Abstract: Cervical Dystonia (CD) is a common form of focal dystonia characterized by abnormal head posture and head tremor (HT). Many patients with CD develop a sensory trick, which is a maneuver used to control or diminish CD motor symptoms including HT. A variety of tricks (alleviating maneuvers) with common characteristics have been described, however, tactile stimulation is not necessarily a defining feature. The standard CD neurologic exam includes a task in which patients are instructed to raise their arms into a horizontal position in pronation, supination, and the winged posture, normally used to examine for upper limb tremor. The objective of this study was to determine how raising the arms, a postural maneuver with no tactile input, affects HT severity. We analyzed data collected from 206 patients with isolated CD recruited through the Dystonia Coalition. Video-recordings of standard patient examination protocol were reviewed by a movement disorders neurologist (CC) who assessed HT presence and severity during periods of rest and arms up on a 0-10 global scale. Changes in HT severity were assessed between the rest period and arms up period and scored as decreased, unchanged, or increased by arms up activation. Of the 206 patients, 84 were excluded due to the lack of HT in either condition, and two were excluded because they were not prompted to do the arms up maneuver. We found that patients were more likely to exhibit no change in HT severity (N = 72) than change (N = 48) during the arms up period (χ^2 (1, N = 120) = 4.8, p = 0.03). Of those who exhibited change in HT severity with arm activation, decrease in HT severity (N = 35 patients) was more common than HT increase (N = 13, χ^2 (1, N = 48) = 10.1, p = 0.002). Demographic factors (age at onset, disease duration, gender, and the interaction term between age at onset and disease duration) were not found to be significant predictors of whether there would be change or no change in HT severity (χ^2 (4, N = 120) = 0.978, p = 0.913) and an increase or decrease in HT severity (χ^2 (4, N = 48) = 2.51, p = 0.643). This study highlights the effectiveness of proprioceptive modulation or postural change (raising arms) in reducing HT severity in some patients with CD. Further exploration into the effects of the arms up maneuver on other CD motor symptoms as well as physiological investigations are needed to better understand the effectiveness of this maneuver to alleviate HT severity and other CD motor symptoms.

Title: Modulating Sirtuin 3 to abrogate toxicity within in vitro and in vivo models of spinal and bulbar muscular atrophy

Authors: D. GARCIA-CASTRO[1], J. MAZUK[1], D. SIMPSON[1], E. HEINE[1], D. MATHIS[1], P. MORRIN[1], T. FARMER[1], Q. TONG[2], *H. MONTIE[1];

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an adult-onset, X-linked neuromuscular disease estimated to affect about 1 in 40,000 men. SBMA is caused by an expansion of a CAG repeat (n > 39) within the androgen receptor (AR) gene, which encodes a glutamine tract in the AR protein. The polyglutamine-expanded AR causes proximal and lower distal limb weakness due to toxicity in both motor neurons and skeletal muscle. To date, there is no cure or therapy. Like other neurodegenerative diseases, there is mitochondria dysfunction in SBMA, which leads to reduced ATP, increased oxidative stress, and diminished mitochondrial biogenesis. Sirtuin 3 (SIRT3) is the main mitochondrial NAD-dependent deacetylase, functioning to regulate mitochondrial homeostasis, biogenesis, and anti-oxidative defense mechanisms. Using PC12 and C2C12 cell models of SBMA, we found that pharmacologic activation of SIRT3 and stable SIRT3 overexpression of the protein abrogated polyQ-expanded AR cytotoxicity and decreased reactive oxygen species. We next tested the effect of SIRT3 overexpression in a transgenic mouse model of SBMA (males only), but failed to identify any significant improvement in motor function. However, there was a trend of increased time on both an accelerating rotarod and a treadmill for the SIRT3-overexpressing SBMA mice compared to control SBMA mice. These data lead us to postulate that the diminished NAD^+ levels in SBMA, as previously reported in another mouse model, may impede effective activity of SIRT3 *in vivo*. We have validated this decrease in NAD^+ in the mouse model utilized in these studies. We are now investigating whether restoring cellular NAD^+ can allow for SIRT3 activation and protection against polyglutamine-expanded AR *in vivo*.

Title: Role of neurofilament subunit dysregulation in motor neuron degeneration in SBMA

Authors: *E. MOLOTSKY[1], C. GRUNSEICH[3], K. H. FISCHBECK[3], D. E. MERRY[2]; [2]Dept Biochem & Molec Biol, [1]Thomas Jefferson Univ., Philadelphia, PA; [3]NINDS, NIH, Bethesda, MD

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an X-linked, slowly progressing neuromuscular neurodegenerative disease that affects 1 in 40,000 men and for which there is no cure. SBMA is caused by polyglutamine repeat expansion in the androgen receptor (AR), and disease progression is dependent on binding of the AR to its ligand hormone testosterone or dihydrotestosterone (DHT). Symptoms such as fasciculations, dysarthria, and dysphagia are caused by pathological motor neuron degeneration in the brainstem and spinal cord. Previous work by Chevalier-Larsen et al (2004) showed that, in a transgenic mouse model of SBMA, spinal cord motor neurons exhibit decreased levels of unphosphorylated neurofilament heavy chain (NFH) compared to non-transgenic controls. NFH is one of four proteins that make up the neuronal structural protein neurofilament, which is critical in maintaining axonal structural integrity and determining axon diameter in peripheral neurons (the other three proteins being neurofilament medium chain, NFM; neurofilament light chain, NFL; and peripherin). However, the role of neurofilament subunit dysregulation in pathological motor neuron degeneration in SBMA has yet to be fully explored. Moreover, SBMA patients show skeletal muscle fiber type grouping and atrophy of fast twitch muscle fibers, indicative of enhanced vulnerability of fast twitch motor units. We hypothesize that neurofilament subunit expression is altered in SBMA, contributing to differential motor unit vulnerability. Our data reveal substantial deficits in phosphorylated NFH staining intensity at the NMJ of motor neurons innervating fast twitch gastrocnemius muscle of 6-month-old transgenic mice, without a significant difference in endplate fragmentation or pre- and post-synaptic colocalization (slow-twitch experiments ongoing). However, preliminary data show that endplate fragmentation in the gastrocnemius is evident in 9-month-old mice. These data provide evidence for neurofilament subunit dysregulation prior to denervation in a mouse model of SBMA. In addition, we found a considerable deficit in NFL and phosphorylated NFH in DHT-treated SBMA patient iPSC-derived motor neurons compared to control iPSC-derived motor neurons. Notably, we did not see a difference in levels of phosphorylated NFM. These studies show a DHT-dependent alteration in neurofilament subunit levels in SBMA patient derived motor neurons. Together, these findings reveal neurofilament subunit dysregulation in SBMA models, *in vitro* and *in vivo,* and provide further context for the potential role of neurofilaments in differential vulnerability of fast twitch motor units in SBMA.

Title: Force dependent recruitment of intrinsic versus extrinsic hand muscles to assess upper motor neuron function

Authors: ***N. PINKES**[1], M. YAROSSI[2,3], O. SOTO[4], E. TUNIK[2];
[1]Dept. of Hlth. Sciences, Bouvé Col. of Hlth. Sci., [2]Dept. of Physical Therapy, Movement and Rehabil. Science, Bouvé Col. of Hlth. Sci., [3]SPIRAL Center, Dept. of Electrical and Computer Engin., Northeastern Univ., Boston, MA; [4]Neurol., Tufts Univ. Sch. Of Med., Boston, MA

Abstract: Techniques to effectively assess upper motor neuron (UMN) function and dysfunction are key to understanding motor neurophysiology in healthy individuals and creating biomarkers of pathology in diseases such as Amyotrophic lateral sclerosis (ALS). Transcranial magnetic stimulation (TMS) offers a unique opportunity to non-invasively inspect the function of UMNs, however novel experimental protocols are needed to dissociate UMN neurophysiology from the rest of the corticospinal pathway. In this study, known differences in the recruitment of the first dorsal interosseous muscle with increasing finger force were leveraged in an attempt to create a direct measure of UMN function. Five young healthy subjects participated in the study following institutionally approved informed consent. Four intrinsic and four extrinsic hand muscles were recorded with EMG during an index finger flexion force production task. TMS was triggered at 110% of the resting motor threshold when the subject produced a force that matched a visual target representing 5, 10, 25, or 50% of their maximal voluntary contraction (MVC). One-way ANOVAs were used to compare the activation ratios of each muscle tested to the FDI. Results indicated a limited contribution of extrinsic hand muscles to finger flexion force below 10% of MVC. The ratio of flexor digitorum superficialis (FDS), the primary extrinsic finger flexor, to FDI activation (FDS:FDI ratio) was found to be monotonically increasing with increased force. The difference between force levels for the FDS:FDI ratio was found to be significant ($F(3,15) = 6.86$, $p = .03$, Greenhouse-Geisser corrected). Given known differences in the UMN contribution to FDI and FDS activation this ratio could serve as a marker of UMN function. Further investigation will explore whether this ratio can be used as a sensitive marker of changes in UMN function with learning or disease.

Title: A novel in vitro modeling system for CLN3 Batten disease

Authors: *J. A. SIERRA DELGADO[1], C. N. DENNYS[1], S. SINHA RAY[2], R. RODRIGO[1], J. M. WEIMER[3], K. C. MEYER[4];
[1]Nationwide Childrens Hosp., Columbus, OH; [2]Res. Inst. At Nationwide Children's Hospit, Columbus, OH; [3]Children's Hlth. Res. Ctr., Sanford Res., Sioux Falls, SD; [4]Ctr. for Genetherapy, Res. Inst. Nationwide Childrens Hosp., Columbus, OH

Abstract: Batten Disease or Neuronal Ceroid Lipofuscinosis (CLN) encompasses fatal lysosomal storage disorders characterized by cognitive and motor deficits, vision impairments, and seizures. Juvenile Neuronal Ceroid Lipofuscinosis (JCLN), is an autosomal recessive subtype caused by loss of function (LOF) mutations in the CLN3 gene. However, the cellular mechanisms by which CLN3 mutations cause Batten disease are poorly understood. Moreover, most research focuses on the function and expression of CLN3 in neurons, with little known about the contributions of other cell types to disease mechanisms. To address this, we used a direct reprogramming method to generate Neural Progenitor Cells (iNPCs) from primary fibroblasts derived from CLN3 patients. We then differentiated the iNPCs into specific cell types of the nervous system to evaluate markers known to be affected by neurological disease. We found cell-type and patient specific alterations in mitochondrial morphology. Interestingly, mitochondrial activity of CLN3 cells did not differ from controls, suggesting that changes in mitochondrial networks did not impact mitochondrial energy production in our assays. Our results indicate that patient specific mutations may have a differential effect on the mitochondria. This suggests that current mouse models may be limited in their evaluation of potential therapeutic strategies. To combat this, we developed a co-culture system using healthy mouse GFP+ neurons and CLN3 patient derived cells. Using this system, we found that CLN3 patient derived cells induced a high degree of neuronal death, with some lines showing a more toxic phenotype than others. Combined, we have developed a patient specific human model of CLN3 Batten's disease that allows investigation of the impact of specific CLN3 mutations on cell mediated disease pathology. In addition, we have developed an assay conducive to drug

screening to evaluate potential therapeutic strategies for patients with diverse genetic backgrounds.

Title: How typical is healthy, adult, male ferret behavior?

Authors: ***A. A. OBASA**[1], S. C. SCHWERIN[1], T. HAIGHT[1], M. STRAYHORN[1], M. RAY[1], S. L. JULIANO[2];
[1]Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [2]USUHS, Bethesda, MD

Abstract: Gyrencephalic animals are becoming increasingly critical to study mechanisms of brain injuries and test therapies. The ferret is the smallest mammal with a gyrencephalic cerebral cortex and their small size enables group housing and imaging in preclinical MRIs, which is beneficial compared to larger gyrencephalic animals. However, the behavioral profile of normal, healthy ferrets is not well known. In this study, we compared the behavior of a number of normal, healthy, young-adult ferrets and report the variability of the results. We investigated motor, social, memory, sleep, and headache behavioral tests. In addition, we followed a small group of ferrets over time to determine the effects of repeated testing. We used 3 cohorts of young-adult male ferrets in 3 age groups (who were an average of 34, 50, or 81 weeks old at testing). We evaluated motor behaviors (open field, beam walk), sociability (socialization, eye contact), memory (novel object recognition), headache (grimace, light/dark box), and sleep (actigraphy). Some of these behaviors required pre-training. We followed a subset of ferrets over time with testing at 1 week and 4 weeks, and an additional group also at 4 months and 6 months. Several behavioral tests were only done at the final time-point. The youngest cohort (average 34 weeks old) had several behaviors that differed significantly from one or more of the other groups, suggesting that there is an age threshold for consistent results. Studies being planned should consider using ferrets of 50 weeks or older prior to injury. Some tests, like eye contact, showed a different amount of variability between cohorts. Eye contact expectedly increased with time and repeated testing, whereas open field test parameters decreased as animals habituated to the test, space and investigators. This investigation provides data assessing normal behavioral measures in healthy, young-adult, male ferrets using multiple behavioral tests. The results will be

helpful in planning future ferret experiments either in healthy ferrets or in studies using interventions.

Title: Circadian-clock gating of memory recall is disrupted in a mouse model of tauopathy

Authors: ***A. KALIDINDI**[1], H. YOON[1], A. JOSHI[1], K. R. HOYT[2], K. OBRIETAN[1]; [1]Neurosci., [2]Pharmacol., Ohio State Univ., Columbus, OH

Abstract: The aggregation of tau protein and the resulting formation of neurofibrillary tangles are thought to trigger a range of pathological processes which ultimately result in the profound cognitive deficits associated with tauopathies. Additionally, circadian-regulated physiological processes, including sleep, are disrupted in tauopathies, notably Alzheimer's disease and frontotemporal dementia. Given both cognition and circadian timing are disrupted in tauopathies, we sought to examine the relationship between tau aggregation and the dysregulation of the circadian timing system, and also to assess potential consequences on cognitive capacity. Here, we examined clock-gated cognition in the Tau P301S transgenic mouse model of human tauopathy. This transgenic mouse harbors the PS301S mutation in the human MAPT gene and develops filamentous tau lesions at 6 months of age, which is followed by marked synaptic loss, cognitive impairment, and neurodegeneration within cortico-limbic brain regions. We first tested the fidelity of the circadian timing system located within the suprachiasmatic nucleus (SCN), the locus of the master circadian clock. Using wheel running activity as a functional output of the SCN, we found no difference between P301S transgenic mice and WT littermates (7-8 months old) in clock phasing or periodicity. This indicates that key functional properties of the SCN clock are intact in the P301S mouse line. Next, we assessed whether circadian clock-gated cognition was altered in the P301S mice. To this end, mice were entrained to a standard light cycle, and then transferred to constant red-light illumination, which uncouples the circadian clock from the light/dark cycle. Mice were then assessed for (1) working memory (t-maze task), (2) intermediate term memory (novel object location test) and (3) long-term memory (contextual fear conditioning recall) during the circadian day and night. Overall, the performance of P301S

mice (8 months old) on these cognitive tests was inferior to WT mice. Interestingly, time-of-day profiling revealed that the relative efficacy of memory recall over the circadian cycle was diminished in P301S mice relative to WT mice; hence, the clock-gating of cognition appeared to be damped as a result of aberrant tau accumulation. Our results raise the prospect that the disruption of circadian time-keeping properties within cortico-limbic circuits that underlie learning and memory could contribute to the diminished/dysregulated cognitive capacity resulting from tauopathies. Studies are underway to identify the potential neuronal signaling pathways that could contribute to this clock-gated cognitive phenotype.

Title: The effects of chronic phasic and tonic locus coeruleus activation patterns on tau pathology and cognitive function in a pre-tangle tau rat model

Authors: ***T. OMOLUABI**[1], A. GHOSH[1], S. E. TORRAVILLE[1], K. D. POWER[1], C. REINHARDT[1], L. A. MACGOWAN[2], Q. YUAN[1];
[1]Biomed. Sciences, Fac. of Med., [2]Biomed. Sciences, Fac. of Medicine, Dept. of Psychology, Fac. of Sci., Mem. Univ., St. John's, NL, Canada

Abstract: Braak and colleagues have proposed that the appearance of soluble hyperphosphorylated, pre-tangle tau in the brainstem structure, locus coeruleus (LC), marks the beginning of the tau pathology that may eventually develop into Alzheimer's disease (AD). Although pre-tangle tau is prevalent in human brains around mid-age, the selective vulnerability of a sub-population of people developing AD is unknown. LC neurons exhibit both phasic and tonic firing modes, which differentially modulate behavior. We hypothesize that LC activity itself may influence tau pathology development. Here we study whether and how phasic and tonic LC activation by optogenetic stimulations alters cognitive function in an LC pre-tangle tau model. Viral vectors carrying a human pseudophosphorylated tau gene (AAV9-DIO-htauE14-EGFP) and an opsin channel (AAVdj-DIO-eChR2-mCherry) were infused bilaterally into the LC of 2-3-month-old TH-Cre rats, mimicking the onset of tauopathy in humans. Control rats were infused with htauE14 and reporter AAV without ChR2 channels. Six-seven months after viral infusion, rats underwent optical cannula implantation. They then received either a 10 Hz phasic (300 msec every 2 sec) or a 25 Hz tonic LC activation for 20-30 min daily for six weeks. Two months following LC light stimulation, rats underwent a battery of behavioral tests, followed by immunohistochemistry. Preliminary results showed that phasic LC activation improved spatial

and olfactory discrimination, paralleled by higher LC fiber densities in both the piriform cortex and dentate gyrus. These results show that phasic and tonic LC activation have distinct effects on cognitive functions in the pre-tangle tau model.

Title: Early physiological defects in motor neurons of Drosophila ALS-related SOD1 mutants

Authors: *T. C. D. G. O'HARROW, A. UEDA, X. XING, C.-F. WU;
Univ. of Iowa, Iowa City, IA

Abstract: Cu/Zn superoxide dismutase (SOD1) is a cytoplasmic antioxidant enzyme. In humans, mutations in the SOD1 gene are associated with familial cases of amyotrophic lateral sclerosis (ALS), a lethal degenerative disease in motor neurons. The *Drosophila* SOD1 gene (*Sod*) shares a highly conserved sequence with the human homolog, and we have shown that *Sod* mutant *Drosophila* display high mortality rates during larval and pupal development, decreased adult lifespan, and attenuated motor function. The *Drosophila* larval neuromuscular junction (NMJ) is well-adapted for the study of early physiological defects underlying later motor neuron degeneration, due to its accessibility for *in vivo* studies, and a long history of study of neuromuscular transmission-altering genetic mutations. This study includes examinations of the established hypomorphic *n108* allele (Sod^{n108}), alongside knock-in constructs of alleles found in human ALS patients: *G85R* and *H71Y* (Sod^{G85R} and Sod^{H71Y}). Immunohistostaining (anti-horseradish peroxidase, anti-HRP) of neuronal membrane at neuromuscular synapses in *Sod* mutant larvae revealed presynaptic terminals of abnormal, swollen morphology. In Sod^{G85R} larvae, *in vivo* mitochondrial staining (tetramethylrhodamine, TMRM) demonstrated the presence of aggregated mitochondria inside the swollen synaptic terminals. To overcome poor penetration of the larval motor axon bundle by TMRM, a genetically encoded GFP construct targeted to mitochondria was employed to reveal that aggregates of mitochondria also appear inside the axon bundles of Sod^{G85R} larvae. In whole-cell recordings of neuromuscular transmission, both Sod^{n108} and Sod^{G85R} exhibited lower muscle input resistance and smaller miniature excitatory junction potentials (mEJPs) compared to WT. However, evoked EJPs were similar to those of WT, indicating homeostatic adjustment of transmitter release. Focal electrophysiological recording showed that both Sod^{n108} and Sod^{G85R} NMJ terminals displayed slightly higher release probability than WT terminals. Treatment of Sod^{G85R} with the *Shaker*

channel (Kv1) blocker 4-aminopyridine (4-AP) and the broad-spectrum K^+ channel blocker tetraethylammonium (TEA) induced prolonged "plateau-like" potentials at the larval NMJ upon electrical stimulation. These potentials were accompanied by extended periods of presynaptic Ca^{2+} influx, made visible by a fluorescent Ca^{2+} reporter (GCaMP6f). Altogether, this study provides a snapshot of the alterations in mitochondrial distribution, synaptic morphology, and neurotransmission that characterize the motor neurons of *Sod* mutants prior to neurodegeneration and death of the organism.

Title: Examining Regeneration Capacity and Innervation of NMJs by iPSC-Derived Motor Neurons

Authors: *K. L. MARSHALL[1], M. E. JAMES[1], L. RAJBHANDARI[2], A. TAGA[2], A. VENKATESAN[2], N. J. MARAGAKIS[2], M. H. FARAH[2];

Abstract: Distal axon degeneration, dying-back, is a hallmark of motor neuron diseases, such as ALS, that precedes symptom onset and motor neuron death both in human patients and animal models. While motor neurons derived from human iPSCs (hMNs) hold promise for advancing ALS research, the length of axons, regenerative capacity, and mutant-specific innervation of neuromuscular junctions (NMJs) by these human neurons is not well-characterized. hMNs cluster into circular groups as they grow, and extend axons to other clusters, confounding quantification of axon outgrowth from individual hMNs. To address this, we have cultured hMNs from ALS patients and controls in custom microfluidic devices, and sequestered neuronal cell bodies in the main compartment that extended processes through microgrooves into two adjacent axonal compartments. We determined that devices with ample room in the axonal compartments are appropriate for examining axonal outgrowth, and allow for individual tracing of axons that are millimeters in length. We are able to sever axons at the entry point to the axonal compartments, and use time-lapse live imaging to quantify regeneration speed. We have performed axotomies and compared regeneration speed of hMNs harboring ALS-linked mutations, including hMNs with a $SOD1^{A4V}$ mutation to an isogenic corrected control. In co-cultures with primary human myoblast-derived myofibers, hMNs form NMJs. This system lays the groundwork for gathering electrophysiological data from myocytes innervated by hMNs in

the axonal compartment, and introducing relevant cell types. Systematic permutations of this microfluidic culture system have the potential to elucidate the ALS mutation-specific effects on axonal regeneration and structural and functional innervation of NMJs.

Title: Novel Methodology for Producing Postnatal Spinal Co-Cultures of Astrocytes and Neurons for Use in the Study of ALS

Authors: *S. BURLEY[1], C. BONTHRON[1], M. BROADHEAD[1], V. METODIEVA[1], S. GRANT[2], G. MILES[1];
[1]Univ. of St Andrews, St Andrews, United Kingdom; [2]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Spinal circuits support a wide range of functions necessary for survival and are composed of neurons, which are supported by glia. Neuro-glial interactions are critical for the healthy function of the nervous system and emerging evidence implicates roles in the pathogenesis of neurodegenerative diseases, including but not limited to Motor Neurone Disease. Currently there are limited tools available to interrogate neuro-glial interactions and respective contributions to function and disease. Here, we present an in vitro primary culture system for neurons and astrocytes derived from the lumbar region of spinal cords of postnatal mice up to 4 days old. This approach allows the generation of cultures obtained from spinal cords of verified, genetically modified mice, which is challenging using traditional approaches derived from embryonic tissue. Neurons and astrocytes can be isolated to produce 'pure' cultures and then be re-combined as mixed-genotype (wildtype and/or genetically modified) co-cultures at later time points to explore neuro-glial interactions. Electrophysiological analysis reveals that primary neuron cultures are functional; cells express sodium and potassium currents and can repetitively fire action potentials. Immunocytochemical analysis indicates neurons in co-culture with astrocytes express postsynaptic markers for glutamatergic (PSD95) and GABAergic (gephyrin) synapses. We also find a proportion of neurons express enriched **motor neuron** marker SMI-32. Glial primary cultures are composed of cells that express glial fibrillary acidic protein (GFAP; 82-96%) and glutamine synthetase (99%) indicating that these cultures are primarily composed of astrocytes. Importantly, GFAP and glutamine synthetase-expressing astrocytes are also colocalized with the excitatory amino acid transporter - 2 and connexin 43; markers of

functionally mature astrocytes, as early as 2 weeks-post plating. Furthermore, little change in marker expression is observed after 2 weeks, allowing co-culture neuron plating to be viable across a wide time-frame. These findings confirm that our protocol reliably produces neurons, astrocytes and co-cultures. Obtaining viable cultures of spinal neurons from postnatal mice has been a challenge in the past, making this approach of interest to the broader motor control and MND communities. We expect that this system, in combination with genetic models in mice, will serve as a valuable tool to study neuro-glial interactions in health and disease.

Title: The role of autophagy in ALS pathology in iPSC-derived motor and cortical neurons

Authors: *K. DORFMAN, C. MARQUES, A. HELD, J. SUNG, M. ADLER, B. J. WAINGER; Massachusetts Gen. Hosp., Boston, MA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a devastating and rapidly fatal disorder of motor neurons. 10% of cases have a familial history, with more than 40 individual genes implicated in a broad range of molecular functions, including protein homeostasis. Indeed, cytoplasmic protein aggregates, containing the autophagy protein p62 (SQSTM1/p62) in more than 98% of ALS cases, represent a key pathological hallmark of ALS. This points to autophagy as a conserved disrupted pathway across a broad range of ALS cases. However, the precise role and timing of autophagy disruption in ALS pathology is still controversial. This study aims to characterize the time-dependent function of autophagy in ALS and decipher key molecular mechanisms upstream and downstream of autophagy disruption. We hypothesize that autophagy dysregulation is an early event that centrally contributes to ALS onset and progression. We use three isogenic pairs of iPSC-derived spinal and cortical neurons, each iPSC pair harboring one of three ALS mutations (TDP-43^{G298S}, PFN1^{G118V}, and SOD1^{G85R}) within a single genetic background, and a cell line carrying C9ORF72 hexanucleotide repeat expansion. We employed immunofluorescence, molecular quantification of autophagy proteins, and live imaging of mitochondria, lysosomes, and autophagosomes at different time points in the maturation of the neurons. Our preliminary data show that autophagy is deficient in all of the ALS cell lines, with

evidence of time dependent accumulation of lysosomes, mitochondria, p62, and ubiquitin. Interestingly, the ALS lines differed in the extent and speed of progression of autophagy deficiency, suggesting ALS-mutation dependent effects on autophagy disruption. To investigate the relationship between autophagy and other pathways affected in ALS, we plan to treat the iPSC neurons with autophagy inducers and inhibitors and assess other ALS-associated pathways including mitochondrial function, DNA damage, and inflammation. This project is intended to provide insight into molecular pathways dysregulated in disease and identify pathways and targets for the development of therapeutic strategies for ALS.

Title: New TDP-43 Proteinopathy Model for ALS

Authors: *M. DOPLER, M. GITCHO;
Delaware State Univ., Dover, DE

Abstract: New TDP-43 Proteinopathy Model for ALS Amyotrophic Lateral Sclerosis (ALS) is characterized by the death of both upper and lower motor neurons. After diagnosis, the average lifespan of the patient is ~5 years, most commonly due to respiratory failure and pneumonia. There are currently no effective treatments for ALS. In addition, 97% of cases are pathologically characterized by cytoplasmic accumulation of hyperphosphorylated and ubiquitinated transactive response DNA binding protein 43 (TDP-43). Familial mutations in TDP-43 account for ~5-10% of all ALS cases. In order to develop better drug treatments, we must have effective animal and cellular models to represent the disease. To this end, we have inserted three familiar mutations (A315T, M337V, S379P) in a TDP-43 construct (3X-TDP-43) in order to create a new cellular pathological model. Cells transfected with 3X-TDP-43 into HEK293T and SH-SY5Y have many of the hallmark characteristics found in ALS. This cellular model induces cytoplasmic accumulation of phosphorylated TDP-43 and a distinct change in solubility that has only been observed in human cases of TDP-43 proteinopathy. Based on these findings, we hope to develop

a better understanding of the disease process. This cellular model may provide a better avenue in the development of therapeutics targeting aggregation.

Title: Developing a human iPSC-derived model of the neuromuscular junction to study functional phenotypes of neurodegeneration

Authors: ***J. M. COLON MERCADO**[1], O. F. VILA[2], A. SNYDER[1], T. C. MCDEVITT[2], M. E. WARD[1];
[1]Inherited Neurodegenerative Dis. Unit, NIH, NINDS, Bethesda, MD; [2]Gladstone Inst., San Francisco, CA

Abstract: Despite advances in rodent models of neurodegeneration, the basic mechanisms linking pathology and genetic function remain unknown. This knowledge gap persists because of technical limitations to evaluate the consequences of mutations and protein loss/gain of function in parallel. Human-induced pluripotent stem cells (iPSCs) provide the advantage of systematically testing disease-related mutations on specific cellular phenotypes on an isogenic background. In this study, we engineered two transgene cassettes to differentiate iPSCs into motor neurons (Ngn2-Isl1-Lhx3; hNIL) or skeletal myocytes (MyoD1-shRNAOct4; MyoD-shO). We used the PiggyBac transposase system to rapidly and efficiently deliver the doxycycline-inducible transcription factor technology into iPSCs. Upon doxycycline induction, the hNIL cassette derived a motor neuron phenotype, as previously shown by our group. The MyoD-shO differentiation resulted in a myotube-like morphology at day 5 and skeletal muscle markers expression at day 14 (MHC, SAA, MyoD1). Next, we optimized the cell density and media conditions to obtain a sustainable co-culture system. Phase-contrast microscopy revealed a successful co-culture of motor neuron aggregates and skeletal muscle myoblasts. To investigate functional phenotypes, we developed a ChR2 and a gCaMP7 motor neuron iPSC lines. Short light pulses induced skeletal muscle contraction, suggesting that the co-culture system recreates functional neuromuscular units. Ongoing experiments will assess the consequences of mutations in a multi-cell system, providing new insights into the cell-autonomous mechanisms driving neurodegeneration. With this newly developed tool, these forthcoming studies will allow us to fully characterize phenotypes that evolve from genetic mutations in every aspect of the neuromuscular unit.

Clin. Neurosci, Umea, Sweden

Abstract: Mutations in *SOD1* account for a proportion of adult-onset ALS. The vast majority of these act in a Mendelian-dominant fashion with varying degrees of penetrance although homozygous mutations have been shown to cause ALS in a subset of patients. The homozygous truncating mutation c.335dupG/p.C112Wfs*11 has recently been identified as leading to absence of SOD1 enzymatic function and a severe pediatric motor neuron disease. The revelation of a distinct neurological phenotype in patients with loss of SOD1 function has major implications for currently explored therapeutic approaches to ALS. Here, we report on the phenotype of 8 pediatric patients homozygous for the c.335dupG variant.
Establishing a cohort of eight individuals homozygous for *SOD1* c.335dupG, metabolomic studies relying on mass spectrometry were used to identify markers of oxidative stress and organ damage. MR imaging and -spectroscopy, neurophysiological and in-depth clinical examinations were employed to characterize their phenotype.
The patients showed a remarkably similar course of symptoms with onset of disease within the first year of life. Following the development of truncal muscular hypotonia beginning at age 6-9 months, severe spastic paresis developed first in the limbs and then in bulbar-innervated muscles. Frontal lobe involvement with affective lability has appeared in some. cMRI identified some cortical atrophy. EMG revealed some signs of neurogenic denervation.
In summary, absence of SOD1 enzyme activity caused by the homozygous truncating variant *SOD1* c.335dupG leads to a severe neurodevelopmental phenotype that can be subsumed under the term infantile superoxide dismutase 1 deficiency syndrome (*iSODDES*). Further research is needed to understand the relevance for SOD1 silencing as a treatment of ALS.

Title: Genetic variants and alterations in WWOX affect mitochondrial function and neuronal survival in amyotrophic lateral sclerosis

Authors: ***S. E. KIM**[1], T. PETROZZIELLO[1], A. N. MILLS[1], S. M. K. FARHAN[2,3], K. VAKILI[4], G. SADRI-VAKILI[1];

Sch., Boston, MA; [3]Program in Med. and Population Genetics, Broad Inst. of MIT and Harvard, Cambridge, MA; [4]Dept. of Surgery, Boston Children's Hosp., Boston, MA

Abstract: The precise molecular mechanisms leading to motor neuron degeneration in amyotrophic lateral sclerosis (ALS) are not yet completely understood. Therefore, identifying the underlying pathogenic mechanisms and disease-modifiers capable of altering the course of ALS is vital for the development of new therapies. One such candidate is the WW domain-containing oxidoreductase (WWOX), which plays a role in DNA damage response, oxidative stress, neuronal differentiation, and neurodegeneration. Here, we investigated whether and how alterations in WWOX signaling may contribute to ALS pathogenesis. Our results demonstrate a significant decrease in WWOX levels in a large cohort of ALS post-mortem motor cortex (mCTX). Genetic analysis also revealed several rare genetic variants in WWOX in 4,366 ALS patients from Project MinE that were completely absent in gnomAD. Four of these variants were associated with a high Combined Annotation Dependent Depletion score (CADD) (>25), including rWWOX^{G57E} in the WW2 domain, WWOX^{STOP261E} in the mitochondria binding region of the short-chain alcohol dehydrogenases (SDR) domain, and rWWOX^{STOP353Q} and rWWOX^{A363P} in the D3 region containing a pro-apoptotic tail. Interestingly, it has been suggested that the SDR domain may regulate the mitochondrial electron transport chain (mtETC). Consistent with previous studies showing changes in the mtETC in ALS, our results revealed a significant decrease in the levels of the ATP synthase subunit alpha of complex V (ATP5A) and the cytochrome c oxidase of complex IV (COX II or MTCO2) in ALS mCTX. Additionally, co-immunoprecipitation experiments revealed that WWOX interacts with ATP5A in ALS post-mortem mCTX. To determine whether the novel ALS mutations in WWOX may affect cell survival or alter mitochondrial function, SH-SY5Y cells were treated with human recombinant rWWOX^{WT}, rWWOX^{G57E}, rWWOX^{STOP261E}, rWWOX^{STOP353Q}, and rWWOX^{A363P} proteins. Our results indicate that the treatment with mutant rWWOX proteins reduced cell

viability in human neuroblastoma SH-SY5Y cells as measured by an MTT assay and the levels of proteins involved in pro-survival pathways. Furthermore, the treatment with rWWOX^{STOP261E} affected the levels of several proteins involved in the mtETC in SH-5YSY cells as well as ATP and reactive oxygen species (ROS) production. Collectively, our findings suggest that alterations in WWOX signaling may lead to mitochondrial dysfunction and motor neuron death in ALS.

Title: Uncovering the pathological role of astrocytes in SMA

Authors: *R. L. ALLISON[1], G. KHAYRULLINA[2], B. G. BURNETT[2], A. D. EBERT[1]; [1]Cell Biology, Neurobiology, & Anat., Med. Col. of Wisconsin, Wauwatosa, WI; [2]Anatomy, Physiology, and Genet., Uniformed Services Univ., Bethesda, MD

Abstract: Spinal muscular atrophy (SMA) is the most common genetic cause of infant mortality and is caused by mutations of the survival motor neuron 1 gene (SMN1) resulting in reduced expression of the SMN protein. Motor neuron loss is the primary phenotypic outcome in SMA patients though it is unclear why motor neurons are particularly impacted. SMA motor neurons show intrinsic deficits in splicing and electrophysiological function, but these defects alone are not sufficient to induce overt motor neuron loss. Data from us and others indicate that there are significant non-cell autonomous astrocyte and microglia influences on motor neuron health and survival, raising the possibility that glia directly contribute to the vulnerability of neurons in SMA.

We have previously found that SMA astrocytes undergo morphological and functional changes very early in disease and are capable of inducing motor neuron pathology. We found that SMA astrocytes have reduced growth factor release and abnormal microRNA production. Additionally, others have shown that SMA microglia exhibit activation later in the disease process and are involved in synapse engulfment. However, the mechanisms of glia-mediated neuron dysfunction and the temporal contributions of astrocyte-microglia crosstalk to SMA pathology have not been elucidated.

We hypothesize that early SMA astrocyte malfunction induces motor neuron pathology and simultaneously activates microglia. In support of this, we found that induced pluripotent stem cell (iPSC)-derived astrocytes exhibit aberrant expression of the transcription factor GATA6, increased NFκB nuclear localization, and increased complement factor C3 release. Moreover, we

found that SMA iPSC-derived astrocyte conditioned medium (ACM) is sufficient to induce motor neuron death. Interestingly, lentiviral knockdown of GATA6 in SMA iPSC-derived astrocytes abrogated ACM-mediated motor neuron toxicity. Separately, we found that SMA iPSC-derived microglia adopted a reactive morphology, increased phagocytosis, and increased expression of complement C1q compared to control microglia. Exposure of SMA iPSC-derived microglia to SMA ACM significantly increased their phagocytic activity compared to untreated microglia, consistent with a role of astrocytes in exacerbating microglial activation in SMA. These data indicate the significant role of astrocyte secreted factors in contributing to disease phenotypes in SMA. Gaining a better understanding of the non-cell autonomous processes involved in SMA will help elucidate the mechanisms of motor neuron malfunction and can help identify targets for therapeutic intervention.

