibition raises the density limits on PF formation. Finally, we find that over-representing a location using these approaches can bias goal-directed behavior.
Overall, this study makes important advances in our understanding of circuit control of PF formation for learning and memory. We demonstrate the importance of local feedback inhibition in regulating PF formation rates, as well as demonstrating for the first time the causal role of PF over-representation in rapid spatial learning. Future work will delineate the degree to which recurrent inhibition can be manipulated to overcome endogenous limits on BTSP in CA1PC ensembles and potentially further enhance learning.

Title: Dynamic dendritic and somatic interactions underlying place field remapping in mouse hippocampal area CA3

Authors: *J. J. MOORE, M. HOPKINS, J. BASU;
Neurosci. Inst., NYU Sch. of Med., New York City, NY

Abstract: Hippocampal “place cells” are tuned to specific locations in an environment[1]. These representations can “remap” in different environments or in the same environment in response to changes in task demand[2-4]. Remapping occurs on fast timescales, so typical plasticity mechanisms cannot completely explain this phenomenon. Dendritic spiking has been implicated in the formation of stable place fields[5]; here we explore the contributions of dendrites to the flexibility of hippocampal representations. We consider two possible remapping mechanisms: “Input remapping” in which inputs to a neuron change but the soma-dendrite correlation relationships remain the same; and “Gate remapping” in which inputs remain constant but the soma becomes more correlated with a new subset of dendritic branches. To assess these possible mechanisms of hippocampal remapping, we utilize an experimental paradigm enabling fast

switching of the physical cues defining an environment. Headfixed mice ran on a treadmill track with proximal cues defining position. The belt was then flipped over during imaging to reveal new cues and textures, enabling continuous recording from the instant the new environment is encountered. We use a 2-photon calcium imaging preparation in which the basal dendrites, cell bodies, and apical dendrites of pyramidal neurons in hippocampal area CA3 are all imaged in the same focal plane. We measured the degree of gate remapping by the change in the correlation matrix computed from the fluorescence traces of all segments (dendrite and soma) of a neuron.To process this data, we developed an automated algorithm to identify dendritic and somatic regions of interest (ROIs) from the calcium signal. The algorithm matches manually-labeled datasets, is easily applied to detecting ROIs from various neuronal morphologies, runs faster than real-time on a standard desktop computer, and has few free parameters to tune. We discovered that an entire place cell could hold on average 4 place fields when taking all dendrites into account, even though the soma expresses fewer, in line with our previous findings[6]. We find evidence for both input remapping and gate remapping, indicating a change in the internal routing of information. These results suggest that dendrites perform independent computations, and that dendritic outputs can be selectively coupled to the soma in a context-dependent manner.

Title: The dendritic spatial code:branch-specific place tuning and its experience-dependent decoupling

Authors: S. K. RASHID[1], J. MOORE[2], R. DELATORRE[2], ***J. BASU**[2];
[1]Neurosci. Inst., NYU, New York, NY; [2]Neurosci. Institute, New York Univ. Sch., New York, NY

Abstract: Dendrites of pyramidal neurons integrate different sensory inputs, and non-linear dendritic computations drive feature selective tuning and plasticity. Yet little is known about how dendrites themselves represent the environment, the degree to which they are coupled to their soma, and how that coupling is sculpted with experience. In order to answer these questions, we developed a novel preparation in which we image soma and connected dendrites in a single plane across days using in vivo two-photon microscopy. Using this preparation, we monitored spatially tuned activity in area CA3 of the hippocampus in head-fixed mice running on a linear track. We identified “place dendrites”, which can stably and precisely represent both familiar and novel spatial environments. Dendrites could display place tuning independent of their connected soma and even their sister dendritic branches, the first evidence for branch-specific tuning in the hippocampus. In a familiar environment, spatially tuned somata were more decoupled from their dendrites as compared to non-tuned somata. This relationship was absent in a novel environment, suggesting an experience-dependent selective gating of dendritic spatial inputs. We then built a data-driven multicompartment computational model that could capture the experimentally observed correlations. Our model indicates that place cells exhibiting branch-specific tuning have more flexible place fields, while neurons with homogenous or co-tuned dendritic branches have higher place field stability. We found evidence for this prediction in our experimental data sets. These findings demonstrate that spatial representation is organized in a branch-specific manner within dendrites of hippocampal pyramidal cells. Further, spatial inputs from dendrites to soma are selectively and dynamically gated in an experience-dependent manner, endowing both flexibility and stability to the cognitive map of space.

Title: Functional investigation of the lateral entorhinal cortex input to hippocampal area CA3

Authors: *V. ROBERT[1], R. DE LA TORRE[2], K. O'NEIL[2], J. BASU[3];
[1]New York Univ. Langone Med. Ctr., New York, NY; [2]NYU Grossman Sch. of Med., New York, NY; [3]Dept. of Neurosci. and Physiol., Neurosci. Institute, New York Univ. Sch., New York, NY

Abstract: The hippocampus receives and processes sensory information from the entorhinal cortex to form episodic memories. Specifically, the lateral entorhinal cortex (LEC) provides contextual signals which are transferred sequentially through the dentate gyrus (DG) - CA3 - CA1 loop in the hippocampus. Amongst these regions, area CA3 displays the unique ability to

perform both pattern separation and completion depending on the degree of similarity of the environment. This likely stems from the unique CA3 circuitry which involves direct LEC inputs on distal dendrites, processed feedforward DG inputs on proximal dendrites, and internally-generated feedback CA3 recurrent inputs on medial dendrites. This organization may enable non-linear integration of LEC inputs in CA3 PN dendrites, which could dictate whether the CA3 network undergoes pattern separation or completion. Indeed, LEC has been shown to send excitatory and inhibitory projections to the hippocampus which allow the generation of dendritic spikes in CA1, and lesions of LEC disrupt CA3 rate remapping. However, the circuit connecting LEC to area CA3 and the consequences of its activation on CA3 output remain unknown. To address this, we expressed the light-gated opsins Chronos and ChrimsonR in LEC excitatory and inhibitory cells respectively, and performed whole-cell patch clamp recordings of CA3 interneurons and pyramidal neurons in acute slices. We found that local interneurons located in the medial apical dendritic layer received mono-synaptic connections from both glutamatergic and GABAergic projections from LEC. LEC direct glutamatergic input strongly excited these interneurons, yielding substantial feedforward inhibition of CA3 pyramidal neurons. LEC direct GABAergic input modulated the recruitment of these interneurons by LEC mono-synaptic excitation, suggesting a role for disinhibitory gating to boost overall excitation. Next, we combined selective optical stimulation of LEC excitatory and inhibitory projections with electrical stimulation of DG mossy fibers and CA3 recurrent collaterals to assess the integration of these inputs in area CA3. While CA3 pyramidal neurons did not fire action potentials in response to single stimulation of LEC excitatory input, its repeated stimulation either by itself or coincidently paired with mossy fiber and CA3 recurrent collateral input stimulations elicited spike output in the same CA3 pyramidal neurons. These results demonstrate that the LEC input can drive CA3 output when coordinated with activation of local inputs, highlighting the role of dendritic integration of LEC signals in CA3 dendrites which will be the focus of our future experiments.

Title: Differences in reward biased spatial representations in the lateral septum and hippocampus

Authors: ***H. S. WIRTSHAFTER**, M. A. WILSON;
MIT, Cambridge, MA

Abstract: The hippocampus innervates the lateral septum (LS) and provides the LS with spatial information. However, it remains unknown how the LS represents place information, and

whether this information is combined with reward signaling. To answer this question, we simultaneously recorded from rat hippocampus CA1 and caudodorsal LS during a rewarded spatial navigation task. We then compared spatial firing between the CA1 and LS. We determined that the LS contains place cells which, while less numerous than in the CA1, are similar to hippocampal place cells in field size and number of fields per cell. Place cells in the LS, however, have field shapes and center distributions that are more skewed towards reward as compared to HPC place cells. Additionally, spike cross-correlations between place cells in the CA1 and LS are greatest for cells that have reward-proximate place fields, suggesting reward-related place cells are preferentially represented in the LS. The LS may therefore play a role in relaying task-relevant hippocampal spatial information to downstream areas, such as the VTA.

Title: Ventral Tegmental Area Stimulation Induces Hippocampal Remapping

Authors: *D. KHATIB[1], G. TOCKER[2], J. GROSS[1], G. MORRIS[1], D. DERDIKMAN[1];
[1]Technion Israel Inst. of Technol., Haifa, Israel; [2]Northwestern Univ., Evanston, IL

Abstract: The hippocampus and associated structures are related to the perception of space, learning, and memory. The hippocampus can represent environments via its place cells in what is known as a cognitive map. These maps are stable representations of the environment but can reorganize when the environment is changed, a phenomenon widely known as remapping.
The midbrain has gained much attention in recent years in relation to its role in learning and memory. Specifically, the dopaminergic cells in the Ventral Tegmental Area (VTA) is associated with reinforcement learning and novelty.
In the current study, we looked at the relationship between the VTA and the hippocampus, as some works suggest a role for the VTA in stabilizing hippocampal maps. The VTA itself contains mainly dopaminergic neurons but contains also GABAergic and glutamatergic populations, with the latter being suggested to have a direct effect on the hippocampus. We investigated the effects of stimulating different cell types in the VTA on the hippocampal map and the place cells constituting it.
We used three Cre-driver mouse lines, TH-Cre, DAT-Cre to target the dopaminergic population

and Vglut2-Cre to target the glutamatergic population within the VTA. We stimulated these neurons using excitatory DREADDs while recording the activity in CA1 using one-photon calcium imaging and extracellular electrophysiological tetrode recordings. We found that stimulating the dopaminergic subpopulation did not affect the representation of the environment in the hippocampus. On the other hand, stimulating the glutamatergic subpopulation induced remapping of place cells while the animal was traversing the same known environment. This suggests a role for the glutamatergic VTA population in hippocampal remapping and novelty.

Title: Communication subspaces for local-field potential defined network states

Authors: *Z. GUO, R. YOUNG, S. P. JADHAV;
Brandeis Univ., Waltham, MA

Abstract: Distributed neural circuits across multiple brain regions coordinate activity and communicate with each other to process information and promote our understanding of the world. The hippocampus (HPC) and prefrontal cortex (PFC) are essential to learning and are thought to work in an integrated fashion to support cognition and memory-guided behavior (e.g., Tamura et al., 2017; Zielinski et al., 2020). The rhythmic fluctuations in the local field potentials of HPC and PFC have been shown to reveal broad behavioral states (e.g., movement) and periods of inter- and intra-regional communication but lack the full information carried by spiking activity of cellular ensembles. To incorporate individual neuronal spiking in analyses of network communication, we applied tools developed by Semedo et al. (2019) to gain insights into the co-fluctuations of neuronal populations in HPC and PFC. Ensembles of co-fluctuating neurons in the HPC and PFC reveal a substructure of interaction during unique hippocampal activity patterns such as theta and delta rhythms and sharp-wave ripples corresponding to network states crucial to memory. Importantly we find these three local-field patterns have lower dimensional neuronal interaction between as opposed to within brain regions. Overall we compare and contrast pattern-specific subspaces linking HPC-PFC neuronal activity across rhythmic states, finding separable but related states with a possible role in memory-guided behavior.

Title: Alzheimer's disease-like network disruptions in hippocampus and anterior cingulate cortex in a model of diabetes mellitus

Authors: *L. A. CREW[1], R. A. WIRT[2], A. A. ORTIZ[5], A. M. MCNEELA[5], E. FLORES[5], B. N. UDIN[5], J. W. KINNEY[3], J. M. HYMAN[4];
[1]Neurosci., [3]Dept. of Brain Hlth., [4]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV; [5]Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Network function in the hippocampus (HC) and anterior cingulate cortex (ACC) is critical for efficient working memory function and network impairments play a significant role in the cognitive deficits seen in Alzheimer's disease (AD). While historically there has been a great concentration of amyloid pathology, recently theoretical and experimental work has linked the other prominent AD pathologies, neuroinflammation and tau hyperphosphorylation to changes in working memory network functioning. Chronic hyperglycemia leads to neuroinflammation and tau hyperphosphorylation in the HC, similar to what occurs in AD, though with no amyloidosis Interestingly, chronic hyperglycemia also leads to mild cognitive impairments, as observed in diabetes mellitus, a risk factor to the development of AD. We hypothesize that hyperglycemia is impairing HC network activity and cognitive performance, perhaps due to neuroinflammation and tau hyperphosphorylation. To test this hypothesis, we injected rats with a series of acute, low doses of streptozotocin (STZ) that damaged pancreatic beta cells and increased blood glucose levels. We then tested animals on a spatial delayed alternation task while simultaneously recording from the HC and ACC, two areas where network activity is essential for effective performance. We found that hyperglycemic animals had no differences in performance accuracy for shorter delay trials but a decrease in accuracy to chance levels for longer delays. Spectral changes observed in STZ animals showed a decrease in HC theta power and an increase in delta power in both areas. This increase in delta power resulted in an overall change in the theta/delta ratio that was more noticeable during the end of the delay period, where theta power should be more pronounced. Interestingly, STZ animals showed strong hypersynchrony, with an increase in cross-frequency coupling, in several different frequency bands, and HC-ACC coherence. The elevated coherence significantly decreased during correct trials in STZ animals compared to the opposite effect seen in controls and previous research. Finally, we found a considerable amount of hyperphosphorylated tau within the HC and ACC of STZ animals, which may be related to the oscillatory and behavioral changes seen here. Collectively, these findings display striking changes in HC and ACC network activity during a working memory task in moderately hyperglycemic animals, suggesting an association with the physiological and cognitive pathologies of AD.

Title: Remote Recall Deficits and Altered Hippocampal Oscillations in Hyperglycemia

Authors: ***A. M. MCNEELA**[1], R. A. WIRT[2], A. A. ORTIZ[1], E. FLORES[1], J. W. KINNEY[3], J. M. HYMAN[4];
[1]Univ. of Nevada, Las Vegas, Las Vegas, NV; [3]Dept. of Brain Hlth., [4]Psychology, [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: It is estimated that by 2050 the global prevalence of Alzheimer's disease (AD) will increase to 13.8 million cases and 95% of these will be the sporadic form of AD (sAD). While the cause of sAD is unknown, several risk factors have been identified. Notably, abnormal insulin signaling in diabetes mellitus (DM) patients increases the likelihood of developing sAD by 65% and is thought to trigger metabolic dysfunction, neuroinflammation, and neurodegeneration similar to that found in AD. Administration of a diabetogenic drug (streptozotocin; STZ) in rodents can mimic sAD-like memory defects and enhanced hippocampal tau expression (Murtishaw et al., 2018). Although the HC is required for recent memory recall, theta-dependent prefrontal-hippocampal synchrony driven by the anterior cingulate cortex (ACC) supports remote recall (Wirt & Hyman, 2019). To explore differences in memory mechanisms related to hyperglycemia, we administered staggered low-dose IP injections (20mg/kg) of either STZ or a control solution. We recorded network activity from ACC and HC throughout sequential exposure to either novel or familiar environments. Consistent with the findings of (Wirt & Hyman, 2019), control animals displayed decreased thigmotaxis during both recent and remote re-exposures, suggesting functional recall for both retention intervals. Although no recall differences were found between STZ and controls during recent exposures, STZ thigmotaxis during remote recall reverted to levels comparable to their initial exposure, corroborating hyperglycemia-induced memory defects (Murtishaw et al., 2018). Electrophysiological data revealed significant disproportions in theta and delta band signal, where STZ animals exhibited decreased theta-delta ratios in the HC. Since hippocampal functionality relies on alternation between behaviorally-relevant theta and delta states to achieve different memory processes, these results suggest that ACC-HC network dysregulation may account for impaired contextual remote recall in hyperglycemic animals. Since EEG slowing is a characteristic hallmark of AD progression, examining similar network disruptions may also assist our understanding of sporadic AD development.

Title: Accelerating and decelerating hippocampal theta oscillations has opposing effects on spatial working memory performance

Authors: N. DEVICO MARCIANO[1], *M. L. FU[1], R. E. SIRETSKIY[1], M. A. JARAMILLO[1], T. L. HUYNH[1], J. K. LEUTGEB[1], S. LEUTGEB[1,2];
[1]Neurobio. Section, Div. of Biol. Sciences, Univ. of California, San Diego, LA Jolla, CA; [2]Kavli Inst. for Brain and Mind, Univ. of California, San Diego, La Jolla, CA

Abstract: Brain oscillations are not only an indication of the precise timing of neural activity within a brain region, but are also thought to organize the coordination of activity across multiple brain regions to support cognitive function. For example, the coordination of hippocampal neural activity with other brain regions by oscillations in the theta range is thought to be essential for spatial working memory. To test this possibility, we took advantage of the finding that the rhythmic optogenetic activation of medial septal GABAergic neurons is sufficient for generating hippocampal oscillation frequencies that supersede endogenous theta oscillations (~8 Hz). By using this technique in a spatial alternation task we previously found that 12 Hz or 20 Hz oscillations impaired working memory performance (i.e., in trials with 10 s delays) but did not alter performance during trials that do not require a hippocampal contribution to memory (i.e., with no delay). Also, optogenetic pacing of oscillations within the endogenous theta range (i.e., at 8 Hz) did not result in any effects on working memory performance. These findings raise the question whether manipulations that slow down theta frequency also result in a memory impairment. We therefore tested mice with different delay conditions (no delay, 2 s delay, 10 s delay) while pacing oscillations across a range of frequencies (4 Hz, 6 Hz, 8 Hz, 10 Hz, and 12 Hz). The stimulation frequency and the order of delays were pseudo-randomized across days, and trials without stimulation were interleaved between trials with stimulation. As before, oscillations were paced with an optogenetic approach by first expressing channelrhodopsin in parvalbumin+ cells of the medial septal area (MSA) and by then delivering rhythmic light stimulation to the MSA. In each mouse, the effectiveness of the pacing was monitored by LFP recordings from the hippocampus, and mice with GFP expression were used to confirm that light delivery alone did not alter the behavior. As before, we found that the pacing of oscillations at 12 Hz impaired spatial working memory performance in trials with 10 s delays (n = 15 mice, p =

0.045, Wilcoxon test followed by Holm-Bonferroni correction for multiple comparisons), while pacing either at or close to the endogenous theta frequency (6 Hz, 8 Hz, and 10 Hz) did not have any effects on memory (n = 15, 15 and 14, all p values > 0.1). In contrast, pacing at 4 Hz resulted in an improvement of working memory (n = 15, p = 0.017) which raises the possibility that slower oscillation patterns may increase the coupling of the entorhino-hippocampal system with other brain regions where these oscillations are more prominent, such as VTA and prefrontal areas.

Title: Type I and Type II theta oscillations in the limbic circuit are uncoupled from respiration-entrained oscillations in the olfactory bulb during an odor-cued working memory task

Authors: *S. SRIKANTH[1], D. LE[1], Y. HU[1], J. LEUTGEB[1], S. LEUTGEB[1,2];
[1]Neurobio. Section, Div. of Biol. Sci., UCSD, San Diego, CA; [2]Kavli Inst. for Brain and Mind, Univ. of California, San Diego, La Jolla, CA

Abstract: Type I theta oscillations (6-10 Hz) are movement-related and are generated in the septo-hippocampal network. They are thought to synchronize activity in the prefrontal-hippocampal network and mediate cognitive functions such as working memory (WM) and spatial navigation. On the other hand, Type II theta oscillations in the hippocampus are unrelated to movement, and are elicited when the animal is exposed to arousing sensory stimuli. Recently, respiration related oscillations (RROs) have been reported to propagate to several neocortical and subcortical areas including the prefrontal cortex and the hippocampus. We asked whether RROs in the limbic circuit couple to canonical theta oscillations during an odor-cued working memory task, and thus potentially integrate sensory processing with working memory retention. We trained mice to perform an odor-cued working memory task on a Figure-8 maze while simultaneously recording LFP signals from the olfactory bulb (OB), medial prefrontal cortex, dorsal and ventral hippocampus. LFP signals were analyzed from these four brain regions during different task phases, the odor sampling period, the central arm (where animals leave the odor port and run towards the choice point), the reward location, and the return arm (where animals run from the reward location back to the odor port). Peak frequencies of the OB oscillations ranged from 3-12 Hz in all task phases (~1200 trials; 7 mice). In addition, type I theta

oscillations were observed in the limbic regions during periods of high running speed (central and return arms), as expected. Type I theta oscillations in the limbic regions were more coherent with each other at the central arm where WM persisted compared to the return arm where mice ran at similar speeds but without a WM demand. Type II theta oscillations were observed in the limbic regions during odor sampling, but not during reward consumption, which are both periods of immobility. In addition to theta oscillations, RROs were observed in the limbic regions for all task phases. These RROs were coherent with the OB oscillations, except when RROs and theta (Types I and II) overlapped in frequency, suggesting that neither type of theta becomes coupled to RROs, even at matching frequencies. Therefore, OB oscillations - although observed at limbic regions do not appear to become coupled to theta oscillations, including when type II theta is generated during odor sampling. These results suggest that entrainment of hippocampal oscillations to sensory-coupled oscillations is not necessary for WM, and that oscillations that are intrinsically paced rather than by sensory inputs are central to information processing by limbic circuits.

Title: Investigating the role of KIBRA-dependent synaptic function on hippocampal and cortical network mechanisms underlying complex cognition

Authors: *L. QUIGLEY, R. PENDRY, M. MENDOZA, L. VOLK, B. PFEIFFER;
Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Revealing how molecular interactions within single cells contribute to experience-dependent changes in circuit-level neural activity across large-scale brain networks is an urgent challenge in neuroscience. Disorders of complex cognition have strong genetic contributions and ultimately manifest via emergent properties of dysfunctional neural networks. However, a clear picture of how heritable factors contribute functionally to pathological symptoms remains elusive. Here I focus on investigating *in vivo* network dysfunction following removal of the synaptic scaffolding protein KIBRA. KIBRA gene variants are linked to normal variation in human memory performance and mice lacking Kibra show substantial impairment in learning and memory. KIBRA also regulates hippocampal AMPA receptor trafficking and synaptic plasticity, a cellular correlate of learning and memory. In addition, KIBRA and the protein complexes it organizes are associated with multiple neuropsychiatric disorders known to have synaptic/circuit etiologies. However, the role of KIBRA in regulating circuit dynamics is

unknown. To determine whether KIBRA-dependent plasticity mechanisms regulate behaviorally relevant circuit dynamics, I monitored simultaneous neural activity in both the hippocampus (HC) and frontal cortex (ACC) of mice with forebrain-specific deletion of KIBRA (KIBRA cKO) using *in vivo* electrophysiology in freely behaving mice. My findings indicate a failure of hippocampal circuits to properly synchronize in response to novel experience in the absence of KIBRA. I first examined whether there were any gross alterations in baseline hippocampal network function and found minimal differences between WT and KIBRA cKO mice. Next, I examined behaviorally regulated changes in oscillatory dynamics in KIBRA cKO mice. I found that KIBRA cKO mice fail to exhibit experience-dependent alterations in theta and gamma oscillatory power within the hippocampus. This finding suggests a failure of hippocampal circuits to adapt to experience in the absence of KIBRA and may impact memory encoding and consolidation. Our results further show that while most fundamental properties of remote sharp wave-ripple events and associated oscillatory dynamics are intact, KIBRA cKO mice fail to show experience-dependent modification of remote ripple properties. This indicates that experience-dependent changes in circuit dynamics that support memory consolidation are impaired in the KIBRA cKO. Together, these data reveal network-level mechanisms by which KIBRA may regulate systems-level memory consolidation in the adult brain.

Title: Learning to synchronize: Midfrontal theta dynamics during rule switching

Authors: *P. VERBEKE, K. ERGO, E. DE LOOF, T. VERGUTS;
Ghent Univ., Ghent, Belgium

Abstract: In recent years, several hierarchical extensions of well-known learning algorithms have been proposed. For example, when stimulus-action mappings vary across time or context, the brain may learn two or more stimulus-action mappings in separate modules, and additionally (at a hierarchically higher level) learn to appropriately switch between those modules. However, how the brain mechanistically coordinates neural communication to implement such hierarchical learning, remains unknown. Therefore, the current study tests a recent computational model (Verbeke & Verguts, 2019) that proposed how midfrontal theta oscillations implement such hierarchical learning via the principle of binding by synchrony (Sync model). More specifically,

the Sync model employs bursts at theta frequency to flexibly bind appropriate task modules by synchrony. 64-channel EEG signal was recorded while 27 healthy human subjects (Female: 21, Male: 6) performed a probabilistic reversal learning task. We fitted the Sync model on behavioral data and compared the fit (via AIC) with two other state-of-the-art models that not learn to switch between modules. Here, the Rescorla-wagner (RW) model learns stimulus-action mappings with the standard RW learning rule. The adaptive learning rate (ALR) model implements RW learning with an adaptable learning rate which increases on task switches. Important individual differences were observed. While some subjects fitted best with the Sync model, other subjects fitted better with the RW model. No evidence was found for the ALR model. Crucially, the Sync model also provides testable predictions for EEG data which we tested. In line with the Sync model, post-feedback theta power showed a linear relationship with negative prediction errors, but not with positive prediction errors. This relationship was especially pronounced for subjects with better behavioral fit for the Sync model. Also consistent with Sync model simulations, theta phase-coupling between midfrontal electrodes and temporo-parietal electrodes was stronger after negative feedback. Our data suggest that the brain uses theta power and synchronization for flexibly switching between task rule modules, as is useful for example when multiple stimulus-action mappings must be retained and used.