Title: Novel neuroprotective mechanisms of cannabidiol (CBD) against tetramethylene-disulfotetramine toxicity to hippocampal neurons

Authors: *L. K. FRIEDMAN[1], M. LAUKOVÁ[2], M. P. SHAKARJIAN[2];
[1]Cell Biol. and Anat., [2]New York Med. Col., Valhalla, NY

Abstract: Tetramethylenedisulfotetramine (TETS), a potent rodenticide and GABAA inhibitor is a chemical terrorist warfare agent that can produce severe seizures, progressive neurodegeneration, and neurocognitive deficits in humans and animals. Cannabidiol (CBD), a non-psychoactive cannabinoid, has anticonvulsant, antioxidant, and antinflammatory effects that may mitigate acute TETS-induced neuropathophysiology. We *hypothesized* that presynaptic Ca^{2+}-dependent neurotransmitter release is a critical target of CBD and that midazolam (MDZ), a GABAergic positive modulator, will facilitate CBD-induced neuroprotection. Therefore, expression of a Ca^{2+} binding protein calmodulin 2 (Calm2), a Ca^{2+} specific controller of several signaling proteins and two high voltage-gated Ca^{2+} channels (VGCC), P/Q and Cav1.2 (L type) to which they bind were immunocytochemically investigated with specific antibodies. At 14 DIV, dissociated hippocampal and sister cortical cultures were exposed to TETS (10 μM) ± CBD (15 μM) ± MDZ (10 μM) for 24 h. $[Ca^{2+}]_i$ was measured with a Flexstation 3 at 25ºC at varied doses of CBD and MDZ following acute TETS application. TETS reduced Calm2 intensely and lightly stained hippocampal neurons; many cells were shrunken. When TETS was co-treated with CBD (15 μM), hippocampal Calm2 and P/Q expression was elevated and intensely-stained neurons were increased; morphology was preserved. In contrast, MDZ reduced Calm2 expression and further reduced P/Q positive cell counts at the concentration tested. Cav1.2

immunostaining increased after TETS in hippocampal neurons; many had compromised morphology which was reversed by either CBD or MDZ. Sister cortical neuronal cultures grown from dissected embryos under the same conditions were nearly unaffected by any of the treatments. Acute application of CBD + MDZ post TETS produced greater suppression of $[Ca^{2+}]_i$ signals than either agent alone suggesting a potential co-treatment strategy. Results suggest a novel mechanism of CBD neuroprotection against severe seizures by suppression of persistent elevations in $[Ca^{2+}]_i$ and upregulation of critical Ca^{2+} binding proteins. Hippocampal neurons were more sensitive to TETS or MDZ toxicity than cortical neurons so that lower non-saturating doses of MDZ would be required to avoid injury to hippocampal Ca^{2+} binding proteins, critical for neuronal survival. At 100 μM CBD, suppression on $[Ca^{2+}]_i$ was maximal in absence of MDZ suggesting CBD alone may improve the standard of care for chemical threats.

Abstract: Ozone (O3) is one of the major air pollutants around the world, it is created by a photochemical reaction of volatile organic compounds, nitrogen oxides and carbon monoxide that accumulates in the troposphere. According to the worldwide organization stipulates that an O3 concentration above 100 μg/m3 (510 parts per million) for 8 hours can be dangerous for humans causing moderate to severe effects in health. Several studies about the exposure to O3 have been made in animal models, concluding to an increase in oxidative stress, resulting in lipoperoxidation, inflammation, metabolic disturbances, alteration in cell signaling and the possible initiation of cell death in vulnerable areas such as the olfactory bulb, cerebellum, striatum, hippocampus and frontal cortex which are not fully described. The inflammatory response can represent an initial factor of cell death since high concentration of TNF-α can activate caspase 3, which is one of the main effectors to bind substrates such as immune molecules that causes cell death. Apoptosis is a programmed cell death, which activates caspases leading to DNA fragmentation, forming and phagocyting apoptotic bodies with or without an inflammatory response. Apoptosis onset can occur through 2 pathways: intrinsic (mitochondrial)

and extrinsic (death receptors), where multiple proteins interfere. Therefore, we aim to evaluate the participation of caspase 3 and caspase 8, BCL-2, cytochrome C, VDA-C, TUNEL and BAX proteins, in the initial damage resulting from ozone exposure in rats cerebellum. We used ten male Wistar rats, who were randomized, in two groups, a control and experimental equally divided. The experimental group was subjected to a hermetic ozone chamber for 12 hours provided with 1 ppm of O3, subsequently they were immediately sacrificed to perform immunohistochemistry analysis. Compared to the control group, we found a decreased in BCL-2, an anti-apoptotic protein, and an increased in TUNEL, caspase 3, 8 and BAX who trigger the cell death, this indicates that the two pathways (extrinsic and intrinsic) were activated. We also found a decreased in VDA-C and cytochrome C, this could be explained because of the release of cytochrome C is independent of its oxidation state and it becomes reduced in the cytosol. O3 induce cell death through the extrinsic and intrinsic apoptotic pathways, this could explain some manifestations in the rats such as motor alterations.

Title: Early S phase events protect neurons from amyloid-β toxicity

Authors: *Y. DENG[1], S. IPPATI[2], E. PARIC[1], G. CHAN[1], A. FEITEN[1], T. FATH[1], Y. KE[1], N. K. HAASS[3], L. M. ITTNER[1];
[1]Macquarie Univ., Sydney, Australia; [2]San Raffaele Scientific Inst., Milan, Italy; [3]The Univ. of Queensland, Brisbane, Australia

Abstract: Neurons are post-mitotic cells that do not undergo division after terminal differentiation. Reactivation of neuronal cell cycle has been reported in Alzheimer's disease (AD) brains and models. Accordingly, the hypothesis has been put forward that re-entering the cell cycle renders neurons vulnerable contributing to AD pathogenesis. Here, we observed transient cell cycle activation events in wild-type neurons by using the fluorescent ubiquitination-based cell cycle indicator (FUCCI) mAG-hGem. Interestingly, neurons have increased mAG-hGem activity did not undergo cell death under the oligomeric amyloid-β (oAβ) challenge. We further use two FUCCI reporter mKO2-hCdt1 and mAG-hGem together to visualize stages of the cell cycle in living cells, where the cell will show red color (mKO2) during the G1(G0) phase and green color (mAG) during S/G2/M stage of cell cycle. Consistent with our previous finding, nearly all neurons are mKO2 positive. However, transient mAG activity can also be detected even those neurons continue to express mKO2-hCdt1. It is noted that the transient mAG-positivity was self-limiting in all recorded cells and only lasted for

several hours. Furthermore, even increasing mAG activity is observed under oAβ challenge, there is no DNA synthesis and replication in these cells. Accordingly, we found high-intensity mAG activity in the brains of human mutant Aβ precursor protein transgenic (APP23) mice. Additionally, increased neuronal expression of the endogenous cell cycle control protein geminin in 3-month-old APP23 mice and human AD brains has been detected. Taken together, our data suggest that the post-mitotic state of neurons is a dynamic process that happens naturally and the rapid induction of pathways that lead to early S phase cell cycle events in response to Aβ may protect neurons and prevent or delay cell death in AD.

Title: Static magnetic fields modulate the response of the brain to different oxidative stress markers in a restraint stress model animal

Authors: F. ESTRADA BERNAL[1], *J. ARROYO-PÉREZ[2], **F. E. ROJO**[1], L. NAVARRO[1], L. VERDUGO-DIAZ[2];
[1]Lab. Neuroendocrinología, Fisiología, Facultad de Medicina, [2]Lab. Bioelectromagnetismo, Fisiología, Facultad de Medicina, Univ. Nacional Autónoma de México UNAM, Mexico City, Mexico

Abstract: Stress alters physiology and behavioral responses; it can induce oxidative damage in organs, such as the brain. Several investigations reveal that magnetic stimulation could modulate the response to oxidative stress and be an effective complementary therapy in different pathologies. The study aimed to describe the effect of static magnetic fields (SMF) in an animal model of restraint stress, focusing on changes in different markers of oxidative damage: nitric oxide (NO), malondialdehyde (MDA), advanced protein oxidation products (AOPP), superoxide dismutase (SOD), and reduced glutathione concentration (GSH), in the brain. Male Wistar rats were used and separated into seven groups (n = 8 each): control, restriction animals during the 30, 60, or 240-minute/day, and rats with restriction plus SMF exposition (O.8mT) during the 30, 60, or 240-minute/day for 5 days. After this period of exposure, the brain of rats was obtained and measured the oxidative markers. Our results show time dependent SMF effects. We found decreasing brain's lipoperoxidation at 60 and 240 minutes of SMF exposure. The magnetic fields can modulate the oxidative radicals in some tissues. SMF could offer complementary therapy in various pathologies, such as neurodegenerative diseases, to reduce oxidative stress.

Title: Genotoxic stress induced by a small interfering peptide derived from heterogeneous nuclear ribonucleoprotein A1 (hnRNPA1)

Authors: ***S. LEE**, Y. SHIN, J. W. TSAO;
Univ. of Tennessee, Memphis, TN

Abstract: Neurodegenerative diseases, such as Alzheimer disease (AD), multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS) are known to be associated with loss of hnRNPA1, but its detailed role is not well characterized. We confirmed an increase in hnRNPA1 truncated in the central nervous system and a decrease in the expression of hnRNPA1A mRNA in PBMCs with disease progression in the experimental autoimmune encephalomyelitis (EAE) animal model of MS. In order to maintain homeostasis of hnRNPA1 in neurons, the quality and quantity of the protein were controlled by cleavage between $AA^{245-286}$ of hnRNPA1, and a hnRNPA1 N-terminal fragment (AA^{1-267}) of approximately 30kDa was produced. However, the C-terminal fragment ($AA^{268-320}$) of roughly 6kDa could not be confirmed with a commercial antibody. It is thought that the epitope for the antibody is not preserved due to the involvement of various proteases. We have previously confirmed the neuronal cytotoxicity of 6kDa C-terminal fragment ($AA^{268-320}$), and a peptide sequence ($^{306}GGSSSSS^{313}$) truncated from the 6kDa C-terminal fragment ($AA^{268-320}$) was generated using the PeptideCutter online tool to predict the potential cleavage site of the protease. A monoclonal antibody was created and used to confirm the presence of $^{306}GGSSSSS^{313}$. To examine the role of $^{306}GGSSSSS^{313}$ peptide-induced neurotoxicity, PCR array analysis of a panel of apoptosis-related genes (PAHS-012Z, Qiagen) was performed using SK-N-SH cells expressing hnRNPA1 fragments (AA^{1-267}, $AA^{306-313}$). Analysis of the apoptosis process through PCR array technology demonstrated high expression of tumor protein p53(TP53) and caspase3(CASP3) when compared to control with $^{306}GGSSSSS^{313}$-transfected SK-N-SH cells. We conclude that $^{306}GGSSSSS^{313}$ induces neuronal death through the p53 pathway. In addition, in the $^{306}GGSSSSS^{313}$-transfected cells, polyadenylate-binding protein 1 (PABPC1) is relocated to the nucleus. This rearrangement of PABPC1 into the nucleus requires a decrease in protein synthesis by inhibiting protein translation. Thus, $^{306}GGSSSSS^{313}$ derived from hnRNPA1 induces a significant loss of hnRNPA1, which is involved in the stability of RNA and DNA in neurons. This results in mRNA processing disorders and genotoxic stress, suggesting a major role for this protein fragment in neuronal death in neurodegenerative diseases.

Title: Role of related MAP triple kinases DLK and LZK in the vincristine-induced neuronal injury response in human neurons

Authors: ***A. SLAVUTSKY**[1], J. GOMEZ-DEZA[1], C. E. LE PICHON[2];
[1]NIH, Bethesda, MD; [2]NIH, NICHD, Bethesda, MD

Abstract: Dual leucine zipper kinase (DLK; MAP3K12) and leucine zipper kinase (LZK; MAP3K13) arekey mediators of the neuronal injury response shared among neurodegenerative conditionssuch as amyotrophic lateral sclerosis (ALS) and chemotherapy-induced neuropathic pain(CIPN). These related MAP3 kinases initiate a transcriptional cascade resulting inphosphorylation of the transcription factor c-Jun, facilitating the fate of neuronal cell death.Previous studies show that, while DLK disruption is partially protective in models of optic nerveinjury and traumatic brain injury, combined disruption of DLK and LZK is ultimately required toprevent retinal ganglion cell (RGC) death (Welsbie et al, 2017 and 2019). Using human iPSC-derived cortical and sensory neurons, we sought to tease apart the distinctive and synergisticroles of DLK and LZK in the transcriptional response to neuronal injury. Single knockout iPSClines of DLK and LZK, as well as a DLK/LZK double knockout, were generated usingCRISPR/Cas9. Vincristine, a chemotherapeutic agent known to cause CIPN and activate theDLK/LZK pathway, induces partial c-Jun activation in both DLK KO and LZK KO neurons, butthis activation is blocked in DLK/LZK double KO neurons. Transcriptomics in these cell lines willelucidate the relative contributions of DLK and LZK to the vincristine-induced neuronal injuryresponse and potentially reveal new drug targets for neurodegenerative pathologies.

Title: Demyelination of cerebellum in a murine heatstroke model

Authors: K. MIYAMOTO[1], H. OHTAKI[3], *A. YOSHIKAWA[4], H. YAMAGA[1], M. NAKAMURA[1], K. SUZUKI[1], K. HONDA[2], K. DOHI[1];

Abstract: Introduction: Selective loss of Purkinje cells has previously been described in heatstroke. There is a report that 22-33 % of survivors were discharged with neurologic disability that remained sustained or worsened at 1- and 2-year follow-up. The damage is maximal in the cerebellum, resulting in marked loss of Purkinje cells, culminating in cerebellar atrophy with debilitating and permanent sequelae for survivors. Thought, it is not well understood the mechanism of delayed cerebellar syndrome. In our study, we investigated the delayed cerebellar syndrome using murine heatstroke model. **Methods:** Male C57BL/6J mice were subjected to heat exposure {(HE), 41 ± 0.5ºC, RH>95%} for 60 min. The rotarod performance test was used to evaluate the motor coordination after HE. Mice were trained once a week for 6 weeks. Then, they were divided into Control (Ct, no heat exposure, n=36) and Heatstroke (HS, n=36) groups depends on the score. The rotarod test was performed at 1, 3, 5, 7 and 9 weeks post HE. Another group (Ct and HS) were prepared. Animals were sacrificed 1, 3, 9 (n=6 in each group respectively) weeks post heat exposure and the brains were collected respectively. Seven sagittal section (5μm) of whole brains were made every 200μm from longitudinal fissure. Klüver-Barrera (KB) stain were performed to quantify the demyelination at cerebellum and corpus callosum. **Results:** The rotarod score initially decreased in the third week compared to the first week in the HS group, then improved from 5 weeks post HE, whereas no decrease was observed in the Ct groups and significant differences were observed at 3 weeks post HE ($p < 0.05$). Demyelination was significantly detected at cerebellum 1, 3 weeks post heat exposure ($p < 0.05$). Then, it improved and there was no differences 9 weeks post heat exposure. However, no significant differences were observed at corpus callosum. **Conclusion:** Motor coordination disorder appeared 1 weeks and it exacerbated to 3 weeks. Demyelination of cerebellum was also detected 1 and 3 weeks at cerebellum. These results indicate demyelination of cerebellum reflect the motor coordination failure of heatstroke.

Abstract: Behavioral Impacts of Pharmacological and Supportive Care in the Treatment of Status Epilepticus in a Rat Model of Soman Poisoning Kathryn A Hundertmark, Julia E Morgan, John H McDonough, and Hilary S McCarrenAbstract Soman (GD) is a highly toxic chemical compound that can result in severe health degradation following exposure. GD works by inhibiting the enzyme acetylcholinesterase from breaking down the neurotransmitter acetylcholine, resulting in status epilepticus (SE). Developing appropriate pharmacological and supportive care measures is important to increase survivability. This experiment used the open field test (OFT) and elevated plus maze (EPM) to evaluate treatment efficacy of animals who were treated for SE in an ICU setting compared to control animals following exposure to GD. Both behavioral tests evaluate the animal's locomotion and anxiety. Behavioral testing was conducted 4 days prior to exposure to GD and 9 days following exposure. Animals who were treated in the ICU (n = 14) were found to spend more time in the closed arms (p = 0.004), while the controls (n = 7) spent more time in the open arms (p = 0.0005). Compared to the ICU-treated group, the control group spent more time immobile (p = 0.011) when in the OFT. The ICU-treated group also made more entries into the closed arms when compared to the control group (p = 0.014). No significant differences were found between groups for total distance traveled in OFT or EPM. These data support ICU treatment efficacy with animals behaving near baseline measurements. The control group, however, experienced behavioral deficits such as lethargy and lack of inhibition following exposure to GD. Further research will be conducted using the novel object recognition test and home cage reactivity evaluation to more fully characterize the effects of GD-induced SE and subsequent treatments on behavior.

Title: The inactivation of glutathione S-transferase by dopamine and its metabolites

Authors: *R. CRAWFORD[1], K. BOWMAN[1], E. GILARDONI[2], B. CAGLE[1], J. DOORN[1]; [1]Univ. of Iowa, Iowa City, IA; [2]Univ. of Milan, Milan, Italy

Abstract: Background. Neurodegenerative disorders such as Parkinson's disease are characterized by disruption of dopamine homeostasis and oxidative stress. The aldehyde metabolite of dopamine, 3,4-dihydroxyphenylacetaldehyde (DOPAL), is known to be cytotoxic through mechanisms of protein modification and oxidative stress. This research has identified glutathione S-transferase (GST) as a protein target of DOPAL; because GST is paramount in the body's antioxidant defense system, this has implications for mechanisms of neuronal injury. Therefore, this research examines the modification of GST by dopamine, DOPAL, and 3,4-dihydroxyphenylacetic acid (DOPAC). Furthermore, we have found that the amino acid L-cysteine is a scavenger of DOPAL and other biogenic aldehydes, forming an identifiable and measurable conjugate. This has implications in neuroprotection as well as the potential for a novel biomarker for dopamine dyshomeostasis. **Methods.** GST was isolated from the dopaminergic N27 cell line and treated with varying μM concentrations of DOPAL, dopamine, or DOPAC. GST activity was measured using a 2,4-dinitrochlorobezene assay. The time dependence and reversibility of this inhibition were evaluated. The ability L-cysteine to protect GST function was assessed. Mass spectrometric methods were employed to assess the mechanism of action of protection by L-cysteine and elucidate the formation of an L-cysteine-DOPAL conjugate. **Results.** DOPAL, dopamine, and DOPAC inhibited N27 GST activity with IC_{50} values of 31.46μM, 82.32μM, and 260.0μM, respectively. This inhibition was irreversible and time dependent. L-cysteine fully protected GST activity from modification by dopamine, DOPAL, or DOPAC. L-cysteine was also found to form a putative thiazolidine conjugate with DOPAL. This conjugate was also found to form in SH-SY5Y neurons after treatment with dopamine and n-acetyl cysteine, or when cells were treated with dopamine and exposed to stress. **Conclusions.** Dopamine and its metabolites inactive GST, which could lead to a breach in the antioxidant defense system. Therefore, we propose that this enzyme inhibition is a mechanism of neurotoxicity relevant to diseases that are marked by dopamine disruption, such as Parkinson's disease. Further, we propose that the L-cysteine-DOPAL conjugate may be a useful biomarker for dopamine dyshomeostasis.

Title: Activity of the Manganese Efflux Transporter SLC30A10 in Catecholaminergic Neurons Protects Against Manganese-induced Motor Dysfunction

Authors: *C. TAYLOR[1], S. HUTCHENS[2], T. JURSA[3], W. SHAWLOT[2], M. ASCHNER[4], D. R. SMITH[5], S. MUKHOPADHYAY[2];

Abstract: Manganese (Mn) is an essential metal required for normal brain development and function. However, elevated levels are neurotoxic and lead to an incurable movement disorder. The specific neuronal subtypes most effected by Mn are still unknown, hindering therapeutic progress. To understand Mn neurotoxicity and subsequent motor deficits, our lab studies the primary Mn efflux transporter, SLC30A10. Our recent work revealed that activity of SLC30A10 in the brain reduced Mn levels in the basal ganglia and thalamus during overexposure (Taylor et al., 2019). Here, we use various *Slc30a10* knockout mice to selectively increase Mn levels throughout the brain (pan-neuronal/glial), in catecholaminergic neurons, or in GABAergic neurons. We found that pan-neuronal/glial *Slc30a10* knockouts exhibited hypolocomotion that is exacerbated by a human disease-relevant Mn exposure regimen. This hypolocomotion is not associated with changes in extracellular levels of striatal dopamine, the dopamine metabolite DOPAC, or GABA. However, catecholaminergic, but not GABAergic, knockouts also exhibited hypolocomotion. Thus, while elevated Mn may not lead to GABAergic or dopaminergic neurodegeneration, it may lead to dopaminergic dysfunction. Future work will use immunohistochemistry to confirm our hypothesis that elevated Mn does not lead to dopaminergic or GABAergic neurodegeneration. Future work will also use in vivo microdialysis to determine how Mn impacts dopaminergic function.

Abstract: Neurotoxicity has been linked to exposure to a number of common drugs and chemicals, yet efficient and minimally-invasive methods for prediction of neurological changes are lacking. Fluid-based biomarkers such as those found in serum, plasma, urine, and cerebrospinal fluid (CSF) have great potential due to the relative ease of sampling, but data on their expression and clinical translation are lacking or inconsistent. As part of the HESI Neurotoxicity Biomarker Subcommittee, we present preclinical data on biomarkers that have some promise for detection and characterization of neurotoxicity and validate such data for their predictive potential. Trimethyltin is known to cause CNS neuropathology in species from mouse to man. A single dose of trimethyltin, TMT (7 mg/kg, ip) to the rat, led to significant alterations in lipid homeostasis, circulating interleukins and related factors, and markers of neuroinflammation in CSF, serum, plasma and urine. A significant correlation of these fluid biomarkers was observed with traditional neuropathology and magnetic resonance imaging (MRI) endpoints that served to define TMT-induced neurotoxicity. Our data demonstrate a novel correlations of several potential neurotoxicity biomarkers and MRI-based endpoints with TMT-induced neuropathology. These findings suggest of an involvement of specific pathways that can be assessed using peripheral fluids in a preclinical model. A clinical translation of these findings can be investigated by analyzing a blood-based safety biomarker panel of five nervous system-derived proteins in the serum of healthy volunteers and of patients with neurological disorders. As part of the IMI-2 TransBioLine Consortum, GFAP, UCH-L1, NFL, pNFH and Tau will be measured in the serum (or plasma if appropriate) of patients with multiple sclerosis (MS), those with non-inflammatory traumatic brain injury (TBI) and those undergoing chemotherapy. Data will be compared with the ranges in serum samples from healthy volunteers. In addition, these proteins will also be measured in the CSF of MS and TBI patients to enable possible correlations with serum data. If successful, regulatory qualification of GFAP, UCH-L1, NFL, pNFH and Tau as fluid-based safety biomarkers of drug-induced neurotoxicity will add to a better insight into the underlying mechanisms of neurotoxicity and its early detection, and to the safety of healthy volunteers in phase I clinical trials and patients treated with potentially neurotoxic drugs.

Title: Secondary structural analysis of enetrovirus D68 5'UTR to identify neurotropism determining structural elements

Authors: *P. OJHA, W. TAPPRICH;
Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Enterovirus D68 is a single-stranded positive-sense RNA virus of the picornaviridae family which utilizes its 5' untranslated region (5'UTR) to recruit ribosome and undergo cap-independent translation. First isolated in 1962 in California, EV-D68 only had minor cases of respiratory illness until 2014. Since the summer of 2014, reported outbreaks for EV D68 have been increasing with a strong association with polio-like acute flaccid myelitis (AFM). Ample evidence suggests that the 750 nucleotides long 5'UTR of enteroviruses include the internal ribosome entry site (IRES) which plays an important role in determining their virulence. Neurotropic strains of EV-D68 have an approximate 20 nucleotide deletion in the spacer region of their 5'UTR. Understanding the structural changes in 5'UTR of current EV D68 strains from the ones in 1962 can help determine the reason for its newly gained neurotropism. We hypothesize the interactions of 5'UTR of neurotropic strains with cell-specific host proteins and non-coding RNAs dictates its ability to exhibit neurovirulence. A robust secondary structure of the 5'UTR is being generated by using the SHAPE- MaP analysis. This method involves chemical modification of the 2' hydroxyl group of nucleotides in the RNA molecules based on their position and flexibility. These modified molecules are converted into cDNA to create high-quality mutational profiles (MaP), which are then subjected to massively parallel sequencing. By using computational tools like the *shapemapper2* and *superfold* to analyze the NGS data, a secondary structure of the 5'UTR can be generated. Elucidating novel 5'UTR secondary structures of EV D68- Fermon (1962) and EV D68- KT347251.2 (2014) strains can reveal the structural changes leading to neurotropism. These novel structures of 5'UTR of EVD68 can also be utilized for comparative studies of 5'UTRs between other neurotropic enteroviruses like EV 71- KF312457.1 (1998), Polio Virus, and non-neurotropic enteroviruses like CVB3 to find key shared structures involved in determining the virulence of enteroviruses. To better characterize the specific roles of key conserved structural elements between neurotropic enteroviruses, a set of in-vivo experiments involving mutated EV-D68 strains are being designed.

Title: Chronic nicotine exposure increases blood-brain barrier permeability and decreases tight junction protein levels in rats.

Authors: ***S. CHO**[1], A. K. REHNI[1], M. A. PEREZ-PINZON[2], A. P. RAVAL[2], K. R. DAVE[2]; [2]Neurol., [1]Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Tobacco use is one of the leading causes of preventable death. Tobacco use not only increases the risk of but also worsens outcomes following ischemic and hemorrhagic stroke in both men and women. The blood-brain barrier (BBB) separates the circulating blood from the central nervous system (CNS) by capillary endothelial cells sealed together with tight junction proteins, and any disruptions of the BBB could significantly impact the CNS. Our hypothesis is that chronic nicotine increases the risk of cerebrovascular diseases by increasing BBB permeability. To determine the effect of nicotine on the BBB, we evaluated BBB disruption using Evans blue dye (EBD) extravasation and measured the tight junction protein levels in animals of both sexes treated with nicotine. Young Sprague-Dawley rats of both sexes were implanted with an osmotic pump containing either nicotine (4.5 mg / kg / day) and saline (vehicle group) and treated for two to three weeks. After, EBD was injected into the animals intravenously. One hour later, animals were perfused with saline, and brains were harvested, weighed, homogenized, and spectrophotometrically analyzed for EBD. In addition, microvessels were isolated from brain tissue, and tight junction protein levels were measured using Western blot. Brain tissue from female animals was collected during the diestrous stage of the estrous cycle to avoid hormonal fluctuation. EBD content in male animals was significantly higher in nicotine-treated rats (800 ± 100 ng / g of brain tissue) than saline-treated rats (284 ± 74 ng / g of brain tissue) by 182% ($p<0.01$). EBD content in female animals was also significantly higher in nicotine-treated rats (800 ± 100 ng / g of brain tissue) than saline-treated rats (284 ± 74 ng / g of brain tissue) by 98% ($p<0.05$). In male animals, Claudin 3, Claudin 5, and occludin levels were significantly lower by 48% ($p<0.05$), 37% ($p<0.05$), and 39% ($p<0.01$), respectively, in nicotine-treated rats than in saline-treated rats. In female rats, Claudin 3, claudin 5, and occludin protein levels were also significantly lower in nicotine-treated rats than in saline-treated rats by 31% ($p<0.05$), 44% ($p<0.05$), and 38% ($p<0.01$), respectively. We are in the process of evaluating the protein levels of other BBB proteins. Our results, so far, show that nicotine exposure increases BBB permeability and decreases tight junction protein levels in animals of both sexes. This increased BBB permeability may be responsible for the increased risk of and worsened outcomes following stroke.

Title: Immunohistochemical detection of $ChAT^+$ cells in and around multiple sclerosis lesions

Authors: *M. M. POON[1], *J. CHAN[3], A. J. GREEN[3], E. PELES[4], *J. BACCEI[2], A. C. CHEN[2], D. S. LORRAIN[1];
[1]Biol., [2]Chem., Pipeline Therapeut., San Diego, CA; [3]Neurol., Univ. of California, San Francisco, San Francisco, CA; [4]Mol. Cell Biol., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Recently, clemastine was found to have clinical benefit in human multiple sclerosis (MS) patients (Green et al., 2017). Using rodent models of MS and selective knockout of muscarinic receptor subtypes, it was established that clemastine induces OPC differentiation and remyelination via inhibition of the muscarinic acetylcholine receptor M1 (M1R; Mei et al., 2016). Direct evidence for M1R protein expression on cells of oligodendroglial lineage, however, has been lacking in human tissue. Using an M1R selective fluorescent probe, we observe $M1^+/Olig2^+$ cells in adult human cortex, optic nerve, corpus callosum, spinal cord, and cerebellum. Further, using adult human organotypic slice cultures, we show that an M1R selective antagonist, PIPE-307, is sufficient to induce oligodendrocyte markers by PCR and immunohistochemistry. These suggest that M1R overactivation by acetylcholine (ACh) may impede remyelination. Coincidentally, Jiang et al., 2017 reported upregulation of ACh and the ACh-synthesizing enzyme choline acetyltransferase (ChAT) in the MOG-EAE mouse model of MS. In the same study, they observed elevated ACh and $ChAT^+$ natural killer cells in human MS tissue. To expand on these findings, we performed immunohistochemistry on human MS tissue and observe the presence of $ChAT^+/HLA\text{-}DR^+$ (Human Leukocyte Antigen - DR isotype) cells at the border of and within lesions. These $ChAT^+$ cells also express the macrophage/microglial marker $IBA1^+$ (ionized calcium binding adaptor molecule 1), but are negative for the microglia specific marker, TMEM119 (transmembrane protein 119), suggesting that the aberrant ACh is, in part, a result of ChAT-expressing infiltrating immune cells. The expression of M1R on $Olig2^+$ cells and $ChAT^+$ immune cells in proximity of human MS lesions support a model whereby excess ACh released by $ChAT^+$ immune cells leads to increased M1R activity in effect hindering OPC differentiation (and subsequent myelin repair) at the lesion. Further studies will be needed to ascertain if there is a correlation between lesion status and ChAT expression. Nonetheless, this data provides an impetus for the use of an M1R selective antagonist as a remyelinating therapy for multiple sclerosis.

Title: Discovery of a Novel M1 Selective Antagonist, PIPE-307, for the Treatment of Multiple Sclerosis

Authors: K. I. LORRAIN[1], M. M. POON[1], A. BROADHEAD[1], K. J. STEBBINS[1], A. CHEN[1], J. BACCEI[1], A. J. GREEN[2], J. R. CHAN[2], ***D. S. LORRAIN**[1];
[1]Pipeline Therapeut., San Diego, CA; [2]UCSF, San Francisco, CA

Abstract: Multiple sclerosis (MS) is an inflammatory demyelinating disease that results in the disruption of neuronal transmission and ultimately neurodegeneration. Current treatments focus on suppressing the immune system to limit inflammation and the further loss of the myelin sheath. The next advance in the treatment of MS has focused on molecules that regulate remyelination. The M1 muscarinic acetylcholine receptor (M1R) has been shown to be a key regulator in the maturation of oligodendrocyte precursor cells (OPCs) into oligodendrocytes (OLs), the cells that make myelin. This discovery was based on non-selective anti-muscarinic compounds such as Clemastine and Benzetropine and subsequently validated through cell type specific M1R knockout studies. Building from this initial discovery, Pipeline Therapeutics initiated a medicinal chemistry effort to discover a novel M1R selective antagonist. These efforts resulted in PIPE-307, a novel, potent, and selective, first-in-class small molecule antagonist of the M1 receptor. Significantly, PIPE-307 produces robust effects in OPCs driving them towards differentiation and expression of myelin basic protein. Furthermore, PIPE-307 elicited positive

results in a diverse set of *in vitro* assays, including OPC differentiation, cortical myelination, and organotypic brain slice. *In vivo* visual evoked potential and MOG-EAE studies have confirmed that PIPE-307 induces functional remyelination as evidenced by positive results in these models. Taken altogether PIPE-307 represents a promising approach for treating demyelinating diseases such as multiple sclerosis.

Abstract: Novel small molecule approaches aimed at stimulating remyelination would greatly complement immunotherapies and provide significant neural protection in demyelinating conditions such as multiple sclerosis (MS). Recently, we described the muscarinic M1 receptor (M1R) as an important regulator of oligodendrocyte precursor cell (OPC) differentiation and a promising target for drug discovery and reported proof of concept preclinical data with the novel, potent and selective M1 antagonist PIPE-359 (SfN 2019, posters # 206.18, 206.19). We developed PIPE-307, a novel, potent and selective M1R antagonist and highlight the potential for remyelination. PIPE-307 binds with high affinity to the M1 receptor and demonstrates selectivity relative to the other muscarinic receptors (M2, M3, M4 and M5). PIPE-307 promotes differentiation of rodent OPCs and increases myelination in cultured rat brain slices. This compound has good oral exposure and brain penetration. PIPE-307 demonstrates good in vivo M1R occupancy in rat and mouse and functional inhibition of M1R signaling as determined by IP1 accumulation. At dose levels which occupy the M1R, we demonstrate remyelination potential in myelin oligodendrocyte glycoprotein (MOG)-induced experimental autoimmune

encephalitis (EAE) model of demyelination where there is an improvement in clinical behavior score and g-ratios in the spinal cord. Furthermore, PIPE-307 exhibits marked improvement of EAE-induced changes in visual evoked potential N1 latency and optic nerve axon g-ratios. These data highlight the therapeutic potential of a selective M1R antagonist to benefit conditions such as MS in which demyelination plays a role. Entry into human-enabling studies with PIPE-307 are ongoing and clinical trials are expected to commence in early 2021.

Title: Divergent roles of CXCR4 antagonism in Dectin-1 and TLR2-driven microglia/macrophage activation and neurodegeneration

Authors: *T. CHU[1], Y. P. ZHANG[3], W. ZENG[1], L. B. E. SHIELDS[3], G. N. BARNES[2], C. B. SHIELDS[3], J. CAI[1];
[1]Pediatrics, [2]Neurol., Univ. of Louisville, Louisville, KY; [3]Norton Neurosci. Inst., Norton Healthcare, KY

Abstract: Innate immune activation develops in neurodegenerative diseases and promotes pathology. The innate ability of microglia/macrophage (M/M) to sense and respond to microbial and host-derived danger molecules relies on its pattern recognition receptors (PRRs). C-type lectin family members like Dectin-1 and toll-like receptors (TLRs) like TLR2 are major PRRs that trigger phagocytosis and neuroinflammation, orchestrating the early host defense to infections and damages. Though they collaborate on M/M, the activation of Dectin-1 or TLR2 shows divergent consequences. The neuroinflammatory response of Dectin-1 or TLR2 activation and their involved signaling during neurodegeneration are not fully understood. To determine the features of activating these receptors in neuroinflammation and axonal degeneration, selective agonists of Dectin-1 or TLR2 (alone or in combination) were microinjected into the dorsal funiculus of spinal cord in female C57BL/6 mice (n=6/group, aged 8-12w). AMD3100 (CXCR4 chemokine receptor antagonist) was injected after surgery to reveal the roles of CXCL12/CXCR4 axis. Detailed pathological changes in axonal degeneration, glial response, M/M phenotype, and somatosensory evoked potential were analyzed and compared between groups. Selective Dectin-1 activation or combined activation results in a sharply demarcated lesion characterized by a dense core of activated M/M, evident axonal injury, and astroglial loss. Oligodendrocyte progenitor cells surround the M/M core, while mature oligodendrocytes disperse outside the epicenter. Selective TLR2 activation elicits abundant M/M scattering throughout the lesion with no axonal loss. The M/M pool is predominantly filled with cells labelled by CD45, Iba1, CXCR4, but not TMEM119, indicating its hematogenous origin. Significant up-regulation of CXCL12 in M/M suggests that CXCL12/CXCR4 signaling may be required for lesion evolution for both receptor agonists. CXCR4 antagonism alleviates M/M response, limits axonal degeneration, and alters the phenotype ratio of proinflammatory/immunoregulatory M/M ($iNOS^+/Arg1^+$) in selective Dectin-1 activation or combined activation, whereas those are exacerbated in selective TLR2 activation. These data indicate a functional dichotomy of Dectin-1 and TLR2 in M/M activation and neurodegeneration. CXCL12/CXCR4 axis plays major but diverse roles when different PRRs are activated, affecting the neuroinflammatory and neurodegenerative process. Receptor dependent effects should be considered in signaling study and regenerative strategy development that target on innate immune receptors like PRRs.