Episodic memory relies on the ability of the hippocampus to process spatial information. This type of memory emerges late in postnatal lifetime, in correlation with hippocampal development. When this memory is build-up by using external/distal environmental cues became known as allocentric memory, and it is the latest form of episodic memory to emerge. It has recently been shown that allocentric memory is observed since postnatal day 18 (P18), but it is not fully developed until P38, when it reaches the adult-like form. However, it has been proposed that early reinforcement by allocentric task training could accelerate its adult-like expression.Although the mechanisms of memory formation remain unclear, research has pointed out sleep as a memory promoter and oscillatory electrical rhythms during sleep, such as slow cortical waves (< 1Hz) and hippocampal sharp-wave ripples (SWRs,100-250 Hz) as correlates of memory consolidation. To determine whether allocentric reinforcement could anticipate episodic memory's maturation in parallel with changes in oscillatory activity, we performed an object-in-place task with or without reinforcement and in vivo LFP recordings, throughout animal development, in the somatosensory and hippocampal cortices. Our results show that allocentric memory emerges around P32 (n=11, $p< 0.042$) independently of early reinforcement and, changes in the power and density of sleep SWRs accompany the emergence of memory consolidation.

Title: Auditory closed-loop stimulation during sleep in mice modulates the retention of spatial memory

Authors: *S. AKSAMAZ[1], M. MÖLLE[2], R. GOLDEN[3], M. BAZHENOV[3], L. MARSHALL[1,2]; [1]Inst. for Exptl. and Clin. Pharmacol. and Toxicology, Univ. of Lübeck, Lübeck, Germany; [2]Ctr. for Brain, Behavior and Metabolism, Lübeck, Germany; [3]Neurosciences Grad. Program and Dept. of Med., Univ. of California, San Diego, CA

Abstract: In humans, auditory closed-loop stimulation (ACLS) in phase with the ongoing SOs enhanced overnight memory retention (Ngo et. al., 2013, Neuron). ACLS is hypothesized to enhance the interaction between slow oscillations (SOs), hippocampal sharp-wave ripples, and thalamocortical sleep spindles presumed to underly memory consolidation. Our aim was to determine the stimulation parameters for a corresponding mouse model, a prerequisite for selective interrogation of brain regions/activity underlying sleep rhythms to determine their role in the facilitation of memory consolidation by ACLS. After a sample run of the object place recognition (OPR) task (30 minutes after lights on; 12:12 h, L/D, lights on at 8 a.m.) subjects (C57BL/6N-Rj, male, 8-10 weeks) were placed in a recording box for 3 hours to sleep. Wire arrays in the cingulate cortex and dorsal hippocampus recorded local field potentials. Upon online detection of the negative SO half-wave a white noise burst was delivered by two loudspeakers (58 dB) at one of four phases of the SO, in different sessions: close to the downstate (DS), the down-to-up transition (D2US), the up-state (UpS) and the up-to-down transition (U2DS). Stimulation was omitted in a fifth session (sham). The OPR test phase took place approximately 3 hours after the sample run. Analyses measured amplitude, density, and length of offline-detected SOs, spindle and ripple events, event-event correlations, and the preference index of the OPR task (PI = time spent with the displaced object/ time spent with both objects). ACLS entrained SOs, sleep spindle, and ripple activity as measured by the RMS (root-mean-square) signals. Preliminary analyses reveal a tendency toward increased SO density (SOs/min) in the UpS-condition compared to the sham condition (paired t-test, $p=0.05$, $n=5$). A biophysical model of the closed loop thalamo-cortico-hippocampal network revealed an increase in power in SOs, spindle, and ripple bands; and an increase in density of ripples occurring at the time of stimulation and a shift in the density of ripples toward the D2US, suggesting an increase in the coupling of ripples and SOs. Blinded rating of the OPR task found that mice performed above chance levels for ACLS delivered at the DS, D2US, and UpS whereas sham performance failed to surpass the chance level (one-sample t-test, sham: $p=0.059$, $n=7$; DS: $p=0.004$, $n=7$; UpS: $p=0.034$, $n=4$; U2DS: $p=0.027$, $n=7$). Together, despite measuring only a minor impact on electrophysiological activity, preliminary results in a small subject sample indicate, that our ACLS protocol enhances retention of spatial memory in mice.

Title: Human cortical ripples reflect a spectrum of synchronous spiking activity across spatial scale

Authors: *A. S. TONG[1], A. P. VAZ[2], S. K. INATI[1], K. A. ZAGHLOUL[1];
[1]Surgical Neurol. Br., Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD; [2]Duke Univ. Sch. of Med., Durham, NC

Abstract: Engagement of the medial temporal lobe (MTL) and neocortex in episodic memory is strongly associated with increases in high frequency activity (HFA). Recent evidence suggests that discrete HF oscillations, termed ripples, are linked to memory processes that are coupled between human MTL and neocortex. While changes in HFA during successful memory retrieval has been widely observed, dynamic changes that occur during individual trials are less clear. We hypothesized that resolving HFA changes in time can reveal discrete ripple events that reflect a spectrum of dynamic spiking activity modulated by low frequency (LF) oscillations. Twenty-one participants completed a paired-associates verbal memory task in which they studied word pairs and were later cued with a word from each pair while we recorded intracranial EEG (iEEG). Six of these participants also had simultaneous microelectrode array (MEA) recording of local field potentials (LFP) and single-unit spiking activity. We extracted spectral power from the iEEG and LFP signals between 1-200 Hz and defined discrete HFA events as ripples when 80-120 Hz spectral power exceeded two SDs for a minimum of 25 ms. Ripples were detected from simultaneous macroscale iEEG and microscale local field potential (LFP) recordings. Synchrony of ripples and spikes were measured using pairwise phase consistency (PPC). We found that HFA changes during successful memory retrieval were correlated with iEEG ripples and the amplitude of these iEEG ripples was correlated with number and synchrony of LFP ripples across MEA electrodes. Furthermore, amplitude of LFP ripples was correlated with number and synchrony of spiking units. Both LFP ripples and spikes were more strongly coordinated by low frequency oscillations within compared to outside of ripples and during correct compared to incorrect memory retrieval. Overall, our data suggest that successful memory retrieval exhibits discrete ripples across spatial scale that reflect synchronous spiking activity modulated by low frequency oscillations.

Title: Camkii α expression levels determine the coherence of oscillations between prefrontal cortex and hippocampus

Authors: *D. RAMIREZ-GORDILLO[1], A. PARRA[3], L. MEDIAVILLO[3], K. BAYER[2], D. RESTREPO[1];
[1]Cell and developmental biology, [2]Dept. of Pharmacol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [3]Dept. of Chem. and Biochem., New Mexico State Univ., Las Cruces, NM

Abstract: The alpha-isoform of calcium/calmodulin-dependent protein kinase II (CaMKIIα) is highly expressed in the brain including the hippocampus and prefrontal cortex. Mutations of CaMKIIα are implicated in a range of diseases including schizophrenia, addiction, depression, heart disease, epilepsy, Alzheimer, Parkinson's, and neurodevelopmental disorders. Important functions of CaMKIIα are participation in long term potentiation and long-term depression (synaptic plasticity). In addition, heterozygous CaMKIIα knockout mice (Het) have problems with development leading to complications with behaviors including immature dentate gyrus, hyperactivity, deficits in working memory, and social withdrawal. To further investigate the role of CaMKIIα in communication between brain regions, we tested mice deficient for CaMKIIα in an go-no go olfactory discrimination task to assess cognitive learning deficits and underlying problems in neuronal oscillatory processing in the hippocampus and prefrontal cortex. Mice learned to associate one of two odorants with a water reward. Subsequently, wild type (WT), Het, and knockout (KO) mice received double tetrode implants aimed at the CA1 region of the hippocampus and medial prefrontal cortex. We find that the strength of phase amplitude coupling to theta oscillations (tPAC) differs between the genotypes. In addition, the variability of the peak angle for tPAC increases for the unrewarded odor. Furthermore, we calculated theta phase-related power (tPRP). tPRP increases for S+ and decreases for S- as the animal becomes proficient and is significantly different between the genotypes. Finally, we analyzed oscillatory coherence between prefrontal cortex and hippocampus. Our results indicate that coherence increases for S+ and decreases for S- as the animal becomes proficient and is lowest for KO. These observations suggest an essential role for CaMKIIα in coherence between prefrontal cortex and hippocampus in associative odorant learning.

Title: Dentate spikes and external control of hippocampal function

Authors: *D. DVORAK, A. CHUNG, E. PARK, A. A. FENTON;
New York Univ., New York, NY

Abstract: Mouse hippocampus CA1 place-cell discharge typically encodes current location but during slow gamma dominance (SG_{dom}), when slow gamma oscillations (30-60 Hz) dominate mid-frequency gamma oscillations (60-90 Hz) in CA1 local field potentials, CA1 discharge switches to represent distant recollected locations. We now report that dentate spike type 2 (DS_M) events initiated by MECII-DG inputs promote SG_{dom} and change CA1 discharge, whereas type 1 (DS_L) events initiated by LECII-DG inputs do not. Just before SG_{dom}, LECII-originating slow gamma oscillations in dentate gyrus and CA3-originating slow gamma oscillations in CA1 become optimally phase and frequency synchronized at the DS_M peak when the firing rates of DG, CA3, and CA1 principal cells increase to promote DG-CA3-CA1 cofiring optimized for the 5-10 ms DG-to-CA1 neuro-transmission that coincides with SG_{dom}. Several properties and consequences of DS_M demonstrate extrahippocampal control of SG_{dom}, identifying a cortico-hippocampal mechanism that switches between memory-related hippocampal information processing modes.

Title: Decreased dynamic range of hippocampal CA1 gamma in aged rats

Authors: *L. CROWN[1,2], D. T. GRAY[1,2], L. A. SCHIMANSKI[1], C. A. BARNES[1,2,3], S. L. COWEN[1,2];
[1]Evelyn F. McKnight Brain Inst., [2]Dept. of Psychology, [3]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Decreased episodic memory is a common age-associated cognitive change that significantly impairs quality of life in the elderly. Changes within the hippocampus and surrounding regions including the medial entorhinal cortex (MEC) likely contribute to these impairments in humans and animal models of brain aging. One mechanism through which these regions are thought to communicate is through synchronized gamma oscillations. Gamma oscillations (30 Hz-120 Hz) are implicated in numerous cognitive processes including sensory

binding, memory, and attentional selection. Within the rodent hippocampus, gamma has been shown to be modulated by running speed (Ahmed & Mehta, 2012), suggesting that gamma frequency reflects the speed of sensory or cognitive processing. In this study we examine gamma oscillations in the CA1 region of the hippocampus in 6 middle aged (9-12 months) rats and 5 old (25-28 months) rats as they ran back and forth on a horseshoe shaped maze while performing a spatial eye-blink conditioning task. We hypothesized that cognitive slowing in aged animals would result in impaired CA1 gamma frequency modulation by running speed. To assess how gamma frequency changed as a function of running speed, normalized power spectral densities were acquired and binned by running speed and averaged for each animal. After obtaining the frequency of maximum gamma power for each speed bin, a robust regression was performed to obtain the slope and intercept of the relationship. We found that aged animals had significantly shallower slopes than younger animals ($t(5.6)=3.92$, $p=0.009$) as well as a higher intercept ($t(8.9)=-3.45$, $p=0.007$). This suggests that aged animals have a narrower dynamic range for gamma frequencies which may be indicative of early age-related cognitive slowing.

Title: Ventral, but not dorsal, hippocampus mediates the context-dependence of signaled active avoidance

Authors: *C. R. OLEKSIAK[1], K. RAMANATHAN[1], O. MILES[2], S. MAREN[3], J. M. MOSCARELLO[3];
[1]Psychological and Brain Sci. & Inst. for Neurosci., [2]Psychological and Brain Sci., Texas A&M, COLLEGE STATION, TX; [3]Psychological and Brain Sci., Texas A&M Univ., College Station, TX

Abstract: Avoidance is a common coping technique for fear disorders like PTSD because the relief experienced with reduced exposure to the trauma reminder reinforces the behavior. Although the effect of context on other common PTSD symptoms such as re-experiencing (represented by freezing in rats) has been well-characterized, the role of context in active avoidance has not been established. Because avoidance involves learning sequential Pavlovian and instrumental associations, we hypothesized that it is context-dependent and depends on the hippocampus. To assess these hypotheses, male rats were trained in a two-way signaled active avoidance task, in which they shuttled across a divided chamber during a tone CS in order to prevent a footshock US. Training entailed 30 trials per day for 4 or 8 days. After training,

avoidance responding was tested in the conditioning context or a novel context in a counterbalanced fashion (10 CS-alone presentations in each test). Rats (n=31) performed significantly more avoidance responses in the same context than in the different context, demonstrating the context-dependence of avoidance. To examine the role of the hippocampus in the context-dependence of avoidance, we reversibly inhibited either the dorsal (DH) or ventral hippocampus (VH) with muscimol before test session. VH inactivation(n=13) increased avoidance responses in the different context compared to controls injected with vehicle(n=12) while having no effect on responding in the same context. In contrast, inactivation of DH(n=14) had no effect on avoidance compared to controls injected with vehicle(n=12) in either context. Therefore, VH, but not DH, mediates the context-dependence of avoidance behavior. This is congruent with earlier work (Burhans and Gabriel, 2007) suggesting a role for the ventral subiculum in the contextual modulation of avoidance behavior. Further studies will examine ventral hippocampal outputs that are necessary for the context-shift deficit.