Title: B cell depletion reduces glial reactivity in an animal model of multiple sclerosis

Authors: ***J. AHN**, R. H. MILLER;
Anat. & Cell Biol., George Washington Univ., Washington, DC

Abstract: Multiple sclerosis (MS) is an autoimmune, demyelinating disease of the central nervous system (CNS), characterized by myelin damage, infiltration of peripheral immune cells and severe functional deficits. Antibody-mediated peripheral B cell depletion therapies have been shown to significantly reduce the volume of MS lesions and formation of new lesions, suggesting a pathogenic role for B cells in MS. However, long-term systemic B cell depletion can severely immunocompromise the patient, and a better understanding of how B cells contribute to neurological dysfunction in MS is needed. In the current study, we aim to define the pathogenic role of both peripheral and CNS infiltrating B cells in MS by spatial depletion of B cells. For peripheral B cell studies, we used a combination of anti-CD19 and anti-B220 to deplete peripheral B cells in mice induced with experimental autoimmune encephalomyelitis (EAE), an animal model for MS. For CNS B cell studies, we utilized an inducible caspase 9 (iCP9) mouse with a CD19 promoter to selectively ablate CNS infiltrating B cells in EAE mice. We report that peripheral B cell depletion reduced splenic and circulating B cells, and iCP9 activation in CNS CD19+ B cells selectively ablated CNS B cells with no effect on the peripheral B cell population. Elimination of peripheral B cells reduced Iba1+ microglial and GFAP+ astrocyte reactivity as shown by morphological changes and decreased expression of neurotoxic factors. Similarly, CNS specific B cells reduced glial reactivity, which was associated with reduced myelin and axonal damage and functional impairment compared to control EAE animals. To determine if EAE B cells directly contribute to increased CNS glial cell reactivity, B cells were isolated from EAE animals and co-cultured with spinal cord glial cells. Glial cells stimulated with EAE B cells showed increased astrocyte and microglia reactivity compared to cells co-cultured with healthy B cells. This was associated with oligodendrocyte death and disrupted myelin sheaths. Our data suggest that pathogenic B cells in EAE invade the CNS and contribute to glial reactivity and myelin damage and as such provide novel insight into the underlying mechanism of MS pathology.

Title: The role of proinflammatory cytokines in retinal ganglion cell death

Authors: *K. M. ANDERSH[1,2,3], O. J. MAROLA[1,4,3], R. T. LIBBY[1,5,3];
[1]Ophthalmology, [2]Neurosci. Grad. Program, [3]Ctr. for Visual Sci., [4]Cell Biol. of Dis. Program, [5]Biomed. Genet., Univ. of Rochester, Rochester, NY

Abstract: Glaucoma is a neurodegenerative disease that leads to the death of retinal ganglion cells (RGCs), the main output neurons of the retina, and is the second leading cause of blindness in the world. Therefore, identifying the molecular mechanisms underlying how glaucomatous injury leads to RGC death is crucial. Recent studies have supported a novel role for inflammatory extrinsic signaling as an early driver of glaucomatous neurodegeneration. Specifically, two cytokines have been implicated as potential early drivers of RGC death: interleukin 1 alpha (IL1A) and tumor necrosis factor (TNF). Intravitreal injection of TNF is sufficient to drive RGC death at a delayed rate, ~8 weeks post-injection. However, the potential contribution of IL1A in driving RGC death has not been assessed.
To assess whether these cytokines alone or in combination are sufficient to drive RGC loss, eyes of 2-5-month-old C57BL/6J male and female mice were intravitreally injected with 2 µL of IL1A alone (1 mg/mL), TNF (100 µg/mL), IL1A+TNF, or PBS. Combined injection of TNF and IL1A resulted in 20% RBPMS+ RGC loss 14 days post-injection (n=10, PBS vs IL1+TNF, $p<0.01$). Injection of TNF (n=9, PBS vs TNF, $p>0.05$) or IL1A alone (n=9, PBS vs IL1A, $p>0.05$) did not result in RGC loss at this early timepoint. Thus, IL1+TNF, but not IL1A or TNF alone, was sufficient to drive RGC loss 14 days post injection.
To determine the downstream signaling required for IL1+TNF-induced degeneration, mice with homozygous *Jun*^{fl} alleles that were conditionally recombined in retinal neurons and macroglia with Six3-cre and mice deficient in *Sarm1* were injected with IL1+TNF at 2-5 months of age. Six3-cre^{+} *Jun*$^{fl/fl}$ RGCs were not protected from IL1+TNF insult (n=6, PBS vs IL1+TNF, $p<0.05$). However, *Sarm1* deficient animals had no significant loss of RGCs 14 days post-IL1+TNF (n=3, PBS vs IL1+TNF, $p>0.05$).
In summary, combined intravitreal injection TNF and IL1A was sufficient to drive RGC loss 14 days after injury. Studies have shown that TNF is sufficient to kill 15-20% RGCs 8 weeks post-injection, but our findings show that combined application of TNF and IL1A acted in a rapid and synergistic manner to drive RGC death. Furthermore, we show that this death was SARM1

dependent and JUN independent, which is in contrast to their roles in RGC death after axonal injury.

Title: Sars-cov-2 spike glycoprotein mediated neuronal infection and dissemination through axonal transport in vivo

Authors: K. KEYS, X.-L. TIAN, X.-H. LU;
LSU Hlth. Shreveport, Shreveport, LA

Abstract: Given the increasing global spread of SARS-CoV-2, many questions remain regarding the clinical outcomes of COVID-19, including the possibility of the development of neurological disorders. Evidence of the severity and persistence neurologic manifestations of SARS-CoV-2 infection have been recognized, and is increasing. Virus infection has been speculated as the trigger of neurodegenerative diseases such as Parkinson's disease (PD). In order to provide causal evidence and to study the viral infectivity/cell-entry in CNS in vivo, we are developing a CRISPR/Cas mediated humanized transgenic mouse model with full-length human ACE2 regulatory regions to faithfully recapitulate structure, tissue distribution, and gene regulation of human ACE2. Furthermore, a recombinant pseudotyped vesicular stomatitis virus (rVSV) was developed in which the glycoprotein of VSV was replaced by the spike protein of the SARS-CoV-2, with a Red fluorescent Protein (RFP), mCherry to trace the routes of infection. The expression and presentation of the spike protein on the viral membrane and the antigenicity are similar to SARS-CoV-2. We observed striking neuronal cell invasion accompanied by neuroinflammation. We describe for the first time the presence along axons of viral particles, suggesting axonal transport to distant brain regions is a valid propagation strategy. The constant presence of the virus in the neurons and axons and the concomitant inflammation is destined to cause long-term or chronic sequelae related to the development or aggravation of chronic neurological diseases. Exploiting knowledge on neuroinvasion and dissemination of SARS-CoV-2 will shed light on underlying mechanisms of neuropathogenesis and uncover potential druggable molecular virus-host interfaces.

Schizophrenia is a psychiatric disease with a neurodegenerative course. There is evidence link mtDNA alterations and neurodegenerative diseases such as Alzheimer and Parkinson disease. We consider that mtDNA could be associated with the CNS biochemical and structural changes causing cognitive impairment in schizophrenia. The total sample consisted of 95 individuals (56 cases and 39 controls). Cases were grouped according to the severity of symptoms (PANSS) in mild, moderate and marked intensity. Also, the cases were regrouped according to MoCA scores in mild and severe deficits. Spearman correlations were made in order to assess the relationship between mtDNA concentration and MoCA scores (significant $p<0.05$. Circulating cell free mitochondrial DNA was identified in plasma of 39 cases with schizophrenia and 3 health subjects of the control group ($P <0.0001$). MoCA scores were significantly lower in cases

compared to the control group (15.5 vs. 26; P <0.0001). No association was found between mtDNA and cognitive deficit. This is the first study to analyze the association of plasma mtDNA with cognitive impairment of patients with schizophrenia in mexican population. Our findings suggest that circulating cell free mtDNA identified in plasma of individuals with schizophrenia is not related to cognitive deficits or any clinical characteristic. Longitudinal studies in larger samples are needed, in order to explore possible changes in mtDNA levels at the different stages of the illness.

Title: Mitochondrial oxidative stress is mitigated by ATP13A2-driven polyamine transport

Authors: *S. VRIJSEN[1], L. BESORA-CASALS[2], S. VAN VEEN[1], J. ZIELICH[2], C. VAN DEN HAUTE[1], N. N. HAMOUDA[1], C. FISCHER[2], B. GHESQUIÈRE[3], I. TOURNEV[4], P. AGOSTINIS[3], V. BAEKELANDT[1], J. EGGERMONT[1], E. LAMBIE[2], S. MARTIN[1], P. VANGHELUWE[1];

Abstract: Loss-of-function (LOF) mutations in *ATP13A2 (PARK9)* lead to a broad spectrum of neurodegenerative disorders. Functional ATP13A2 protects cells against environmental Parkinson's disease risk factors, such as the pesticide rotenone and heavy metals like zinc and manganese. Our group recently identified ATP13A2 as a primary active transporter present in the lysosomal membrane that transports the endocytosed polyamines spermine and spermidine from the lysosomal lumen to the cytosol, thereby preventing lysosomal polyamine accumulation and maintaining lysosomal health and integrity. Since polyamines are potent antioxidants, we here tested the hypothesis that polyamines transported by ATP13A2 may counter mitochondrial-generated reactive oxygen species (mitoROS) induced by rotenone. Indeed, rotenone induced a

steep increase in mitoROS in ATP13A2 deficient cells, whereas mitoROS levels were reduced in cells overexpressing wild-type ATP13A2, but not a transport dead mutant D508N. Interestingly, D508N ATP13A2 expressing cells also displayed lower mitochondrial polyamine levels. In ATP13A2 deficient cells, high mitoROS induced an ATF4-CHOP marked stress response and cell death, which could be reversed by the mitochondrial superoxide scavenger MitoTEMPO. Also heavy metal exposure and inhibition of polyamine synthesis with α-difluoromethylornithine (DFMO) resulted in increased mitoROS in ATP13A2-deficient cells, indicating that ATP13A2 mediated polyamine transport effectively counters oxidative stress. Importantly, we recapitulated key results in patient-derived fibroblasts with LOF mutations in *ATP13A2* and *in vivo*, in a *Caenorhabditis elegans* strain deficient in the ATP13A2-orthologue CATP-6. Our data on ATP13A2-mediated polyamine transport reveal a highly conserved cell protective pathway that lowers mitochondrial-derived oxidative stress representing a novel form of lysosomal/mitochondrial communication that may be impaired in neurodegenerative disorders.

Title: Environmental organochlorines disrupt dopamine homeostasis.

Authors: *B. CAGLE[1], M. STURGEON[2], R. CORNELL[2], D. ROMAN[1], H.-J. LEHMLER[3], J. DOORN[1];
[1]Pharmaceut. Sci. and Exptl. Therapeut., Univ. of Iowa Col. of Pharm., Iowa City, IA; [2]Anat. and Cell Biol., Univ. of Iowa Col. of Med., Iowa City, IA; [3]Univ. of Iowa Col. of Publ. Hlth., Iowa City, IA

Abstract: Background. Disruption of dopamine (DA) homeostasis is a proposed mechanistic link between environmental insults and disease. Environmental insults include dieldrin (DI), which is an organochlorine (OC) pesticide. Another class of OCs are polychlorinated biphenyls (PCBs). Both PCBs and DI persist in the environment posing a public health concern. Specifically, DI has been association with an increased risk of Parkinson's disease, while PCBs have been linked to neurodevelopmental conditions. These neurological conditions - both neurodevelopmental and neurodegenerative - are characterized by an imbalance of DA, including metabolism and trafficking. DA is metabolized to 3,4-dihydroxphenylacetaldehyde (DOPAL) by monoamine oxidase (MAO), producing reactive oxygen species. DOPAL is converted to 3,4-dihydroxyphenylacetic acid (DOPAC) by aldehyde dehydrogenase (ALDH). Recent in vitro and in vivo data implicate DOPAL, a biogenic aldehyde, as a toxic factor relevant to disease. This includes increased DOPAL:DOPAC ratios in PD patients revealing an imbalance in DA metabolism. Here, the purpose of this study was to characterize the mechanistic link between OCs and DA disruption. **Methods**. The toxicity of OCs was determined using a dopaminergic cell culture model. Additionally, both cellular and mitochondrial ROS was analyzed using MitoSox and CellRox staining. To study DA metabolism, N27 cells were stably transfected with the human dopamine transporter (hDAT), which allowed for rapid uptake of DA and turnover. **Results.** PCB-52, a major component of PCBs in indoor and outdoor air was studied along with its metabolite 4-OH PCB-52. The metabolite was more toxic and increased mitochondrial ROS more than the parent PCB compound. DI was also found to increase mitochondrial ROS at non-toxic concentrations in dopaminergic cells. Overexpression of hDAT in N27 cells was found to be an efficient model for studying DA metabolism and to assess changes to DA homeostasis in the presence of OCs. Future work will characterize potential changes in DA metabolism, identify protein targets of DOPAL and/or OC agents, and explore the role of glia in maintaining DA homeostasis.

Title: Activating transcription factor 4 regulates dopaminergic neuron death induced by parkinson's disease neurotoxins and alpha synuclein aggregates

Authors: *M. D. DEMMINGS, S. P. CREGAN;
Univ. of Western Ontario/ Robarts Res. Inst., London, ON, Canada

Abstract: Parkinson's Disease (PD) is a neurodegenerative disease characterized by the loss of dopaminergic neurons in the substantia nigra resulting in severe and progressive motor impairments. However, the mechanisms underlying this neuronal loss remain largely unknown. Oxidative stress and ER stress have been implicated in PD and these factors are known to activate the Integrated Stress Response (ISR). Activating Transcription Factor 4 (ATF4), a key mediator of the ISR, and has been reported to induce the expression of genes involved in cellular homeostasis. However, during prolonged activation ATF4 can also induce the expression of pro-death target genes. Therefore, in the present study we investigated the role of ATF4 in neuronal cell death in models of PD. We demonstrate that PD neurotoxins (MPP+ and 6-OHDA) and α-synuclein aggregation induced by pre-formed human alpha-synuclein fibrils (PFFs) cause sustained upregulation of ATF4 expression in mouse cortical and mesencephalic dopaminergic neurons. Furthermore, we demonstrate that PD neurotoxins induce the expression of the pro-apoptotic factors Chop, Trb3 and Puma in dopaminergic neurons in an ATF4-dependent manner. Importantly, we have determined that PD neurotoxin and α-synuclein PFF induced neuronal death is attenuated in ATF4-deficient dopaminergic neurons. Furthermore, ectopic expression of ATF4 but not transcriptionally defective ATF4ΔRK restores sensitivity of ATF4-deficient neurons to PD neurotoxins. Finally, we demonstrate that the eIF2α kinase inhibitor C16 suppresses MPP+ and 6-OHDA induced ATF4 activation and protects against PD neurotoxin induced dopaminergic neuronal death. Taken together these results indicate that ATF4 is a key regulator of dopaminergic cell death induced by PD neurotoxins and pathogenic α-synuclein aggregates and highlight the ISR factor ATF4 as a potential therapeutic target in PD.

Title: Investigation and rescue of SNARE-mediated macroautophagy inhibition in Parkinson's disease

Authors: ***C. PITCAIRN**, J. R. MAZZULLI;
Northwestern Univ., Chicago, IL

Abstract: Parkinson's disease (PD) is the second most common age-related neurodegenerative disease and is characterized pathologically by insoluble protein aggregates of alpha-synuclein (a-syn). Genetic studies have demonstrated that changes in the autophagic-lysosomal pathway (ALP) are a strong risk factor for developing PD, and this finding has been corroborated by biochemical studies showing a-syn is degraded by the ALP in health and disease. Investigation and facilitation of the endogenous ALP is thus one promising approach to developing disease-modifying therapies. While a-syn has been shown to inhibit macroautophagy (MA) - the ALP process by which bulk cytoplasmic aggregates are transported to lysosomes for degradation - molecular mechanisms explaining this inhibition remain undetermined.
Our previous findings indicate that a-syn may cause disruption of the ALP through binding to the

SNARE protein ykt6. This v-SNARE mediates vesicular trafficking, autophagosome formation, and autophagosome-lysosome fusion by facilitating membrane fusing events, and we found that ykt6 overexpression in cultured PD neurons partially rescues lysosomal activity. We therefore investigated the influence of ykt6 and pathogenic a-syn specific to MA in human cell lines and patient-derived midbrain neurons carrying familial triplication of the gene encoding a-syn. We found that wild type a-syn overexpression decreases autophagic flux but not baseline LC3 levels, suggesting a block of autophagosome-lysosome fusion. This inhibition is associated with decreased interaction between ykt6 and two of its autophagy-related SNARE binding partners: SNAP-25 and SNAP-29. Overexpression of a constitutively active ykt6 mutant and pharmacologic activation with a farnesyltransferase inhibitor were each sufficient to rescue autophagic flux in diseased cells. These data suggest that a-syn inhibits MA by reducing ykt6 participation in autophagosome-lysosome fusion SNARE complexes. Ykt6 activation can amplify both cargo delivery into lysosomes through MA and protein degradation. Because ALP dysregulation is a common feature of neurodegenerative diseases, these findings may contribute to disease-modifying therapies in PD and provide insights into the pathogenesis of proteinopathy more generally.

Title: Dysregulation of PLA2G6 activity induce degeneration in human dopaminergic neurons

Authors: *J. CALANDRIA[1], S. KALA-BHATTACHARJEE[2], S. BHATTACHARJEE[3], N. G. BAZAN[3];
[1]Neurosci. Ctr. of Excellence, LSU Hlth., New Orleans, LA; [2]Neurosci. Ctr. of Excellence, LSUHealth, New Orleans, LA; [3]Neurosci. Ctr., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Deleterious effects produced by the removal or failure to curb PLA2G6 activity from brain cells include neuroaxonal degeneration with iron accumulation, which is lethal during childhood and may induce Parkinsonian-like disease in adulthood (Guo et al, 2018. Front Neurol. 9: 1100). Recently, it was found that fibroblasts of idiopathic or sporadic PD patients showed impaired store-operated calcium entry (SOCE) (Zhou, et al 2016. Nature Communications volume 7, Article number: 10332). SOCE controls the activity of Calmodulin, a negative

regulator of PLA2G6, so the impairment of intracellular calcium flux suggests a role for PLA2G6 in the PD pathology. We determined that the silencing or overexpression of PLA2G6 induce a decreased content of DHA containing phospholipids concomitantly with a reduced amount of RvD5, a derivative of DHA, by Mass Spec. To determine the damage produced by the dysregulation of PLA2G6 in dopaminergic neurons, a culture of pluripotent cells in vitro differentiated into human dopaminergic neurons was exposed to Bromoenol lactone (BEL), an inhibitor of PLA2G6, and SKF96365, an inhibitor of the store-operated calcium entry (SOCE), in the presence or absence of lipid mediators derived from docosahexaenoic acid (DHA), eicosapentanoic acid (EPA), and arachidonic acid (AA). Immunocytochemistry targeting Tyrosine Hydroxylase (TH) and imaging analysis in IMARIS was used to determine the cell death and integrity of the surviving neurons. Maresin 1, RVD1, and RVD5, bioactive lipids derived from DHA, rescued the deficits in PLA2G6 activity induced by BEL. PLA2G6 is proposed to hydrolyze DHA to be converted into Maresin1, RVD1, and RVD5. LipoxinA4, a derivative of AA, and RVE1, a derivative of EPA, did not rescue PLA2G6 deficiency. Maresin 1 strongly reversed the neurodegeneration induced by SKF96365 and, to a lesser extent, RVD1. Future studies are required; however, these results suggest a role of PLA2G6 dysfunction in dopaminergic neurons and point to bioactive lipid messengers as candidate molecules to be used therapeutically to prevent or halt the neurodegeneration induced by PLA2G6 in PD.

Title: Mitochondrial Dysfunction Induces Epigenetic Dysregulation by H3K27 hyperacetylation to Perturb Active Enhancers in Parkinson's Disease Models

Authors: *M. HUANG[1], D. LOU[2], A. CHARLI[1], *D. KONG[2], H. JIN[1], V. ANANTHARAM[1], A. KANTHASAMY[1], Z. WANG[2], A. KANTHASAMY[1];

Abstract: Genetic mutations explain only 10-15% of cases of Parkinson's disease (PD), while an overriding environmental component has been implicated in the etiopathogenesis of PD. But

regardless of where the underlying triggers for the onset of familial and sporadic PD fall on the gene-environment axis, mitochondrial dysfunction emerges as a common mediator of dopaminergic neuronal degeneration. Herein, we employ a multidisciplinary approach to convincingly demonstrate that neurotoxicant exposure- and mitochondrial transcriptional factor A (TFAM) knockout-driven mitochondrial dysfunction share a common mechanism of epigenetic dysregulation. Under both scenarios, lysine 27 acetylation of likely variant H3.3 (H3.3K27ac) increased in dopaminergic neuronal models of PD, thereby opening that region to active enhancer activity via H3K27 hyperacetylation. These vulnerable epigenomic loci represent potential transcription factor motifs for PD pathogenesis. We further confirmed the mitochondrial dysfunction induced H3K27ac in *ex vivo* neurodegenerative models of PD. Our results reveal an exciting axis of 'exposure/mutation-mitochondrial dysfunction-metabolism-H3K27ac-transcriptome' for PD pathogenesis. Collectively, the novel mechanistic insights presented here links mitochondrial dysfunction to epigenetic transcriptional regulation in dopaminergic degeneration as well as offer potential new epigenetic intervention strategies for PD. **Support:** R01ES027245, R01ES026892, R01NS100090 and R01NS088206, Eugene and Linda Lloyd Endowment and Armbrust Endowment.

Abstract: C-terminal fragments of Tar DNA-binding protein 43(TDP-43) have been identified as the major pathological protein in several neurodegenerative diseases including amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). However, how they affect cellular toxicity and neurodegeneration remain largely unknown. Furthermore, how this process could be modulated is largely unknown. In this study, we found that C-terminal fragment of TDP43 (TDP25) mostly was localized to mitochondria and caused abnormal mitochondria morphology and parkin recruitment, leading to parkin-mediated mitophagy. We further found that knockdown of selective autophagy receptors such as Tax1BP1, Optineurin, or NDP52 accumulated TDP25, indicating that TDP25 is degraded by mitophagy. Very intriguingly, myosin IIB, a non-muscle-type of myosin as an actin-based motor protein, was mostly co-localized to TDP25 associated with abnormal mitochondria. In addition, inhibition of myosin IIB by siRNA or by blebbistatin accumulated insoluble TDP25, Tom20 in mitochondria, abnormal mitochondria and reduced neuronal cell viability. Taken together, our study suggests a novel role of myosin IIB on TDP25 mediated mitophagy. Therefore, our study proposes that regulation of myosin IIB activity might be a potential therapeutic target for neurodegenerative diseases associated with TDP-43 pathology.

Title: Lipid-mediated sequestration of motor-adaptor proteins impairs axonal lysosome delivery leading to autophagic stress and axonal dystrophy in Niemann-Pick disease type C neurons

Authors: ***J. C. RONEY**[1,2], T. FARFEL-BECKER[1], S. LI[1], T. SUN[1], N. HUANG[1], Y. XIE[1], M.-Y. LIN[1], F. M. PLATT[2], Z.-H. SHENG[1];

Abstract: Neurons face unique challenges in maintaining cellular homeostasis in axons far removed from the cell body where lysosomes are enriched. Niemann-Pick disease type C (NPC) is a neurodegenerative lysosomal storage disorder characterized by lipid accumulation in endolysosomes. An early pathologic hallmark of NPC is axonal dystrophy with bulbous swellings that contain accumulated organelles at presymptomatic stages prior to neuron loss in

NPC mice. However, the mechanisms underlying these axonal pathologic changes remain obscure. Here, we demonstrate that organelles of the endocytic and autophagic pathways accumulate in NPC dystrophic axons. Using STED super-resolution and live-neuron imaging, we reveal that elevated cholesterol on NPC lysosome membranes in the soma leads to sequestration of kinesin-1 and Arl8, resulting in impaired anterograde transport of mature degradative lysosomes to distal axons, contributing to axonal autophagosome accumulation. Pharmacologic reduction of lysosomal membrane cholesterol with 2-hydroxypropyl-β-cyclodextrin (HPCD) or elevated expression of Arl8b rescues lysosome transport into axons, thereby reducing axonal autophagic stress and neuron death in NPC. Collectively, these findings suggest a new pathological mechanism by which altered membrane lipid composition impairs lysosome delivery into axons of NPC neurons and provide biological insights into the translational application of HPCD in restoring axonal homeostasis at early stages of NPC disease.

Abstract: TBI is a major cause of death and disability worldwide. Evidence is also accumulating that TBI may be a risk factor for developing dementia. To study this problem, we used a small mammal with a gyrencephalic cortex, the ferret. The brains of these animals have substantial sulci and gyri as well as a large amount of white matter, compared to lissencephalic animals.Our initial findings using ferrets revealed that after a blast (shock wave) injury, ferrets expressed abnormal forms of tau and changes in the ratio of the 3R and 4R tau isoforms at 4 weeks post injury (WPI), which increased expression at 12 WPI. The telecephalon of these animals also showed substantial increases in astrocytic reactivity at grey-white matter interfaces, the subpial plate, surrounding blood vessels, and generalized in the white matter. Although many of these findings were observable at 4 WPI, they did not show statistically significant differences until 12

WPI. These outcomes suggest that ferrets represent a good model to study TBI as a potential link to dementia given the increase and persistence in expression of tau related markers. Our current experiments implement a brain injury model that includes a strong rotational injury (e.g. similar to whiplash) in addition to repetitive blast injury. This injury model results in significant increases in astrogliosis and 3R expression more quickly than observed after blast injury alone especially in the prefrontal cortex and hippocampus. Four weeks post injury, the increases in tau isoforms and astrocytosis significantly differed from sham using immunohistochemistry and western blot. Several neocortical areas were assessed including occipital, lateral temporal (including hippocampus) medial frontal, and prefrontal. The area most affected was the prefrontal cortex. We also observed that several, but not all, markers persisted their significant increase in expression until 6 months post injury. This was especially true for 3R, which remained increased in neocortical locations. We also observed several behavioral alterations at 4 WPI including changes in parameters measured with Open Field, Socialization, Eye Contact, and Actigraphy; activity patterns measured with Actigraphy are highly correlated with sleep. At 4 weeks and up to 4 months post injury, control ferrets showed activity patterns that were clustered into distinct bouts during a 24 hour period, while the injured animals displayed significantly altered sleep/activity patterns that were fractured and less focused.These findings confirm the ferret as an important animal model to investigate the consequences of TBI and potential links to dementia.

Title: Blast shockwaves from detonated explosives produce correlative indicators of dementia risk including tau pathology and NCAM breakdown products in hippocampus

Authors: *M. FERNANDES DE ALMEIDA[1], T. PIEHLER[2], M. C. PAIT[1], C. J. NORTON[1], M. H. GIANG[1], K. L. G. FARIZATTO[1], B. A. BAHR[1];
[1]Univ. of North Carolina at Pembroke, Pembroke, NC; [2]U.S. Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Blast-mediated shockwaves account for many of the hundreds of thousands of veterans from 21st century wars with brain injuries, due to both military and improvised explosives. Studies linking TBI to an increased risk of Alzheimer's disease (AD) are numerous, and Barnes et al. (*JAMA Neurol* 2018 75:1055) studied >350,000 veterans and found even mild

TBI was associated with 2.51-, 2.36-, and 3.05-fold increases in dementia risk (with, without, or unknown loss of consciousness, respectively). Using a unique brain explant protocol (Smith et al. 2016 *Exp Neurol* 286:107), our new report tested if blasts from military-grade explosives (RDX) produce AD-type changes in the hippocampus (Almeida et al. *Brain Path*, revision submitted). While blast intensities from 1.7-g spherical RDX did not cause cell death or neuromorphological alterations when directed at hippocampal explants, the detonations did in fact cause reductions in synaptic markers that are known to be down-regulated in cognitive disorders (e.g. synaptophysin, GluA1, synapsin IIb). Interestingly, synapsin IIa labeling remained unaltered, while neuropilar staining of synapsin IIb and neural cell adhesion molecule (NCAM) decreased, along with evident breakdown products of NCAM (NBDPs). Across explant groups, the extent of synaptic marker decline correlated with measures of AT8-positive tau levels, and the pre-tangle tau pathology was found among stochastic patterns of CA1 pyramidals. We further evaluated adhesion components due to their link to AD (Murray et al. 2016 *Neuroscience* 330:359). Compared to their respective levels in control explants, blast-induced reduction in NCAM180 was found ($p<0.001$), while NCAM140 ($p=0.0283$) and NCAM120 ($p=0.565$) exhibited smaller or no reductions. While RDX shockwaves reduced neuropilar NCAM180, mechanical stretching or flexing stress applied to the culture insert did not affect the NCAM isoform. Synaptic marker immunoreactivity levels after mechanical stress were 98.4 ± 11.8% of control explants. Our findings reveal that explosives produce distinct synaptopathy in a brain region involved in learning, emotional-laden memories, and social behavior, thus likely contributing to episodes of depression, anxiety, and attention problems. Given the prevalence of blast waves in wars, terrorist attacks, and training exercises, it is vital to understand the invisible actions of explosives. The identified indicators of blast-mediated synaptopathy will advance biomarkers and detection methods to improve diagnoses, treatment strategies, and therapeutic monitoring, in order to maintain cognitive health and manage the risk of developing dementia later in life.

Sci. and Engin., Univ. of Maine, Orono, ME

Abstract: Glaucoma is a leading cause of blindness characterized by death of retinal ganglion cells (RGCs). There is growing evidence that the endothelin (EDN) system is an important mediator of glaucomatous neurodegeneration. Our previous gene profiling studies in DBA/2J mice, a widely used mouse model of glaucoma, showed the EDN system is activated early in glaucoma, prior to RGC death, and components of the system are produced by multiple cell types. While the ligands EDN1 and EDN2 are expressed by microglia and macroglia (astrocytes and Müller glia), the receptors appear to be expressed by vascular mural cells (EDNRA) and neurons and macroglia (EDNRB). Injection of EDN ligands causes RGC death, and pharmacological inhibition of the EDN system delayed optic nerve damage in DBA/2J mice. We are now taking a genetic approach to dissect the cell-specific roles of the EDN system. First, we determined the apoptotic pathways controlling EDN-induced RGC death. The transcription factor JUN was shown to regulate RGC death after glaucoma-relevant injury. Here, we tested whether JUN mediates EDN-induced death. EDN1 or vehicle was injected into the vitreous of 7-24 week old male and female C57BL/6J mice, and mice with *Jun* deleted from retinal neurons and macroglia with Six3-cre. EDN1 caused caspase-3 activation in RGCs 5 days post-EDN1 ($n\geq5$, $p<0.001$) and 26% RGC loss after 28 days ($n\geq7$, $p<0.001$). *Jun* deletion prevented nearly all caspase-3 activation 5 days after EDN1 ($n\geq7$, $p<0.001$), and nearly all RGC loss after 28 days ($n\geq12$, $p=0.012$). Therefore, JUN activation was required for the majority of RGC death after EDN1 insult. Second, we investigated whether retinal neurons and macroglia cause EDN-induced RGC death via EDNRB. Interestingly, *Ednrb* deletion from retinal neurons and macroglia with Six3-cre did not prevent caspase-3 activation 5 days after EDN1 ($n\geq8$, $p=0.487$) nor did it attenuate RGC loss after 28 days ($n\geq6$, $p=0.850$). Therefore, neuronal and macroglial EDNRB was not necessary for EDN1-induced RGC death. We are now testing the hypothesis that EDN ligands mediate their effect through vascular cells. In support of this, EDN ligands act through vascular EDNRA to elicit potent vasoconstriction. EDN1 injection caused retinal arterial thinning ($n=6$, $p<0.001$), loss of retinal vascular perfusion, and RGC hypoxia. Therefore, EDN1 ligand could cause RGC death by eliciting vasoconstriction via vascular EDNRA. Studies are underway to conditionally ablate EDN ligands specifically from microglia and macroglia in DBA/2J mice to critically test the cell-specific roles of EDN ligands in glaucoma. Ultimately, we aim to determine the potential for targeting the EDN system to treat glaucoma.

Title: Brain Organoids: A novel tool to study oxidative stress-induced central nervous system damage using ionizing radiation

Authors: *F. OYEFESO[1], G. GOLDBERG[3], M. VAZQUEZ[2], A. BERTUCCI[2], X. MAO[1], A. MUOTRI[4], M. J. PECAUT[1];
[1]Div. of Biomed. Engin. Sci., [2]Dept. of Radiation Med., Loma Linda Univ., Loma Linda, CA; [3]Sanford Consortium for Regenerative Med., [4]UCSD, La Jolla, CA

Abstract: Oxidative stress (OS) and the associated increases in inflammatory markers are known to play major roles during neurodevelopment, aging, and progressive degenerative disease states including Alzheimer's disease, Parkinson's disease, and neurodevelopmental deficits. Among the many endogenous and exogenous sources of oxidative stress, ionizing radiation (IR) is well known to trigger OS by producing pro-oxidants such as reactive oxygen species (ROS) and other free radicals. Increased levels of ROS could overwhelm antioxidant defensesprotecting lipids, proteins, and DNA, from OS and cause lasting changes to cell and tissue physiology and morphology. Despite progress in understanding the roles of OS in central nervous system (CNS) pathophysiology, studies using 2D neural cell culture models have been limited for their translational impact. However, three-dimensional (3D) brain organoid cell culture systems have emerged as novel models to simulate the organization and cell diversity of human brain regions in vitro. This model could also be a novel alternative to study the effects of IR on normal neural tissue preserving the CNS' 3D cytoarchitecure and functional integrity. In this study, we aim to investigate OS-induced changes to brain organoid cytoarchitecture, cell state, and secreted factors induced by proton exposures. Proton radiation is part of the space radiation environment as well as a source of radiation totreat cancer. These studies will investigate the effects of low-doses of IR (<2 Gy) to characterize the acute responses of cortical brain organoids to IR. This research will first explore changes to cell morphology and expression of proliferation, apoptotic, and cell-type specific markers using immunofluorescence and confocal microscopy. Then, we will evaluatechanges to markers for lipid peroxidation and DNA damage. Results from this study will support the use of brain organoids as a translational tool to investigate OS-induced cellular and molecular changes potentially involved in progressive CNS neurodegenerative diseases as well as toxicity to the CNS.

Title: Oligodendrocyte differentiation from primary progressive multiple sclerosis patient hiPSCs show intrinsic differences contributing to disease pathology

Authors: *M. J. PLASTINI, H. L. DESU, M. SAPORTA, R. BRAMBILLA;
Univ. of Miami, Miami, FL

Abstract: Multiple sclerosis (MS) is the most common neurological disorder in young adults. Hallmarks of MS are CNS demyelination, inflammation and axonal damage, which lead to neurological impairments. Primary progressive MS (PPMS), the rarest form of the disease, is characterized by progressive and irreversible loss of neurological function with no periods of recovery and a far less pronounced immune-inflammatory response as the more common relapsing remitting MS (RRMS). Effective treatments for PPMS are lacking, likely due to an incomplete understanding of the pathophysiological processes underlying this disease form. Accumulating evidence suggests that intrinsic oligodendrocyte (OL) dysfunction may be responsible for, or at least contribute to, PPMS etiopathology. A recent single-nucleus RNA-seq study of OLs isolated from white matter lesions of PPMS patients revealed significantly reduced levels of multiple myelin-associated genes and upregulation of immune-specific genes (Jakel et al, 2019). This suggests that OLs in PPMS patients have intrinsic alterations compared to OLs from healthy individuals. On this basis, our hypothesis is that intrinsic dysfunction in OLs triggers OL cell death and demyelination, which leads to immune activation and PPMS initiation. To test this hypothesis we obtained human induced pluripotent stem cells (hiPSCs) from PPMS patients and matching controls and differentiated them into OLs to investigate intrinsic differences. We found that, following differentiation, the percentage of mature $O4^+$ OLs was significantly lower in PPMS patient lines compared to controls. RNA-seq analysis showed that the transcriptional profile of PPMS-derived $O4^+$ OLs was significantly different from that of control-derived $O4^+$ OLs, with upregulation of immune-related genes such as NLRP2, and downregulation of adhesion genes such as HEPACAM. Together, these data suggest that cells from PPMS patients may have a lower ability to form new OLs, possibly due to a switch toward a more inflammatory and less reparative phenotype.Pinpointing the intrinsic alterations in OLs of PPMS patients will uncover pathways and cellular processes that could be targeted for therapeutic purposes in this form of the disease for which treatments are limited.

Title: Neurotrophic factor-α1, a novel tropin is critical for the prevention of stressinduced hippocampal CA3 cell death and cognitive dysfunction in mice:comparison to BDNF

Authors: L. XIAO, *V. SHARMA, L. TOULABI, Y. XUYU, A. PELTEKIAN, I. ARNAOUTOVA, D. ABEDE, H. LOU, Y. LOH;
NICHD, NIH, Bethesda, MD

Abstract: Stress induces various pathophysiology in the brain such as impaired neuronal network and cognitive dysfunction that are associated with neurodegenerative diseases. Carboxypeptidase E (CPE), a proneuropeptide/prohormone processing enzyme, also named neurotrophic factor-α1(NFα1) is highly expressed in the stress-vulnerable hippocampal CA3 neurons which receive contacts from granule cell projections that release BDNF. Whether NF-α1-CPE and/or BDNF are critical in protecting these CA3 neurons against severe stress-induced cell death is not well known. Here we show that stress induced by maternal separation, ear tagging and tail snipping at weaning in 3-week-old NF-α1-CPE-KO mice led to complete hippocampal CA3 degeneration, despite having similar BDNF and active phosphorylated TrkB receptor levels in comparision with WT. Mice administered with TrkB inhibitor, ANA12 showed no degeneration of the CA3 neurons after the weaning. Transgenic knock-in mice expressing CPE-E342Q, an enzymatically inactive form, replacing NF-α1-CPE, showed no CA3 degeneration and exhibited normal learning and memory after the weaning stress, unlike NF-α1-CPE-KO mice. In addition, radiolabeled NF-α1-CPE bound HT22 hippocampal cells in a saturable manner and with high affinity (Kd=4.37nM). Furthemore, treatment with NF-α1-CPE or CPE-E342Q equivalently activated ERK and increased BCL2 expression to protect against H2O2- or glutamate-induced cytotoxicity in HT22 $^{cpe-/-}$ cells. Our findings suggest that NF-α1-CPE is more important compared to BDNF in protecting CA3 pyramidal neurons against stress-induced cell death and cognitive dysfunction, independent of its enzymatic activity.

Abstract: Myo/Nog cells are found at low frequencies in a variety of different tissues in adults and during embryogenesis. They can be identified by the expression of the skeletal muscle-specific transcription factor MyoD, the bone morphogenetic protein inhibitor Noggin, and via binding of a monoclonal antibody against BAI1. Myo/Nog cells are critical in ontogeny and for the development of the central nervous system. There is increasing evidence that Myo/Nog cells are neuroprotective in the neuronal retina. In this study, we examined Myo/Nog cell response to neuronal cell death in the rat neocortex 24 hours following a needlestick injury. Additionally, we studied the effects of adding or depleting Myo/Nog cells at the site of the needlestick lesion. Exogenous Myo/Nog cells promoted neuronal survival and suppressed apoptosis at the site of injury. We found that the addition of exogenous Myo/Nog cells to the lesion reduced the number of apoptotic cells around the injury site (ANOVA: F = 22.948, R2 = 61.09%, p = 6.695 x 10-14). Additionally, the death of mature neurons caused by the injury was ameliorated by the exogenous addition of Myo/Nog cells (ANOVA: F=34.825, R2=69.92%, p=2.395X10-18). Additional studies are needed to both understand the precise molecular mechanisms of neuroprotection these cells employ and to determine if exogenous Myo/Nog cells can be adapted as a form of therapy for neuronal injuries.

Title: Comparing the Antiseizure and Neuroprotective Efficacy Midazolam and LY293558-Caramiphen Combination Against Soman in a Rat Model Relevant to the Pediatric Population

Authors: J. P. APLAND[1], *M. D. FURTADO[2], V. ARONIADOU-ANDERJASKA[3], T. FIGUEIREDO[2], V. PIDOPLICHKO[2], K. ROSSETTI[2], M. BRAGA[2,3];
[1]Neurosci. Br., USAMRICD, Aberdeen Proving Ground, MD; [2]Anatomy, Physiol. and Genet., [3]Psychiatry, Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD

Abstract: The currently FDA-approved anticonvulsant for the treatment of status epilepticus (SE) induced by nerve agents is the benzodiazepine midazolam. However, midazolam does not appear to offer neuroprotective benefits. This is particularly concerning with respect to the protection of children, because in the developing brain, synaptic transmission mediated via GABAA receptors, the target of midazolam, is still weak. In the present study, we exposed 12-day-old male and female rats to 1.2xLD50 soman, and compared the antiseizure, anti-lethality, and neuroprotective efficacy of midazolam (3 mg/kg) and the combination of LY293558 (an AMPA/GluK1 receptor antagonist; 10 mg/kg) and caramiphen (an antimuscarinic with NMDA receptor-antagonistic properties; 50 mg/kg) administered 1 h post-exposure. Despite that there was no statistically significant difference between the two treatment groups in the time it took for the anticonvulsants to stop initial seizures or survival rate, the latency for re-occurrence of seizures after cessation of the initial SE was dramatically longer in the rats treated with LY293558+CRM, and the total duration of SE was significantly shorter in this group ($p<0.001$; t-test). The difference between the two treatment groups in the total duration of SE was accompanied by differences in neuropathology. Total neuronal loss and loss of interneurons in the CA1 hippocampal area and the basolateral amygdala (BLA) were significant in the MDZ-treated group in comparisons with control non-exposed rats and with the LY293558+CRM-treated rats, at 1, 3 and 6 months post-exposure. There is an apparent deterioration over time, and at the 6-month time point, there is also some neuronal and interneuronal loss in the BLA of the LY293558+CRM treated group. Hippocampal volume was significantly reduced in the MDZ-treated rats but not in the LY293558+CRM-treated rats, at 3 and 6 months post-exposure. Spontaneous, background inhibitory activity was significantly reduced in the MDZ-treated group but not in the LY293558+CRM group, at all three time points (1, 3 and 6 months post-exposure), and this was accompanied by increased anxiety only in the MDZ-treated group, as determined by the Open Field and the ASR tests. The appearance/incidence of spontaneous recurrent seizures was greater in the MDZ-treated group, and the difference from the LY293558+CRM group reached statistical significance at the 6-month time point. The combined administration of

LY293558 and caramiphen, by blocking mainly AMPA, GluK1, and NMDA receptors, is a very effective anticonvulsant and neuroprotective therapy against soman in immature rats.

Title: Triterpenoid saponin attenuates mortality associated with AQP4 and astrogliosis in Plasmodium yoelli infection in mice

Authors: *P. SANGUANWONG[1], E. M. OO[1], C. TURBPAIBOON[1], P. UAWITHYA[2], S. CHOMPOOPONG[1];
[1]Anat., [2]Physiol., Fac. of Med. Siriraj Hospital, Mahidol Univ., Bangkok, Thailand

Abstract: The anti-inflammatory effect of Astragaloside IV triterpene saponin (TS) has been previously reported in many studies but not in *Plasmodium yoelli* 17XL (*Py*) infection. This study aimed to study the effect of TS on the attenuation of the BBB damages in *Py* infected mice after combined treatment with the standard antimalarial drug, Artesunate (ART). At day 3 post-infection, *Py* mice have received TS for 5 days with 25 mg/kg of TS. ART 2.4 mg/kg was used as a standard antiparasitic drug which also given from day 3 until day 7 post-infection. Survival time, percent parasitemia, and anemia conditions were daily determined. On day 7, leakage of BBB was investigated by Evans blue extravasation assay. Meanwhile, serum and the brain were collected to determine the inflammatory cytokine proteins by Enzyme-linked immunosorbent (ELISA) assay. The changes in AQP4 and reactive astrogliosis-associated GFAP expression were determined by immune-peroxidase staining. The neurological symptoms were daily assigned by the Rapid murine coma and behavior scale (RMCBS) assignment. The result is that TS was not shown non-antiparasitic activity. However, TS was extended survival rate and time both single and co-treatment. Interestingly, TNF-alpha, IL-1beta, and IL-10 were significantly decreased when compared to the Py-ART group in both serum and brain tissue. Importantly, the TS+ART group was significantly shown more integrity than Py and Py-ART group. The AQP4 and GFAP expression were significantly reduced in TS+ART. Neurological symptoms of the TS+ART group significantly decreased when compared to the Py and Py-ART groups. In conclusion, co-treatment of TS with the antimalarial drugs could improve the survival time of mice. Moreover, it could attenuate systemic inflammation-associated BBB disruption in Py-infected mice via reduced critical pro-inflammatory cytokines followed to maintain BBB

integrity, resulting in suppressed dysregulation of astrocytes BBB. It worth mention that TS could be used as a promising novel adjunctive therapy for severe malaria pathology or neuroinflammatory situation.

Title: An Essential Oil Blend Modulates Neuronal Health Responses after Chemical Stress

Authors: *R. PRICE[1], N. STEVENS[2], C. BASCOUL[2], B. RIGGS[2], R. OSGUTHORPE[2], A. ESSEX[1];
[1]Phenovista Biosci., San Diego, CA; [2]doTERRA, Pleasant Grove, UT

Abstract: Despite growing scientific evidence that essential oils possess important therapeutic benefits, research on their biological activities in complex human disease models is scarce. To enhance understanding in this regard, we analyzed the biological activities of an essential oil blend (EOB) in human iPSC-derived dopamine neurons. PhenoVista has established a range of high-content imaging assays for neuronal health, including neuronal viability, mitochondrial function, and neurite outgrowth. Briefly, iPSC-derived neurons are plated and cultured for 3 days, a neuroprotectant is added for 24 h, stressors for 24 h, and then cells are fixed, stained using Hoechst (nuclei), Tuj-1 (neurites), MitoTracker (mitochondrial function) and DRAQ7 (dead cell marker) for subsequent imaging and analysis. These models allow for measurement of changes in neuronal features impacted by stressors (here we used FCCP, a mitochondrial toxin, as well as tunicamycin and brefeldin-A) as well as improvements induced by EOB treatment. This EOB is primarily composed of essential oils and extracts from turmeric. As expected, the stresses impacted neuronal health in most measures, particularly viability levels and mitochondrial function. Interestingly, the EOB significantly reversed many (but not all) of these deficits. In conclusion, this turmeric EOB may potentially impact the overall health of human iPSC-derived neurons in response to environmental stress.

Title: Protective effect of cobra venom NOX & hypothalamic peptide PRP on electrophysiological & behavioral characteristics of rats after the unilateral Labyrinthectomy

Authors: *N. BEHNAM DEHKORDI, V. H. SARKISIAN, L. V. DARBINYAN, L. E. HAMBARTSUMYAN, L. P. MANUKYAN, E. A. AVETISYAN, N. V. SARKISIAN; Natl. Acad. of Sci. Republic of Armenia, Yerevan, Armenia

Abstract: Protective effect of cobra venom *NOX* and hypothalamic peptide *PRP* on electrophysiological and behavioral characteristics of rats after the unilateral labyrinthectomy

Neda Behnam Dehkordi. Sarkisian V.H., Darbinyan L.V., Hambartsumyan L.E., Manukyan L.P. Avetisyan E.A, Sarkisian N.V. *L.Orbeli Institute of Physiology, NAS of Armenia, Yerevan*

ABSTRACT **Objectives:** Research is devoted to the study of systemic compensatory reactions

of the rat's brain developing in response to unilateral labyrinthectomy (UL) under the conditions of pharmacological intervention of PRP (Hypothalamic Proline-Rich Peptide) and NOX (Cobra Venom Naja Naja Oxiana).
Methods: The studies were carried out on 26 outbred white male rats weighting 250 ± 30 g. In order to study the dynamics of neurodegenerative changes in the hypothalamo-vestibular projections in UL conditions a comparative analysis of changes in the frequency of the of impulse activity stream of the lateral vestibular nucleus (LVN) deafferented neurons in response to high-frequency stimulation of paraventricular (PVN) and supraoptical (SON) hypothalamic nuclei was carried out. Changes in the behavior of rats in the "open field" caused by unilateral labyrinthectomy were also evaluated followed by administration of PRP and NOX.**Results:** 4, 9, and 17 days after UL, in the dynamics of neurodegenerative changes, high-frequency stimulation of PVN and SON leads to an increase in the imbalance of inhibitory (TD) and excitatory (TP) tetanic and post-tetanic potentiations (PTP, PTD) of Deiters nucleus neurons, the ratios of which after PRP injection remain almost at the same level as compared with the norm. On the damaged side, on day 4 after UL, TD and PTD prevail, and on day 9, reactions characterized by TD and TP proportional correlation and corresponding to the norm intensity. Vestibular disturbances in rats in an "open field" after UL are manifested primarily in changes in the indicators of vertical activity of the operated animals - the number and duration of rearing without support on the board of the installation decreases most significantly.**Conclusion:** In general the results obtained allow considering inhibitory processes mediated by GABA, as a protective effect of NOX and PRP against neurodegeneration.

Title: B-funaltrexamine inhibits lipopolysaccharide-induced chemokine expression and sickness behavior in mice.

Authors: *S. MYERS, D. BUCK, K. MCCRACKEN, J. T. CURTIS, R. L. DAVIS;
Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Neurological conditions including, infection, neurodegeneration, and psychiatric disorders involve neuroinflammation. Yet, most of the medications used to treat these disorders are not considered potently anti-inflammatory. We previously discovered that beta-funaltrexamine (β-FNA), a selective mu-opioid receptor (MOR) antagonist, inhibits inflammatory signaling *in vitro* in human astroglial cells. Notably, the mechanism of action does not seem to involve actions at the MOR. We also determined that β-FNA inhibited bacterial lipopolysaccharide (LPS)-induced sickness behavior and neuroinflammation in mice. In these initial *in vivo* experiments, mice were administered β-FNA, immediately followed by LPS administration, then assessed 24 h later. In the present study, we examined the extent to which β-FNA is protective when treatment occurs several hours after LPS administration. Also, we investigated the protective effects at an earlier time point (8 h) after LPS administration, when sickness behavior is more pronounced. Lastly, previous *in vitro* findings indicated that naltrexone (a non-selective opioid receptor antagonist from which β-FNA is derived) does not inhibit inflammatory signaling in astrocytes, thus we questioned if it would also be ineffective *in vivo*. In the current study, male C57BL/6J mice were administered LPS (0.83 mg/kg, i.p.) followed by treatment with β-FNA (50 mg/kg, i.p.) at 4 and/or 10 h post-LPS, depending on the experiment. At 8 or 24 h post-LPS, sickness behavior was assessed using a 10-min open-field test, followed by termination and collection of plasma and brain. Levels of inflammatory chemokines (interferon γ-induced protein, CXCL10; and monocyte chemotactic protein 1, CCL2) in tissues were measured using an enzyme-linked immunosorbant assay. β-FNA treatment 4 or 10 h after LPS administration inhibited CCL2 levels in plasma and brain (but did not significantly affect CXCL10 levels), and it failed to reduce sickness behavior. Conversely, β-FNA treatment within minutes of LPS treatment resulted in attenuation of both sickness behavior and chemokine expression. Delayed β-FNA treatment was not protective against LPS-induced behavioral deficits or inflammation 8 h post-LPS. Interestingly, naltrexone did not significantly reduce LPS-induced CCL2 and CXCL10 levels or sickness behavior. These results suggest that the timing of β-FNA treatment is critical for neuroprotection, and support earlier findings that the protective effects of β-FNA likely involve mechanisms beyond actions at MOR. However, further examination of the anti-inflammatory and neuroprotective effects of β-FNA is necessary.

Title: Transcriptional regulation of iNOS mediated by a novel long non-coding RNA in microglia

Authors: *N. W. MATHY, A. SHIBATA;
Creighton Univ., Omaha, NE

Abstract: Upon activation by inflammatory stimuli, microglia can produce a profoundly neurotoxic inflammatory response. Increased understanding of the regulatory factors controlling microglial activation may be critical to modulating inflammation in the CNS. Long non-coding RNAs (lncRNAs) are transcripts which lack protein coding potential, but have been shown to regulate gene expression via interactions with RNA-binding proteins, such as transcription factors.

Our previous work has shown that one lncRNA, referred to as lncRNA-25B, is highly induced in murine microglia in response LPS, TNF-α, and Ifn-γ. Knockdown of lncRNA-25B prior to LPS stimulation resulted in a significant decrease in the expression iNOS when compared to scrambled siRNA. Conversely, overexpression of lncRNA-25B prior to stimulation resulted in a significant increase in iNOS when compared to an empty vector control. This informed our hypothesis that lncRNA-25B is involved in the transcriptional regulation of iNOS.

We probed for an interaction between lncRNA-25B and NF-κB p65 by using RNA immunoprecipitation, as iNOS is an NF-κB target gene. Results showed that in a basal state, there was no significant enrichment of lncRNA-25B and NF-κB p65 when compared to control IgG. However, after LPS stimulation, there was a significant increase in the interaction between NF-κB p65 and lncRNA-25B compared to control IgG (11.2 fold). There was no significant enrichment in any condition using Actin as a control gene.

To test whether lncRNA-25B enhances NF-κB p65 binding to the promoter region of iNOS, chromatin immunoprecipitation was used. Microglia were transfected with either a scrambled control siRNA, or an siRNA to knockdown lncRNA-25B prior to stimulation with LPS. Knockdown of lncRNA-25B significantly reduced the enrichment of NF-κB p65 to the iNOS promoter at two distinct sites (53.7 fold and 2.8 fold) when compared to the scrambled siRNA control. No significant differences were present in the Actin control gene.

Further evidence revealing the binding of lncRNA-25B to the iNOS promoter region was demonstrated by chromatin isolation by RNA purification. Probes to lncRNA-25B were split into two pools, odd and even, while probes to LacZ were used as a negative control. Both odd and even probe pools revealed significant interaction between lncRNA-25B and two specific sites on the iNOS promoter after LPS stimulation when compared to unstimulated microglia. Taken together, these results suggest lncRNA-25B is involved in the transcriptional regulation of iNOS via NF-κB p65 in microglia in response to LPS stimulation. Future directions will investigate the role of lncRNA-25B *in vivo*.

Title: The emerging role of microglia in AQP4-IgG positive neuromyelitis optica

Authors: *T. CHEN, V. LENNON, L. WU;
Mayo Clin., Rochester, MN

Abstract: The emerging role of microglia in AQP4-IgG positive neuromyelitis optica Tingjun Chen,[1] Vanda A. Lennon,[1,2,3] and Long-Jun Wu[1,2,41]Department of Neurology, [2]Department of Immunology, and [3]Department of Laboratory Medicine/Pathology, Mayo Clinic, Rochester, Minnesota, USA.[4]Department of Neuroscience, Mayo Clinic, Jacksonville, Florida, USA.Neuromyelitis optica (NMO) is an autoantibody-triggered neuroinflammatory disease which preferentiallyattacks the spinal cord and optic nerve. Its defining autoantibody is specific for the water channel, proteinaquaporin-4 (AQP4), which primarily localized at astrocytic end-feet. Histopathology studies of NMOlesions demonstrated complement deposition and microglia activation in AQP4 lost area. Complementdependent cytotoxicity in NMO was well studied in previous researches. However, how microglia activityinvolved in NMO pathogenesis still remained unknown. We investigated early events in the evolvingpathophysiology of NMO in mice by continuously infusing IgG (NMO patient serum-derived or AQP4-specific mouse monoclonal), without exogenous complement, into the spinal subarachnoid space. Motorimpairment and sublytic NMO-compatible immunopathology were IgG dose dependent, AQP4 dependent,and, unexpectedly, microglia dependent. Astrocytes lost AQP4 but remained viable and upregulatedcomplement C3. In vivo spinal cord imaging revealed a striking physical interaction between microgliaand astrocytes, which is mediated by astrocytic C3 and microglial C3a receptor signaling. Moreover,activated microglia released complement C1q, indicating microglia activity induced early-activated CNS-intrinsic complement components and evolving NMO lesioned neuronal dysfunction. Our results indicatethat microglia merit consideration as a potential target for NMO therapeutic intervention.

Title: Inflammation exacerbates reduced uterine perfusion pressure-induced spinal cord inflammation and hyperalgesia in rat dams

Authors: *L.-W. FAN[1], H. J. LEE[3], J. CHUNG[3], L.-T. TIEN[4], J. W. LEE[1], N. DANKHARA[1], M. H. LEE[1], E. CHEN[1], X. DAI[2], M. A. TUCCI[2], Y. PANG[1], A. J. BHATT[1], N. B. OJEDA[1]; [1]Pediatrics/Newborn Med., [2]Anesthesiol., Univ. of Mississippi Med. Ctr., Jackson, MS; [3]AXONIS Therapeut. Inc., Cambridge, MA; [4]Sch. of Med., Fu Jen Catholic Univ., Xinzhuang Dist, New Taipei City, Taiwan

Abstract: Emerging epidemiological and experimental studies suggest that systemic inflammation induced by preeclampsia during pregnancy may affect CNS functions including pain signal processing. Our previous studies in rats with reduced uterine perfusion pressure (RUPP) demonstrated that systemic inflammation during pregnancy induced CNS inflammation of rat dams, which has shown to increase pain sensitivity in other pathological conditions. This study was designed to further examine whether maternal inflammation via lipopolysaccharide (LPS) exposure enhances pain sensitivity associated with RUPP in dams. LPS (100 μg/kg) was administered intraperitoneally into pregnant rats on day 13 of gestation (G13) and RUPP surgery was performed on G14. Four groups of 8 dams per group were included in the following treatments: Saline+Sham, Saline+RUPP, LPS+Sham, and LPS+RUPP. The dams were subjected to tail flick testing via thermal stimuli and von Frey filament testing via mechanical stimuli in a double-blind manner. Spinal inflammation and unmyelinated c-fiber projections were examined on day 21 after delivery. To ensure scientific rigor the molecular assays and histological assessment were evaluated by triplicate, and the sample sizes were calculated to reach a statistical power of at least 0.85 for a $P<0.05$. All animals were from the same strain and same vendor. Data were analyzed by two-way ANOVA followed by the Student-Newman-Keuls test. All induced inflammation groups (Saline+RUPP, LPS+Sham, and LPS+RUPP) showed significant increases in thermal sensitivity across postnatal days but only the LPS+RUPP group showed significantly increased sensitivity to mechanical stimuli across postnatal days. Additional LPS exposure enhanced the RUPP-induced microglia and astrocyte activation and unmyelinated c-fiber projections in the lumbar spinal cords of dams on day 21 after delivery. Collectively, LPS-induced systemic inflammation during pregnancy exacerbates RUPP-induced nociceptive afferent plasticity which alters spinal pain signal processing contributing to the development of nociceptive hypersensitivity in rat dams.

Abstract: Microglia are the resident myeloid cells of the Central Nervous System (CNS). In addition to their role in CNS immunity, microglia participate in synapse development and plasticity and provide trophic support for brain cells. Their dynamic nature allows them to execute a variety of tasks under normal and pathological conditions. Gangliosides are sialic acid-containing glycosphingolipids enriched in the CNS. Their location in the outer leaflet of the plasma membrane positions them as mediators of cell-to-cell communication and, as a component of lipid rafts, they play important roles in cell signaling. The deletion of specific ganglioside biosynthetic enzymes in mouse leads to neurodegeneration as well as microgliosis and up-regulation of pro-inflammatory cytokines. On the other hand, the administration of exogenous gangliosides, GM1 in particular, results in neuroprotection in various models of neuronal injury and neurodegeneration. However, little is known about the function/s of gangliosides in microglia. Furthermore, it is unclear whether at least some of the neuroprotective effects of GM1 might be mediated by a direct effect on microglia and neuroinflammation. The goal of this study is to shed light on the role of gangliosides in microglia physiology and pathophysiology. We measured the effects of GM1 administration on the response of BV2 cells as well as mouse, rat and human primary microglia to inflammatory stimuli (LPS, IL-1beta and phagocytosis of latex beads). Exogenous administration of GM1 dramatically decreased inflammatory microglia responses, even when administered after microglia activation. The anti-inflammatory action of GM1 was confirmed *in vivo*, via intraperitoneal administration of LPS followed by intracerebroventricular administration of GM1 in mice. These anti-inflammatory effects were partially reproduced *in vitro* by increasing endogenous ganglioside levels with L-t-PDMP. On the contrary, inhibition of ganglioside synthesis with GENZ-123346 exacerbated microglial activation in response to LPS stimulation. Exogenous GM1, but not L-t-PDMP, also increased microglial phagocytic activity and chemotaxis, two important microglia functions in health and disease conditions, while inhibition of ganglioside synthesis decreased both. In summary, our data suggest that gangliosides are important modulators of microglia functions that are crucial for healthy brain homeostasis. Furthermore, we also demonstrated that the administration of ganglioside GM1 exerts an important anti-inflammatory activity and other beneficial effects on microglia that could open new avenues for therapeutical interventions.

Abstract: [Background] Acrylamide (ACR), is an environmental electrophile widely used in the production of polymers and gels and recently also reported to be formed when carbohydrate-rich foods are cooked at high temperature. Neurotoxicity of ACR has been reported in humans and experimental animals, while the underlying mechanism remains obscure. Our previous studies demonstrated that exposure to environmental electrophiles such as 1-bromopropane or acrylamide (ACR) causes degeneration of noradrenergic axons. In this study, 1C11 mouse neuroectodermal stem cell line and BV2 microglia cell line were used to investigate the mechanisms of ACR-induced degeneration of monoaminergic neurons. [Methods] 1C11 stem cells were differentiated into noradrenergic neural cells $1C11^{NE}$ or serotonergic neural cells $1C11^{5\text{-}HT}$ neural cells, and then exposed to ACR or to conditioned medium from ACR-treated BV2 microglial cells. Cell viability and loss of plasma membrane integrity were determined using MTS assay and LDH assay respectively, to evaluate the cytotoxicity of ACR exposure on $1C11^{NE}$ and $1C11^{5\text{-}HT}$ cells. Changes in neurite length of noradrenergic or serotonergic neurons were examined by optical microscope and quantified by NIH Image J. Transcriptomic RNA-seq analysis were performed to indentify differential expressed genes in $1C11^{NE}$ after exposure to ACR or conditioned medium from BV2. [Results] Results of MTS and LDH cell viability/cytotoxicity assay showed that exposure to ACR at lower than 1 mM didn't decrease $1C11^{NE}$ or $1C11^{5\text{-}HT}$ cell viability or increase LDH release, suggesting no induction of cell death in neural cells. Quantification results of neurite length showed that treatment with ACR at 1 mM did not decrease the neurite length of $1C11^{NE}$, but treatment with supernatant from BV2 microglial cells exposed to ACR at 1 mM significantly decreased neurite length of $1C11^{NE}$ or $1C11^{5\text{-}HT}$. The addition of 1mM ACR into supernatant of BV2 culture medium also significantly decreased the neurite length of $1C11^{NE}$ or $1C11^{5\text{-}HT}$. Moreover, transcriptomic RNA-seq analysis identified 2544 differential expressed genes in $1C11^{NE}$ after exposure to ACR or conditioned medium from BV2. In conclusion, the above results suggest that microglia play a critical role in ACR-induced retraction of monoaminergic neurons. Further analysis of RNA-seq data is ongoing to investigate changes of gene expression profile.

Title: Status-dependent differences in acute stress-induced neuroinflammation in the hamster vmPFC

Authors: ***R. M. RODRIGUEZ**[1], J. A. GRIZZELL[2], T. T. CLARITY[3], M. S. JENKINS[3], M. A. COOPER[3];
[1]Psychology, Univ. of Tennessee Knoxville, Knoxville, TN; [2]Univ. of Colorado Boulder, Boulder, CO; [3]Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: 90% of humans experience traumatic stress, however, only 10% develop psychopathologies like PTSD. Social status influences stress reactivity such that social dominance can promote stress resilience, representing an environmental factor that buffers individuals from maladaptive responses to stress. The negative consequences of severe and chronic stress include neuroinflammation, which is associated with neuronal degeneration and oxidative stress. We use a Syrian Hamster model of social defeat to investigate status-dependent differences in susceptibility and resiliency to acute social stress. We hypothesized that neuroinflammation mediates susceptibility in the status dependent pairs such that dominants show an increased protective neuroinflammatory response compared to subordinates, from a social defeat stressor. We paired hamsters for 14 days in daily 5-minute social encounters to allow them to form a social hierarchy with one another. After dominance relationships were established, the animals were socially defeated in a resident intruder model. Twenty-four hours later, the animals were tested for stress-related behavior using a conditioned defeat test and social interaction test. Brains were collected and analyzed for markers of neuro -inflammation and -degeneration in the ventral medial prefrontal cortex. Overall, we found that dominants were more resistant to stress-induced changes in neuroinflammation compared to subordinates. Dominant hamsters demonstrated a protection against morphological changes in neuroinflammatory markers that are indicative of a negative phagocytic response in the infralimbic cortex. While dominants did show increased markers of synaptic degeneration similar to subordinates, they showed protection from overall cellular degeneration in the vmPFC. This result, especially when compared with previous studies, suggests that synaptophysin may not be good marker for status dependent synaptic degradation (Thome et al., 2001; Grizzell et al., 2014a,b). After CD testing, we found that there was a significant increase in submissive like behavior among subordinates in comparison to dominants which suggests that the neuroinflammatory markers correspond to the alteration in social avoidance behavior. However,

the results from SIT testing were inconclusive and may suggest that it may be an inappropriate test for anxiety like behaviors in male Syrian hamsters, barring the implementation of social vigilance and or a larger scoring arena. Altogether, this study provides a neurobiological basis for the development of novel pharmacological interventions used to treat traumatic stress exposure.

Title: Bryostatin-1 inhibits CNS inflammation through modulation of the innate immune system

Authors: *E. ABRAMSON[1], M. SMITH[1], S. HWANG[1], P. A. CALABRESI[1], S. H. SNYDER[2], P. KIM[3], M. KORNBERG[1];
[1]Neurol., [2]Neurosci., [3]Psychiatry, Johns Hopkins Univ. Sch. Med., Baltimore, MD

Abstract: Multiple sclerosis (MS) is a neurodegenerative disease characterized by chronic inflammation and remyelination failure. Current therapies have anti-inflammatory effects on the peripheral immune system, aimed at alleviating the relapsing-remitting stage, but fail to target the compartmentalized innate immune-mediated inflammation seen during the progressive phase of disease. A growing body of evidence suggests that the phenotype of innate immune cells such as microglia/macrophages dictates the success or failure of remyelination and modulates neurodegeneration. We previously found that bryostatin-1 (bryo), a CNS-penetrant PKC modulator, has immunomodulatory properties that are most prominent in myeloid-lineage cells. We hypothesized that bryo acts directly on CNS macrophages/microglia to inhibit neurotoxic phenotypes and promote functions associated with remyelination and repair. Mixed glial cultures (MGC) derived from neonatal C57BL/6 mice were treated with vehicle or bryo (50 or 200 nM) +/- LPS (100 ng/ml), IFNγ (20ng/mL), or IL4 (20 ng/mL). Expression of iNOS (inflammatory) and Arg-1 (anti-inflammatory) were assessed by immunoblot and verified through immunofluorescence, and transcriptional profiling was performed with RNAseq. To evaluate the impact of bryo on innate immune phenotypes in vivo, we induced MOG_{35-55}/CFA experimental autoimmune encephalomyelitis (EAE) in 8-week-old female C57BL/6 mice and began treatment with vehicle or bryo (30 μg/kg) by daily intraperitoneal injection beginning on post-immunization day (PID) 28. This time-point corresponds to late-stage disease, when peripheral inflammation has subsided, but innate immune activation persists in the CNS. Flow cytometry was performed from the CNS at PID 42, and CD206 expression was assessed on CNS-resident

macrophages/microglia. In MGC, bryo prevented iNOS expression induced by LPS and dramatically potentiated Arg-1 expression in the presence of IL-4, at a dose as low as 1 nM. RNA sequencing demonstrated that bryo upregulated genes associated with repair and anti-inflammatory pathways. Following LPS/LPS-IFNγ treatment, bryo decreased expression of A1 reactive astrocyte markers like C3 and Gbp2 while augmenting expression of A2 markers. Systemic treatment with bryo led to a significant increase in CD206+ macrophages/microglia in the CNS at EAE PID 42 ($p < 0.05$, student t-test). Our results demonstrate that bryo acts directly on CNS macrophages/microglia, promoting regenerative functions while inhibiting neurotoxic phenotypes. Bryo has therapeutic potential in progressive MS.

Abstract: Microglia contribute to a range of neuroinflammatory and neurodegenerative disorders, but scientists have long suffered from a lack of quality in vitro models for these cell types. We have developed a robust and scalable method to produce highly pure, functionally validated, and ready-to-use microglia from human induced pluripotent stem cells (iPSC). These microglia show greater than 97% purity as measured by immunostaining for IBA1 and TMEM119. These cells can be cryopreserved, thawed, and cultured in defined maintenance media with or without astrocytes or neurons for prolonged culture. We have used high-content imaging for phenotypic characterization of these models, including observing a re-distribution of inflammasome proteins (NLRP3 and ASC) from diffuse and cytoplasmic to organized punctate structures. This inflammasome formation could be blocked by the inhibitor MCC950. These data show functionally relevant and measurable phenotypes in these human iPSC-derived microglia may be suitable for modeling neuroinflammatory diseases and in drug-screening assays.

Title: Characterizing microglial lipidome and metabolome with amyloid beta exposure and phagocytosis

Authors: *P. PRAKASH, P. K. WIJEWARDHANE, G. CHOPRA;
Chem., Purdue Univ., West Lafayette, IN

Abstract: Microglia are specialized immune cells in the brain that maintain tissue homeostasis by eliminating misfolded protein deposits and cellular debris by the process of phagocytosis. In Alzheimer's disease (AD), microglia are exposed to amyloid β (Aβ) aggregates but are unable to clear them from the environment. There has been an increasing interest in using Aβ-targeting therapies for AD, however, the Aβ-associated cellular and molecular changes in glia remain poorly understood. Lipids and metabolites orchestrate critical regulatory events within the cells or by their secretion into the cellular microenvironment. How does Aβ treatment affect microglial lipid and metabolite response? To answer this question, we used Multiple-Reaction Monitoring (MRM)-profiling, a sensitive mass spectrometry technique, to characterize the changes in cellular and secretory lipids and metabolites that were differentially regulated in Aβ-treated primary mouse microglia and in their conditioned medium. Microglia were isolated from male and female C57B/6 adult mice and cultured in highly defined media with reduced serum condition. The cells were treated with aggregated human $A\beta_{1-42}$ for 1, 12, or 24 hours. We screened around 1500 total lipid species categorized into 10 main classes and around 700 metabolites to identify the Aβ-associated molecular changes in microglia. We found that inflammation-associated long-chain saturated free fatty acids (C20:0, C22:0, etc.) increased at initial timepoints but reduced with longer Aβ treatment. Triacylglycerides and phosphatidylglycerols were the most abundant lipid classes at 24 hours indicating a metabolic shift in microglial molecular repertoire with prolonged Aβ exposure. Further, we identified 42 significant metabolites in Aβ-treated microglia that are associated with alanine, aspartate and glutamate metabolism, arginine biosynthesis, citrate cycle, etc., including L-2-aminobutyric acid, hydroxybutyric acid, etc. Selected metabolites identified in the conditioned medium, for example, stearic acid, palmitic acid, etc. have also been shown to affect the phagocytic properties of peripheral macrophages and may also play a role in the microglial phagocytic response. Ongoing work involves evaluating the lipid and metabolite changes in different phagocytic and

non-phagocytic glial cell subsets in Alzheimer's mouse models such as 5xFAD mice to identify functional targets for phagocytosis. We thus conclude that identifying key functional molecules involved in Aβ phagocytosis, metabolism, and signaling is critical for elucidating microglia's role in health and disease.

Title: Morphologic and molecular activation of microglial cells by stimulation of the P2X7 receptor follows mechanical strain

Authors: *K. E. CAMPAGNO[1], W. LU[1], H.-Y. TSO[1], A. CENAJ[1], P. SRIPINUN[1], F. ALBALAWI[1], N. MAS-GOMEZ[1], C. H. MITCHELL[2];

Abstract: The initial processes that link mechanical strain to neuroinflammation provide critical targets for intervention in disorders like traumatic brain injury and glaucoma. We hypothesize that stimulation of P2X7 receptors after mechanosensitive release of agonist ATP can activate microglial cells and increase neuroinflammation. *In vivo* retinal activation of P2X7 with BzATP led to reduction of overall size of microglia and elevated expression of Iba1, suggestive of activation of microglia. Primary cultures of retinal microglia expressed P2X7 receptors, with BzATP triggering a rapid rise in intracellular Ca^{2+} that was blocked by antagonist A839977. BzATP also led to process retraction, cell body enlargement and increased expression of *NOS2* and *ARG1*. Expression of mRNA for microglial marker *TMEM119* decreased *in vitro* after exposure to BzATP or LPS and *in vivo* after elevation of pressure; immunoblots confirmed the decline in TMEM119 protein with ATP. Early responses of microglial cells to transient elevation of intraocular pressure were examined. Microglial morphology was altered by pressure elevation, with cell bodies enlarging and processes retracting. Expression of genes associated with non-M0 microglial states (*NOS2*, *TNFα*, *ARG1*, *YM1*) were also detected in the retina. Pressure elevation increased levels of extracellular ATP, while morphological and molecular changes were reduced in retina from $P2RX7^{-/-}$ mice. In summary, the P2X7 receptor plays a key role in the rapid activation of microglial cells following mechanical strain.