Title: Mapping hippocampal synaptic circuits changes in remote place avoidance memory.

Authors: *A. B. GRAU-PERALES[1], A. A. FENTON[2];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY

Abstract: Several input-specific populations of synapses in the hippocampus can undergo synaptic changes, potentially to store memory, but which synaptic populations change with experience is unknown. The recurrent connectivity amongst CA3 collaterals has motivated hypotheses that CA3 functions as a storage site. Place cell dynamics and their discharge relationships with gamma oscillations in the LFP identified a specific role for CA3-CA1 stratum radiatum (sr) synapses in memory recollection, and an information encoding role for EC3-CA1 stratum lacunosum moleculare (slm) synapses. Inputs from spatially-tuned medial entorhinal (MEC) cells and less-spatially tuned lateral entorhinal (LEC) cells, differentially target dendritic compartments in the supra- and infra-pyramidal blades of dentate gyrus (DG), such that LEC inputs are hypothesized to provide contextual inputs and MEC spatial signals. The atypical protein kinase C isoform PKMζ is both necessary and sufficient for the maintenance of LTP at hippocampal synapses and is crucial for the persistence of a long-term hippocampus-dependent active place avoidance memory. We used PKMζ immunostaining to test hypotheses for which

input-specific synaptic populations might change in long-term memory storage. To investigate the subcellular distribution of PKMζ we used ArcCreER^{T2} x ChR2-EYFP mice to label memory-associated cells. Trained (n=4) mice had 30-min trials to learn a conditioned place avoidance, and untrained (n=4) control mice only explored the environment. Prior to the last training trial when trained mice expressed strong avoidance memory, all mice received 4-OH tamoxifen to tag memory activated Arc-expressing cells with EYFP. A month later, the persistence of the conditioned avoidance was confirmed prior to sacrifice followed by PKMζ and EYFP immunohistochemistry. EYFP memory-tagging identified that CA1 more than CA3 pyramidal cells are activated, and also more DG granule cells in the suprapyramidal blade than the infrapyramidal blade. Memory-induced increases of PKMζ also followed this pattern, with increases in CA1 > CA3 and increases in supra-DG > infra-DG, which did not differ from untrained controls. PKMζ expression in EYFP memory-tagged cells identified input-specific patterns of memory-related synaptic populations. In CA1, memory-training caused increased PKMζ co-expression with EYFP at sr synapses, but not at slm. These observations putatively identify memory-related sites of synaptic storage and support hypotheses that predict input-specific changes in the storage of specific long-term memories.

Title: Sex-specific memory deficits and hippocampal activation following neuroimmune activation

Authors: *C. K. POSILLICO, N. C. TRONSON;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: The neuroimmune system is critical for carrying out normal neural processes and cognition, and as such, it is not surprising that neuroimmune dysfunction induces significant cognitive deficits including with learning and memory. Despite evidence that memory processes and the neuroimmune system are intricately linked, and that there are sex differences in immune and neuroimmune cells and responses, we do not know precisely how neuroimmune activation interacts with mechanisms of learning and memory and how this differs in males and females. This is particularly relevant for the current pandemic. Coronavirus disease 19 (COVID-19) caused by the virus SARS-CoV-2 presents with significant cognitive impairments that have been linked to neuroimmune activation, and men typically have worse outcomes than women. We used central administration of a synthetic viral mimic, polyinosinic:polycytidylic acid (poly I:C) in male and female C57Bl/6 mice to determine how activation of the neuroimmune system

disrupted hippocampal-dependent memory in both sexes. We found that poly I:C induced significant acute cytokine and chemokine responses in the hippocampus in both sexes, but males showed a greater magnitude response than females. This was evident for IL-1α, IL-1β, IL-6, IL-10, IFNα, TNFα, CCL2, and CXCL10. Next, we tested whether neuroinflammation disrupted learning and memory consolidation of context fear conditioning. While pre-training poly I:C disrupted learning of context fear in both sexes, males were more vulnerable to post-training poly I:C disruption of memory consolidation. We measured cFos in the hippocampus after pre-training poly I:C to determine if changes in hippocampal activation played a role in the disruption of learning in both sexes. Females treated with poly I:C and trained in context fear conditioning showed exaggerated hippocampal activation, whereas poly I:C in males did not alter cFos induction following training. Taken together, these data suggest that while neuroimmune activation disrupts learning in both sexes, it is via separate cellular mechanisms. Specifically, males showed greater neuroimmune responses, and females showed more cFos+ cells in the hippocampus at the same time that both sexes showed learning deficits in context fear conditioning. Future experiments will identify intracellular signaling mechanisms impacted by both neuroimmune activation and memory, with the goal of determining novel, sex-specific target pathways that play a role in memory- and cognitive-related diseases, including Alzheimer's Disease and Post-Traumatic Stress Disorder.

Abstract: Transcranial direct current stimulation (tDCS) in humans and animals has been shown to produce beneficial effects on cognition and memory. We previously reported that the cognitive enhancement induced by a single 30 minute session of anodal tDCS at 250 μA is strongly associated with the modification of hippocampal proteins. However, the effects of anodal tDCS dosimetry on cognitive performance and the hippocampal proteome remain largely unknown. Thus, the purpose of this study was to investigate the effects of different current intensities of anodal tDCS on memory performance and protein regulation in hippocampal

synaptosomes. Two different current intensities (250µA and 500µA) of anodal tDCS were applied to Sprague Dawley rats (male, 8-10 weeks old) for 30 min for 2 days, just before the training and testing sessions of the passive avoidance test (PAT). Isolated hippocampal synaptosomes were profiled using the Waters Acquity UPLC M-class LC and normalized proteomic abundance datasets were analyzed by multiple bioinformatics methods and advanced statistical analyses. Our results show that anodal tDCS at both 250 µA and 500 µA enhance PAT memory performance. Moreover, both current intensities significantly modify hippocampal synaptosomes compared to sham conditions. Although similar modifications in hippocampal synaptosomes were detected at both current intensities, a significant number of proteins were differentially regulated. In conclusion, we report that anodal tDCS at 250 µA and 500 µA both enhance memory performance in the PAT with potentially different underlying mechanisms. Future studies are warranted to further investigate the effects of tDCS dosimetry on behavior and hippocampal protein regulation.

Title: Hippocampome.org - a simulation-ready knowledge base of the hippocampal neuron-type circuit

Authors: *D. W. WHEELER[1], A. O. KOMENDANTOV[1], D. J. HAMILTON[1], K. MORADI[1], S. M. ATTILI[1], C. TECUATL[1], J. D. KOPSICK[1], N. SUTTON[1], A. SANCHEZ-AGUILERA[2], L. M. DE LA PRIDA[2], G. A. ASCOLI[1,2];
[1]George Mason Univ., Fairfax, VA; [2]Inst. Cajal CSIC, Madrid, Spain

Abstract: Hippocampome.org is an open-access knowledge base of the rodent hippocampal formation at the level of neuron types. In this knowledge base, peer-reviewed literature is used to define over 120 neuron types by their main neurotransmitter and the patterns of their axonal and dendritic presence across the parcels of the hippocampal formation: dentate gyrus, CA3, CA2, CA1, subiculum, and entorhinal cortex. For each of the neuron types in Hippocampome.org, information is included about molecular markers; intrinsic electrophysiological parameters; quantitative firing-pattern classification; parameters of single- and multi-compartmental Izhikevich models; estimated counts; known and potential connectivity, and statistical estimations of the probabilities of the potential connectivity between the various neuron types; the amplitude, kinetics and short-term plasticity of each potential connection; and the in-vivo

phase locking of neuronal firing to theta oscillations and sharp-wave ripples in the hippocampal formation. All data are cross correlated with each other and linked to extracted publication excerpts and illustrations. We are also proceeding to use the collated knowledge in a real-scale spiking-neural-network computational simulation of the complete hippocampal formation, starting with subregion CA3. As always, we endeavor to expand the foundations of Hippocampome.org by continually data mining the literature for new neuron types and neuronal properties while cross-linking and integrating new and prior knowledge.

Title: The tired hippocampus: memory engrams in the sleep-deprived brain

Authors: *Y. G. BOLSIUS[1], P. R. A. HECKMAN[2,1], M. J. H. KAS[1], S. RAMIREZ[3], P. MEERLO[1], R. HAVEKES[1];
[1]Univ. of Groningen, Groningen, Netherlands; [2]Univ. of Maastricht, Maastricht, Netherlands; [3]Boston Univ., Boston, MA

Abstract: Sleep loss is a common problem in our modern 24/7 society due to social and economic demands. Sleep deprivation negatively impacts brain function and particularly affects cognitive processes that require the hippocampus. We previously showed in mice that a brief period of sleep deprivation following training impairs memory processes in the object-location task. It is unclear, however, whether these deficits are due to a failed storage of information or rather a result of attenuated retrievability of the stored information. To address this question, we used 8 week old male c-fos tTA mice injected with a TRE-ChR2-mCherry AAV in the dentate gyrus to specifically tag a memory engram in this region of the hippocampus. Mice were kept of doxycycline 24 hours prior to training in the object-location memory task and immediately put back on doxycycline at the end of training. All mice were then sleep deprived for 6 hours. During the retention test 24h later, we optogenetically reactivated the spatial memory engram (20Hz, 15 ms for 3 min) in half of the sleep deprived-mice. In line with our previous studies, we found that sleep deprived mice failed to detect the spatial novelty (*i.e.* detect which object was moved to a novel location). However, this impairment was overcome by optogenetic stimulation of the memory engram prior to the retrieval test. Even 5 - 8 days after the training, optogenetic stimulation of the engram resulted in proper memory retrieval in the sleep deprived mice. Altogether, these observations demonstrate that sleep deprivation does not prevent the storage of

hippocampal memory engrams. Rather, it makes the engrams stored under sleep deprivation conditions inaccessible for natural retrieval. These findings underscore the exciting possibility that more information is stored in the brain under sleep deprivation conditions than expected, and may support the development of novel therapeutic strategies to combat cognitive deficits associated with sleep deprivation.

Title: Do engram cells discharge like memory cells?

Authors: ***C. JOU**[1,2], E. PARK[3], D. DVORAK[3], E. LEVY[3], A. A. FENTON[3,4];
[1]City Univ. of New York, New York, NY; [2]Dept. of Psychology, Hunter Col., New York, NY; [3]Ctr. for Neural Sci., New York Univ., New York, NY; [4]Neurosci. Inst. at the NYU Langone Med. Ctr., New York, NY

Abstract: Engram cell (EC) experiments genetically tag neurons that are active during learning so that they can be optogenetically manipulated to test whether their reactivation is necessary and sufficient for the expression of a memory. Hippocampal ECs have been identified in mice using threat-conditioning paradigms, but the results challenge established notions of how the hippocampus encodes and processes information. Consider for example, that hippocampal ECs are place cells that discharge at specific locations of a conditioning environment to represent that environment. During conditioning, a pair of cells with coincident firing fields in the north of the environment may discharge together, but never when cells with firing fields in the south discharge. However, these three place/engram cells would be activated synchronously during optogenetic activation, making it difficult to imagine how the optogenetic activation could result in replaying or reactivating the representations that were stored during conditioning. We have begun to investigate this contradiction. We first established that optogenetic tagging and activation of CA1 was sufficient to express a conditioned-place avoidance known to require place cells and their dynamic temporal discharge. Next, we recorded ensembles of CA1 cells in these same mice under anesthesia after the optogenetic test and behavioral demonstration of sufficiency. Firing rates increased ~77% during 7 mW, 473 nm, 10 Hz optogenetic activation, and increased their likelihood of discharging to 1% in response to each 15 ms light pulse. Remarkably, CA1 cell pairs maintained their pre-established co-firing relationships such that pairs of cells that cofired before stimulation continued to cofire during stimulation, and cell pairs that did not cofire continued not to cofire (7mW: $r = 0.36$, compared to control: $r = 0.51$).

Ensemble CA1 recordings in awake, head-fixed mice also confirmed that the 10 Hz optogenetic stimulation produces an evoked discharge pattern in single cells that can be distinguished from control discharge. These initial observations indicate the importance of monitoring patterns of neural discharge during EC experiments in order to assess whether or not memory-related temporal discharge patterns are maintained during optogenetic stimulation in EC experiments that elicit conditioned responses.