Title: Immunomodulatory effects of chondroitin sulfate proteoglycans after spinal cord injury are mediated via a TLR4-dependent mechanism

Authors: *I. FRANCOS-QUIJORNA[1], M. SANCHEZ-PETIDIER[2], E. R. BURNSIDE[3], A. TORRES ESPÍN[4], L. MARSHALL[1], J. VERHAAGEN[5], V. MORENO-MANZANO[2], E. J. BRADBURY[1];

Abstract: Chondroitin sulfate proteoglycans (CSPGs) are highly expressed in spinal injury scar tissue and are well established to be potent inhibitors of axonal growth and neuroplasticity. Here we report a role for CSPGs that goes far beyond inhibition of neuronal sprouting and demonstrate their critical role in mediating pathological chronification of the inflammatory response. CSPG digestion by Chondroitinase ABC enzyme (ChABC) demonstrated a remarkable immunomodulatory role of CSPGs, which was predominant in the resolution phase of the inflammatory response. By the use of flow cytometry and protein expression luminex analysis we demonstrated that CSPG digestion enhances immune cell clearance, modulates macrophage and microglial cell phenotype and reduces pro-inflammatory cytokine expression in the lesion site. Moreover, in vitro mechanistic studies reveal that TLR4 signalling is critical in driving CSPG-mediated inflammatory pathology, being essential in the development of an inflammatory phenotype of immune cells and delaying the resolution phase of inflammation.
Overall, our findings demonstrate that CSPGs modulate immune cell responses and this ECM-immune cell interaction suggests a potential new avenue of treatment not only for SCI, but also other neurological diseases with a marked inflammatory component.

Title: Dissecting cell-type specific gene expression patterns temporally in the brain during systemic inflammatory response syndrome

Authors: ***M. KODALI**[1,2], H. CHEN[1], F.-F. LIAO[1];
[1]Pharmacology, Addiction Sci. and Toxicology, Col. of Med., [2]Integrated Biomed. Sci. Program, Col. of Grad. Hlth. Sci., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Sepsis-associated encephalopathy (SAE) is an acutely progressing brain dysfunction that develops during systemic inflammatory response syndrome. The mechanism of initiation of neuroinflammation during SAE, which ultimately leads to delirium and cognitive dysfunction,

remains elusive. To understand the succession of events and to get a cell-type specific snapshot of transient as well as sustained gene expression changes, it is essential to study the acute inflammatory responses in the central nervous system (CNS) in a time course manner. We thus aimed to study the molecular events of SAE to capture its onset and progression into the CNS, and further identify the cellular players involved in mediating acute inflammatory signaling. Gene expression profiling on the cerebral vessels isolated from the brains of the mice treated with peripheral lipopolysaccharide (LPS) revealed that the cerebral vasculature responds within minutes to acute systemic inflammation by upregulating the expression of immediate early response genes, later followed gradually by inflammatory cytokine genes and simultaneous activation of the NF-κB pathway. Intriguingly, this early response was detected only in the cerebral vessels but not in the rest of the brain. To identify the earliest responding cell type, we used fluorescence-activated cell sorting (FACS) to sort the glial and vascular cells from the brains of the mice treated with LPS at different time points. RNA-seq was then performed on microglia and cerebral endothelial cells (CECs). Bioinformatic analysis followed by further validation in all the cell types revealed that panendothelitis i.e. the activation of CECs is the earliest event in the CNS during the inception of acute neuroinflammation. Microglial activation occurs later than that of CECs suggesting that CECs are the most likely initial source of pro-inflammatory mediators which could further initiate glial cell activation. This is then followed by the activation of apoptotic signaling in the CECs which is known to lead to the blood-brain barrier disruption and allow peripheral cytokines to leak into the CNS, exacerbate the gliosis, and result in the vicious neuroinflammatory cascade. Our results reveal the chronological expression of acute inflammatory signaling in each of the gliovascular cells and portray the temporal kinetics of gene expression in a cell-type specific manner during the induction of SAE. Together, these results model the earliest sequential events during the advancement of systemic inflammation into the CNS and facilitate to understand the interplay between the vascular and glial cells in initiating and driving acute neuroinflammation.

Title: Endothelial caspase-9 plays an inflammatory role in neurovascular injury

Authors: ***C. COLÓN ORTIZ**, M. AVRUTSKY, J. LAWSON, J. SMART, C. M. TROY; Columbia Univ. Irving Med. Ctr., New York, NY

Abstract: Neurovascular injuries can lead to neuroinflammation and to the development of neurodegenerative diseases. However, the molecular link between the neurovasculature, glial cells and their contribution to neurodegeneration remains to be understood. The mouse model of retinal vein occlusion (RVO) provides an avenue to investigate the endothelial-glial signaling mechanisms and its contribution to neuroinflammation. Using the RVO mouse model, previous studies in the laboratory revealed that neurovascular injury triggered activation of endothelial caspase-9 (EC-Casp9) in a non-apoptotic manner. Further, inhibition of caspase-9 caused a decrease in neuronal death, retinal edema and astrocytic caspase-6. But this intervention did not change the total number nor the activated state of microglia after injury. In this study we aimed to test the hypothesis that non-apoptotic activation of EC-Casp9 does not lead to microgliosis but to an increase in astroglial caspase-6 which will result in upregualted levels of GFAP and decrease of aquaporin-4 (AQP4) post RVO. To test this hypothesis, we used a tamoxifen-inducible endothelial caspase-9 knockout (iEC Casp9KO) mouse line. After tamoxifen administration, we induced RVO blinded to genotypes in two months old, male endothelial caspase-9 knockouts (iEC Casp9KO, n= 7) and endothelial caspase-9 littermate controls (Casp9 WT, n=11) by laser photocoagulation of major retinal veins (n=2-3). Uninjured Casp9 WT (n=3) and iEC Casp9KO (n=4) were used as controls. After collecting the retinas, we examined microglia and astroglia using different immunohistochemical markers to test for glial activation 1 and 2 days post-RVO. Confocal images were blindly quantified with Image J using threshold and color threshold analysis. Welch's t test, one-way ANOVA and Dunnett's multiple comparisons were performed for statistical analysis. Ablation of endothelial caspase-9 did not affect the total number of microglia (Iba-1^{+}) cells in injured animals, but caused a significant decline in the area of the macrophagic microglial marker, CD68. Retinas from injured iEC Casp9KO showed a significant decrease of GFAP expression in astrocytes 1 day post-RVO and a downward trend in AQP-4 2 days post-RVO. Moreover, astrocytes from iEC Casp9KO had a significant decrease in the expression of cl-caspase-6 1 and 2 days after injury. Overall, these data suggest that EC-Casp9 leads to increased microglial phagocytic activity and astroglial caspase-6 in neurovascular injury. Future studies include assessing the contribution of astroglial caspase-6 signaling to neurodegeneration.

Title: Inflammation as a driving force for optic nerve regeneration: comprehensive characterization of the cellular and molecular players

Authors: *L. ANDRIES[1], L. DE GROEF[1], L. MASIN[1], E. LEFEVERE[1], M. SALINAS-NAVARRO[1], I. SCHEYLTJENS[2], K. MOVAHEDI[2], L. MOONS[1];
[1]KU Leuven, Leuven, Belgium; [2]VUB, Brussels, Belgium

Abstract: Despite intensive research, induction of long-distance axonal regeneration and functional recovery of the damaged central nervous system (CNS) remain a challenge. The ever-innovating insights into the dichotomous role of neuroinflammation sprouted the idea that, instead of suppressing the inflammatory machinery, directing and instructing it may be a better therapeutic objective to trigger axonal regrowth. The overarching goal of this project is to unravel the underlying cellular and molecular players that link inflammation to axonal regeneration using optic nerve crush (ONC) (degeneration model) and ONC combined with inflammatory stimulation (ONC+IS) (regeneration model). The responses of resident glia and invading inflammatory cells during neuroregenerative processes are still controversial and insufficiently described. Therefore, we investigated the kinetics of myeloid cell influx in the retina and optic nerve, at different time points after ONC and ONC+IS, in wild-type, *Cx3Cr1.CreERT2xR26.STOP.YFP* and *LysMGFP* mice combining flow cytometry and immunohistochemical stainings. A large influx of monocytes, monocyte-derived macrophages (MDMs) and neutrophils was noticed in both tissues after ONC+IS from 2dpi onwards, which was not observed after ONC only. In both experimental conditions we detected a significant increase in the number of microglia at 6 and 8dpi, but microglia became larger and more internally complex after ONC+IS, a sign of augmented activation. Next, the immune cell heterogeneity in the retina was analysed using a single-cell RNA sequencing (scRNAseq) and subsequent bioinformatics analysis on $CD11b^+$ retinal cells to identify transcriptomic changes after ONC(+IS). In the regenerating retina, an increased heterogeneity and a higher number of the infiltrating myeloid cells, mainly macrophages, were detected. Depleting these macrophages, using *Ccr2*$^{-/-}$ mice, resulted in a lower number of MDMs but more neutrophils and in a decreased axonal regeneration upon ONC+IS, suggesting these macrophages and their transcriptome are important during axonal regeneration. With our research, we created a single-cell atlas of the healthy, injured and regenerating retina. We also initiated experiments in mice treated with plexxicon to further define a role for the different cell population involved in inflammatory-induced axonal regeneration.
Taken together, these data combined with an even more comprehensive bioinformatic analysis of the transcriptomics approach will enable us to pinpoint the inflammatory cell populations and processes that are specific to a pro-regenerative response.

Title: Endogenous neurosteroids increase anti-inflammatory mediators in immune cells and brain

Authors: *I. S. BALAN[1], L. AURELIAN[2], R. B. MEEKER[1], T. K. O'BUCKLEY[1], G. BOERO[1], A. MORROW[1];
[1]Univ. of North Carolina, Chapel Hill, NC; [2]Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Peripheral and brain inflammation are increasingly recognized as critical mediators in the initiation and progression of neurologic and psychiatric disorders (Cervellati et al., 2020, PMID: 32143546; Morrow & Price, 2019, PMID: 31637451). We have previously shown that endogenous neurosteroids, including pregnenolone and allopregnanolone (3α,5α-THP) inhibit inflammatory toll-like receptor 4 (TLR4) signal activation in mouse RAW264.7 macrophages and the brain of alcohol-preferring (P) rats (Balan et al., 2019, PMID: 30718548). Our recent data indicate that 3α,5α-THP inhibits activation of MyD88- but not TRIF-dependent TLR pro-inflammatory signals and the production of pro-inflammatory mediators (TNFα, MCP1, IL-1β, IL-6) through its ability to block TLR-MyD88 binding in P rat brain and mouse and human macrophages (unpublished data). As TLR4 activation can also increase anti-inflammatory signals (Siegemund & Sauer, 2012, PMID: 23080196), we examined whether endogenous neurosteroids have effects on anti-inflammatory TLR4 signals in peripheral immune cells (mouse and human macrophages) and P rat brain. Aurelian and Balan (2019, PMID: 31030249) previously showed that P rats exhibit innate suppression of the TLR4-associated anti-inflammatory chemokine CX3CL1 in the nucleus accumbens (NAc) compared to non-alcohol preferring (NP) counterparts. Using immunoblotting assays, we report that IP administration of 3α,5α-THP (15 mg/kg), pregnenolone (75 mg/kg) or 3α,5α-tetrahydrodeoxycorticosterone (3α,5α-THDOC; 15 mg/kg) significantly increases the NAc levels of CX3CL1 and anti-inflammatory cytokine IL-10 in male P rats. Using ELISA, we confirm that 3α,5α-THP significantly increases CX3CL1, in both male (30%, $p<0.05$) and female (45%, $p<0.05$) P rats NAc. Furthermore, 3α,5α-THP (1 μM) and 3α,5α-THDOC (1 μM) increased the level of IL-10 (~30%) in LPS-activated RAW264.7 macrophage cells. Finally, we studied these effects in human macrophages that were differentiated from PBMCs by GM-CSF (15 ng/ml; 1 week). Cells were treated with TLR4 agonist LPS (1 μg/ml; 24h) with/without 3α,5α-THP (1 μM) or 3α,5α-THDOC (1 μM). Both 3α,5α-THP and 3α,5α-THDOC increased (~35%) the level of CX3CL1. Collectively, the data indicate that the therapeutic potential of these neurosteroids involves modulation of TLR signaling pathways resulting in diminished pro-inflammatory signal activation and enhancement of anti-inflammatory signaling. Ongoing studies are designed to evaluate the mechanisms of the neurosteroid enhancement of anti-inflammatory CX3CL1 and IL-10 signaling both in immune cells and the brain.

Title: Tissue dynamics in CNS injury: exploring mechanisms underlying selective neuronal resilience

Authors: *I. BENHAR[1], J. DING[1], K. SHEKHAR[1], I. E. WHITNEY[2], M. SUD[1], G. BURGIN[1], A. JACOBI[3], N. M. TRAN[2], W. YAN[2], C. WANG[3], Z. HE[3], J. R. SANES[2], A. REGEV[1]; [1]Broad Inst. of MIT and Harvard, Cambridge, MA; [2]Mol. and Cell. Biol., Harvard Univ., Cambridge, MA; [3]F.M. Kirby Neurobio. Ctr., Boston Children's Hospital, Harvard Med. Sch., Boston, MA

Abstract: The inability of neurons in the adult mammalian central nervous system (CNS) to regenerate after injury or in disease leads to devastating physiological outcomes. Both neuron-intrinsic and extrinsic mechanisms play a role in this deficit. A key challenge in analyzing responses to CNS insult is the diversity of cell types involved - neuronal and non-neuronal - and dynamic changes in their composition and interactions over time. We addressed this complexity using the mouse optic nerve crush (ONC) injury model, which results in extensive death of retinal ganglion cells (RGCs), and is a tractable CNS injury model system for studying processes underlying neuronal degeneration and regeneration. Curiously, although ~80% of RGCs die within 2 weeks of ONC, death is not uniform across different RGC types. We set out to chart the tissue response following ONC, and gain insight into mechanisms underlying selective neuronal resilience. Using single-cell RNA-sequencing, we first generated a comprehensive molecular atlas of 46 RGC types in adult (P56) mouse retina, which we tracked after ONC, identifying resilient and susceptible types and their gene expression profiles. Manipulating some of these genes in vivo improved RGC survival and regeneration (Tran et al., 2019). Broadening our view to the tissue level, we additionally profiled >130,000 immune, glial and epithelial cells from retina at baseline and at six time points after ONC. By analyzing changes in gene expression throughout the time course, we identified distinct subsets of these cells, and temporal changes in

their composition and transcriptional states. We charted the immune cell cascade in the retina, highlighting changes in resident microglia, as well as blood-derived infiltrating leukocytes, and used immunohistochemistry and in situ hybridization to visualize these cells in the tissue. Combining computational analysis and experimental validation, we are inferring the cellular circuitry, spatial relationships and molecular interactions governing post-injury tissue dynamics. These findings could help identify potential targets for promoting neuroprotection and regeneration in the CNS.

Title: Rnf216 as a regulator of neuroinflammatory pathways

Authors: *D. GROSSMAN, A. GEORGE, A. MABB;
Georgia State Univ., Atlanta, GA

Abstract: Ubiquitin E3 ligases are enzymes that mark substrates with ubiquitin proteins which leads to different cellular fates. Ring finger protein 216 (RNF216) is a ubiquitin E3 ligase in the nervous system that is involved in synaptic plasticity, cellular autophagy, and the immune response. Previous literature shows that RNF216 participates in inflammation by regulating ubiquitination and subsequent proteasomal degradation of receptor-interacting serine-threonine kinase 1 (RIPK1), toll-interleukin 1 receptor domain containing adaptor protein (TIRAP), and TIR-domain-containing adapter-inducing interferon-β (TRIF), targeting TNF receptor associated factor 3 (TRAF3) for degradation. Toll-like receptors (TLRs) initiate signal transduction pathways which can lead to cytokine production, proliferation, survival, adaptive immunity, phagocytosis, and apoptosis. One of the RNF216 isoforms, TRIAD3A, controls the intensity and

duration of TLR signaling, specifically TLR4 and TLR9, through ubiquitination and subsequent proteolytic degradation. The role of RNF216 in regulation of the factors that contribute to inflammation is not well studied in the central nervous system (CNS). Using a mouse hypothalamic cell line (GT1-7) in which *Rnf216* was knocked down using the Crispr-Cas9 system, we sought to determine whether RNF216 might regulate TLR signaling pathways in the CNS. The findings of this exploratory project elucidate how disruptions in RNF216 may alter neuroinflammation. This is significant because elucidating potential mechanisms of neuroinflammation could lead to novel therapeutic targets for neuroinflammatory disorders.

Title: Evidence for mast cell proliferation in the developing brain

Authors: *A. C. BLANCHARD, L. A. PICKETT, E. L. REINL, M. M. MCCARTHY; Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Perinatal brain development is characterized by distinctive phases of neuronal proliferation and synaptic pruning to establish appropriate connections required for normal brain function. Disturbances in this tightly orchestrated process pre- and post-natally lead to both developmental disorders including autism and neurological conditions in adulthood including seizures and schizophrenia. The peripheral immune system can be a source of both homeostatic regulation of neurodevelopment and chronic pro-inflammatory damage. Recent studies implicate mast cells, a population of innate immune cells, in maintaining proper sexual differentiation in the rat preoptic area through interactions with resident microglia. However, factors recruiting mast cells to other regions of the brain, including the mast cell-dense choroid fissure, and their brain-specific activities are poorly understood. Here, we sought novel insights into the origin and regulation of this large population of granule-rich immune cells positioned adjacent to the hippocampus throughout development. Establishment of a flow cytometric protocol to isolate mast cells from the postnatal rat brain enabled characterization of their phenotype, replication status, and migration patterns in the postnatal (PN) period. Through immunohistochemical analysis, we discovered that mast cells in the lateral ventricles of the neonatal brain replicate during the first week of life – an activity previously thought to be restricted to bone marrow. This replicative activity of mast cells exhibited both brain region specificity and tissue specificity across the first postnatal week. Mast cells replicated at higher rates in the choroid fissure than in the skin at both PN1 and PN7. Our findings suggest brain mast cell (MC_B) replication is

differentially regulated compared to peripheral mast cells in the highly replicative bone marrow (MC_{BM}) and more quiescent skin (MC_s). Continued exploration of this immunogenic niche and its potential contribution to nearby neurogenic niches will illuminate the homoeostatic role of the innate immune system in shaping brain development in both males and females.

Title: Abnormal expression of neuroinflammation-related genes is associated with the C9orf72 mutation in a human stem cell model of ALS and FTD

Authors: *C. P. CHOSSIS, S. I. VAN DEURSEN, A. L. O'NEIL;
Neurosci. & Chem. Dept., Wesleyan Univ., Middletown, CT

Abstract: Neurodegenerative diseases affect millions of adults world-wide and pose a massive socio-economic burden. Amyotrophic Lateral Sclerosis (ALS) is a fatal and incurable neurodegenerative disease marked by the loss of motor neuron function leaving the patient unable to use their muscles. Frontotemporal Dementia (FTD) presents with the loss of cortical neurons in the frontal lobes of the brain leaving FTD patients confused and with behavioural issues. On the surface, ALS and FTD seem like very different diseases. However, a hexanucleotide repeat expansion at C9ORF72 has been determined to be the most common mutation in both diseases. For the past thirty years, most research on neurodegenerative diseases have focused on the cell autonomous aspect of the disease- how a dysfunction inside the neuron causes its malfunction and subsequent death. It has now become evident that non-cell autonomous events, mainly neuroinflammation imposed by the glia in the disease niche, is a hallmark of all neurodegenerative diseases. The work described here uses human induced pluripotent stem cells derived astrocytes from healthy patients and patients suffering from C9ORF72 ALS and FTD to model the inflammatory cascade present in neurodegeneration. Using reverse transcription-polymerase chain reaction to quantify RNA transcription for genes involved in different aspects of the astrocyte inflammatory response, data suggests that C9ORF72 astrocytes have an aberrant reaction to inflammatory signals compared to healthy patient derived astrocytes. Additionally, C9ORF72 astrocytes show an abnormal cellular morphology. This data suggests that an atypical inflammatory response may contribute to C9ORF72 ALS and FTD.

Title: Cigarette smoke dose dependently exacerbates clinical symptoms and pathology in a mouse model of multiple sclerosis

Authors: *K. KOSHIBU[1], J. HO[2], W. XIA[2], L. GARCIA[1], A. KONDYLIS[1], B. PHILLIPS[2], K. LUETTICH[1], J. HOENG[1], M. PEITSCH[1];

Abstract: Multiple sclerosis (MS) is an inflammatory autoimmune disease of the central nervous system. The etiology of the disease is complex and involves an interplay between genetic and environmental factors. Cigarette smoking has emerged as a major risk factor associated with the onset of MS. To further address this topic, we studied the effect of chronic cigarette smoke (CS) exposure in an experimental autoimmune encephalomyelitis (EAE) mouse model. Among several models of human MS, EAE is the most commonly employed animal model for investigating the pathogenesis of and therapeutic interventions for MS. In our study, we chose a myelin oligodendrocyte glycoprotein amino acid 35-55 (MOG35-35)-induced EAE mouse model to investigate the effect of CS exposure on EAE prevalence, onset, progression, severity, and spinal cord pathology. Our results show that CS can affect clinical symptoms and spinal cord lesions in a dose-dependent manner.

Title: The effect of bacterial endotoxin LPS on synaptic transmission in various models

Authors: *N. T. MARGUERITE[1], *J. BERNARD[1], A. GREENHALGH[1], O. ISTAS[1], C. R. BALLINGER-BOONE[1], S. M. BIERBOWER[4], E. E. DUPONT-VERSTEEGDEN[2], A. GHOWERI[3], D. A. HARRISON[1], M. C. MCNABB[1], C. M. SAELINGER[1], O. THIBAULT[3], R. L. COOPER[1];
[1]Biol., [2]Rehabil. Sci., [3]Pharmacol. & Nutritional Sci., Univ. of Kentucky, Lexington, KY; [4]Biol., William Paterson Univ., Wayne, NJ

Abstract: The release of the endotoxin lipopolysaccharides (LPS) from gram-negative bacteria is key in the induction of the downstream cytokine release from cells targeting other cells throughout the body. However, LPS itself has direct effects on cellular activity and can alter synaptic transmission. In investigating the direct actions of LPS on synaptic transmission various animal models were investigated and differences in responses were observed. Since antidepressants related to the serotonergic system have been shown to have a positive outcome for septicemic conditions impacting the central nervous system, the actions of serotonin (5HT) on neurons also exposed to LPS were investigated. At the model glutamatergic synapse of the crayfish neuromuscular junction (NMJ), 5HT primarily acts through a 5-HT2A receptor subtype to enhance transmission to the motor neurons. LPS from *Serratia marcescens* also enhances transmission at the crayfish NMJ but by a currently unknown mechanism; however, LPS depresses glutamatergic transmission at the Drosophila NMJ, but this NMJ is non-responsive to 5-HT. The serotonergic response remains intact in the presence of LPS at low and high concentrations. LPS blocked transmission at the cholinergic frog NMJ and glutamatergic rodent CNS but can be reversed with wash out.

Title: In vivo imaging of the microglial landscape after whole brain radiation therapy

Authors: *B. S. WHITELAW, S. TANNY, E. HERNADY, C. JOHNSTON, D. ROSENZWEIG, K. O'BANION, B. MARPLES, A. MAJEWSKA;
Univ. of Rochester, Rochester, NY

Abstract: WBRT (whole brain radiation therapy) is a standard of care treatment for primary brain tumors and patients with multiple brain metastases, but can lead to cognitive dysfunction, dementia, and even death. Radiation affects many cell types in the brain, causing complex pathological responses that are incompletely understood. Microglia, the resident immune cells of the brain, promote a pro-inflammatory environment following WBRT, with wide-ranging effects. Pharmacological depletion of microglia ameliorates WBRT-induced cognitive dysfunction in mice, suggesting a causative role for microglia consistent with findings in other neurodegenerative diseases. However, little is known about the dynamics of the microglial reaction to WBRT *in vivo*. In this study, we investigated the effects of WBRT (single dose 10 Gy using two 5Gy AP/PA beams) on the microglial landscape using longitudinal 2-photon imaging *in vivo*. First, using CT-image-guided WBRT, we validated radiation dosimetry in the brain of a mouse with a cranial window implant. Within 1-week after WBRT, we saw significant changes in the microglial landscape, characterized by apparent loss of microglial cells (~20%) and re-arrangements of microglial location. Despite these large-scale changes, microglial motility and surveillance at the cellular level were largely unaffected. We are currently investigating the longer-term effects of WBRT, as well as microglia-dendrite interactions. Overall, this study provides new insights into how microglia react to WBRT by combining image-guided WBRT with longitudinal *in vivo* imaging.

Title: SARS-CoV-2 of olfactory epithelial and pyriform cortical cells in moderate and recovering infections in non-human primates

Authors: *H. LI[1], C. MACTUTUS[1], K. MCLAURIN[1], J. RAPPAPORT[2], R. BOOZE[1]; [1]Univ. of South Carolina, Columbia, SC; [2]Tulane Natl. Primate Res. Ctr., Covington, LA

Abstract: As the major reason for COVID-19, the pandemic of coronal virus SARS-CoV-2 potentially induces olfactory dysfunction w/ anosmia. However, the mechanism(s) of SARS-CoV-2 associated anosmia and viral presence in the brain is unknown. ***Methods:*** To address the SARS-CoV-2 viral distribution and potential reservoir in the brain, four aged African Green monkeys and four Indian rhesus macaques were exposed via small particle aerosol or multiple mucosal routes to SARS-CoV-2 isolated from USA-WA1/2020. The infected primates were followed up to four weeks post-infection with clinical assessments and viral titers via mucus swab (buccal, nasal, and pharyngeal). RNAscope *in situ* hybridization was used to identify the distribution of SARS-CoV-2, ACE2 and TMPRSS2 expression in olfactory epithelium and pyriform cortex. Additionally, we performed dual-labeling of PDGFR-β, a cell marker for pericytes in the pyriform cortex, and SARS-CoV-2 probes to clarify the major cell type for viral infection in the brain. ***Results:*** Our data revealed abundant SARS-CoV-2 mRNA expression in the olfactory epithelium, especially in the sustentacular and basal stem cell layers, which co-localized with expression of ACE2 and TMPRSS2. SARS-CoV-2 mRNA and DNA, ACE2, and TMPRSS2 were notable in the pyriform cortex. The SARS-CoV-2 viral expression co-localized with the PDGFR-β positive cells in pyriform cortex. However, there was no relationship between viral loads (from buccal, nasal, pharyngeal, bronchial brush, etc.), clinical assessment or lung histopathologic score and SARS-CoV-2 expression in pyriform cortex. ***Conclusions:*** 1) SARS-CoV-2 mRNA and DNA in the olfactory epithelium were located in the sustentacular layer, basal stem cell layer, and Bowman's gland cells; 2) The pyriform cortex is a viral reservoir in the brain, evidenced by harboring SARS-CoV-2 mRNA and DNA; 3) Pericytes were the predominant cell type to express SARS-CoV-2 in brain; 4) Independent of viral loads (from buccal, nasal, pharyngeal, bronchial brush), clinical assessment, or lung histopathologic scores, SARS-CoV-2 expression was present in the pericytes of the pyriform cortex. Collectively, the present study has significant implications for our understanding of SARS-CoV-2 infection and reservoirs in the olfactory system, and the persistence of CNS infection of the pericytes in the pyriform cortex.

Title: Temperature dependence on the passive effects of K+ on membrane potential and synaptic transmission

Authors: *D. BUENDIA CASTILLO, *P. NAIDUGARI, *E. E. DUPONT-VERSTEEGDEN, R. L. COOPER;
Univ. of Kentucky, Lexington, KY

Abstract: In modifying a typical physiological laboratory protocol that measures resting membrane potential in relation to the concentration of extracellular potassium ions $[K^+]_o$, the additional effects of temperature were addressed. These temperature effects are of interest because they are not commonly addressed in experimental physiology in relation to the effect of altered $[K^+]_o$. One aim focuses on the effects of environmental change using heterothermic animals as the model organism. A second aim focuses on clinical therapies related to the use of varied temperatures in mammals. A third aim addresses a unified issue with all organisms regarding the effects of temperature changes on cellular metabolism. Experimentally, the skeletal muscle of a crayfish and larval Drosophila serve as motor unit models to obtain data. The crayfish model is robust for long term survival in minimal physiological saline, is easily obtainable, and allows for a relative ease in dissection, whereas the larval Drosophila is small, but serves as a comparison in generalities to the effects. Both neuromuscular junctions are glutamatergic, and have graded excitatory junction potentials. Graphing membrane potential in relation to both $[K^+]_o$ and temperature, along with theoretical curves for the Nernst and Goldman-Hodgkin-Katz (G-H-K) equations, provides important distinctions and understanding of the relationship of temperature in these equations. Freely available online software is used in addressing the theoretical values one would expect. Discussion of other factors impacted by temperature for biological membranes will also be covered. It appears that the permeability to K+ may be altered with temperature changes.

Title: Socializing reduces distress-associated behavior in mice

Authors: H. WEI, A. ADEWAKUN, ***R. FROEMKE**;
NYU Sch. of Med., New York, NY

Abstract: Lipopolysaccharide (LPS) induced neuroinflammation is a shared symptom for most neurodegenerative diseases. One of the harmful outcomes of presence of LPS in the brain is the cognitive impairment which is a result of a downstream inflammatory responses that had been initiated in the gut.In animal models these cognitive impairments include lethargy, arched or curled body posture, inactivity, and reduced consumption. Socialization in animals is positively correlated with physical and mental, learning, and reduced mortality. The main goal of this study is to investigate if socialization through co-housing has a direct therapeutic effect on LPS induced neuroinflammation.We utilized an LPS-induced endotoxemia model for our experiments. A total of 24 mice C57/BL6 mice were divided into two groups: socially isolated mice or co-housed mice.Continuous seventy-two hours recording sessions were performed and videos were analyzed and scored. We found that co-housing mice not only reduced the recovery time but also decreased the duration of exhibition of the sickness behavior. Analysis showed that the single-housed mice displays sickness behavior, including extended hunched posture, for about thirty-five minutes following the LPS injection, while the co-house mice only spent twelve minutes displaying sickness behavior. In addition, there was a significant weigh loss in the LPS injected mice. Motion tracking analysis revealed that socially isolated LPS injected mice remained stationary for hours compared to co-housed mice. In conclusion, our findings show that co-housing mice post endotoxemia endotoxemia demonstrate therapeutic which could be further exploited for translational studies.

Title: Remodeling Neuronal Circuitry via a SERBA Modifies the Progression of HIV-1 Associated Neurocognitive Disorders

Authors: *K. A. MCLAURIN, H. LI, R. M. BOOZE, C. F. MACTUTUS;
Psychology, Univ. of South Carolina, Columbia, SC

Abstract: Given the prevalence of neurodegenerative diseases (e.g., Alzheimer's disease, HIV-1 associated neurocognitive disorders (HAND), Parkinson's disease), there is a critical need to develop therapeutics to modify disease progression. Here, we demonstrate that treatment with S-

Equol (SE), a selective estrogen receptor beta agonist (SERBA), modifies the progression of preattentive processes, a neurobehavioral mechanism mediating alterations in higher-order cognitive processes, in the HIV-1 transgenic (Tg) rat by remodeling neuronal circuitry at the synaptic level. HIV-1 Tg and F344/N control rats were treated with either a daily oral dose of 0.2 mg SE (HIV-1 Tg: male, *n*=17, female, *n*=18; Control: male, *n*=18, female, *n*=17) or placebo (HIV-1 Tg: male, *n*=16, female, *n*=16; Control: male, *n*=20, female, *n*=17) from postnatal day (PD) 28 to PD 90. First, a longitudinal experimental design was utilized to critically test the efficacy of SE for modifying the progression of preattentive processes from PD 60 to PD 210. HIV-1 Tg rats treated with placebo exhibited prominent alterations in the progression of preattentive processes relative to control animals; deficits which occurred independent of biological sex. Treatment with SE, however, enhanced the progression of preattentive processes in HIV-1 Tg rats, resulting in a development trajectory that approximated control animals. Second, morphological characteristics of dendritic spines, a proxy for synapse function, were assessed in pyramidal neurons from layers II-III of the medial prefrontal cortex to evaluate the mechanism by which SE exerts its therapeutic effects. In animals treated with placebo, presence of the HIV-1 transgene decreased the efficacy of synapses by shifting the morphological parameters of dendritic spines towards an immature phenotype and reducing the complexity of pyramidal neurons. Profound long-term modifications in dendritic spines and neuronal morphology, consistent with increased synaptic efficacy, were observed in HIV-1 Tg rats treated with SE; results which support a mechanistic basis for enhancements in preattentive processing. Collectively, results support SERBAs as an innovative therapeutic approach for modifying the progression of HAND; an approach that exerts its effects by enhancing synaptic efficacy. Furthermore, understanding the mechanism by which SERBAs enhance cognitive function affords an opportunity to evaluate its broader therapeutic utility for other neurodegenerative diseases resulting from aberrations in synapse structure and function.

Title: Progressive dendritic spine alterations in the nucleus accumbens from HIV-1 viral protein exposure: a mechanism for apathy and treatment with S-Equol

Authors: *V. A. MADORMO, K. A. MCLAURIN, H. LI, C. F. MACTUTUS, R. M. BOOZE; Univ. of South Carolina, Columbia, SC

Abstract: As combination antiretroviral therapy (cART) significantly increases life expectancy of HIV-1 seropositive individuals, understanding the progression of HIV-1 associated neuropsychiatric complications is a critical need. Apathy, operationally defined as reduced self-initiated cognitive, emotional, and behavioral activity, is a frequent neuropsychiatric sequelae of HIV-1, with estimates suggesting a frequency as high as 65% in HIV-1 seropositive individuals. Prior work has demonstrated that the HIV-1 transgenic (Tg) rat shows a dysregulation of self-generated voluntary and goal-directed behaviors in various behavioral tests involving rewards, supporting the utility of the HIV-1 Tg rat as a biological model for motivational impairments. Motivational impairments have been experimentally linked to dysfunction with medium spiny neurons (MSNs) in the nucleus accumbens (NAc) and are readily correlated with decreases in spine number, degradation of synaptic proteins, and dendritic pruning. Further, S-Equol (SE) has been implicated as a potential adjunctive therapeutic for the aberrations in synapse structure and function from HAND. Thus, in the current study, a longitudinal experimental design was used to investigate progressive synaptodendritic alterations in the NAc from long-term HIV-1 viral protein exposure in HIV-1 Tg rats (n = 10 male, 10 female per age group) compared to controls (F344/N, n = 10 male, 10 female per age group). DiOlistic labeling was used to explore alterations in spine morphology of MSNs in the NAc at successive 30 day intervals to observe spine profile shifts in vivo due to HIV-1 from postnatal day (PD) 30 to PD 180 and after treatment with SE from PD 30 to PD 90. Relative to F344/N controls, HIV-1 Tg rats spines displayed a population shift towards a greater size in all measures (i.e. volume, backbone length, head diameter, and neck diameter) from PD 30 through 90, followed by a drastic population shift to decreased sizes at PD 120 through PD 180. The shift at later ages suggests HIV-Tg animals have a decreased synaptic connectivity as they age. Further, on all measures, HIV-Tg animals treated with SE displayed morphological similarities to control MSNs than to HIV-Tg animals. Dendritic spine alterations support a potential underlying neural mechanism for HIV-1 associated apathy and demonstrate the progression of the alterations; a progression which may be altered by SE. These findings provide insight into the underlying pathophysiological neural mechanism of motivational alterations in HIV-1 patients and a potential structural target for the development of therapeutics and cure strategies.

Title: Drugs repurposing for the treatment of HIV-Associated Neurocognitive Disorder by AI-based literature mining

Authors: *B. C. CUI[1], M. AKSENOVA[1], J. SYBRAND[4], D. ODHIAMBO[1], M. LUCIUS[1], H. JI[1], J. TURNER[5], E. PENA[2], S. B. LIZARRAGA[3], J. ZHU[1], M. D. WYATT[1], I. SAFRO[4], M. SHTUTMAN[1];

Abstract: HIV-1 Associated Neurocognitive Disorder (HAND) is a common and clinically detrimental complication of HIV infection. Viral proteins including Tat, released from infected cells, cause neuronal toxicity. Substance abuse in HIV-infected patients greatly exacerbates the severity of neuronal damage. To repurpose small molecule inhibitors for anti-HAND therapy, we employed MOLIERE, an AI-based literature mining system that we developed. All human genes were analyzed and prioritized by MOLIERE to find previously unknown targets connected to HAND. The list was narrowed to those with known small molecule inhibitors developed for other applications and lacking systemic toxicity in animal models. We tested the activity of small molecules targeted against the proteins of five prioritized genes to protect against the combined neurotoxicity of HIV-Tat and cocaine in primary neuronal cultures. Four prevented Tat and cocaine toxicity. The compounds are: the FDA approved drug Amlexanox; Tazemetostat (EPZ-6438), a potent selective EZH2 inhibitor that is in Phase II clinical trials; DEAD-Box RNA helicase 3 inhibitor RK-33, and DNA-Dependent Protein Kinase inhibitor NU7441. Both RK-33 and NU7441 were shown to selectively kill tumors without any observed systemic toxicity in animal models. Despite the disparate molecular targets of these drugs, analysis revealed a common mechanism of neuroprotection; namely that modulation of astrocyte and microglia status prevents the toxicity of Tat and cocaine. These findings show that MOLIERE literature mining provides a novel way to identify new mechanisms of neurotoxicity of HIV and drugs of abuse, and also accelerates the possibility of repurposing drugs for novel HAND treatments.

Title: Long-term changes in the adult human brain linked to Zika virus infection

Authors: *S. JUN[1], R. O. BIDO-MEDINA[2], J. OVIEDO[3], I. MICHES[5], L. TUSEN[6], P. STOETER[4], M. RODRIGUEZ[6], S. SADAGHIANI[1];

Centers and Advanced Med. and Telemedicine and Med. Conference, Santo Domingo, Dominican Republic; [5]Inst. Cultural Dominico Americano, Santo Domingo, Dominican Republic; [6]Neurol., Hosp. Salvador B. Gautier, Santo Domingo, Dominican Republic

Abstract: Systemic viral infections pose a global health challenge. In contrast to the currently pandemic-causing SARS-CoV-2 virus, the Zika virus (ZIKV) is highly neurophilic, as apparent in congenital syndromes (e.g. microcephaly) and increased neurological complications in some adults, such as Guillain-Barré syndrome (GBS). However, despite the observation that such adult neurological manifestations extend to functions of the central nervous system and may result in long-term sequalae, little is known about the impact of ZIKV on the adult brain. In particular, the majority of neuroimaging studies on adult ZIKV patients are case reports. Therefore, the present study performed extensive structural neuroimaging in rare adult ZIKV patients with both peripheral and central neurological manifestations (ZIKV-CNS-GBS group). We focused on the chronic phase (1 year after the onset of neurological symptoms) to understand the long-term structural effects of ZIKV infection. Importantly, the study included a GBS patient group with non-ZIKV etiology (NZIKV-GBS) and healthy controls to specifically investigate the neuroimaging evidence of the ZIKV-associated CNS complications. We examined voxel-wise fractional anisotropy (FA) and mean diffusivity (MD) differences in white matter (WM) tracts, whole-brain analysis of volumetric differences in gray matter (GM), and WM lesions using FLAIR hyperintensities. Both FA and MD revealed compromised WM integrity in the corticoreticular pathway (CRP) and the posterolateral superior longitudinal fasciculus (SLF II) in ZIKV-CNS-GBS compared to NZIKV-GBS. Given the functional role of the CRP in motor control, the diminished WM integrity may underlie the more severe and atypical GBS manifestation that we observed in ZIKV-CNS-GBS patients. Conversely, reduced WM integrity in the SLF may additionally contribute to the CNS manifestations; E.g. the role of SLF II in visuospatial processing may be compromised in ZIKV-CNS-GBS patients with vertigo and diplopia. Furthermore, we observed increased GM volume in the inferior temporal gyrus and the inferior orbitofrontal region in both patient groups compared to controls, which may support the WM results given their structural link to the CRP. To the best of our knowledge, this is the first case-control study to provide preliminary neuroimaging evidence for the long-term impact of ZIKV infection on adult brain structure in the context of CNS manifestations, and to report the impact of GBS etiology on GM and WM changes.

Title: HIV-1 Tg Rat: Telomere Length Assessment following SSRI or phytoestrogen treatment

Authors: *A. DENTON, H. LI, K. MCLAURIN, C. MACTUTUS, R. BOOZE;
Univ. of South Carolina, Columbia, SC

Abstract: Affective alterations, including motivational dysregulation and depression, significantly impact the quality of life in HIV-1 seropositive individuals; the neural mechanisms underlying these alterations, however, have not yet been fully elucidated. Telomere attrition, which is associated with inflammation in adults with affective alterations, may underlie affective alterations in HIV-1. Thus, three complementary aims were utilized to evaluate telomere attrition, and the potential utility of two proposed therapeutics (i.e., escitalopram, S-Equol (SE)), in the HIV-1 transgenic (Tg) rat. First, using a longitudinal experimental design the impact of genotype and/or biological sex on the progression of telomere length was evaluated in skin tissue of HIV-1 Tg (*n=7* per group) and F344/N control (*n*=7 per group) animals every thirty days from postnatal day (PD) 30 to PD 180. Both HIV-1 Tg and control groups exhibited an initial increase, followed by a prominent decrease, in telomere length; albeit significant genotypic differences in age of peak telomere length was observed. Specifically, HIV-1 Tg animals displayed a prominent rightward shift in age of peak telomere length relative to control animals (i.e., PD 90 versus PD 60, respectively). HIV-1 viral proteins, therefore, alter telomere development. Second, telomere length was evaluated in blood collected from HIV-1 Tg (*n*=31) and F344/N control (*n*=42) animals following chronic (i.e., 6 weeks) treatment with either escitalopram (4 mg/kg) or placebo. Presence of HIV-1 viral proteins, biological sex, and/or escitalopram treatment had no statistically significant effect ($p>0.05$) on telomere length. Finally, long-term modifications in telomere length were examined in the skin tissue of HIV-1 Tg (*n*=7 per group) and F344/N control (*n*=7 per group) animals following daily, oral SE (0.2 mg) treatment during the formative period (PD 28 to PD 90). Independent of treatment or biological sex, HIV-1 Tg animals exhibited increased telomere length relative to control animals (Main Effect of Genotype: $F(1,38)=5.4$, $p\leq0.03$). Furthermore, independent of genotype, treatment with SE increased telomere length in female, but not male, animals (Sex x Treatment Interaction: $F(1,38)=10.3$, $p\leq0.003$). Taken together, HIV-1 viral proteins have the most profound impact on early telomere development, supporting a potentially early inflammatory environment in the HIV-1 Tg rat; inflammation which dissipates across time and is not present at advanced ages. Furthermore, SE precludes the shortening of telomere length in female animals, supporting a potential efficacious therapeutic for diseases linked to telomere attrition.

Title: Lentiviral delivery provides improved HIV-1 Nef expression in astrocytes in vivo

Authors: *J. G. PLA-TENORIO, M. CRUZ-RENTAS, R. NOEL, Jr.;
Ponce Hlth. Sci. Univ., Ponce, PR

Abstract: HIV has remained a global epidemic infecting over 76 million people globally. Current therapy can prevent death due to AIDS and reduce transmission by reducing viral replication to low levels. With this advance, new challenges have emerged, including the increased prevalence of HIV associated neurocognitive disorders (HAND) in people living with HIV. Even with the presence of cART, the virus quickly invades the brain, establishing a reservoir. HAND is thought to be caused by the ongoing production of HIV neurotoxins in the brain, even when replication is suppressed. This damage is particularly relevant in astrocytes because they serve as a reservoir for HIV and produce HIV neurotoxic proteins, with Nef being the most abundant. In the past, we have expressed HIV-1 Nef by infusing ex-vivo transfected astrocytes into rats' brains to study loss of spatial learning. While that model had the advantage of cell-specific expression, it suffered the limitations of infusing new cells into the brain and transient expression of Nef. To overcome these limitations, we compared the effectiveness of infusing a lentiviral vector that expresses HIV-1 Nef using the astrocyte-specific GFAP promoter into the brain with the infusion of exogenous cells. We hypothesized that even if the Nef gene is delivered by a lentivirus that infects multiple cell types, this GFAP construct will limit expression to astrocytes, giving the best combination of duration and exposure, with less tissue disruption. To test this, 60-day old Sprague Dawley rats underwent bilateral stereotaxic surgery to infuse ex-vivo transfected astrocytes or a Lenti-GFAP-SF2Nef-IRES-mCherry viral vector into the rats' brains. Later, immunofluorescence for astrocytic markers was done to verify the weekly expression of both methods. Our data shows that after one week, ex-vivo transfected astrocytes were expressed. However, after three weeks, coronal slices of the brain showed longevity of expression of the vector and faded expression of the exogenous cells. The integrity of the expression was also verified in culture as a control for the infused materials. Altogether, these data suggest that the infusion of the lentiviral vector provides a superior approach due to steadier expression and duration of exposure, despite requiring a longer time to reach full expression. Moreover, as previously observed in other studies, comorbid use of illicit drugs, such as cocaine, represents an additional potential contributor to worsened HAND as cocaine accelerates the damage to the CNS by HIV neurotoxins. Future studies will address the specificity of the vector's expression in astrocytes to study HIV-1 Nef modulation of drug seeking.

AbstractInhibition of the dopamine (DA) transporter (DAT) by the HIV-1 protein transactivator of transcription (Tat) has been implicated as a mediating factor of HIV-1 associated neurocognitive disorders (HAND). Our laboratory has demonstrated that DA uptake through DAT is reduced in an inducible Tat transgenic (iTat-tg) mouse model. This study determined the extracellular DA dynamics in iTat-tg mice using slice voltammetry. DA release was stimulated using either tonic (1 Hz, 1 pulse) or phasic (20 Hz, 5 pulses) parameters in the presence of nomifensine (1 nM, 10 nM, 100 nM, 1 μM, and 10 μM) in the caudate putamen of iTat-tg mice following 7-day administration of saline or doxycycline (Tat expressing). Compared to saline control mice, the change in the peak extracellular DA vs. baseline was significantly increased in response to nomifensine in iTat-tg mice [$F(1,10) = 8.18$, $p < 0.017$]. The increase in the change in peak DA vs. baseline was in a concentration-dependent manner [$F(4,40) = 44.5$, $p < 0.001$]. Furthermore, there was a significant interaction of nomifensine and Tat expression [$F(4,40) = 4.62$, $p < 0.01$]. There was no significant difference in DA peak levels vs. baseline, T20, or T80, with either tonic or phasic stimulation. No significant effect of doxycycline for the change in peak DA vs. baseline using tonic stimulated DA release was found. These findings suggest that increased extracellular DA in response to nomifensine may be mediated by Tat induced inhibition of DAT. Future work focused on attenuation of Tat induced inhibition of DAT may serve as a potential treatment option for HAND.

Res. Inst. At VTC, Virginia Tech., Roanoke, VA; [6]Univ. at Buffalo, Buffalo, NY; [7]Virginia Tech. Carilion Sch. of Med., Roanoke, VA

Abstract: Prolonged infection and inflammation within the brain can alter the connectivity and function of neuronal circuits. The intracellular protozoan parasite, *Toxoplasma gondii*, is one pathogen that can chronically infect the brain and lead to encephalitis and seizures. Currently, over 30% of the human population worldwide is infected with *Toxoplasma gondii,* and these infections are associated with behavioral alterations and an increased risk for developing psychiatric illness, including schizophrenia. Current evidence from studies in humans and mouse models suggest that both seizures and schizophrenia result from a loss or dysfunction of inhibitory synapses. In line with this, we recently reported that persistent *Toxoplasma gondii* infection alters the distribution of glutamic acid decarboxylase 67 (GAD67), an enzyme that catalyzes GABA synthesis in inhibitory synapses. These changes could reflect a redistribution of presynaptic machinery in inhibitory neurons or a loss of inhibitory nerve terminals. To directly assess the latter possibility, we employed serial block face scanning electron microscopy (SBFSEM) and quantified inhibitory perisomatic synapses in neocortex and hippocampus following parasitic infection. These ultrastructural analyses (coupled with genetic and immunohistochemical analyses) revealed that persistent infection not only led to a significant loss of perisomatic synapses, it induced the ensheathment of neuronal somata and perisomatic nerve terminals by myeloid-derived cells (including microglia), suggesting they may actively displace or phagocytose synaptic elements. This neural-glia interaction coincides with increased expression of classical complement cascade components, an immune pathway that has been shown to play a critical role in microglia-induced synapse loss during neurodegeneration or disease by opsonization. Our recent studies exploit various visualization techniques, including 2-photon *in vivo* imaging to explore the innate complement pathway as a mechanism by which microglia phagocytose inhibitory nerve terminals in long-term parasitic infection.

Title: Rab7a regulates endothelial tight junction protein trafficking and paracellular permeability of the blood-brain barrier after ischemic stroke

Authors: *A. COTTARELLI[1], M. HSU[2], S. SHAHRIAR[1], M. GLENDINNING[1], G. PROCHILO[1], J. R. SMITH[3], J. NEAL[1], A. L. EDINGER[4], A. ARAC[5], D. AGALLIU[6]; [1]Columbia Univ., New York, NY; [2]Univ. of Wisconsin - Madison, Madison, WI; [3]Univ. of Washington, Seattle, WA; [4]Univ. of California Irvine, Irvine, CA; [5]Neurol., UCLA, Los Angeles, CA; [6]Neurol., Columbia Univ. Med. Ctr., New York, NY

Abstract: Brain endothelial cells (ECs) form a paracellular and transcellular barrier to blood-borne solutes via tight junctions (TJs) and scarce endocytotic vesicles. The blood-brain barrier (BBB) plays a pivotal role in the healthy and diseased CNS. BBB damage after ischemic stroke contributes to increased mortality; yet the roles of paracellular versus transcellular mechanisms in this process are not well-understood. We have previously shown by intravital two-photon microscopy, using a transgenic strain in which endothelial TJs are labeled with eGFP, that stepwise impairment of transcellular followed by paracellular barrier mechanisms accounts for BBB deficits in stroke. Moreover, Caveolin-1 deficient mice, which have reduced endothelial transcellular permeability, display a normal increase in paracellular permeability after transient MCAO, suggesting that these two mechanisms are independent.Here, we address the role of TJ remodeling in regulation of endothelial paracellular permeability following stroke. The small GTPase Rab7a plays an essential role in regulation of trafficking inside the cell as proteins move from the late endosome to the lysosome for degradation. By generating mice lacking Rab7a in ECs (Rab7a iEC-KO), we demonstrate that the absence of endothelial Rab7a prevents junctional dismantling occurring 48 hours after ischemic stroke, thus reducing paracellular BBB permeability. As a consequence, Rab7a iEC-KO mice display reduced neuronal death in the cortex and an improved neurological outcome 48 hours after stroke induction. Moreover, we demonstrate in murine brain ECs (mBECs) that the active, GTP-bound, form of Rab7a is increased after 48 hours of treatment with TNFα and IL-1β, indicating that the proinflammatory environment in the ischemic brain is responsible for Rab7a-mediated BBB disruption. Consistent with these results, we find that cytokine treatment increases expression of Ccz1, a GTP exchange factor (GEF) known to promote Rab7a activation. Silencing Rab7a in mBECs rescues the cytokine-induced impairment in paracellular barrier properties without interfering with the endocytic pathwayThese findings suggest that Rab7a regulates TJ protein trafficking and degradation at the late phase of stroke, which is responsible for the enhancement of paracellular permeability of the barrier, and that inhibition of Rab7a activation in ECs may protect CNS damage after ischemic stroke.

Title: Evaluation of enzymes associated with the glutathione system in the cerebral ischemic process in rats

Authors: *I. CESAR ARTEAGA[1,2], D. JUÁREZ SERRANO[1,2], C. GARCIA-OLVERA[1,3], P. AGUILAR-ALONSO[1,2];
[1]Lab. de Investigaciones Químico-Clínicas, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico; [2]Biochemistry-Molecular Biol., Posgrado en Ciencias Químicas, BUAP, Puebla, Mexico; [3]Facultad de Ciencias Químicas, BUAP, Puebla, Mexico

Abstract: Cerebral ischemia is a neurodegenerative disease, considered the second cause of death in the world, developing countries being the most affected. It is known that the initiating factors of oxidative stress during the cerebral ischemic process are the production of nitric oxide (NO) and peroxynitrite ($ONOO^-$), which trigger the mechanisms of cell damage. Under extreme conditions of oxidative stress, antioxidant systems such as the glutathione system are activated, the enzymes Glutathione reductase (GR), Glutathione peroxidase (GPx) and Glutathione transferase (GST) make up this system and have been associated with cell survival and good biological functioning. The aim of this work is to evaluate the enzymes of the glutathione system, by varying their enzymatic activity during a cerebral ischemic process in rats. 45 male rats of the Wistar strain with a weight of 190-230 g were used, kept under animal storage conditions. They were randomly divided into 3 groups: Control group (no treatment) with n = 3; Ischemia group, who underwent surgery for obilateration of the left primitive carotid artery (OAPC) for 10 min and subsequent reperfusion of blood flow, tissue was obtained at 2, 4, 6, 8, 12, 24 and 36 hours after reperfusion with n = 3 for each time evaluated; Group L-NAME + Ischemia, rats administered the inhibitor intraperitonally, one hour before OACP; then surgery and damage follow-up were performed in the same way as in the second group with n = 3 for each time evaluated. In this research L-NG-Nitroarginine Methyl Ester (L-NAME) was used as a potent inhibitor of neuronal and endothelial nitric oxide synthesis, in order to prevent the toxic effects of NO and $ONOO^-$. Subsequently, the activity of the enzymes GR, GPx and GST was evaluated, as well as the total lipoperoxidation process and its main components: malonyldialdehyde (MDA) and 4-hydroxyalkenals (4-HDA) using spectrophotometric techniques. The results show that in the early stage of the cerebral ischemic process, oxidized glutathione is generated which is then reduced by the GR enzyme and an increase in the levels of MDA and 4-HDA. In the late phase, GR and GST increase their activity, however, the GPx enzyme decreases its activity, while the products of lipoperoxidation increase with time. In the

group treated with L-NAME, a decrease was observed both in the activity of the three enzymes analyzed and in the levels of the lipoperoxidation products compared to the group without inhibitor. It is concluded that the enzymes GR, GPx and GST modify their activity in response to the cellular detoxification needs in each post-reperfusion stage of a cerebral ischemic process.

Title: Concurrent use of nicotine and oral contraceptives in female rats alters brain metabolism and exacerbates ischemic injury

Authors: *J. SIEGEL, F. DIAZ, A. P. RAVAL;
Neurol., Univ. of Miami, Miami, FL

Abstract: Smoking-derived nicotine (N) and oral contraceptives (OC) synergistically induce mitochondrial complex IV dysfunction and cause severe ischemic brain damage in female rats (1, 2). The goal of the current study is to understand the impact of N+OC on brain metabolism, we investigated the global metabolomic profile of adolescent and adult female rat brains exposed to N +/-OC. Adolescent (6 weeks old) and adult (12 weeks old) Sprague-Dawley female rats were randomly (n=8/group) exposed to either saline, N +/- OC for 16-21 days. The metabolic analysis of brain tissue shows significant changes in glycolysis, TCA cycle, lipid metabolism, and neurotransmitters in both adult and adolescent rats exposed to N +/- OC in relation to saline treatment, with changes more pronounced in adolescent rats. Since glucose and lipid metabolisms are critical for neuronal function, alterations in these energy producing pathways can deteriorate and further exacerbate ischemic brain damage. References: 1. Title: Lymphangiogenesis near the cribriform plate after cerebral ischemia

Authors: *Y. CHOI, M. HSU, C. LAAKER, M. SANDOR, Z. FABRY;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Conventional lymphatic vessels typically reside within the tissue parenchyma and facilitate drainage of fluid, lipid, and immune cells to local lymph nodes. However, the central nervous system (CNS) has traditionally been described as "immune privileged" because there are no conventional lymphatic vessels or peripheral immune cells within the CNS parenchyma. Recently, it has been hypothesized that antigens, antigen-presenting cells (APCs), and cerebrospinal fluid (CSF) may drain from the CNS into lymphatics near the cribriform plate or meningeal lymphatics in order to provide antigen drainage and fluid homeostasis. This recent re-discovery of lymphatic vessels surrounding the CNS under steady-state conditions ignited an intense debate about mechanisms of how antigens or immune cells drain from the CNS parenchyma to lymphatic organs. Additionally, the role of lymphatic vessels in the CNS during neuroinflammation is not well understood yet. Here, we study how lymphangiogenesis near the cribriform plate contributes to recovery of brain tissues following transient ischemic stroke. We employed the transient middle cerebral artery occlusion (tMCAO) model of ischemic stroke to 10-12 weeks old C57BL/6J male mice by placing a filament through internal carotid artery to occlude MCA for 60 minutes, followed by reperfusion after removing the filament. We showed that lymphangiogenesis occurs near the cribriform plate, which peaked at day 7 and decreases after 14 days following tMCAO. The lymphangiogenesis occurred through interaction of vascular endothelial growth factor receptor (VEGFR)-3 and vascular endothelial growth factor (VEGF)-C which are produced by $CD11b^{+}$, $CD11c^{+}$ dendritic cells. These lymphangiogenic vessels could transport CSF and immune cells which were confirmed by injection of Evans Blue dye through cisterna magna and flow cytometry, respectively. Flow cytometry analysis showed robust leukocyte accumulation, which include macrophages ($CD45^{hi}$, $CD11b^{+}$, $CD11c^{low}$), dendritic cells ($CD45^{hi}$, $CD11b^{+}$, $CD11c^{hi}$), CD8 T cells ($CD45^{hi}$, $CD11b^{-}$, $CD11c^{-}$, $CD8^{+}$), and CD4 T cells ($CD45^{hi}$, $CD11b^{-}$, $CD11c^{-}$, $CD4^{+}$) near the cribriform plate after 7 days of tMCAO, which also correlated with lymphangiogenesis ($CD45^{-}$, $Podoplanin^{+}$, $CD31^{+}$). Inhibition of VEGFR-3 reduced lymphangiogenesis near the cribriform plate and improved motor ability at earlier time points following tMCAO. Understanding the biology and mechanisms of CNS lymphatic drainages may lead to novel therapeutics for neuroinflammatory diseases.

Title: Sema3a antibody for neurodegenerative diseases of the optic nerve

Authors: *A. S. SOLOMON[1], I. BENHAR[2], A. BARZILAI[2];
[1]Tel Aviv Univ., Tel Hashomer, Israel; [2]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Abstract
Glaucoma and other ischemic or neurodegenerative diseases of the optic nerve are associated with a process of progressive apoptosis of the retinal ganglion cells (**RGC**) that, once initiated, is not stopped by current treatments. Dying RGC send apoptotic signals to neighboring healthy RGC. This leads to further loss of RGC which induces further loss of RGC which induces substantial loss of visual function leading to blindness .Glaucoma is one such condition,but the same phenomenon of self-reinforcing degenerative process is also apparent in other central nervous system(**CNS**) disease. Semaphorin3A (**Sema3A**) is a protein involved in the signal cascade leading to apoptosis of neural cells in the CNS. Sema3A inhibitors interfere with this signal cascade and preserve RGCs.Our goal is to create an antibody to block the apoptotic program of Sema3A.
We created animal models of optic nerve assaults analog to diseases of optic nerve in human. The antibodies created were evaluated in vitro in neural cells culture and the most potent one, 3H4, was loaded in implants which were implanted in the right eye of rats or rabbits . Four models of optic nerve and retina were used: complete transaction of optic nerve and retinal detachment in rats, acute glaucoma and ischemic optic nerve (**NAION**) in rabbits. Two weeks following injury the retinae were stained retrograde with Di-Asp 10. Viable RGC were counted on flat mounted retina. We succeeded to save 46% -52% of the RGC in the implanted eyes with 3H4. Control injured optic nerves, treated with implants and loaded with DMEM presented 10% - 12% RGC of the normal count. The antibody 3H4 was found to be a potent substance that blocks the apoptotic program of Sema3A.

Title: Neuronal activity mapping during exploration of a novel vs. familiar environment in young adult mice following neonatal hypoxia ischemia.

Authors: M. MAZURKIEWICZ, P. WAGLEY, A. KAMBHAM, B. PACE, D. SKWARZYNSKA, *J. BURNSED;
Univ. of Virginia, Charlottesville, VA

Abstract: Background: Hypoxic ischemic encephalopathy (HIE) is a major cause of neonatal seizures and later cognitive and behavioral problems. Early-life seizures may result in permanent changes to neuronal circuitry which likely have consequences on cognitive and memory outcome. Use of transgenic mice, tissue clearing and advanced microscopy allow mapping of neuronal activity involved in memory and learning in young adult mice following neonatal HI.Objective: Map neuronal activity in HI and uninjured mice during novel and familiar environment exploration.Methods: HI is created using unilateral carotid ligation+45 min of 8% O2 in Cre-tamoxifen transgenic mice (TRAP2) on postnatal day (p)10. Sham mice receive incision+anesthesia without hypoxia/ligation. Mice are exposed to novel environment on p30 and again to this environment (familiar) on p31. Injection of 4-hydroxytamoxifen 1hr after experiment on p30 or p31 allows expression of fluorescent protein (TdTomato) in neurons active (expressing immediate early gene, cfos) during the prior 90 minutes of behavior. Mice are perfused and 200µm thick tissue is processed using tissue clearing methods, stained with DAPI and imaged on a confocal microscope. Zeiss Zen is utilized to obtain and process images, Imaris 9.2 and Fiji are used for analysis.Results: Mice in both groups explored the environment significantly less on the second day (familiar environment) compared to the first day (novel environment) ($p=0.00001$). Increased neuronal activity was observed during novel environment exploration in the somatosensory cortex, motor cortex, hippocampus (dentate gyrus, CA1 and CA3), amygdala and lateral thalamus compared to familiar.Conclusions: Young adult mice exhibit increased exploratory activity in a novel environment vs. familiar. Unbiased, whole brain mapping of neuronal activity during both conditions revealed that the exploratory circuit, learning and memory circuit and anxiety circuit are highly active during exploration of a novel environment, compared to a familiar environment. Ongoing studies are quantifying neuronal activity in exploratory circuit, learning and memory circuit and anxiety circuit and exploring the impact of HI on this behavior and the neuronal activity map.

Title: Neurochemically identified cortical interneuron subtypes are differentially vulnerable to hypoxic-ischemic brain injury in neonatal piglet

Authors: *C. E. O'BRIEN[1], E. KULIKOWICZ[1], R. C. KOEHLER[1], L. J. MARTIN[2], J. K. LEE[1];
[1]Anesthesiol. and Critical Care Med., [2]Pathology, Johns Hopkins Univ., Baltimore, MD

Abstract: Introduction: Post-cardiac arrest seizures are common and are associated with worse neurologic outcomes in children. The etiology of post-cardiac arrest seizures is unknown. We hypothesized that neocortical inhibitory GABAergic interneurons (INs), cells known to regulate cortical neuron excitability, degenerate after cardiac arrest. We localized and counted two subtypes of INs that differentially express the calcium-binding proteins parvalbumin and calretinin in neonatal piglet cerebral cortex at 4 days after hypoxic-ischemic injury. Methods: Male piglets (3–5 days old) were randomized to sham surgery or hypoxic-ischemic (HI) injury with 45 minutes of hypoxia, 8 minutes of asphyxia, and cardiopulmonary resuscitation. Pigs were recovered for three hours, extubated, and survived 4 d. Neuronal injury was evaluated on hematoxylin and eosin staining. Immunohistochemistry was used to identify parvalbumin (PV) and calretinin (CR) in forebrain sections. Comparisons between the two groups were made with the Mann-Whitney test. Results: The brains from 16 pigs (n=8 for both sham and HI groups) were studied. The HI insult was confirmed by neuronal injury in putamen (a vulnerable subcortical region in this model). The HI group had significantly fewer normal neurons as compared to the sham group (29.5 [19.2, 38.6] versus 57.0 [50.3, 80.7]; $p<0.001$). There were significantly more ischemic-necrotic neurons in the somatosensory cortex of HI pigs (8.9 [2.3, 31.9] versus 1.4 [0.9, 2.4]; $p=0.008$); however, the number of total normal neurons in layers 2 through 6 were similar. The parvalbumin positive IN numbers in putamen ($p=0.705$) and somatosensory cortex ($p=0.747$) were not different in HI compared to sham. However, calretinin positive INs in layer 2 of the somatosensory cortex were significantly reduced in HI piglets compared in sham piglets (44 [38, 57) versus 102 [80, 114]; $p=0.003$). Conclusions: The neocortical calretinin positive subtype of IN, but not the parvalbumin positive IN class, is vulnerable to HI brain injury when overall cortical damage is mild. Selective damage to local inhibitory IN networks that target distal dendrites of pyramidal neurons, such as calretinin INs, could be involved in initiation and propagation of post-cardiac arrest seizures at early stages in the evolution of cortical damage.

Title: A biomarker of poor outcome for neonatal encephalopathy using MRI diffusion-weighted imaging connectome and fixel-based analysis

Authors: Z. SHI[1], J.-W. JEONG[2], M.-H. LEE[1], N. FERNANDES[1], S. DEOL[3], S. MODY[1], S. ARSLANTURK[4], R. B. CHINNAM[5], *S. TAN[6,1];
[1]Pediatrics, [2]Neurol., [4]Computer Sci., [5]Industrial and Systems Engin., [3]Wayne State Univ., Detroit, MI; [6]Pediatrics, Children's Hosp. of Michigan, Detroit, MI

Abstract: Better biomarkers of eventual outcome are needed for neonatal encephalopathy. To identify the most potent neonatal imaging maker associated with 2-year outcomes, we retrospectively performed diffusion-weighted imaging connectome (DWIC) and fixel-based analysis (FBA) on MRI obtained in the first four weeks of life in term neonatal encephalopathy newborns. Diffusion tractography was available in 15 out of 24 babies with MRI, 5 each with normal, abnormal motor outcome, or death. All fifteen except one underwent hypothermia as initial treatment. In abnormal motor and death groups, DWIC found 19 white matter pathways with severely disrupted fiber orientation distributions. Using random forest classification, these disruptions predicted the follow-up outcomes with 89%-99% accuracy. These pathways showed reduced integrity and myelination in abnormal motor and death vs. normal tone groups ($p < 10-6$). FBA identified three regions, thalamus, internal capsule, and cerebellar peduncle, of which fiber densities were reduced in abnormal motor and death vs. normal tone groups ($p < 0.016$). This study suggests that early DWIC and FBA may be helpful in distinguishing normal from abnormal follow-up outcomes, based on the severity of white matter injury. These neonatal markers could facilitate improved prognostication, better elucidate plasticity and repair, and evaluate treatments for neonatal encephalopathy.

Title: Studying Cerebral Palsy Using the Transition From Partial to Total Placental Insufficiency in a Rabbit Model

Authors: *N. VENKATESH;
Wayne State Univ. Sch. of Med..

Abstract: Studying Cerebral Palsy Using the Transition From Partial to Total Placental Insufficiency in a Rabbit Model Neha Venkatesh[2], Zhongjie Shi[1], Kehuan Luo[1], Sanket Jani[1], Melissa February[1], Nithi Fernandez[1], Nadiya Sharif[2], Sidhartha Tan[1]
Objective: All placental abruptions have their beginnings from a partial abruption. We developed a new rabbit model mimicking the partial-to-total placental insufficiency and compared it with the previous model of only complete uterine ischemia.**Methods**: Global fetal

hypoxia ischemia (H-I) was induced by uterine ischemia at E22 or E25 (70% or 79% term gestation, respectively), in pregnant New Zealand white rabbits. Full H-I was complete uterine ischemia for 40 min, and the new Partial+Full H-I added a 30-min partial ischemia before the complete 40-min ischemia. Fetuses were delivered either at E31.5 (full term) vaginally for neurobehavior test, or by C-section at E25 for *ex-vivo* brain cell-viability evaluation at 24, 48 and 72 hours thereafter. **Results**: Onset of fetal bradycardia was within the first 2 minutes of either H-I protocol. There was no difference between the Full H-I (n=435) and Partial+Full H-I (n=122) groups in death or severely affected kits (79% vs 80%), or normal kits (14% vs 11%), or any of the individual newborn neurobehavioral tests at E22, nor at E25 (n=312 in Full H-I group, and n=80 in Partial+Full H-I group; death or severely affected: 62% vs 64%; normal kits: 27% vs 29%). There was no difference in cell viability between the Full H-I (n=8) and Partial+Full (n=6) groups ($p>0.05$).**Conclusions**: The E22 or E25 Partial+Full H-I model produced similar neurobehavioral CP phenotype as our previous Full H-I model, and may be more suitable for testing of potential neuroprotectants after the onset of fetal bradycardia.

Title: Effect of prenatal hypoxia-ischemia on cognitive testing in newborn rabbits using conditioning

Authors: *N. SHARIF[1], Z. SHI[2], K. LUO[2], S. TAN[2];
[2]Dept. of Pediatrics, [1]Wayne State Univ., Detroit, MI

Abstract: Prenatal fetuses surviving hypoxic-ischemia (H-I) typically show postpartum symptoms of intellectual disability and cerebral palsy. Also, some children who show no signs of motor deficits remain at risk for cognitive deficits, while others may show no signs of cognitive deficits but live with motor deficits. In this study, a rabbit model was used to reflect acute placental insufficiency in humans, which results in global fetal brain H-I. Surviving rabbit kits after birth were conditioned with human feeding and underwent cognitive tests to evaluate their capabilities to identify a human face, and therefore, the prospect of classical and operant conditioning on minimizing cognitive deficits. H-I in fetuses was induced via uterine ischemia at 79% term gestation in pregnant New Zealand White Dams. Postpartum, half of the randomly selected post H-I and naïve surviving newborns (motor non-affected determined by neurobehavioral tests) were conditioned to recognize a human face (i.e. the original feeder) via consistent exposure to the individual for 9 days. A series of tests were then conducted using a six-arm maze to identify if the fetuses were able to recognize the original feeder, as well as isolate the source of cognitive recognition. Statistical significance was determined by Fischer's Exact tests. In unconditioned kits, both the H-I and naïve testing groups demonstrated a response

to both the negative and positive stimuli, showing no preference to go to the feeder. In conditioned kits, both naïve and H-I newborns showed a preference for the feeder, ($p = 0.0142$ and 0.0001, respectively). Since conditioning had been done with feeder in a lab coat, conditioned kits still showed a preference for the feeder without a lab coat. There was a difference in performance between the conditioned and unconditioned kits within the H-I ($P= 0.0001$) and Naïve ($P= 0.0215$) groups. Test 3 demonstrates that the conditioned kits, naïve ($P = 0.0037$) and H-I ($P= 0.035$) still preferred the original feeder even when she was wearing a mask of the bystander over the bystander wearing a mask of the original feeder. The ability to identify the discriminative stimulus amongst other stimuli, suggests that cognitive deficiencies could have been alleviated. Early-stage conditioning of fetuses affected by intellectual disabilities associated with H-I creates a possibility to minimize cognitive damage while the brain is still in early development. It is speculated that the conditioned kits relied more on olfactory systems rather than visual perception.

Title: Bdnf mrna expression level in the ipsilateral motor cortex correlates with motor impairment of paralyzed forelimb after intracerebral hemorrhage in rats

Authors: *T. INOUE[1,3], Y. TAKAMATSU[2], M. OKAMURA[1], H. MAEJIMA[2];
[1]Grad. Sch. of Hlth. Sci., [2]Dept. of Rehabil. Science, Fac. of Hlth. Sci., Hokkaido Univ., Sapporo, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Intracerebral hemorrhage (ICH) is a subtype of stroke that causes major motor impairments. It is well-recognized that functional recovery after stroke is attributed to both brain remodeling and neural plasticity. Brain-derived neurotrophic factor (BDNF) is known to have important roles for neural plasticity, so that it is expected that BDNF could be a potential biomarker for stroke recovery. However, BDNF expression after ICH remained poorly understood, because most of the stroke studies addressed the ischemic stroke. This study aimed to characterize BDNF expressions in the motor cortex after ICH and investigate the relationship between behavioral impairments and BDNF expression using an ICH rat model. 7-weeks-old male Wistar rats were divided into 2 groups: a SHAM group ($n = 7$) and an ICH group ($n = 8$). ICH was induced by the injection of collagenase in the left striatum near the internal capsule (AP: -2.0 mm, ML: 3.7 mm, DV: -6.0 mm). For behavioral assessments, the cylinder test and the

open field test were performed before surgery and 3 days, 1 week, 2 weeks, and 4 weeks after surgery. Following these behavioral assessments for 4 weeks, BDNF mRNA and protein expressions in the ipsilateral and contralateral motor cortex were assayed using RT-PCR and ELISA. All study procedures were approved by the ethics committee for animal research of Hokkaido University in Japan and conducted according to the guidelines of the committee. Forelimb motor impairment and decrease in locomotor activity were observed in the ICH group, whereas ICH rats did not present anxiety-related behavior. There was no significant difference in cortical BDNF expression between the SHAM and ICH group at 4 weeks after stroke. However, the asymmetry index of BDNF mRNA expression showed that the interhemispheric balance of BDNF mRNA expression shifted to the ipsilateral hemisphere after ICH. Furthermore, BDNF mRNA expression in the ipsilateral cortex positively correlated with paralyzed forelimb motor function only in the ICH group. There was no significant correlation between cortical BDNF expression and the other behavioral outcome such as locomotor activity and anxiety-related behavior. This study found for the first time that BDNF mRNA expression in the ipsilateral motor cortex could be related to post ICH motor impairment. These results might help to develop a novel treatment strategy for neurotrophin-dependent recovery after stroke.