Title: Individual CA1 place cells automatically encode local sensory cues via rate remapping

Authors: *W. HOCKEIMER[1,2], R.-Y. LAI[1], J. J. KNIERIM[1,2];
[1]Zanvyl Krieger Mind/Brain Inst., [2]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Beyond their well-described role in representing spatial location, CA1 place cells also modulate their firing in response to non-spatial cues. This dual role in spatial and non-spatial information processing led to the proposal that CA1 neurons utilize a multiplexed code for location and items via rate remapping. Significantly, this code could provide the mechanistic underpinning of a cognitive map. Further, it has been proposed that CA1 automatically encodes the content of episodic experience into a short-term buffer to support later, offline computations. To address the role of CA1 in automatic attending, and to further characterize the nature of rate remapping, tetrode recordings were taken from four Long-Evans rats (3 M / 1 F) as they completed laps around a rectangular track containing nine reward zones. Each reward zone contained one of three textured floorplates which bore no relation to the probability of reward. The plates were pseudo-randomly interchanged across trials to allow an analysis of the place cell response to each stimulus at each location. Cells were pooled across days for analysis. Approximately 8-15% of neurons displayed significantly different firing rate responses to the stimuli, according to a permutation test (8.3%, $p = 0.035$) and a linear mixed effects model (16%, $p = 2.4e-7$). A majority of days contained a greater abundance of texture-responsive cells compared to the proportion stipulated by the alpha level (alpha = 0.05) (6/9 days, permutation test, $p = 0.2$; 8/9 days LMER models, $p = 0.02$). Texture-responsive cells did not alter their firing rates throughout the place field, but rather displayed micro-fluctuations within the field. These data support the hypothesis that CA1 automatically encodes information about experience in the

framework of a stable spatial map, possibly to support an episodic buffer. Further, the data suggest that CA1 neurons are capable of representing information on a finer spatial scale than that of their place fields, suggesting the presence of under-explored computational properties of the network.

Title: Distinct representations of task-related variables in dorsal and ventral CA1 during associative learning

Authors: *J. S. BIANE[1], M. A. LADOW[1], F. STEFANINI[2], S. P. BODDU[1], A. FAN[1], S. T. HASSAN[1], D. L. APODACA-MONTANO[1], N. DUNDAR[1], K. M. LITKE[1], N. I. WOODS[1], M. KHEIRBEK[1];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Columbia Univ., New York, NY

Abstract: The dorsal and ventral (d/v) hippocampus exhibit distinct anatomical, genetic and functional properties. Although both regions have been implicated in associative learning, their individual roles in this process are not well understood. Here, we used 2-photon imaging to track the activity of single neurons in the dorsal or ventral CA1 (dCA1, vCA1) across phases of an odor-reward learning task in which an odor and delay period preceded reward delivery. We found robust coding of odor identity in populations of neurons in dCA1 across all phases of the task (baseline, learning, extinction and reinstatement), indicating that dCA1 neurons code for stimulus identity. In contrast, encoding of odor identity in vCA1 neurons was highly dependent on the perceived value of the odorants. Analysis of the delay period between odor and reward found that both dCA1 and vCA1 showed little/no response at the onset of learning. However, following learning both regions displayed robust responsivity to the CS+ delay period, but not the CS- delay period. This signal faded following extinction of the CS+/US contingency, but was rapidly restored when the contingency was reinstated. Moreover, in well-trained animals this pre-reward signal displayed considerable overlap across sessions, suggesting a stable representation

for reward expectation. Finally, we examined the within-trial temporal dynamics of population activity. After associative learning, dCA1 exhibited distinct ensembles of neurons representing each component of the trial (odor, delay, reward). In contrast, in vCA1 we found overlapping representations to these trial epochs, and these neural representations persisted for seconds after the trial was over. This suggests that dCA1 neuronal ensembles may represent the distinct epochs of a trial while vCA1 combines these representations into a format that allows downstream areas to extract meaning from the experience. Collectively, these data indicate a shift from externally based (stimulus ID) to internally based (value) encoding of environmental variables along the d/v axis of the hippocampus.

Title: Chronic and transient suppression of adult born granule cell function reduce neural flexibility

Authors: *S. N. TUNCDEMIR, C. LACEFIELD, V. LUNA, R. HEN;
RFMH Columbia Univ., New York, NY

Abstract: The dentate gyrus (DG) exhibits a unique form of neural plasticity that results from continuous integration of newly born excitatory granule cells, termed adult hippocampal neurogenesis. Recent studies have proposed that adult neurogenesis promotes cognitive flexibility, the ability to encode new memories without interference from previously stored memories that share similar features. While recent evidence suggested that adult born neurons differentially modulate input to the mature granule cells during processing of spatial information, the manner in which adult neurogenesis contributes to DG network activity and computations is incompletely understood. Here, we employed a well-established method of focal X-ray-irradiation (IR) of the hippocampus to completely eliminate neurogenesis and examined population neural activity using *in vivo* 2-photon Ca^{2+} imaging. Granule cells are thought to implement a pattern separation computation by remapping their firing fields in response to a contextual change. To assess the degree of remapping of neural representations of space, we

compared the similarity between single-cell spatial tuning profiles by subjecting the mice to two sequential exposures of either identical or different environments in different sessions while foraging for randomly dispersed water rewards. While spatial rate maps in Sham mice were less stable across than within environments (i.e., display remapping), IR mice exhibited significantly lower levels of remapping compared to controls. To address the role of adult born neurons specifically during their critical period of maturation (4-6 weeks) we chemogenetically inhibited immature granule cells. In line with chronically suppressing adult neurogenesis, albeit to a lesser degree, transient and selective silencing of immature granule cells resulted in significantly higher levels of stability in spatial rate maps across different environments compared to control mice. Furthermore, a higher proportion of mature granule cells that are matched between sessions exhibited increased activity upon transiently silencing immature granule cells compared to controls, consistent with the prevailing model of adult born neurons' function in regulating the activity of mature granule cells. Our results highlight the long-hypothesized role of adult neurogenesis in providing flexibility for DG to rapidly generate a context specific, distributed representation of important sensory stimuli such as spatial cues, which ultimately promotes cognitive flexibility.

Title: The conditions under which acquisition of conditioned freezing requires NMDA receptor activation in the basolateral amygdala complex.

Authors: *M. J. WILLIAMS-SPOONER, F. WESTBROOK, N. M. HOLMES;
Sch. of Psychology, Univ. of New South Wales, Sydney, Australia

Abstract: NMDA-type glutamate receptors (NMDAR) play a key role in aversive Pavlovian conditioning, including the acquisition of conditioned freezing to a context or discrete cue conditioned stimulus (CS) paired with a shock unconditioned stimulus (US). Acquiring conditioned freezing to a discrete cue CS (e.g., tone or light) requires NMDAR activity in the basolateral amygdala complex (BLA), while acquiring freezing to a context CS requires NMDAR activity in the BLA and the dorsal hippocampus. Learning in the BLA remains NMDAR-dependent when conditioning multiple cues and contexts (Lee & Kim, 1998), including reconditioning to a previously-extinguished context (Laurent & Westbrook, 2009). Interestingly, however, context-shock learning in the dorsal hippocampus is NMDAR-dependent when animals are naïve or the shock US is delivered at unexpected times (Finnie et al., 2018),

but is NMDAR-independent when rats have previously undergone the same learning in a different context (Finnie et al., 2018; Hardt et al., 2009; Sanders & Fanselow, 2003). The present series of experiments examined the conditions under which acquisition of conditioned freezing requires activation of NMDAR in the BLA. The experiments used a conditioning protocol in which rats were exposed to presentations of a serial S2-S1 compound (tone and light, counterbalanced) paired with shock, and then tested for freezing to S2. BLA infusions of the NMDAR antagonist, D-AP5, disrupted acquisition of conditioned freezing to S2 when the animals had not undergone prior training (Experiment 2), but had no effect when the animals underwent S1-shock training prior to serial-order conditioning (Experiments 1-2). However, the requirement for NMDAR activity in the BLA could be restored by omitting the shock US or the already-conditioned S1 from stage two of training (Experiments 3-4), or by conducting the two stages of training in different contexts (Experiment 5). Finally, we confirmed that that NMDAR-independent conditioned freezing to S2 requires AMPA receptor (AMPAR) signalling in the BLA (Experiment 6), including calcium-permeable AMPAR (CP-AMPAR) (Experiment 7). Our results extend NMDAR-independent findings from the dorsal hippocampus to the BLA, and suggest that the animal's prior history determines whether NMDAR activation in the BLA is required for new learning. Our results are also consistent with in vitro work from the BLA, which showed that NMDAR-independent LTP required CP-AMPAR activity (Mahanty & Sah, 1998; Polepalli et al., 2010, 2020). This plasticity took place in inhibitory interneurons, which are also necessary for the acquisition of conditioned freezing in the BLA (Krabbe et al., 2018).

Title: The medial entorhinal cortex mediates basolateral amygdala effects on spatial memory and downstream ARC protein expression

Authors: *K. L. WAHLSTROM[1], A. ALVAREZ-DIEPPA[3], C. K. MCINTYRE[4], R. LALUMIERE[2];
[1]Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA; [2]Univ. of Iowa, Psychological and Brain Sciences, IA; [3]Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX; [4]Sch. Behav and Brain Sci., Univ. Texas at Dallas, Richardson, TX

Abstract: The basolateral amygdala (BLA) modulates the consolidation of dorsal hippocampus (DH)-dependent spatial and dorsolateral striatum (DLS)-dependent cued-response memories, often in competition with one another. Evidence suggests that a critical mechanism for BLA

influences on memory consolidation is via effects on activity-regulated cytoskeletal-associated protein (ARC) in downstream brain regions. However, the circuitry by which the BLA modulates ARC in multiple competing memory systems remains unclear. Prior evidence indicates that optogenetic stimulation of BLA projections to the medial entorhinal cortex (mEC) enhances the consolidation of spatial learning and impairs the consolidation of cued-response learning, suggesting this pathway provides a circuit for favoring one system over another. Therefore, we hypothesized the BLA-mEC pathway mediates effects on downstream ARC-based synaptic plasticity related to these competing memory systems. To address this, male and female Sprague-Dawley rats underwent spatial or cued-response Barnes maze training and, 45 min later, were sacrificed for ARC analysis in synaptoneurosomes from the DH and DLS. Initial experiments found that spatial training alone increased ARC levels in the DH above those observed in control rats and rats that underwent a cued-response version of the task. Post-spatial training optogenetic stimulation of the BLA-mEC pathway altered the balance of ARC expression in the DH vs. DLS, specifically shifting the balance in favor of the DH-based spatial memory system, although the precise region of ARC changes differed by sex. These findings suggest that BLA-mEC pathway influences on ARC in downstream regions are a mechanism by which the BLA can favor one memory system over another.

Title: Homeostatic Synaptic Scaling Establishes the Specificity of Aversive Taste Memory

Authors: *C.-H. WU[1], R. A. RAMOS[1], D. B. KATZ[2], G. TURRIGIANO[1];
[1]Dept of Biol., [2]Dept of Psychol, Brandeis Univ., Waltham, MA

Abstract: Hebbian plasticity mechanisms such as long-term potentiation (LTP) are widely considered critical for learning and memory. Nonetheless, LTP can initiate a positive feedback process that, if left uncontrolled, will pervasively increase synaptic strengths, and result in a failure to achieve memory specificity. Synaptic scaling, a form of homeostatic plasticity, has been theorized to constrain this run-away LTP by globally adjusting post-synaptic strengths and thus ensure faithful encoding of memory. While compelling on theoretical grounds, it has not been tested whether synaptic scaling partners with LTP *in vivo* during memory formation. Furthermore, the impact of disrupted synaptic scaling on memory fidelity remains unknown. Here we directly examined how synaptic scaling shaped memory specificity in conditioned taste

aversion (CTA), a form of associative learning that relies on Hebbian plasticity within the gustatory cortex (GC). We hypothesize that perturbation of synaptic scaling in the GC, the brain region involved in both acquisition and maintenance of CTA, will degrade the stimulus-specificity of CTA. We first demonstrated that after CTA conditioning, young rats transitioned from a generalized to a taste-specific aversion over a timescale of ~24 hours. Furthermore, the duration of this transient general aversion correlates with the strength of conditioning. To elucidate whether synaptic scaling established the specificity of CTA, we perturbed homeostatic synaptic scaling *in vivo* using viral vectors to introduce either the C-terminus fragment of GluA2 or a mutant GluA2, both known to block synaptic scaling *in vitro*. Notably, we found that blocking synaptic scaling in the GC prolonged the phase of CTA-induced general aversion without impairing the acquisition of CTA. This result was further corroborated by a third viral manipulation known to specifically block synaptic downscaling. Next, we found that GC neuronal ensembles active during conditioning were robustly reactivated by the generalized tastant when animals manifested general aversion. Abolishing synaptic scaling in the GC conditioning-active ensembles led to a striking and persistent increase in postsynaptic strengths that correlated with the prolonged general aversion. Taken together, our work establishes that synaptic scaling is important for sculpting the transition from a generalized to a specific state of associative memory, and that homeostatic regulation of synaptic strengths contributes to precise and stable memory formation.