Title: Synergistic effect of an PAF-receptor antagonist with an inflammatory response modulator on cerebral ischemia reperfusion injury in rats: a dose-response study

Authors: *L. S. BELAYEV[1], L. KHOUTOROVA[1], M. M. REID[1], A. OBENAUS[2], C. R. ROQUE[3], P. K. MUKHERJEE[1], N. A. PETASIS[4], R. B. ORIA[3], N. G. BAZAN[1];
[1]Neurosci., Louisiana State Univ., New Orleans, LA; [2]Pediatrics, Univ. of California, Irvine, Irvine, CA; [3]Morphology, Federal Univ. of Ceara, Fortaleza, Brazil; [4]Chem., USC, Los Angeles, CA

Abstract: Ischemic stroke is characterized by the sudden loss of blood circulation to an area of the brain, resulting in a corresponding neurologic function loss. Despite significant signs of progress achieved, effective stroke treatment remains a formidable challenge due to the complexity of the disease. Using a model of transient focal cerebral ischemia, the present study tested the hypothesis that blocking pro-inflammatory platelet-activating factor receptor (PAF-R) plus selected docosanoid after middle cerebral artery occlusion (MCAo) would lead to neurological recovery. The following small molecules were investigated: LAU-0901 (LAU), a

PAF-R antagonist that blocks pro-inflammatory signaling, Aspirin-triggered NPD1 (AT-NPD1), which activates cell-survival pathways, and their combination are exerting potent anti-inflammatory activity in the brain. Male Sprague-Dawley rats subjected to 2h of MCAo and were randomly assigned to seven treatment groups: LAU (45 and 60mg/kg, IP, at 3h), AT-NPD1 (111, 222, and 333µg/kg, IV, at 3.15 h after onset of stroke), LAU+AT-NPD1 or vehicle (n=5-6 per group). The behavioral function was evaluated on days 1, 3, and 7; a grading scale of 0-12 was employed. *Ex vivo* MRI of the brains was conducted using 11.7 T MRI on day 7. Physiological variables showed no significant differences among groups. Treatments with LAU-0901 (45 and 60 mg/kg) alone improved total neurological scores on days1-7 by 34-36%; AT-NPD1 (222 and 333 µg/kg) by 23-29% compared to vehicle groups. AT-NPD1 in a low dose (111 µg/kg) was not different from the vehicle group. The neuroprotective effect was enhanced using the LAU-0901+AT-NPD1, which resulted in improved total neurological scores up to 32-38% on days 1-7. Total lesion volumes, which were computed using T2WI, were significantly reduced with LAU-0901 (45 and 60 mg/kg) by 73-90% and AT-NPD1 (222 and 333 µg/kg) alone by 83-85% compared to the vehicle group. Ischemic core, penumbra, and total lesion volumes were dramatically reduced with LAU-0901+AT-NPD1 by 94, 92, and 93% compared to the vehicle. In conclusion, these data suggest that LAU-0901 and AT-NPD1 alone in moderate doses provide high-grade neuroprotection in a model of focal cerebral ischemia. Combination therapy with LAU-0901 and AT-NPD1 is more effective than the single therapy, affording synergistic neuroprotection with improved neurological recovery. Altogether, our findings support combinatory therapy as the basis for future therapeutics for ischemic stroke.

of Organic and Pharmaceutical Chemistry, NAS of Armenia, Yerevan**ABSTRACTObjectives**: Gangleron has hypotensive, antianginal, antiarrhythmic actions. Unlike other ganglioplegics, it has a moderately hypotensive effect and does not have a pronounced orthostatic hypotension. It predominantly blocks the N-cholinergic receptors of the parasympathetic ganglia, moderately depresses the respiratory center due to the inhibiting of pCO2- sensitive carotid glomus chemoreceptors. The impact of Gangleron on the sensitivity of depressive function of arterial baroreceptor reflex (ABR) was studied.**Methods:** The studies were carried out on 2 series (experimental 6 and control 7 animals) anesthetized white outbred rats of both sexes weighing 220-270 g. ABR testing was performed by the Oxford method, an increase in BP was caused by phenylephrine (15 μg / kg, i.v.) 10" after the administration of Gangleron (3 mg / kg, i.v.). The index of the sensitivity of the ABR depressor function was the regression coefficient linking the changes in BP (blood pressure) and heart rate (HR) during the first 15" testing of the ABR.**Results:** Gangleron by 15" significantly reduced the hypertensive effect of phenylephrine by 22.8% and reduced the time of development of the maximum cardiochronotropic response, shifting it from 15" to 10", did not change BP_{max} value achieved in both groups to 25" and did not significantly affect HR (heart rate) values. The sensitivity of the depressor ABR was significantly higher in the experimental group (-3.2 ± 0.7 mm Hg / bp/m) than in the control group (-2.1 ± 0.48 mm Hg / bp/m), the correlation coefficient r = 0.9 in both groups.**Conclusion:** A single use of Gangleron (3 mg / kg, i.v.) increased the sensitivity of ABR in rats. This fact may serve as the basis for starting studies of the use of Gangleron in complex antihypertensive therapy, where stimulation of carotid ABR with the help of implantable devices is a rapidly developing direction in the treatment of resistant hypertension. The property of Gangleron to improve depressive ABR along with depression of the respiratory center and moderately hypotension can be used in psychogenic cardiology, and to prevent panic attacks.

Med., New Orleans, LA; [4]Neurocritical Care and Neurology, Univ. of Queensland, Ochsner Clin. School, Ochsner Med. Ctr., New Orleans, LA

Abstract: Background: Intracerebral hemorrhage (ICH) results in increased intracranial pressure, blood-brain barrier damage, and cerebral edema. Pro-oxidant and pro-inflammatory milieu formed as a result of cell damage and cell lysis contributes to further injury. NPD1 is a docosahexaenoic acid (DHA) derived mediator with potent anti-inflammatory and anti-apoptotic properties and is highly enriched in the brain. NPD1 is made in response to tissue injury and counteracts the deleterious effects of inflammation and cell death. We hypothesized that ICH patients with better recovery/outcome will have increased levels of NPD1 in the blood. **Methods:** We have analyzed blood samples from sixteen patients with spontaneous ICH. RNA was extracted from PAXgene blood RNA tubes for 15-LOX-1 gene expression, critical in the endogenous synthesis of NPD1. Additionally, plasma was also isolated for Lipid analysis via Mass Spectrometry. Following a liquid-liquid lipid extraction, samples were analyzed using liquid chromatography-mass spectrometry (LC-MS/MS). The results were compared to controls (normal patients) and normalized to internal standards. Outcome measures included 90-day modified ranking score (MRS). **Results:** This is the first study to show the identification of NPD1 in ICH patients. The results show significantly higher NPD1 levels in ICH patients with 90-day MRS 0-3 (49.63pg/mL SD 43.78) vs. MRS 4-6 (1.88pg/mL SD 1.7) p=0.0012. We have also measured the gene expression of 15-LOX-1, a critical enzyme in the synthesis of NPD1. 15-Lox-1 is almost non-detectable in samples from patients with MRS 4-6, while patients with better outcome had higher 15-Lox-1 gene expression. NPD1 levels were higher in patients <65 yrs, ICH volume <30ml, and non-white, while PDX, was higher in patients >65 years, though changes in PDX were not significant. The amounts of DHA, EPA, and Arachidonic acid, as well as other lipid mediators such as resolvins and prostaglandins, did not show any significant variations. **Conclusions:** NPD1 and its stereoisomer PDX from the plasma of patients with spontaneous ICH were at very substantial levels. Furthermore, NPD1 levels and the expression of its critical enzyme 15-LOX-1 were elevated in patients who had better outcome and faster recovery. The results prompt further studies to comprehend the full scope of the effects of NPD1 in ICH. NPD1 plasma levels can also be used as an outcome predictor and a potential therapeutic option to enhance neuro-repair and neuro-recovery.

Title: Changes in occupational and instrumental activities after a cerebrovascular event in a Mexican sample

Authors: G. RAMÍREZ-ALVARADO, B. PALACIOS-HERNANDEZ, *B. TELLEZ-ALANIS;
CITPSI, UAEM, Cuernavaca, Morelos, Mexico

Abstract: Objective: To identify the changes in occupational and instrumental activities (functional independence), and the presence of depressive symptoms after a cerebrovascular event (CVE) in a sample of Mexicans patients. Reasons to attend cognitive rehabilitation were also assessed. Participants and Method: A sample of 17 Mexicans adults with 22 through 92 years of age, who had suffered any type of CVE were included in the study. Participants included 6 women and 11 men, with a mean age of 60 years old (SD=20) and 12 average years of education (SD=6). Participants were assessed through a clinical interview to identify attendance characteristics to rehabilitation process and to record changes in occupational and instrumental activities after a CVE. The Barthel index was applied to assess functional independence and the Yesavage scale (for elderly adults) or the Beck Depression Inventory (for young adults) were used to examine depressive symptoms. Results: Before the CVE most of men were employed (e.g. gardener, driver, salesman) and most of women were housewives. Main changes after the CVE, included that 53% of participants (2 women and 7 men) quit their employment or any previous activities. Four participants didn´t reported any data related to their income sources, 5 of them increased their financial support and in six of them it was decreased after the CVE. In 41% of the sample, the functional independence disappeared and 23.5% reported depressive symptoms. Meanwhile 71% (n=12)) attended to a rehabilitation program: 4 received neuropsychological therapy, 7 received physical rehabilitation and 1 participant had both types of treatment. Five patients (29%) did not attend a rehabilitation process, 4 had no obvious physical or cognitive sequelae, so this service was not indicated, and one of the participants did not provide this information. Conclusions: These results reflect a change in occupational and functional state in patients after a CVE, which results in a reduction of economic incomes. Also, more than half of the sample attended some type of rehabilitation, with the 29% participating in a neuropsychological therapy. In general, these results suggest the importance of rehabilitation services in patients with brain damage sequelae, particularly of a neuropsychological type which may support their possible functional and occupational reincorporation.

Abstract: Objective: This exploratory study examined the performance of individuals with traumatic brain injury (TBI) and stroke on various KINARM robotic tests and their potential associations with clinical scales of severity at both subacute (T1) and 6-month post event (T2) timepoints. Methods: Twenty-seven individuals (age 18-78 years; 74% male) with stroke (6 minor, 6 moderate) or TBI (6 mild, 4 moderate, 5 severe) were recruited within 3 weeks of injury (T1) and at a 6 month follow-up (T2). Injury severity was determined using the NIH Stroke Scale (NIHSS) and the Glasgow Coma Scale (GCS) for stroke and TBI, respectively. Neurological impairment was quantified using the KINARM robotic device. Five standard KINARM tasks [Visually Guided Reaching (VGR), Arm Position Matching (APM), Kinesthesia (KIN), Object Hit (OH), and Object Hit and Avoid (OHA)] evaluated aspects of sensorimotor, visuospatial, proprioceptive, and cognitive function. Overall Task Scores for each injury group were calculated on each task to evaluate performance compared to normative values. Spearman correlations were used to assess the relationship between robotic assessments vs injury severity at each time point. Results: Most stroke participants performed outside the 95% range of normative data on every robotic task (90.0% on VGR, 80.0% on APM, 77.8% on KIN, 88.8% on OH, and 70.0% on OHA) at T1. In comparison, fewer individuals with TBI performed outside the range of normative data (33.3% on VGR, 13.3% on APM, 40.0% on KIN, 33.3% on OH, and 33.3% on OHA). At the second time point, severity of stroke was more strongly correlated with performance on some measures (KIN ρ=-0.731) than others (APM ρ=0.240). We did not observe similar relationships between TBI severity and the robotic scores (KIN ρ=0.014, APM ρ=-0.445). Robotic scores improved by T2, on average, in both stroke and TBI. Conclusions: Robotic assessment successfully detected neurological impairment after stroke at both time points and individuals with stroke more commonly showed impairments than those with TBI. Interestingly, the robotic measures most likely to detect impairment in TBI were tasks requiring the recruitment of multiple brain regions and increased cognitive demand, perhaps due to the injury mechanisms of TBI being more diffuse in nature. While preliminary, these findings reveal the strengths and weaknesses of the KINARM to evaluate neurological impairment in different severities of acquired brain injury.

Title: Acute neurophysiological dynamics during focal ischemic lesioning in non-human primate sensorimotor cortex

Authors: *K. KHATEEB[1], S. CHAVAN[1], K. COUBROUGH[1], J. BLOCH[1], M. RAHIMI[2], D. J. GRIGGS[2], T. LIU[1], M. LE[1], R. WANG[1], A. YAZDAN-SHAHMORAD[1,3,4];

Abstract: The primate cerebral cortex is a complex structure responsible for a variety of sophisticated tasks and behaviors including somatosensation and movement, which can be severely impaired following stroke. However, the development of effective treatments for sensorimotor dysfunctions arising from stroke is hindered by a lack of understanding of the underlying neural dynamics following injury. To drive the development of novel stimulation-based therapies, it is critical that these phenomena are investigated in a model sharing a high degree of complexity and evolutionary history with human cortex: the non-human primate (NHP) cortex. Here, we employ our previously developed lesion-based toolbox to investigate neurophysiological dynamics during injury of the NHP sensorimotor cortex. We induced focal ischemic lesions using the photothrombotic technique in the NHP sensorimotor cortex. Lesion induction was validated *in vivo* with optical coherence tomography angiography imaging and histologically post-mortem. We recorded neurophysiological dynamics as unilateral lesions developed over the course of three hours using implanted semi-transparent electrocorticographic (ECoG) arrays. To assess the changes in neural activity during the formation of a lesion, we calculated changes in local field potential power across different frequency bands (high gamma: 60-150 Hz, gamma: 30-60 Hz, beta: 12-30 Hz, theta: 4-7 Hz). As expected, recording sites in the lesioned area and the surrounding region exhibited decreases in power with some adjacent regions increasing in power. Interestingly, we observed global decreases in power across the network in both beta and theta bands. We also assessed functional connectivity changes across the network using signal coherence between electrode pairs. We observed an average decrease in functional connectivity across the network in all frequency bands following lesioning. Surprisingly, channels within the lesioned area and between the lesioned area and nearby regions exhibited an increase in connectivity in the higher frequency bands. In this study, we address the short-term changes in neural activity and connectivity during the induction of a lesion. While neural activity decreased in the lesioned region, increased activity and functional connectivity in the nearby regions may be evidence of compensatory activity following stroke that can be

exploited to promote functional recovery. The results of this study have great implications for the development of neurorehabilitation strategies for stroke and other neurological disorders.

Title: Alterations in the fronto-parietal brain network for balance control in chronic stroke patients

Authors: ***N. RAO**[1], H. RABIEH[1], M. MUTNICK[3], S. SHAH[1], S. CHAUDHARI[1], N. MEHTA[1], E. TODD[2], M. GALE[2], J. L. CONTRERAS-VIDAL[2], P. J. PARIKH[1];
[1]Hlth. and Human Performance, [2]Electrical and Computer Engin., Univ. of Houston, Houston, TX; [3]Georgia Inst. of Technol., Atlanta, GA

Abstract: Impaired balance control following stroke contributes to falls among patients, thus limiting their mobility and independence in activities of daily living. Designing effective interventions require mechanistic framework. However, mechanisms by which stroke impairs balance control remain poorly understood. Remarkably, the contribution of cortical reorganization following stroke to impaired balance control remains unknown. We aim to address this knowledge gap by investigating cortical mechanisms associated with balance control in chronic stroke patients. Our recent work in healthy individuals identified a network of fronto-parietal brain regions that adjusts its activity based on the difficulty of the balance control task. We hypothesize that stroke disrupts the response of the identified fronto-parietal network, leading to impaired balance control among patients. This ongoing study is intended to study stroke survivors with mild-to-moderate severity and healthy adults age- and gender-matched to stroke patients. Participants are instructed to maintain balance in response to balance perturbations with varying difficulty levels on a computerized balance platform. We use 64-channel electroencephalography (EEG)-based neuroimaging analysis to assess the activation within the frontal and parietal brain regions while participants perform the balance task. Our preliminary findings (planned sample: n = 20, recruited: n = 5, 2 females) showed increased modulation in parietal areas as patients with stroke performed the balance control task. Consistent with previous studies, stroke patients' performance on the clinical tests reflected impaired balance and mobility when compared with healthy controls. Findings from this study

will be critical to determine how stroke influences the cortical network essential for balance control, as well as inform the design of interventions aimed at reducing falls among patients.

Title: Transcutaneous electrical trigeminal nerve stimulation in chronic hemiparetic stroke

Authors: *J. A. BEAUCHAMP[1], C. J. HECKMAN[2], J. YAO[3], J. P. DEWALD[4];
[1]Dept. of Biomed. Engin., [2]Dept. of Physiology, Feinberg Sch. of Med., [3]Physical Therapy & Human Movement Sci., [4]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Accumulating evidence suggests that chronic stroke induced motor impairments exhibit a dependence on heighted brainstem mediated monoaminergic drive to the spinal cord. Explicitly, a relative increase in descending monoamines is believed to increase spinal motoneuron excitability and thus (1) give rise to spasticity and (2) amplify the diffuse neural commands postulated as responsible for flexion synergy expression. This yields a potential investigational avenue, whereby altering monoaminergic drive may causally manipulate stroke induced motor impairments while also providing insight into their pathophysiological generation. Thus, we hypothesize that modulation of monoaminergic brainstem areas, such as the locus coeruleus, through non-invasive transcutaneous trigeminal nerve stimulation (TNS) will alter motoneuron excitability in individuals with chronic hemiparetic stroke and change the expression of motor impairments.
To investigate this potential, we recruited 8 individuals with moderate to severe chronic hemiparetic stroke (> 1 year post stroke) and quantified spinal motoneuron excitability before, during, and after one hour of both real and sham TNS. Real TNS was accomplished via biphasic electrical stimulation applied bilaterally to the supraorbital nerve at an individual's perceptual threshold (TNS; 100 Hz, 300 μs, avg: 4.0 mA). Spinal motoneuron excitability was estimated via the tonic vibration reflex of the paretic biceps brachii. Specifically, participants were instructed to generate and maintain 15% of maximum voluntary elbow flexion torque for 10s, after which a tonic vibratory stimulus (128 Hz) was applied to the paretic biceps brachii muscle for 5 s at a constant force of application. During this 5 s vibratory stimulus, visual torque feedback was removed and individuals were instructed to maintain their perceived level of force. The reflexively generated elbow flexion torque during this vibratory stimulus was then used as an

estimate of spinal motoneuron excitability.
When compared to an active sham stimulus, real TNS elicited greater decreases in reflexively generated elbow flexion torque during stimulus. This was observed as a significant decrease in the reflexively generated elbow flexion torque evoked by tonic vibration of the biceps brachii during real TNS and not sham conditions. This suggests that greater monoaminergic drive may increase spinal motoneuron excitability in this population and that TNS may be used as a method of probing this drive. Further work to understand the effects of TNS on estimates of intrinsic spinal motoneuron excitability with high-density surface electromyographic arrays is ongoing.

Title: Quantifying stretch reflex modulation during volitional reaching

Authors: *T. A. M. PLAISIER, A. ACOSTA, J. P. A. DEWALD;
PTHMS, Northwestern Univ., Chicago, IL

Abstract: The stretch reflex is an important monosynaptic pathway, involved in maintaining posture, joint stabilization, and perturbation rejection. During movements, these reflexes are modulated by supraspinal structures via corticofugal pathways to achieve high movement accuracy even in unpredictable environments at low energy costs. By measuring reflex excitability during voluntary movement, the modulation can be used as a proxy measure for neural activity in supraspinal structures. This allows for studying how these structures control movement, and how neurological injuries like stroke may affect stretch reflex modulation.
We have developed a novel protocol to quantify stretch reflex excitability during a ballistic reaching task and assessed the protocol on a group of control participants (n = 2) and participants with chronic hemiparetic stroke (n = 4). This novel method relies on a newly developed haptic device (NACT3D) capable of combining unconstrained 3D motion with 270°/s elbow extension perturbations. Participants moved ballistically from a near to a far target, with perturbations occurring in random catch trials. Reflexive muscle activity was defined as a change in EMG (normalized to Maximal Voluntary Contraction or MVC) 25-150 ms following the perturbation, relative to unperturbed movements.
Preliminary results show that reflexive activity following a perturbation in controls is minimal (+0% to +10% MVC) across all muscles and motion phases. In hemiparetic stroke, perturbations prior to voluntary movement cause an increase in reflexive muscle activity in all muscles (+16 to +84% MVC). While reaching, perturbations cause an increase in reflexive muscle activity in the

biceps and pectoralis major (+17% to +45% MVC) but a decrease in muscle activity in the triceps and deltoid muscles (-9% to -27% MVC). Post-hoc analysis showed significant differences in muscle activity prior to motion vs. in motion ($p < 0.0001$), stroke vs. control ($p < 0.0001$), paretic vs. non-paretic limb within the stroke cohort ($p < 0.0001$), paretic vs. non-dominant across cohorts ($p < 0.0001$), and short- vs. long-latency reflexes in the stroke cohort ($p < 0.0001$). These results indicate that reflex modulation is affected by hemiparetic stroke, and for the first time show altered reflex modulation during movement following hemiparetic stroke. The developed protocol and device allow for studying reflex modulation during a variety of motion tasks and increase our understanding of the complex role of supraspinal structures in modulating stretch reflexes.

Title: Resting state connectivity associated with skilled motor practice in individuals with stroke: dissociable networks for learning and recovery

Authors: *S. N. KRAEUTNER[1], C. RUBINO[1], S. RINAT[1], B. LAKHANI[1], M. R. BORICH[2], K. P. WADDEN[3], L. A. BOYD[4];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Emory Univ., Atlanta, GA; [3]Mem. Univ. of Newfoundland, St. John's, NL, Canada; [4]Univ. British Columbia, Vancouver, BC, Canada

Abstract: Activity patterns across brain regions that can be characterised at rest (i.e., resting state functional connectivity; rsFC) are disrupted after stroke, and linked to impairments in motor function. While changes in rsFC are associated with motor recovery, it is not clear how functional connectivity is modulated by skilled motor practice. The current study examined how rsFC is modulated by skilled motor practice after stroke, and whether or not changes in rsFC are linked to both motor learning and recovery. Two groups of participants (individuals presenting with chronic stroke, $n = 32$; and age-matched controls, $n = 31$) engaged in four weeks of skilled motor practice of a complex, gamified reaching task designed to prevent early plateaus in performance. Clinical assessments of motor function and impairment, and brain activity (via functional magnetic resonance imaging) were obtained before and after training. We employed an ROI-to-ROI approach to examine changes (post vs. pre) in functional connectivity for each group. Further, graph theory metrics were computed to quantify network characteristics and interconnectedness. While no differences in rsFC were observed in the healthy control group, increased connectivity was observed in the sensorimotor network (linked to learning; e.g., between motor and posterior parietal cortices) and circuitry underlying higher cognitive

processes (linked to recovery; e.g., between the thalamus and frontal regions) in the stroke group. Relative to healthy controls, a decrease in network efficiency was observed following training. Findings show that the dissociable rsFC patterns related to learning and recovery reflect distinct offline processing that occurs over the course of training. Ultimately, we suggest that patterns of rsFC changes observed after stroke reflect a shift towards a compensatory network configuration characterised by decreased network efficiency.

Title: Structural connectivity correlates of upper and lower limb coordination in individuals with chronic stroke

Authors: *D. M. PETERS[1], M. WINGOOD[1], J. C. STEWART[2], L. BONILHA[3], S. L. FRITZ[2], J. FRIDRIKSSON[2];

Abstract: Preservation of white matter (structural) fibers connecting brain regions critical for motor control may directly enhance functional recruitment of these regions modulated by neurorehabilitation to improve motor recovery post-stroke. We have shown that reduced structural connectivity of the ipsilesional primary motor cortex is an independent predictor of gross upper extremity motor performance/strength and walking speed impairment in chronic stroke, even after statistically controlling for lesion volume. Little is known, however, about structural connectivity damage and intra- or interlimb coordination deficits post-stroke. The purpose of our study was to examine the relationship between structural connectivity among key sensorimotor brain regions and upper/lower extremity (UE/LE) coordination in chronic stroke. Data were collected from 55 participants (20 female; mean age 60.0 ± 10.2 years; time post-stroke 60.7 ± 56.0 months) and retrospectively analyzed. Participants underwent MRI and a comprehensive behavioral assessment that included UE/LE dexterity tasks (unilateral and bilateral tapping paradigms). Interrater reliability of tapping counts was assessed using intraclass correlation coefficients (ICCs), and relationships between structural connectivity amid a predefined sensorimotor subnetwork and UE/LE coordination tasks were examined using

Spearman's correlations. Interrater reliability for tapping counts was excellent, with ICC values ranging from 0.97-1.00. Correlations between structural connectivity and UE/LE coordination tasks were strongest involving ipsilesional cortico-subcortical connectivity between the primary motor cortex (M1)/supplementary motor area (SMA) and the cerebral peduncle/thalamus, and between the primary sensory and anterior cingulate cortex and the thalamus ($r=0.46$-0.79, $p\leq0.002$). Ipsilesional M1-SMA connectivity was specific to LE interlimb coordination ($r=0.44$, $p\leq0.002$). Structural connectivity among key sensorimotor regions, especially cortico-subcortical connectivity, is positively related to UE/LE coordination tasks in chronic stroke. There is a large degree of overlap between gross motor neural connections and those related to coordination, suggesting these tasks share similar motor networks. Greater insight regarding structural disconnection after stroke may inform targeted rehabilitation interventions aimed at improving motor coordination in this patient population.

Hosp. Nottingham, Notthingham, United Kingdom

Abstract: Background: One third of stroke patients are at risk of developing post-stroke dementia[1]. Alzheimer dementia is associated with pathology of the Hippocampus[2]. **The aim** of this study was to investigate the impact of hippocampus health on post-stroke cognition. **Methods:** 42 stroke patients (mean=63±12, 32 males) were recruited. Inclusion criteria: within three months of ischaemic stroke, MoCA[3] less 25, ability to consent, high chances of survival. Exclusion criteria: stroke affecting middle temporal structures, MR counter-indication, inability to concentrate for 30 minutes. Cognition was assessed using the BCoS[4]. Hippocampus[5] health

was examined using; T1-weighted imaging (volumetric, CAT12[6]) and magnetic resonance spectroscopy (NAA metabolite). Inter-measurement correlations were used to assess the validity of MR measurements. Multiple regression analyses was used estimate the relation between hippocampus health and cognition, while controlling for demographic and crude measures of brain health (lesion size, Framingham Risk Score[7], cortical atrophy[8], and small vessel disease[8].
Results: Hippocampus grey matter volume correlated negatively with age and Framingham Vascular risk ($r < -.49$) and positively with education and NAA ($r > .43$). Cognition was reliably predicted by hippocampus volume (standardised $\beta = .40$) and NAA ($s\beta = .48$), even after controlling for confounding factors.
Conclusion. This study highlight the role of hippocampus health in post-stroke cognitive recovery, offering a potential mechanism for diagnosing a risk for post-stroke dementia.

Title: Custom DTI probabilistic tractography techniques to estimate muscle fascicle morphology in the biceps brachii muscle for chronic hemiparetic stroke

Authors: *D. JOSHI[1,2], W. M. MURRAY[1,2,3], J. P. A. DEWALD[1,2,3], C. INGO[2,4];
[1]Dept. of Biomed. Engin., Northwestern Univ., Evanston, IL; [2]Dept. of Physical Therapy &

Human Movement Sci., [3]Dept. of Physical Med. & Rehabil., [4]Dept. of Neurol., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Introduction: Motor pathways are thought to be reorganized after the onset of hemiparetic stroke, resulting in altered neural input to the paretic limb's skeletal muscles. This change in neural drive gives rise to disuse and secondary adaptations in muscle architecture, such as shorter muscle fascicles and decreased muscle volume, which can critically impact already existing functional impairments. Here, we implement custom diffusion tensor imaging (DTI) probabilistic tractography techniques to non-invasively measure fascicle lengths in arm muscles following a hemiparetic stroke. Methods: Diffusion-weighted imaging (spin-echo echo planar imaging sequence, voxel resolution=1.25x1.25x5 mm3) and T1 anatomical (voxel resolution=0.78x0.78x3 mm3) scans were taken of the biceps brachii (BIC) muscles in one participant with chronic hemiparetic stroke (M, 73 yo) and one control participant (M, 63 yo). Anatomical scans were used to select seed regions within the muscle, from which probabilistic tractography analyses were performed. Tractography results represented muscle fascicle bundles and were fitted to 3D polynomial curves to estimate fascicle lengths. Results: Fascicle lengths in the individual with stroke exhibited interlimb differences, with the median fascicle length of the paretic BIC being 43% shorter than the median of the non-paretic BIC. Meanwhile, fascicle lengths in the control individual did not exhibit interlimb differences. These results are consistent with previously published ultrasound measurements (Adkins et al., 2020) and indicate that the DTI method is similarly sensitive to the structural changes that are present in skeletal muscles in chronic stroke. Most importantly, our new results indicate that DTI techniques can capture a broader distribution of fascicles in comparison to the superficial measurements of ultrasound, which ultimately allows for the capability to analyze morphology across all muscles in individuals with stroke-induced motor impairments. Conclusion: The stroke-induced disuse of the paretic elbow results in shorter muscle fascicles in the paretic BIC, which causes a reduced elbow range of motion and further exacerbates functional impairments after stroke. The broad range of fascicle lengths captured in the current study suggests that there is a complex organization of fascicles, which is consistent with previous ex vivo cadaveric studies (Loeb et al., 1987), but has yet to be shown using in vivo techniques. Future work will apply these new DTI probabilistic tractography techniques to better understand how the inherent organization of muscle fascicles may be altered following a neuromuscular injury.

Title: The efficacy of curcumin to facilitate recovery of function in a rhesus monkey model of cortical injury.

Authors: M. A. PESSINA, Y. ZHOU, M. SAKHARKAR, B. G. E. BOWLEY, D. L. ROSENE, M. MEDALLA, ***T. L. MOORE**;
Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Curcumin is a primary component of the spice turmeric and is a potent anti-inflammatory and anti-oxidant compound. In rodent models, curcumin acts primarily on microglia and astrocytes to inhibit pro-inflammatory signaling pathways and in rodent models of stroke, ischemia, and traumatic brain injury it reduces inflammation and levels of reactive oxygen species. Further, rats with cortical injury treated with curcumin have smaller lesions and fewer neurological impairments than those treated with vehicle. However, the promising effects of curcumin have not yet been extensively tested in rhesus monkeys so it is not clear whether curcumin exerts the same biological effect in primate brains as in rodent brains. However, our prior cognitive studies recently demonstrated that curcumin enhances spatial working memory and motor function in aging monkeys receiving daily oral doses of dietary curcumin. Building on these findings, we administered oral doses of curcumin to adult, male rhesus monkeys following induced cortical injury to the hand-representation of primary motor cortex (M1). Treated monkeys demonstrated significantly enhanced recovery of function in terms of time to retrieve a food reward. In addition, treated monkeys returned to pre-injury grasp patterns, while monkeys that received vehicle developed a compensatory grasp pattern and did not return to pre-injury grasp patterns. Post-mortem assessment of brain tissue from these monkeys showed that within the perilesional grey matter of curcumin-treated monkeys the total density of microglia increased, with a greater proportion of antigen-presenting MHCII+ microglia. Further, in vitro whole-cell patch-clamp recording in acute slices of perilesional cortex showed that curcumin reduced injury-related hyperexcitability in perilesional layer 3 pyramidal neurons. These findings suggest that while curcumin treatment promoted microglial proliferation and activation, it also ameliorated neuronal excitotoxicity. While further work is needed to establish the link between these two processes, it is possible that curcumin promoted neuroprotection after injury through microglial proliferation that facilitated clearance of damaged neurons. Our findings show that curcumin is an effective treatment for enhancing recovery of function after cortical injury in our rhesus monkey model, but the precise cellular and molecular mechanisms remain unclear and will be further investigated.

Abstract: Ischemic stroke triggers a pattern of cellular and molecular disturbances that include lipid peroxidation, uncompensated oxidative stress, and neuronal injury. Although neuroprotective strategies have shown promise, no treatment has demonstrated efficacy after stroke. This study focuses on the neuroprotective bioactivity of docosanoid (DOC) mediators: Neuroprotectin D1 (NPD1), Resolvin D1 (RvD1), and their combination (NPD1+RvD1) against experimental ischemic stroke. These lipid mediators are biosynthesized "on-demand" in response to the onset of stroke to resolve neuroinflammation and restore homeostasis. Male Sprague-Dawley rats were anesthetized with isoflurane/nitrous oxide and underwent 2h of middle cerebral artery occlusion (MCAo). Behavior was evaluated on days 1, 3, and 7; a grading scale of 0-12 was employed. Animals were randomly assigned to eight treatment groups: NPD1 (111, 222, and 333µg/kg), RvD1 (111, 222, and 333µg/kg), NPD1 + RvD1 or vehicle (n=4-5 per group). All treatments were administered IV at 3h after the onset of MCAo. *Ex vivo* MRI was conducted on day 7. Physiological variables showed no significant differences among groups. Treatments with NPD1 (111, 222, and 333µg/kg) alone greatly improved neurological scores (by 32, 28, 35%) and RvD1 (111, 222, and 333µg/kg) alone by (by 35, 44, 31%) compared to the vehicle group. The neuroprotective effect was enhanced using the NPD1+ RvD1, which resulted in improved total neurological scores on days 1, 2, 3, and 7 by 25, 28, 28, 40% compared to the vehicle group. Ischemic core and penumbra volumes (computed from T2WI) were significantly reduced compared to the vehicle-treated group. We have shown that treatment with NPD1, RvD1 alone, and combination therapy provides high-grade neurobehavioral recovery and decreases ischemic core and penumbra volumes. Thus, these findings support the potential clinical feasibility of administering novel docosanoids therapy to patients with acute ischemic stroke.

Title: Intranasal delivery of precursors of N-32 and N-34 elovanoids, novel homeostatic mediators, improves behavior and protect ischemic penumbra in rats after ischemic stroke

Authors: *M. M. REID[1], L. KHOUTOROVA[1], B. K. PARK[1], N. DESAI[1], P. K. MUKHERJEE[1], B. JUN[1], A. OBENAUS[2], N. A. PETASIS[3], L. BELAYEV[1], N. G. BAZAN[1]; [1]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [2]Univ. of California, Irvine, Irvine, CA; [3]USC, Los Angeles, CA

Abstract: Ischemic stroke alters the neurovascular unit, neuroinflammatory responses, and synaptic activity causing tissue death. Recently, we discovered and characterized a novel class of homeostatic lipid mediators, termed elovanoids (ELVs), which are derivatives from very long-chain polyunsaturated fatty acids (VLC-PUFAs,n-3). ELVs displays neuroprotective bioactivities, both *in vitro* and *in vivo* experimental ischemic stroke. We also found that intravenous administration of ELVs is neuroprotective in middle cerebral artery occlusion in rats. The aim of this study was to examine whether intranasal ELV is equally effective as intravenous ELVs in a rat model of MCAo. Male Sprague-Dawley rats (280-300g) received 2h MCAo by intraluminal suture. Treatments with VLC-PUFAs (C-32:6 or C-34:6) and vehicle were administered at 1h, 24h, and 48h after 2h of MCAo by intranasal delivery. The composite neurological battery was performed on days 1, 2, 3, and 7 after stroke; a grading scale of 0-12 was employed (normal score=0, maximal deficit=12). *Ex vivo* imaging of the brains was conducted on 11.7T MRI on day 7 for lesion volumes and edema (T2WI), followed by immunohistochemistry. No adverse physiological effects were observed in any treatment group. Behavioral scores were improved with C-32:6, C-34:6, on day three by (42% and 21%) and on day 7 (45% and 23% respectively) compared to the vehicle group. Total lesion volumes computed from T2WI were reduced with C-32:6, C-34:6, compared to the vehicle by 88% and 57%, respectively, on day seven. In addition, ischemic core and penumbra volumes were significantly reduced by all ELV treatments. We conclude that the intranasal administration of precursors of N-32 or N-34 ELVs provides high-grade neuroprotection. Our study opens avenues of exploration of ELVs as a possible therapeutic approach for ischemic stroke.

Title: Low dose ionizing radiation reverses motor deficits and promotes brain rewiring after ischemic stroke in mice

Authors: *G. KUMAR[1], N. P. B. AU[1], S. L. CHAN[1], J. H. C. LAI[2], K. W. Y. CHAN[2,4], K. N. YU[3], C. H. E. MA[1];

Abstract: Stroke is the most common form of acquired brain damage caused by blockade of cerebral artery. Patients surviving from stroke often experience life-long motor impairment and disability which require long-term rehabilitation. Motor functional restoration is limited even after intense rehabilitation. Approximately 30% of the stroke survivors cannot walk properly without assistance, and show high dependence in their daily lives. Currently, there is no effective treatment to reverse the motor deficits after ischemic stroke. Growing evidence suggested that low dose of ionizing radiation (LDIR) displayed strong neuroprotective effects on various neurological disorders such as retinitis pigmentosa, spinal cord injury, glaucoma and Parkinson's disease. Our pilot study also demonstrated that LDIR accelerated motor functional recovery after traumatic brain injury in mice via promoting anti-inflammatory M2 polarization in microglia. Here, we extended our study to investigate the therapeutic potential of LDIR on ischemic stroke. We induced a focal ischemic stroke in adult mice by photothrombotic lesion on the right motor cortex using Rose Bengal, and observed an increase in microglial clustering associated with the reduced deposition of chondroitin sulfate proteoglycans at the lesion in irradiated mice shortly after stroke induction. LDIR also markedly reduced the wound area at 7 days post stroke. After confirming the beneficial effects of LDIR on ischemic stroke, we then assessed motor functional recovery by narrow beam walking, pole climbing and grip strength tests over a period of 56 days. While sham-irradiated mice exhibited sustained motor deficit after stroke, the irradiated mice displayed a remarkable restoration in motor function as they returned to their baseline values within 7-21 days in all the behavioral tests. Depletion of the resident microglia in the brain completely abolished the beneficial effects induced by LDIR. Further analysis on the infarct development using TTC staining and magnetic resonance imaging revealed a marked reduction in average infarct volume in the irradiated mice. More importantly, LDIR induced an extensive bi-hemispheric axonal sprouting in the pre-motor cortex area, which led to a marked improvement in average local field potential oscillations in irradiated mice two months after stroke. Taken together, our study demonstrated that promoting microglial M2 polarization using LDIR is a promising therapeutic approach to reverse the motor deficits in a mouse model of ischemic stroke. Further optimization of the dosage of LDIR could pave the path for clinical use in treating patients with ischemic stroke.