Title: Evidence that an HDAC2-targeted ASO persistently upregulates cortical acetylcholine and dopamine signaling via a CREB-Gs positive feedback loop

Authors: *T. H. SANDERS;
Molecular, Cellular, and Developmental Biol., Univ. of Colorado, Boulder, CO

Abstract: Previous studies have shown that modulation of chromatin accessibility through histone deacetylation can facilitate learning and memory. In this study, we examined the effects of a single injection of histone deacetylase 2 (HDAC2)-targeted anti-sense oligonucleotides (ASOs) on cognitive behavior and gene expression. HDAC2 ASO-injected rats displayed increased novelty preference, decreased cortical and hippocampal HDAC2 mRNA and protein, and upregulated gene expression that persisted 1-month post-injection. Cortical RNA-seq

analysis revealed strongly increased transcription of a subset of cyclic adenosine monophosphate (cAMP)-response element binding (CREB) genes known to influence synaptic plasticity, along with dopamine (DRD1, DRD2) and adenosine (ADORA2A) G-protein-coupled receptors (GPCRs). Our analysis identified evidence of a positive-feedback loop that amplified expression of CREB-regulated Gs GPCRs and genes in cAMP/Gs/Gi signaling pathways. Additionally, we found differential expression of enzymes that shift neurotransmitter biosynthesis away from norepinephrine and toward dopamine and acetylcholine (DBH, CHAT). We also observed increased expression of genes important for neurotransmitter packaging (SV2C, VMAT) and release (SYT9). The data indicate that persistent inhibition of HDAC2 expression enables long-lived enhancement of aspects of cognition through increased cortical transcription of a subset of CREB-regulated genes amplified by a positive-feedback mechanism that increases synaptic plasticity and shifts neurotransmitter balance toward increased dopaminergic and cholinergic signaling.

Title: Impact of type 1 diabetes on cerebral microcirculation and cognitive function

Authors: *S. SHARMA, C. E. BROWN;
Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction Recent work from our lab has shown that the brain capillaries routinely get "stuck," clogged by cells and debris even under healthy conditions. We reported that about one third of these clogged capillaries were eliminated from the blood vessel network and never get replaced. The present study was undertaken to determine how diabetes affect the capillary obstruction in the brain. **Methods** C57BL/6 male and female mice were injected with streptozotocin to induce type 1 diabetes. To assess rates of capillary stalling and the composition of plugged capillaries, mice were implanted with cranial windows and cortical volumes were repeatedly imaged *in vivo* from 4-8 weeks after induction of diabetes. Furthermore we intravenously injected 5μm diameter fluorescent microspheres in diabetic (treated with or without insulin) and control mice to assess group differences in susceptibility to capillary stalling. The density of microsphere obstructed capillaries was quantified across 15 different

brain regions at 30min and 3 days after injection. To determine the impact of diabetes on cognitive and sensorimotor activity, mice were subjected to a battery of behavioural tests. **Results** Longitudinal 2-photon imaging indicated that diabetic mice displayed higher rates of capillary stalling that became more pronounced with increased duration of diabetes. Diabetic mice also showed a trend towards more vessel pruning events over time. Preliminary imaging of Rhod6G labelled leukocytes and platelets suggests that the majority of stalled capillaries are plugged by leukocytes. Our fluorescent microsphere obstruction assay yielded similar results as both male and female diabetic mice showed significantly higher density of capillary obstructions at both 30 minutes and 3 day time intervals. These effects were most apparent in cortical (frontal, motor, somatosensory, retrosplenial, visual), hippocampal and white matter regions while no differences were detected in the amygdala, striatum and substantia nigra. Behaviourally, diabetic mice showed significantly higher mean escape latency than the control mice in the Morris water maze task. No significant effect of diabetes was observed for the other tests of sensorimotor activity, anxiety, vision or locomotion. **Conclusions** These pilot studies suggests that diabetes is associated with greater risk for capillary obstructions in the brain as well as spatial learning deficits. Our future aims will provide insight into the mechanistic understanding of how diabetes leads to increased capillary obstructions and the ways to clear these obstructions in both the healthy and diabetic brains.

Title: Visualizing and quantifying mitochondria in the hippocampus with protein-retention expansion microscopy

Authors: *K. E. PANNONI[1], L. CAMPBELL[1], N. SAVORY[2], S. FARRIS[1,2,3];
[1]FBRI, [2]Sch. of Neurosci., [3]Virginia-Maryland Col. of Vet. Med., Virginia Tech., Roanoke, VA

Abstract: In neurons, mitochondria are critical organelles that produce energy and buffer calcium to support synaptic transmission, maintenance and plasticity. There is increasing evidence of diversity in mitochondrial morphology and function across, and even within, cell types. Our lab found that the expression of mitochondrial genes differs regionally in the hippocampus. Specifically, genes encoding mitochondrial proteins that are involved in bioenergetics and calcium handling are selectively higher in area CA2 compared with neighboring areas CA1 and CA3. Because larger mitochondria tend to be more metabolically active, we looked at the number and size of mitochondria labeled with mitochondrial marker COX4 in the three hippocampal areas. We saw both regional and subcellular differences in

number and size of mitochondria, suggesting that mitochondria can be regulated differently based on their local environment. Unfortunately, subcellular organelles are hard to visualize within a single neuron in dense tissue. To overcome this, we used protein-retention expansion microscopy (Pro-ExM) in combination with immunolabeling of mitochondria in transgenic reporter mice to physically expand and optically clear tissue to better resolve mitochondrial morphology and number in the adult mouse hippocampus. A limitation of Pro-ExM is that florescent proteins and antibodies are digested and diluted during the process. To optimize the pro-ExM protocol for co-visualizing immunolabelled mitochondria and reporter proteins, we varied the length of digestion (2, 4, 8 hours or overnight) and compared reporter florescence retention and expansion factors from individual neurons across conditions. We also assessed the quality of labeling under different digestion conditions (Proteinase K or autoclave) and varied the order of immunostaining, either before or after Pro-ExM. We demonstrate that we can visualize and segment mitochondria best with IHC pre-ExM and digestion in Proteinase K for 8 hours. We quantified COX4-labeled mitochondria in two male genetic reporter mice, one which was expanded with the optimized Pro-ExM protocol and one which was similarly immunostained but left unexpanded. After correcting for expansion, expanded mitochondria were on average smaller, more numerous and less variable in size than unexpanded mitochondria. This suggests that mitochondria, which are too close to be resolved in unexpanded tissue, can be properly segmented in expanded tissue. Moving forward with this optimized Pro-ExM protocol, we can further probe how regional mitochondrial diversity impacts hippocampal neuron function.

Title: The relationship between microglia density and age-associated perineuronal net alterations in the retrosplenial cortex of rhesus macaques

Authors: *S. O. KHATTAB[1,2], D. T. GRAY[1,2], K. MCDERMOTT[1,2], I. SINAKEVITCH[1,2], R. SCHWYHART[1,2], A. C. SMITH[1], W. HÄRTIG[4], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Dept. of Psychology, [3]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ; [4]Univ. Leipzig, PFI, Leipzig, Germany

Abstract: Perineuronal nets (PNNs) are extracellular matrix (ECM) structures around certain neuron types and provide a support structure to maintain synapse function (Sorg et al., 2016). In early adulthood, the emergence of PNNs has been linked to reductions in neuroplasticity that define the closing of the critical period. The characteristics of PNNs later in life and their

potential roles in declining cognition are less clear. Microglia-derived proteases have also been shown to play a role in regulating synaptic plasticity by modifying ECM composition (Crapser et al., 2020). These cells are vulnerable to age-related changes and show increased activity with normative and pathological aging (Conde & Streit, 2006; Spittau, 2017). The present study sought to further understand 1) the possible contributions of PNN and microglia densities to age-associated cognitive decline, and 2) the role of microglia in regulating PNNs in older brains. To these ends, we used fluorescence labeling and unbiased quantification of the PNN marker *Wisteria floribunda agglutinin* (WFA) and the microglial marker IBA1 on the brains from a colony of 30 rhesus macaque monkeys ranging in age from 7 to 32 years (human equivalent ~21 – 96 years). All monkeys underwent tests of spatial short-term memory, object recognition memory, and object discrimination, which allowed relationships between PNN density and microglia expression and cognition to be investigated. Preliminary results indicate that aged animals had fewer PNNs in the retrosplenial cortex (RSC) compared to younger animals, and this decrease correlated with lower performance specifically on object recognition tasks. Microglia density was higher in the RSC of the aged monkeys compared to adults. Notably, this increase was also significantly associated with poorer performance on object recognition tasks. Importantly, a weak yet significant negative relationship emerged such that animals with greater microglia density had lower PNN densities. Together these results suggest that microglial networks may contribute to an age-associated degradation of the ECM that has circuit-specific impacts on cognition in older monkeys, likely through a destabilization in synapse function.

Title: Anodal and cathodal tDCS regulates synaptosomes in cerebral cortex in rats

Authors: *S. H. JUNG, R. MOORE, N. BECHMANN, A. V. QUALLEY, J. MARTIN, S. HARSHMAN, R. JANKORD, C. HATCHER-SOLIS;
Cognitive Neurosci., U.S. Air Force Res. Lab., Dayton, OH

Abstract: Transcranial direct stimulation (tDCS) in humans and animals has been shown to produce beneficial effects on cognition and memory. Previously, we reported how anodal tDCS at 250μA and 500μA modified transcriptomic levels in the cerebral cortex without cellular/tissue damage. However, it is still unclear how tDCS polarity and intensity affect protein expression in the cortex and to our knowledge no previous study has investigated the effects of a one-time

tDCS application on proteomic regulation in the cerebral cortex. In this study, we employed anodal and cathodal tDCS at the 250uA and 500uA current intensities to Sprague Dawley rats (male, 8-10 weeks old) for 30 min, immediately followed by collection of the cerebral cortex. Cortex synaptosomes were profiled. Normalized proteomic abundance datasets were analyzed by multiple bioinformatics methods and advanced statistical analysis. Total number of 2966 proteins were detected. Only 2763 proteins were analyzed because they were detected from more than 90% of samples. IPA comparison analysis between 2 current intensities of anode and cathode detected 2 (scores ≥ 20) and 3 (scores ≥ 17) networks, respectively. Further network analysis detected significant functions, including cell-to-cell signaling and interaction (anodal network-1: 11 nodes; p = 1.06E-3 – 2.01E-2), nervous system development and function (anodal network-2: 15 nodes; p = 7.86E-7 – 1.74E-3), RNA damage and repair (cathodal network-1: 29 nodes; p = 1. 27E-63 – 1.27E-63), memory (cathodal network-2: 6 nodes; p = 0.0106), and post-translational modification (cathodal network-3: 6 nodes, p = 1.79E-4 – 4.75E-3). Comparison analysis across all groups detected only 3 intersection proteins: ActL7A, Gpt & Nubp1. Protein-protein interaction (PPI) network for 3 proteins (confidence cutoff = 0.4; max. additional interactors = 10; species = Rattus norvegicus) was constructed and analyzed (PPI enrichments p = 1.0E-16; enrichments clustering coefficient = 0.555; enrichments average degree = 4.31). PPI network analysis resulted in significant associations with metabolism (rno00250, FDR q = 3.88E-10; RNO-1430728, FDR q = 0.00045; rno01100, FDR 1 = 0.00097). In conclusion, we provided evidence for the safety use of both anodal and cathodal tDCS with the max current intensity of 500uA and beneficial effects of tDCS based on our synaptosomes proteomics data. However, a further study is needed to investigate whether these beneficial modifications in the synaptosomes are associated with positive changes in behaviors, especially cognitive performance.

Abstract: Ca^{2+}/calmodulin dependent protein kinase II (CaMKII) plays important roles in processes crucial to learning and long-term memory formation. Each subunit of CaMKII is comprised of a kinase domain, hub domain, variable linker region and regulatory segment. A fully assembled CaMKII complex is comprised of an oligomer of 12-14 subunits. CaMKII in humans is expressed from 4 genes (α,β,δ,γ) and each of these are alternatively spliced. All of these variants are highly conserved in all domains except for the variable linker region. From 3 human hippocampal samples, we sequenced over 70 different CaMKII variants. We are trying to understand why all these variants are necessary for function. Previously, it has been shown that there is a relationship between the variable linker length and kinase activity. We measured the activity of a wide range of CaMKII variants expressed in the human hippocampus to better understand the role of these variants in memory. We measured the activity of human CaMKII (expressed recombinantly) using a coupled-kinase assay. The three variants of alpha tested show that linker-containing variants are much more easily activated compared to the zero-linker variant. When β variants were tested, surprisingly the length/composition of the variable linker did not make a difference in Ca^{2+}/CaM sensitivity, with a similar EC_{50} value in variants that ranged from 0 to 217 residues in linker length. Further study revealed an activity regulation role for the hub domain; this has not been previously characterized before. This opens up the possibility as a potential drug target for this protein in human neurological diseases where mutations in CaMKII cause disruptions in functionality.

Title: Exercise opens a 'molecular memory window' to facilitate memory and synaptic plasticity

Authors: A. A. KEISER[1,1], T. DONG[1], E. KRAMÁR[1], C. BUTLER[2], D. MATHEOS[1], N. BERCHTOLD[2], S. CHEN[3], M. SAMAD[3], C. MAGNAN[3], S. SHANUR[1], P. BALDI[3], C. COTMAN[2], M. WOOD[1];
[1]Neurobio. & Behavior, [2]Neurol., [3]Inst. for Genomics and Bioinformatics, Univ. of California, Irvine, Irvine, CA

Abstract: Our labs have previously demonstrated that in males, exercise enables hippocampal-dependent learning in conditions that are normally subthreshold for encoding and memory formation and depends on hippocampal induction of brain-derived neurotrophic factor (BDNF) as a key mechanism. In male mice with prior exercise experience, only a brief exercise period is required to reactivate the increase of BDNF in the hippocampus, suggesting that there exists a 'molecular memory' for the prior exercise experience that facilitates subsequent learning. However, the underlying mechanisms that mediate the 'molecular memory' are currently unknown. We hypothesize that an epigenetic molecular memory of exercise as a previous experience primes specific genes for subsequent activation upon new learning, resulting in facilitated memory formation. In this study, we used RNA-sequencing to begin to define the molecular and epigenetic signature underlying exercise-enhanced learning in the hippocampus. Adult male mice underwent different periods of initial exercise (0-3 weeks), a sedentary delay period (0-2 weeks), and a brief 2-day period of reactivating exercise, followed by 3 min subthreshold training in an object location memory task. This allowed us to identify exercise parameters that enable the formation of robust long-term memory for object location in conditions that are normally subthreshold for encoding. Those parameters were then used to examine hippocampal long-term potentiation (LTP). Our results indicate that 2 weeks of initial exercise is sufficient to engage robust memory and enhance LTP compared to sedentary controls. Additionally, we found that a brief 2-day period of reactivating exercise was sufficient to re-gain elevated levels of LTP after they had returned to baseline following a 2-week sedentary delay. Using the same parameters, we also examined gene expression using RNA sequencing during the memory consolidation period, one hour after training. We found that different exercise parameters led to distinct transcriptional profiles in dorsal hippocampus. Of particular interest, was a gene coding for a novel plasticity protein, ACVR1C, which was found to be up-regulated only in mice that underwent exercise parameters that were capable of facilitating LTM formation. Sequencing data has also suggests a link between exercise and cellular metabolism. Together, these data provide a number of interesting target genes and mechanisms to explore that may be key contributors in the maintenance of the 'molecular memory window' for exercise and suggests that changes in the transcriptional profile of the hippocampus contribute to exercise-enhanced learning.

Abstract: Our labs have demonstrated that exercise engages epigenetic mechanisms that prime brain-derived neurotrophic factor (BDNF) induction in the hippocampus to allow for stable changes in neuronal plasticity to improve learning. Particularly, our studies have demonstrated that in male mice, exercise enables hippocampal-dependent learning in conditions that are normally subthreshold for long-term memory (LTM) in sedentary animals. A previous study by the Cotman lab demonstrates that following a break from exercise (during which elevated BDNF levels in the hippocampus decline to baseline), only a brief exercise period can reactivate the increase in BDNF, suggesting a 'molecular memory' of the initial exercise experience that enables the subsequent brief exercise to facilitate learning. We have recently identified specific exercise parameters that establish and maintain this 'molecular memory' of exercise to facilitate synaptic plasticity and LTM formation. Here, we investigate the molecular and epigenetic mechanisms underlying this 'molecular memory'. We hypothesize that the previous exercise experience establishes an epigenetic molecular memory of exercise that primes specific genes for subsequent activation upon new learning to facilitate LTM formation. To understand the extent of this 'molecular memory', RNA-sequencing was used to examine the gene expression profiles in the hippocampus within the memory consolidation window, 1h following a 3-minute subthreshold object location memory acquisition session in mice that underwent initial exercise (2 weeks), a sedentary break (1-2 weeks) followed by brief reactivating exercise (2 days). We found exercise parameters that facilitated learning, engaged distinct transcriptional profiles compared to those that did not. A particular gene target, *ACVR1C*, was one of the two genes found to be upregulated only in conditions in which exercise facilitated learning. We chose to further investigate this target as a previous study has shown *ACVR1C* to be necessary for LTP

maintenance and synaptic tagging. This upregulation of *ACVR1C* was confirmed via RT-qPCR. In addition, we found a number of genes associated with cellular metabolism to be upregulated in conditions where exercise facilitated learning. Together, these data suggest that *ACVR1C* and metabolic processes might contribute to the maintenance of the "molecular memory window" associated with exercise. Currently, we are investigating the causal role for identified targets such as the novel plasticity protein, ACVR1C, and metabolic mechanisms in the maintenance of a 'molecular memory' for exercise and how this may be different in females and aging mice.

Title: Arhgef4 (Rho guanine nucleotide exchange factor 4) deficiency enhances long-term memory

Authors: K.-S. YOO[1], K. LEE[1], *H. KIM[2];
[1]Chungbuk Natl. Univ., Cheongju, Korea, Republic of; [2]Chungbuk Natl. Univ., Chongju, Korea, Republic of

Abstract: Guanine nucleotide exchange factors (GEFs) play multiple functional roles in neurons. In our previous study, *Arhgef4* (Rho guanine nucleotide exchange factor 4, also known Asef1) functioned as a negative regulator of the excitatory synaptic function by sequestering postsynaptic density protein 95 (PSD-95). However, much of *Arhgef4* role in behavioral level has not been examined. Thus we performed comprehensive behavioral tests in knockout (KO) mice to investigate of the effects of *Arhgef4* deficiency. In consistent with our previous *in vitro* findings, the size of PSD-95 particle was significantly increased in hippocampal neuronal cultures from *Arhgef4* KO mice. *Arhgef4* KO mice exhibited general motor activity and anxiety-like behavior comparable to those of the wild type littermates. However, spatial memory and object recognition memory were significantly enhanced in the *Arhgef4* KO mice, whereas depression-like behavior was decreased. Taken together, these data confirm the role of *Arhgef4* as a negative synaptic regulator at the behavioral level.

Abstract: Cornichon homolog-3 (CNIH3) is an AMPA receptor (AMPAR) auxiliary protein highly expressed in the dorsal hippocampus (dHPC), a region where AMPARs are critical for spatial memory and synaptic plasticity. However, the role of CNIH3 on synaptic plasticity and behavior is currently unknown. In this study, *Cnih3*$^{-/-}$ female C57BL/6 adult mice displayed significantly attenuated short-term memory in a Barnes maze spatial memory task compared to *Cnih3*$^{+/+}$ females, reduced synaptic density in the dHPC, altered levels of post-synaptic proteins in the dHPC, and attenuated synaptic plasticity compared to controls, whereas *Cnih3*$^{-/-}$ males were unaffected. Further study revealed that impairments in spatial memory were most pronounced during the metestrus phase of the estrous cycle only in *Cnih3*$^{-/-}$ female mice. In addition, viral overexpression of *Cnih3* in the dHPC was sufficient to improve short-term spatial memory in females compared to females injected with a control virus, but viral overexpression of *Cnih3* had no effect in males. To ensure scientific rigor, multiple cohorts of samples and animals were tested in each experiment to confirm reproducibility of the results, sample sizes were consistent with prior literature for each experiment, and experimenters were blinded to sample group when analyzing estrous cycle data and in synaptic density experiments. This study identifies a previously unknown role for CNIH3, as manipulation of this gene unmasks sexually dimorphic and estrous-specific effects in spatial memory and hippocampal plasticity.

Title: Genetic variants in TP53BP1 are associated with superior memory in human SuperAgers

Authors: *I. S. PIRAS[1], A. SINIARD[2], A. BONFITTO[1], M. DE BOTH[1], R. RICHHOLT[1], C. BALAK[1], J. POUYA[3], E. BIGIO[3], S. WEINTRAUB[3], B. MAKOSKI-WOIDAN[3], M. HUENTELMAN[1], M. MESULAM[3], C. GEULA[3], E. ROGALSKI[3];

Abstract: SuperAgers (SA) are adults aged 80 or older with episodic memory performance that is at least as good as that of cognitively average individuals in their 50's and 60's. In this study, we performed whole-exome sequencing (WES) to identify genetic variants that are associated with the SA phenotype. WES was conducted on 72 SA, and as a control group, we used genotypes from 22 cognitively-average controls (CTLs) from the Alzheimer's Disease Neuroimaging Initiative (ADNI). DNA was extracted from whole blood, and libraries were sequenced on the HiSeq 2500 System (Illumina) using 150 basepair paired-end read chemistry. Preprocessing was conducted using BWA and GATK, and association analysis was conducted using the multi-marker SKAT test accounting for both common and rare variants.The final dataset included 45,275 single nucleotide variants (SNVs). Total genotyping rate across these SNVs was 98.7%. SKAT analysis identified a significant signal in *TP53BP1* (adj p = 2.2E-04), including three common (rs2230451-T, rs689647-T, rs560191-C) and one rare SNV (rs201906661-A). The frequency of the three common variants was higher in the SAs, whereas the frequency of the rare variant was higher in the CTLs. Allele frequencies in CTLs were in the same range of those reported in the *gnomAD v2.1.1* database (non-Finnish European cohort) for rs560191-T and rs201906661, but not for rs2230451 and rs689647-T (higher and lower in *gnomAD*, respectively). rs689647-T and rs560191-C are missense variants, with CADD scores 17 and 15, respectively.We found new common and rare genetic associations with the SA phenotype in the coding sequence of the *TP53BP1* (Tumor Protein P53 Binding Protein 1) gene. The protein encoded by this gene is involved in the DNA double-strand break repair pathway. A polymorphism in *TP53*, a binding partner of TP53BP1, was previously associated with human longevity, and TP53BP1 itself was linked to healthy aging through increased response against stress-induced DNA damage. These findings suggest that genetic variation in DNA repair may be linked to cognitive resilience during aging and not simply human longevity. Validation of these findings is needed in additional SAs.

Title: Investigating the underlying mechanisms by which vortioxetine reverses cognitive impairment mediated by the medial prefrontal cortex and hippocampus after androgen deprivation therapy for prostate cancer treatment

Authors: ***A. VAIANA**[1,2,3], A. DORNBUSCH[1,2], R. FERNANDEZ[4], J. GELFOND[4], T. JOHNSON-PAIS[3,5], R. LEACH[3,6], C. RAMAMURTHY[3,7], I. THOMPSON[5,8], D. A. MORILAK[1,2,3,9];

Abstract: Androgen deprivation therapy (ADT) is a mainstay treatment for prostate cancer but is accompanied by profound cognitive impairment in areas of executive function, visuospatial learning, memory, and attention. Imaging studies of prostate cancer patients given ADT have found reduced functional connectivity within the medial prefrontal cortex (mPFC). Further, decline on cognitive tasks mediated by the hippocampus (Hipp) are reported across multiple studies. Vortioxetine (VTX) is a novel multimodal antidepressant that has been shown to improve cognition in depressed patients, and we hypothesized that VTX may be efficacious in improving cognition after ADT. In a rodent model of ADT, rats display cognitive impairments mediated by the mPFC and the Hipp. Chronic treatment with VTX (28 mg/kg/day) administered through the diet reversed these deficits. VTX also reversed the attenuated response of the mPFC to input from the Hipp after ADT. The androgen receptor is a transcription factor, so ADT-induced impairment is likely to be related to changes in gene expression. VTX has been reported to induce changes in gene expression related to neuroplasticity in healthy rats. Therefore, we further hypothesized that VTX may overcome changes in plasticity-related gene expression induced in mPFC and Hipp by ADT. To test this, gene expression was analyzed in tissue collected from the mPFC, and the dorsal and ventral Hipp using a whole genome microarray

(Agilent Technologies, Inc.). Castration significantly altered over 1,000 genes in each of the three brain regions (adjusted p value<0.05). VTX on its own, and within castrated animals, had no significant effects on gene expression, but pathway analysis revealed significant changes in processes involved in synaptic plasticity, such as synapse formation, axonogenesis, and the MAPK signaling cascade. As castration was found to affect gene expression, we investigated genes that were similarly affected in all three brain regions to serve as candidate genes for further exploration. There were 145 genes that overlapped between all three regions and included a number of factors involved in the MAPK and mTOR/PI3K pathways, such as Akt, ERK, and eIF4B, as well as a number of glutamate receptors, ATM, Rac, RhoB, and CREB. Analysis is still underway to determine the full effects of VTX to compensate for or reverse changes in mechanisms disrupted by ADT, including alterations in gene expression which were implicated in plasticity-related processes. In conclusion, VTX may be a potential therapeutic option for patients that experience cognitive changes with ADT, as it is already FDA-approved for depression and is relatively well-tolerated.

Title: Changes in levels of NMDA receptor subunits in perirhinal cortex relate to their dynamic roles in object memory destabilization and reconsolidation.

Authors: *C. WIDEMAN, J. NGUYEN, S. JEFFRIES, B. D. WINTERS;
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: The storage of long-term memory is dynamic. This is reflected by the fact that the presentation of reminder cues can destabilize consolidated memories, rendering them modifiable before they return to a stable state through the protein-synthesis dependent process of reconsolidation. However, not all memories destabilize following reactivation. Older and stronger memories resist this process and require the presentation of reminders along with salient novel information in order to destabilize. We have previously demonstrated in rats that novelty-induced object memory destabilization requires acetylcholine (ACh) activity at the M_1 receptor. Other research predominantly focuses on glutamate, which modulates both fear memory destabilization and reconsolidation, through GluN2B- and GluN2A-containing NMDARs, respectively. In the current study, we demonstrate the same dissociable role of GluN2B/N2A-containing NMDARs in perirhinal cortex (PRh) for object memory destabilization and

reconsolidation when boundary conditions are absent. However, neither GluN2 receptor subunit was required for novelty-induced destabilization of remote, resistant object memories. Furthermore, GluN2B and GluN2A subunits were upregulated in PRh 24h following learning, but returned to baseline by 48h, suggesting that NMDARs, unlike muscarinic receptors, have only a temporary role in object memory destabilization. Indeed, activation of M_1-receptors in PRh at the time of reactivation effectively destabilized remote memories despite inhibition of GluN2B-containing NMDARs. These findings suggest that cholinergic activity at M_1 receptors can overcome boundary conditions to destabilize resistant memories when other established mechanisms are insufficient.

Title: Reactivation-based object memory updating in rodents is reliant on M1 muscarinic acetylcholine receptor signaling in perirhinal cortex

Authors: *K. JARDINE, C. WIDEMAN, C. SGARBOSSA, C. MACGREGOR, S. MCGRAW, D. ORR, K. MITCHNICK, B. D. WINTERS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Previously consolidated memory traces can be reactivated with reminder cues, and this reactivation (RA) can destabilize memories for modification. Reactivated memory traces can be “erased” or strengthened, but little is known about mechanisms facilitating constructive memory changes. Our recent work has implicated an M1 muscarinic ACh receptor (mAChR) cascade in object memory destabilization; here, we assessed whether this cascade similarly gates RA-based object memory updating. To test this, we developed the post-RA object memory modification (PROMM) task for rodents. In this task, animals study two identical copies of an object, then 24h later receive a brief re-exposure to the same objects. Immediately post-RA, the rodent is placed into a separate empty context to explore for 5min. In the test phase, another 24h later, the rodent explores the objects in either the same alternate context that was seen post-RA, or a different alternate context. We found that male rats and mice tend to explore the objects less in the ‘same alternate context’ condition compared to the ‘different alternate context’ condition. This suggests that the object-context combination in the ‘same alternate context’ condition seems more familiar, despite the fact that the objects have never been directly explored in that context before the test phase. Thus, context information introduced post-RA appears to incorporate into the original object memory. Subsequently, we found that pre-RA blockade of M1 mAChRs, their downstream signaling molecules, or proteasome functioning within perirhinal cortex prevented

this behavioural effect in male rats, supporting our hypothesis that M1 mAChR functioning is critical for RA-induced object memory updating. Furthermore, young male mice displayed the object memory updating effect, but aged male mice were impaired. Age-related deficits in the PROMM task are consistent with the notion that M1 mAChR functioning is critical for object memory updating because cholinergic dysfunction and cognitive inflexibility are characteristic of the aging brain. This research therefore has implications for understanding and treating disorders characterized by extreme cognitive inflexibility, such as PTSD, phobias, and dementia.

Title: Unlocking persistent memories: Hippocampal M1 muscarinic cholinergic receptor activation drives destabilization of strongly encoded object location memories

Authors: *A. E. HUFF[1], S. D. MCGRAW[1], W. S. MESSER, Jr.[2], B. D. WINTERS[1]; [1]Univ. of Guelph, Guelph, ON, Canada; [2]Pharmacol. and Exptl. Therapeut., Univ. of Toledo, Toledo, OH

Abstract: Following exposure to cues associated with the original learning experience, previously consolidated memories can become destabilized, rendering them vulnerable to disruption, strengthening or other modifications. This necessitates a protein-synthesis dependent process of reconsolidation in order to re-stabilize the memory trace to ensure its survival within long-term memory. Stronger or older memories are destabilization-resistant, but destabilization can be promoted by exposure to contextual novelty during memory reactivation. Our recent work has demonstrated that acetylcholine acting at muscarinic cholinergic receptors (mAChRs) within perirhinal cortex, a brain region important for object memory storage, is critical for both the destabilization of weaker object memories, as well as novelty-induced destabilization of strongly encoded object memories. We hypothesized that this mechanism is not specific to perirhinal cortex and would generalize to the dorsal hippocampus (dHPC), a brain region that is important for the storage of spatial memories. Using the object location (OL) task, which is dHPC dependent, we conducted six within-subject experiments in male Long-Evans rats showing that 1) protein synthesis is required within the dHPC for reactivation-dependent reconsolidation of OL memories; 2) strongly encoded OL memories require exposure to novelty during memory reactivation to promote destabilization; 3) dHPC mAChR activation is required for standard and

novelty-induced OL memory destabilization; and 4) activation of M1 mAChRs within the dHPC promotes destabilization of strongly encoded OL memories, even without the presence of explicit contextual novelty during memory reactivation. These findings suggest that this mAChR-dependent process could be a general neurobiological mechanism for memory destabilization, and suggests implications for the understanding and treatment of disorders characterized by maladaptive strongly encoded memories such as those that drive post-traumatic stress disorder and phobias. This also suggests implications for the understanding of memory flexibility deficits in populations with cholinergic deficiencies, such as the aging population and those with Alzheimer's Disease. Title: Muscarinic cholinergic receptor antagonism blocks reconsolidation-based object memory updating in mice

Authors: *S. D. MCGRAW, K. H. JARDINE, B. D. WINTERS;
Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: For behavior to remain adaptive in changing environments, memories require updating to incorporate new relevant information. The inability to update memories likely underlies an array of psychiatric disorders and the cognitive impairments seen in aging and Alzheimer's Disease (AD). Memory updating occurs during a labile window after a consolidated memory trace has been reactivated and destabilized by presentation of a reminder. Novel information presented during the labile period can be integrated with the existing memory, which is then reconsolidated into long term memory. While much work has focused on memory weakening or strengthening during the reconsolidation process, the mechanisms driving destabilization preceding integrative memory updating remain unclear. We hypothesize that memory destabilization is mediated by muscarinic acetylcholine receptor (mAChR) activity. To test this hypothesis, we developed a novel object memory updating task for rodents. The post-reactivation object memory modification (PROMM) task exposes mice to novel contextual information immediately after a previously consolidated object memory is reactivated. Total object exploration is measured on test day in the same or different alternate context seen post-reactivation. Consistent with our previous findings with rats, young adult male mice tested in the same alternate context displayed decreased object exploration levels compared to those tested in

the different alternate context. Based on innate rodent preference for novelty, this decreased exploration suggests that the object-context configuration is familiar due to the integration of the contextual information presented during the labile period. Next, we antagonized mAChRs with systemic scopolamine (0.4mg/kg, ip) prior to reactivation to assess the role of mAChR activation on post-reactivation information integration. Scopolamine negated the difference between same and different alternate context exploration, suggesting that mAChR blockade prevented the memory destabilization required for updating. These results are consistent with our recent findings using the PROMM task in rats, further supporting a role for mAChRs in integrative memory updating, and could have implications for cognitive impairment in aging and AD, conditions characterized by compromised cholinergic system function.

Title: A straightforward and sensitive homecage-based novel object recognition task for rodents

Authors: *J. LEASURE[1], J. WOODEN[2], M. SPINETTA[3];
[1]Univ. of Houston, Houston, TX; [2]Univ. of Texas at Austin, Austin, TX; [3]Psychology, Seattle Univ., Seattle, WA

Abstract: The detection of novel objects is a common cognitive test for rodents, but current paradigms have shortcomings that limit their utility, such as low sensitivity, potential for odor confounds and increased stress due to being performed outside of the homecage. We have developed a paradigm that takes place in the homecage to reduce stress and utilizes 4 stimuli per trial, to increase sensitivity. Odor confounds are eliminated because stimuli consist of inexpensive, machined wooden beads purchased in bulk, so each experimental animal has its own set of beads. In Step 1, animals freely explore Familiar Objects (FO) overnight. Novel Objects (NO1 and NO2) are soiled with bedding from the homecage, to acquire odor cues identical to those of the FO. Steps 2 and 3 serve as tests of novelty preference (see graphical representation). Herein we report results of this paradigm from neurologically intact adult rats and mice of both sexes (results shown for rats). In this iteration of the paradigm, delay between steps was 24-hr. Identical procedures were used for both species, except that the stimuli used for the mice were smaller. As expected in Step 2, male and female rats and mice explored NO1 significantly more than FO. Interestingly, in Step 3, rats of both sexes demonstrated a preference for NO2, while this preference for NO2 was seen only in female mice. Male mice preferred both novel stimuli equally over FO. These results indicate robust novelty detection and preference

during Steps 2 and 3 in rats. In mice, this was reliably seen only in Step 2, suggesting that Step 3 is difficult for mice under the given parameters. Thus, it is important to adjust the length of the sampling phase, and the delay between test and sampling phases, to fit the model being tested. In sum, this paradigm is simple to perform, requires no expensive supplies or equipment, is conducted in the homecage (reducing stress), eliminates odor confounds, is sensitive to novelty preference, can be performed in both rats and mice, and is highly flexible, as the delay between steps can be adjusted to tailor task difficulty.

Title: Maintenance and consolidation of memory using repetitive transcranial magnetic stimulation

Authors: *A. M. HEATH[1], M. BREWER[2], J. YESAVAGE[1], M. MCNERNEY[3];
[1]Stanford Univ. Sch. of Med., Stanford, CA; [2]Stanford Univ., Stanford, CA; [3]Dept. of Veterans Affairs Palo Alto Hlth. Care Syst., Palo Alto, CA

Abstract: Brain stimulation is known to affect canonical pathways and proteins involved in memory. However, literature has shown conflicting results on the ability of brain stimulation to improve to memory due to variation in protocols. Time dependent protein synthesis is important for long term memory consolidation and periodic reactivation of consolidation pathways maintains hippocampus dependent memories. Research has shown the potential to promote increased activation of these pathways after the learning event to maintain consolidation. Therefore, we hypothesized that repetitive transcranial magnetic stimulation (rTMS) given following a learning task and within the time period before retrieval could help consolidate and maintain the memory. We first implanted male C57/Bl6J mice (n=32) with a cranial attachment to secure the rTMS coil so that the mice could be given consistent stimulation to the frontal area whilst freely moving. Mice then underwent object recognition test (ORT) familiarization for ten minutes and then given treatment +3, +24, +48 hours following the test. Treatment consisted of ten minutes 10Hz rTMS stimulation (TMS, n=10) or sham treatment (SHAM, n=11). At +72 hours mice were tested for their exploration of the novel vs familiar object. Only TMS mice distinguished between the two objects, indicated by their greater exploration of the novel object than the SHAM mice. We also included a group of naïve mice which did not do the ORT or receive treatment (NAIVE, n=11). Following the behavior test, the phosphorylation of specific proteins was analyzed through Western Blot. In the hippocampus, TMS mice had significantly greater ERK phosphorylation than NAIVE and TMS also increased from SHAM but statistically significant. Whereas in the frontal cortex there was an overall increase in GLUR1 phosphorylation at S831 with TMS, but contrarily a decrease in synaptic GLUR1 S845 phosphorylation. Using immunohistochemistry, we showed region specific changes to co-localized PSD95 and SV2A staining, indicating active synaptic connections. Overall, in the frontal cortex and entorhinal cortex we saw an increase in synaptic connections in both TMS and SHAM mice compared to NAIVE. Whereas, in the perirhinal cortex and CA1 only the mice which had TMS had increased synaptic connections. We have shown rTMS can promote the consolidation and maintenance of a specific memory if given within the time between encoding and retrieval. This effect was supported by changes to synaptic connections in the perirhinal

cortex and CA1, elevated activation of immediate response proteins and a dynamic shift in activation of receptors relating to synaptic plasticity.