Title: Translational tools and approaches of cellular therapies in different neurological disorders in drug discovery

Authors: *K. M. PALDANIUS, T. HUHTALA, D. MISZCZUK;
Charles River Discovery, Kuopio, Finland

Abstract: Regenerative therapies of central nervous system (CNS) diseases offer innovative strategies to promote tissue and functional repair. As part of cell therapeutic approach, understanding basic biodistribution and ADME profile of studied cell product in early phase is important before proceeding towards more complex and comprehensive study designs. In addition to the ADME profile of the cells, safety and efficacy of cell products are crucial steps in development of novel treatment approaches. Efficacy of cell therapies is highly dependent on route of administration of transplanted cells, biodistribution, graft survival, and integration in the affected brain/spinal cord area. Intra-arterial (i.a.) infusion of cells bypass the filtering organs enabling the cells to transplant the target region more efficiently compared to e.g. intravenous delivery. In addition to used administration route, one approach to affect transplantation efficacy of cell product, can by altered by transducing cells with viral vectors. In this work we studied biodistribution of stem cell with or without viral transduction in rat stroke model. In case of stroke, successful and efficient homing of the cells to traumatic brain area without complications is important for the therapeutic potential of cell therapy. Here we studied the biodistribution of human stem cells after a direct i.a. administration in rat stroke model. Cells were radiolabeled using 111In and biodistribution over time was studied using SPECT/CT imaging. Our results showed that i.a. infusion of cells was a safe and efficient administration route for studied cells resulting in a transient localization of cells in the rat brain. For early distribution studies of cells, radiolabeling and SPECT/CT imaging offers efficient and fully translational tool for early ADME profiling of novel cell products.

Title: Delivery of hSOX2 gene using PAMAM dendrimer nanomolecules to reprogram astrocytes into neurons in ischemic stroke rats

Abstract: Stroke is the fifth leading cause of death in the US with ischemic stroke accounting for 87% of the cases. A major limitation of currently available treatment strategies is that they are time sensitive and must be administered within 3 hr of the patient's first symptoms to achieve maximum therapeutic efficiency. Alternative treatments are being developed that are not as time sensitive and utilize *in vivo* reprogramming to replenish the lost neurons in sufficient numbers. Our work suggests that the use of dendrimers can facilitate delivery of therapeutic biomolecules and gene vectors. Dendrimers are nanomolecules with a well-established capacity of delivering drugs/ large biomolecules across the BBB, while possessing anti-inflammatory properties themselves. They are comprised of a central core, an interior dendritic structure , and an exterior surface with functional surface groups. The surfaces can be manipulated in order to efficiently enter the cells without damaging the integrity of, thus keeping toxicity to a minimum; they can also be labeled for efficient tracking. The G4 PAMAM dendrimers (4 nm) used in this study have 10% of the surface covered with amine groups and 90% of the surface covered with hydroxyl groups (D-90/10) and labelled with Cy5.5. They have been shown to be less toxic and readily form complexes with plasmids up to 14kb in size while successfully delivering cargo in vitro and in vivo In this study, we tested whether a transcription factor, *SOX2,* when expressed under a glial cell-specific gfa2 promoter, could sufficiently reprogram astrocytes at the site of insult/inflammation to enhance their differentiation into neurons. Four days after inducing strokes via a middle cerebral artery occlusion (MCAo). in Sprague Dawley rats, a novel gfa2-pomoter-containing dendriplex was injected into the corpus callosum. The dendriplex allowed for *hSOX2* gene expression under an astrocyte-specific GFAP promoter which was complexed with a mixed-surface PAMAM G4 90% OH and 10% NH2 dendrimers tagged with Cy5.5 (D-Cy5.5-gfa2-hSOX2-GFP-Luc2 dendriplex). Eight weeks following the injections, the brains were collected and analyzed for the presence of the complex and *hSOX2* gene expression using IHC (Abcam; Anti-SOX2 antibody #ab97959). The stained tissues were mounted on slides and imaged using Zeiss AxioImager M2.0. When injected in the stroked brains complexed with hSOX2, we were able to observe a clear co-localization of the hSOX2 protein, the GFP reporter protein, as well as the PAMAM G4 90/10-Cy5.5 dendrimer. Thus, we conclude that the

dendrimer-plasmid complex was successfully delivered to the cells, giving rise to hSOX2 protein expression at the infarct site.

Abstract: Introduction: Therapeutic advances for ischemic stroke in the past few decades include intravenous tissue plasminogen activator administered within 4.5 hr and mechanical thrombectomy up to 24 hr after stroke onset. Although this has led to a 30% increase in survival rates after stroke, more than 50% of stroke survivors are chronically disabled. Hence, novel more effective therapies are needed. Research in the last 2.5 decades has shown great promise in the use of cell-based therapies for stroke. Our group and others have shown the safety and efficacy of intra-arterial (IA) stem cell therapy in a rodent model of stroke and safety in a clinical study, RECOVER-Stroke. The IA route of delivery is minimally invasive and allows for targeted delivery of cells. We pursued a pre-clinical project to study the safety, efficacy, and optimum dosage of IA mesenchymal stem cell delivery in a canine model of stroke. This model is well-suited for translation due to its gyrencephalic brain and a white to gray matter ratio that is similar

to humans. The objectives of this study were: 1) Develop a reproducible endovascular model of canine focal cerebral ischemia with reversible middle cerebral artery occlusion (rMCAO). 2) Test the safety, efficacy and optimal dosage of IA MSC therapy in this model. Methods: An endovascular canine rMCAO model using retractable platinum coil for 60-120 min was established. At 48 hr post-rMCAO, canine MSC (10-80 million) were delivered using a microcatheter in the ipsilateral upper cervical internal carotid artery. Serial MRIs and neurological deficit scoring (NDS) were performed over 30 days. Animals were euthanized at 15-30d post-rMCAO and brains were harvested for histology and molecular analyses. Results: Our study yielded a highly reproducible, minimally invasive endovascular large animal model of rMCAO. Significantly higher infarct volume reduction was seen at IA 10 million and 40 million doses in dose dependent manner as compared to the control group. This correlated with improvement in focal neurological deficits with faster and more complete recovery in the treated groups as compared to controls. Delivery of high dose, 80 m cells, led to worsened outcome and new infarct lesions 4 days post-injection with spontaneous resolution at day 15 were observed. Conclusions: In conclusion, our study suggests that IA delivery of MSC at 48 hr post-stroke is safe and effective in a dose-dependent manner up to 40 m MSCs. IA delivery of 80 million MSCs is toxic leading to new severe cerebral ischemia from the cell dose. Collectively, our study has established a successful preclinical canine model of stroke and reported dose-dependent efficacy of IA MSC therapy after stroke.

Title: Effect of dietary genistein on functional recovery and chronic poststroke inflammation in ovariectomized middle-aged rats

Authors: *A. OPPONG-GYEBI, D. METZGER, P. VANN, N. SUMIEN, D. SCHREIHOFER; UNT HEALTH SCIENCE CENTER, Fort Worth, TX

Abstract: PURPOSE: Increasing age is associated with an increased risk of stroke in women after the menopausal transition. A drop in circulating estrogens after menopause has been described as a key reason for the age-related risk, considering that estrogen has shown neuroprotection preclinically. However, the use of estrogen therapy for chronic prevention of cardiovascular diseases is limited by inconsistent outcomes including both benefits and detriment. For this, other agents are investigated as possible alternatives to protect women against the stroke-related physiological changes that come with aging and low plasma estrogen concentrations. In the current study, we hypothesized that genistein, a neuroprotective plant-derived estrogen will confer neuroprotection following hypogonadism and experimental stroke. METHOD: We used proven retired breeder Sprague-Dawley rats (aged ~9 months old) that were ovariectomized and categorized into two hypogonadal time points (2weeks= short-term and 12 weeks= long-term) during which they were treated with a soy-free diet. Each time point was followed by treatment with isoflavone-free diet, genistein diet (GEN) or 17-β estradiol (E2) implant. All animals were subjected to intraluminal middle cerebral artery occlusion or sham surgery followed by behavioral tests assessments for motor and cognitive functions over 21-days and brains collected were used for biochemical analysis for chronic poststroke inflammation. RESULTS: Sham-operated animals performed better on the locomotor task with cylinder test compared to stroked animals after both short-term and long-term hypogonadism. Both GEN and E2 improved performance on cylinder test after long-term hypogonadism. GEN but not E2 improved reversal learning on the Morris water maze test after short-term hypogonadism. GEN but not E2 reduced activated calcium-binding adaptor molecule 1 (Iba1) and increased transforming growth factor-β1 (TGF-β1) after short-term hypogonadism. CONCLUSION:

Dietary Genistein may improve locomotor function in the acute phase of stroke following long-term hypogonadism, improve aspects of cognitive function and reduce inflammation after short-term hypogonadism.

Title: Brain-computer interface system for lower extremity rehabilitation of chronic stroke patients

Authors: ***C. GUGER**[1,2,3], M. SEBASTIAN-ROMAGOSA[3], R. ORTNER[3], W. CHO[2]; [1]g.tec neurotechnology GmbH, Schiedlberg, Austria; [2]g.tec medical engineering GmbH, Schiedlberg, Austria; [3]g.tec medical engineering Spain S.L., Barcelona, Spain

Abstract: Neurorehabilitation based on Brain-Computer Interfaces (BCIs) show important rehabilitation effects for patients after stroke. Previous studies have shown improvements for patients that are in a chronic stage and/or have severe hemiparesis and are particularly challenging for conventional rehabilitation techniques.
For this publication ten stroke patients in chronic phase with hemiparesis in the lower extremity were recruited. All of them participated in 25 BCI sessions about 3 times a week. The BCI system was based on the Motor Imagery (MI) of the paretic ankle dorsiflexion and healthy wrist dorsiflexion with Functional Electrical Stimulation (FES) and avatar feedback. Assessments were conducted to assess the changes in motor improvement before, after and during the rehabilitation training. Our primary measures used for the assessment were 10-meters walking test (10MWT), Range of Motion (ROM) of the ankle dorsiflexion and Timed Up and Go (TUG). Results show a significant increase in the gait speed in the primary measure 10MWT fast velocity of 0.16 m/s (SD = 0.14). This improvement is above of the minimally clinically important difference (MCID). The speed in the TUG was also significantly increased by 0.06 m/s, P = 0.002. One patient was not able to perform TUG assessment before the rehabilitation training but was able to perform it after the BCI treatment with time 92.2 seconds. The passive ROM assessment increased 8.61° (SD = 6.54), P = 0.002, and active ROM increased 8.50° (SD = 7.23) after rehabilitation training, P =.008.
These outcomes show the feasibility of this BCI approach for chronic stroke patients, and further support the growing consensus that these types of tools might develop into a new paradigm for rehabilitation tool for stroke patients. However, the results are from only ten chronic stroke

patients so the authors believe that this approach should be further validated in broader randomized controlled studies involving more patients.
MI and FES-based non-invasive BCIs are showing improvement for the gait rehabilitation of the patients in the chronic stage after stroke. This could have in impact on the rehabilitation techniques used for these patients, especially when they are severely impaired, and their mobility is limited.

Abstract: Lack of blood flow to the brain, i.e., ischemic stroke, results in loss of nerve cells and therefore loss of function in the effected brain regions. There is no effective treatment to improve lost function except restoring blood flow within the first several hours. Rehabilitation strategies are widely used with limited success. The purpose of this study was to examine the effect of electrical stimulation on the impaired upper extremity to improve functional recovery after stroke. We developed a rodent model using an electrode cuff implant onto a single peripheral nerve (median nerve) of the paretic forelimb and applied daily electrical stimulation. The skilled forelimb reaching test was used to evaluate functional outcome after stroke and electrical stimulation. Anterograde axonal tracing from layer V pyramidal neurons with biotinylated dextran amine was done to evaluate the formation of new neuronal connections from the contralesional cortex to the deafferented spinal cord. Rats receiving electrical stimulation on the median nerve showed significant improvement in the skilled forelimb reaching test in comparison with stroke only and stroke with sham stimulation. Rats that received electrical stimulation also exhibited significant improvement in the latency to initiate adhesive removal from the impaired forelimb, indicating better sensory recovery. Furthermore, axonal tracing analysis showed a significant higher midline fiber crossing index in the cervical spinal cord of

rats receiving electrical stimulation. Our results indicate that direct peripheral nerve stimulation leads to improved sensorimotor recovery in the stroke-impaired forelimb, and may be a useful approach to improve post-stroke deficits in human patients.

Title: Temporal profiles of microglial genes driving neuroinflammation in the acute to chronic aftermath of repetitive mild traumatic brain injury

Authors: *A. J. PEARSON, C. ORTIZ, M. BROWNING, F. CRAWFORD, J. OJO;
Roskamp Inst., Sarasota, FL

Abstract: Repetitive mild traumatic brain injury (r-mTBI) is a strong risk factor for the development of neurodegenerative diseases such as Alzheimer's disease. One of the hallmark features of r-mTBI is persistent neuroinflammation typified by the activation of microglial cells, which serve as the innate immune cells of the brain. Microglia represent a promising target to beneficially alter the disease progression of r-mTBI, however, attempts to broadly target immune activation have been so far unsuccessful in improving clinical outcomes, due in part due to a lack of understanding of the precise molecular mechanisms driving the inflammatory changes at chronic time points post-injury. To better understand the sequelae of inflammatory changes in r-mTBI, we performed next-generation RNA sequencing of CD11b+ microglia from our mouse model of chronic r-mTBI, and analyzed the temporal course of changes in microglial gene expression at 14, 90, and 180 days post-injury. We exposed animals to their injuries at 3 and 12 months of age, to explore the impact of age on TBI mediated microglial inflammation. We reveal multiple time-dependent and injury responsive changes in microglial gene expression profiles. In the young cohort, at acute stages of injury, we identified an increase in genes associated with chemokine and cytokine signaling, suggesting a role of microglia in the initiation of inflammation and the recruitment of peripheral immune cells, notably, neutrophils into the CNS. At 3 months post-injury we noted that microglia maintained their upregulation in several pro-inflammatory genes notably IFNγ and TNFά. We also noted a distinct change in lipid and lipoprotein metabolism indicative of a disease associated microglia signature. At 6 months post-injury we noted a distinct change in the metabolic profiles of isolated microglia with a downregulation in oxidative phosphorylation accompanied by a shift towards glycolytic

metabolism, indicative of chronically activated microglia. Further analysis of these transcriptomic changes identified PPARγ as a key upstream regulator driving these metabolic changes in microglia at chronic time points after injury, to confirm this we undertook a treatment study utilizing the potent PPARγ agonist Pioglitazone and analyzed its effects on glial pathology and the ability to reduce learning deficits following r-mTBI. Further analyses of the aged cohort are underway. Thus far, these data identify putative microglia specific targets with the potential to beneficially alter r-mTBI mediated neuroinflammation.

Title: Characterization of neuroinflammatory markers in the fluid percussion injury model of traumatic brain injury and posttraumatic epilepsy

Authors: V. RAWAT[1], C. L. EASTMAN[2], R. D'AMBROSIO[2], R. DINGLEDINE[1], T. GANESH[1];
[1]Pharmacol. and Chem. Biol., Emory Univ., Atlanta, GA; [2]Neurolog. Surgery, Univ. of Washington, Seattle, WA

Abstract: Traumatic brain injury (TBI) is a leading cause of morbidity and mortality, worldwide. Over 1.4 million TBIs result in 50,000 deaths, annually in the USA, and survivors frequently suffer long-term disability due to neuropsychiatric or neurological disorders. Studies in patients indicate that neuroinflammation, broadly defined as induction of inflammatory mediators, glial activation and oxidative stress in the brain following TBI, exacerbate the disease pathology promoting posttraumatic epileptogenesis. However, precise nature and temporal profile of epileptogenic neuroinflammation is not known. In this study, we utilized a well-characterized rostral parasagittal-fluid percussion injury (*rp*-FPI) rat posttraumatic epilepsy model to investigate the expression pattern of inflammatory mediators, oxidative stress, astrogliosis and microglial activation markers from 3h to 24h following FPI injury. Our results show FPI in rats results in increased mRNA expression of proinflammatory cytokines, enzymes, receptors, markers of oxidative stress and gliosis in cortex. However, there are notable differences in expression pattern among these markers. Specifically, the inflammatory mediators COX2, EP2, IL1β, IL6, TNFα, COX1, and mPGES1 were highly induced 3h post FPI, with expression returning to basal levels by 8h post-FPI for all but TNFα, which returned to basal

levels by 16h post FPI. Markers of oxidative stress (NOX2), astrogliosis (GFAP) and microglial activation (CD11b) started to show increased levels beginning 8h post FPI, with expression remaining elevated 24h after injury. Continuing our investigation at protein level, we observed a significant increase in expression of COX2 at 3h post FPI with levels staying significantly elevated until 24h post FPI. Our results indicate that the inflammatory pathways are induced first followed by gliosis and oxidative stress in FPI rats.

Title: Sleep fragmentation following traumatic brain injury alters neuroinflammation and hippocampal neuronal activity

Authors: *Z. M. TAPP[1,2], J. KUMAR[3], S. CORNELIUS[3], A. OBERSTER[3], R. ATLURI[3], K. WTICHER[1], J. VELASQUEZ[2], C. BRAY[2], J. F. SHERIDAN[2], J. P. GODBOUT[1], O. KOKIKO-COCHRAN[1];

Abstract: Traumatic brain injury (TBI) impairs the body's ability to restore homeostasis in response to stressors, reflecting dysregulation of the hypothalamic-pituitary-adrenal (HPA)-axis. We hypothesize that sleep fragmentation (SF) is a physiologically relevant stressor that engages the HPA-axis after TBI and upon a dysregulated stress response promotes increased neuroinflammation. To test this, male and female mice were given moderate lateral fluid percussion TBI or control sham-surgery and either left undisturbed or exposed to SF for 7 or 30 days. At 7 days post-injury (DPI), TBI increased cortical Iba1 labelling regardless of SF. NanoString nCounter analysis of ipsilateral cortex revealed that pro-inflammatory gene expression was decreased with sham SF but increased with TBI SF, indicating differential effects of SF with injury. Further, interferon-associated genes were uniquely increased in TBI SF mice compared to TBI control. TBI also increased hippocampal Iba1 labelling regardless of SF; however, this was associated with a striking increase in phosphorylated glucocorticoid receptor (GR) and CA1 neuronal activity in TBI SF mice, indicative of GR hypersensitivity in areas important for inhibitory HPA axis regulation. We next determined if these changes in inflammation and neuronal circuitry persist with chronic SF. At 30 DPI, TBI SF exacerbated cortical Iba1 labeling near the site of injury that was associated with increased expression of

genes encoding proteins and transcription factors that, when dysregulated, are associated with an exacerbated pro-inflammatory and neurodegenerative state. Hippocampal Iba1 labelling remained elevated 30 DPI following TBI; however, TBI SF mice displayed a suppression in CA1 neuronal activity compared to sham SF mice. This was associated with decreased neuronal activity in the paraventricular nucleus of the hypothalamus (PVN), indicating persistent HPA axis dysfunction with post-TBI SF. These data indicate that post-TBI SF is a physiologically relevant stressor that engages the dysfunctional HPA axis to differentially influence inflammation and neuronal responses sub-acutely and chronically after injury. Hippocampal circuitry seems to be particularly vulnerable to influences of post-TBI SF as the ipsilateral CA1 is highly activated at 7 DPI but then suppressed at 30 DPI and may influence behavioral recovery after TBI. Further elaboration of how post-TBI stressors, such as SF, influence outcome may be critical in promoting post-injury recovery.

Title: Activation of hypoxia-inducible factor-1 alpha signaling and oxidative stress response in the developing mice after rotational acceleration-deceleration traumatic brain Injury

Authors: T. CHU[1], W. ZENG[1], N. MELLEN[2], Y.-P. ZHANG[3], L. B. E. SHIELDS[3], C. B. SHIELDS[3], **J. CAI**[1];

Abstract: Shaken baby syndrome (SBS) or shaken impact syndrome is a form of abusive head injury (AHT), in which a child is subjected to severe repetitive rotational acceleration-deceleration (RAD) forces without blunt impact to the head. We previously reported that RAD injury (RADi) results in subdural/subarachnoid hemorrhage, brain-blood barrier (BBB) damage, parenchymal edema, global cerebral blood hypoperfusion, inflammatory response, neuronal degeneration, cognitive deficits, and anxiety-like behavior in the developing mouse brain. However, little is known about the underlying mechanisms and preventive/therapeutic interventions are lacking. Here we test the hypothesis that early ischemic hypoxia mediates the secondary RAD induced brain injury using a mouse RADi model. Anesthetized neonatal mice at

12 days after birth were subjected to repetitive head rotations with a +55°/-35° angle and 60 fire-fashion hits in sagittal plane. The cerebral hypoxia-inducible factor-1α (HIF-1α) accumulates in cortex at least during the first 3 days after injury, probably due to the inhibited expression of HIF prolyl hydroxylase domain protein 1 (PHD1). The expressions of HIF-1 target molecules, including glucose transporter 1 (Glut 1), nuclear factor like 2 (Nrf2), and heme oxygenase-1 (HO-1), are greatly changed. Meanwhile, nitrotyrosine (3-NT, marker for indirectly detecting $ONOO^-$) and 4-hydroxynonenal (4-HNE, marker for lipid peroxidation) are significantly elevated in RADi cortex as early as 1hr after injury in the developing brain. At the later stage, HIF-1α is significantly down-regulated with the activation of p38 mitogen-activated protein kinase (MAPK). In addition, strong intracellular calcium influx is detected in layer II/III of cortex and hippocampal area starting at 24 hours after RADi, which declines after 7 days after injury. Furthermore, the calcium network-level recordings on ventral hippocampal slices indicate that Ca^{2+} overload in RADi brain induces the electrophysiological changes, which may lead to neurocognitive impairment. These findings suggest that hypoxia-activated HIF-1α signaling and oxidative stress may play a vital role in SBS-related neurological and/or psychological sequelae.

Abstract: Species differences in brain function and blood-brain barrier often preclude accurate extrapolation from animal models to human patients. There is an unmet need for human relevant systems that can recreate key aspects of brain physiology and pathophysiology of common diseases. We are developing a human Brain-Chip to model neuroinflammation, a hallmark of many neurodegenerative diseases, to enable studies on mechanistic aspects of neural pathology and disease progression. We provide evidence that this complex human Brain-Chip model can support co-culture and establishment of extensive interconnection between human iPSC-derived neurons and primary glial cells (astrocytes and microglia). Human iPSC-derived brain endothelial cells successfully maintained at the vascular channel of the Brain-Chip in the presence of fluidic shear stress while exhibiting hallmark features of the human blood-brain

barrier, such as the formation of specific tight junctions and minimal barrier permeability. Exposure to inflammatory triggers (e.g., TNF-α) or toxic protein oligomeric species (e.g., alpha-synuclein), resulted in neuronal death, glia activation, increased secretion of the corresponding proinflammatory cytokines, and a compromised barrier function. In summary, our current findings demonstrate that human Brain-Chip could support the development of models for the study of neuroinflammation and blood-brain barrier dysfunction in neurological disorders.

Abstract: Introduction: Post-Traumatic Stress Disorder (PTSD) is one of the major disorders affecting many veterans and active duty soldiers. However, objective diagnosis and effective

therapies for PTSD are still unmet needs. Identification of altered molecular signatures and signaling pathways could aid in diagnosis, treatment decision-making, and risk evaluation. **Methods:** In the search for molecular basis and markers for PTSD, we carried out blood based proteomic, metabolomic and epigenomic (genome wide methylation and microRNA) assays. Multi-omics assays were carried out on samples collected from well characterized cohorts of 340 veterans with chronic PTSD (40F – 21P-/19P+; 300M – 148P-/152P+) and 180 active-duty service-members with recent PTSD (21F – 13P-/8P+; 159M – 44P-/47P+/68 subthreshold). Vitals and clinical assessments, blood chemistry and endocrine assays were also carried out. Molecular and clinical datasets from each cohort were computationally integrated. **Results:** We identified both inhibited and activated molecular pathways that were persistent and distinct between the two-cohort participants with recent and chronic combat-PTSD. Cellular processes and pathways that are important in wound healing, vasculature development (angiogenesis) and coagulation were persistently inhibited across cohorts. On the other hand, pathways and processes that are important in inflammatory response, age-rage signaling, and oxidative stress were activated more significantly in veterans compared to active duty participants. Molecules and pathways that were consistently altered across cohorts were correlated with severity and chronicity of the different facets of PTSD symptoms. **Discussion:** Significantly altered multimodal molecular signatures convergently indicate impaired wound healing, and speculatively with an implication for stress caused vasculature damage with delayed healing, which in turn acting as the basis for the persistence of the disorder. **Conclusion:** We have identified altered molecular and pathway signatures that can potentially link stress related disorders with that of impaired wound healing and vascular morphogenesis. Our observations support that inflammation and oxidative stress potentially dysregulate multiple biological processes, and hence might be involved in the chronicity of PTSD. Profiled multimodal molecules and pathways were correlated with core symptoms of PTSD and its somatic comorbidities. **Disclaimers:** The views, opinions, and findings contained in this report are those of the authors and should not be construed as official Department of the Army position, policy, or decision.

Title: Chemokine CCL5 promotes optic nerve regeneration and mediates the major effects of CNTF gene therapy

Authors: ***L. XIE**[1], Y. YIN[2], L. I. BENOWITZ[3];
[1]Boston Children's Hospital, Harvard Med. Sch., Brighton, MA; [2]boston children's hospital, harvard medical school, Boston, MA; [3]Labs Neurosci Res. Neurosurg, Boston Children's Hosp/Harvard Med. Sc, Boston, MA

Abstract: Ciliary neurotrophic factor (CNTF) is a leading therapeutic candidate for several ocular diseases and induces optic nerve regeneration in animal models. Paradoxically, however, although CNTF gene therapy promotes considerable regeneration, the recombinant CNTF protein (rCNTF) has little effect (1). Because intraocular viral vectors induce inflammation and because CNTF is an immune modulator, we investigated whether CNTF gene therapy acts indirectly through other immune mediators. The beneficial effects of CNTF gene therapy were unaffected by deleting the CNTF receptor CNTFR-alpha (CNTFRα) in retinal ganglion cells (RGCs), the projection neurons of the retina, but were diminished by immune depletion of neutrophils (anti-Ly6G) or by genetically suppressing monocyte infiltration (deletion of CCR2) (2). CNTF gene therapy increased expression of C-C motif chemokine ligand 5 (CCL5) in immune cells and retinal glia, and recombinant CCL5 induced extensive axon regeneration. Conversely, CRISPR-mediated knockdown of the cognate CCL5 receptor (CCR5) in RGCs or treating wild-type mice with a CCR5 antagonist (DAPTA) strongly repressed the effects of CNTF gene therapy. Thus, CCL5 is a previously unrecognized, potent activator of optic nerve regeneration and mediates the major effects of CNTF gene therapy.

Title: Polycomb group protein Ezh2 promotes mammalian axon regeneration in central nervous system

Authors: ***X.-W. WANG**[1], C. ZHANG[1], M.-W. HU[1], S.-G. YANG[1], A. KOSANAM[1], J. QIAN[1], C.-M. LIU[1,2], F.-Q. ZHOU[1];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Inst. of Zoology, Chinese Acad. of Sci., Beijing, China

Abstract: In mammals, neurons in the central nervous system (CNS) gradually lose their axon growth capacity as they mature. On the contrary, mature neurons in the peripheral nervous system (PNS) still possess such a capacity and can spontaneously regenerate their axons upon axonal injury by initiating a regenerative response. Emerging evidence suggests that the switch from non-regenerative state to regenerative state of injured PNS neurons largely involves the epigenetic regulation of chromatin accessibility. Here we first investigated the role of Ezh2, a histone methyltransferase that adds methyl groups onto lysine 27 on histone H3 (H3K27) to suppress gene transcription, in PNS axon regeneration, and then tested if its modulation could promote CNS axon regeneration. We found that Ezh2 level was upregulated in mouse lumbar 4 and 5 dorsal root ganglia (L4/5 DRGs) 3 days following sciatic nerve axotomy. Functionally, Ezh2 knockdown/knockout in DRG neurons impaired axon growth speed *in vitro*. Consistently, knockdown/knockout of Ezh2 in L4/5 DRGs or conditional knockout of Ezh2 in sensory neurons impaired sensory axon regeneration *in vivo*. In addition, Ezh2 overexpression in retinal ganglion cells (RGCs) both before and after optic nerve injury significantly promoted axon regeneration. RNA-seq of RGCs enriched by fluorescence-activated cell sorting revealed that Ezh2 might promote axon regeneration by suppressing transcription of various neurotransmitter transporters.

Title: NMN, NAD^+, and SARM1 signaling in Wallerian degeneration of mammalian axons: temporal dynamics and interactions

Authors: ***A. ALEXANDRIS**[1], J. RYU[1], Y. WANG[1], L. RAJBHANDARI[2], A. VENKATESAN[2], V. KOLIATSOS[1,2,3];
[1]Pathology, [2]Neurol., [3]Psychiatry and Behavioral Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Wallerian degeneration (WD) is an evolutionary conserved axon self-destruction program that is activated in mechanically and/or metabolically compromised axons and as such contributes to diverse neurological disorders, including traumatic brain injury, peripheral neuropathies and possibly neurodegenerative diseases. WD has several and not fully understood decision points including the degradation of nicotinamide mononucleotide adenylyltransferase (NMNAT2), the built up of its substrate NMN, and the activation of the NAD^+ degrading sterile α and Toll/interleukin-1 receptor (TIR) motif containing 1 (SARM1) protein, all of which are

necessary for the eventual axon fragmentation hours or days after injury. Yet, the time course of these events and critical interactions are still unclear. Here we utilized an *in vitro* mouse dorsal root ganglion axotomy model to interrogate the timing and interplay between two critical molecular pathways/cascades (MAPK stress cascade and SARM1 pathway) by pharmacological means, including inhibition of the NMN-synthesizing enzyme NAMPT and the NMNAT2-degrading MAPK stress pathway. Axons were grown in microfluidic devices or drop cultures, cut with a razor blade and treated with drugs or vehicle at different time points. Images of axons were taken at different intervals and the degeneration index was calculated. Axonal preparations at different time points post-injury were also used for metabolomic and proteomic profiling of injury-related signals. We found that NMN plays a critical role in SARM1-dependent axon fragmentation within a time window corresponding to 2-4 hours post-injury. We also found that the protective effect of lowering NMN with NAMPT inhibition also depends on axonal NAD^+ levels and is enhanced by nicotinic acid riboside supplementation. Moreover, we found a temporal correlation of these events with NMNAT2 degradation by the MAPK pathway. In conclusion, we demonstrated that the decision to commit to WD is temporally separated from the time of injury, evolves within a narrow window determined by the degradation of NMNAT2, and depends on the effects of both NMN and NAD^+ on SARM1 signaling. The existence of a time window of commitment and the availability of NMN-lowering compounds, i.e. NAMPT inhibitors, may have translational significance for the treatment of traumatic and other axonopathies.

Title: Neuronal network changes after in vitro stretch injury

Authors: *C. ROJVIRAT[1], T. NGUYEN[2], J. BERLIN[3];
[1]Dept. of Pharmacology, Physiol. & Neurosci., Rutgers Sch. of Grad. Studies, Newark, NJ; [2]Physics, The Col. of New Jersey, Ewing, NJ; [3]Dept. of Pharmacology, Physiol. & Neurosci., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: To understand acute changes in neuronal network dynamics after traumatic injury, Ca^{2+} imaging was used to record individual neuron responses during spontaneous and triggered activity in cultures of rat neocortical neurons and glia in the presence of bicuculline. Triggered activity was initiated by single-cell photolysis of caged-glutamate (photostimulation) to reveal

connections, or links, between neurons. We integrated this technique with a stretch injury model that mimics mild traumatic brain injury (mTBI).Parameters were derived to quantify changes in network dynamics post-injury at two different strain and strain rate levels, 45%, 20 s^{-1} (n = 18 cultures) or 70%, 35 s^{-1} (n = 13). Compared to non-injured controls (n = 10), stable links, number of responsive neurons to photostimulation, and participation of neurons in and amplitude of spontaneous, synchronous activity (i.e. bursting activity) was significantly decreased, while lost links were significantly increased after injury at both strain levels. These results (Table 1) showed that network activity was acutely depressed after injury, consistent with prior reports, but more prominent was the appearance of network instability characterized by variability, shown as interquartile range (IQR), in link properties when compared to controls. Additional experiments were undertaken to determine if network instability was due to changes in neuron excitability and/or synaptic transmission properties. Ca^{2+} response amplitude of the photostimulated neuron, a measure of cell excitability, was significantly decreased after injury in a strain-dependent manner. Furthermore, variability of link properties between some neurons was consistent with a depression of synaptic transmission. These results suggest that acute mTBI decreases cell excitability acutely after injury and alters synaptic transmission between neurons. Overall, our novel approach integrating photostimulation, Ca^{2+} imaging and stretch injury enables us to investigate drivers of injury-induced neuronal network changes. In future work, this approach will be used to investigate interventions that can confer neuroprotection to the network after injury.

Abstract: Intimate partner violence is a leading cause of TBI in women, with pregnant women or women with children in the home at the highest risk for acquiring a TBI (Sharps et al., 2007; Peek-Asa et al., 2017; Valera et al., 2018). Although pregnancy induces profound acute and long-term physiological changes (Duarte-Guterman et al, 2019), the consequences of such changes on brain injury susceptibility and outcomes are unclear. Here, we examined the effects of parity (previous pregnancy and maternal experience) on the neuroinflammatory response to TBI induced by lateral fluid percussion injury (FPI). Multiparous females (2-3 pregnancies and motherhood experiences) and age-matched nulliparous (no previous pregnancy and motherhood experience) females were administered either FPI or sham injury. Brain tissue was collected 3 days post-injury (DPI). Our results show that cortical Iba1 immunolabeling increased following injury independent of parity. The number of deramified Iba1+ cells near the site of injury did not differ between TBI mice. Similarly, TBI increased cortical GFAP immunolabeling 3 DPI. While no differences in cortical CD68 immunolabeling were identified between TBI groups, an interaction between parity and injury was evident in cortical CD45 labeling. Specifically, the number of $CD45^+$ cells near the site of injury was higher in nulliparous compared to multiparous animals. Together, these data confirm that FPI induces a cortical immune response in brain resident microglia and astrocytes and show that this effect is independent of parity. Notably, these are the first data to demonstrate that previous parity may act as a factor in attenuating leukocyte recruitment to the site of injury following TBI. Together these data suggest that previous pregnancy and maternal experience can influence the acute neuroinflammatory response to TBI.

Title: Traumatic brain injury-like pathology in a muskox brain and implications for the natural occurrence of TBI

Authors: *N. L. ACKERMANS[1], T. WILLIAMS[4], A. ALIPOUR[2], B. PRITI[2], M. VARGHESE[5], J. REIDENBERG[3], P. R. HOF[5];
[1]Neurosci. / Anat., [3]Anat., [2]Icahn Sch. of Med. at Mount Sinai,, New York, NY; [4]UCSC, Santa Cruz, CA; [5]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Muskoxen (*Ovibos moschatus*) are large tundra-dwelling bovids that can strike heads at speeds around 30 mph (48 Km/h). Their wide horn base armors the skull against such impacts, however, it is unknown if this successfully prevents brain trauma. Our research explores the brain and skull anatomy of combative bovids, focusing on whether these animals sustain traumatic brain injury (TBI) after head-butting, and if not, what features most likely provide protection. Achieving a better understanding of brain injury in animals with extreme adaptations will provide insight to develop strategies for the reduction of traumatic brain injury in humans. In a preliminary study, the brain of an adult male muskox was collected after humane euthanasia and preserved in formalin. It had been observed clashing heads in the wild moments before its death. Brains from two female muskoxen were used as comparisons. The brains were MR scanned and the right prefrontal cortex was examined histologically for evidence of traumatic brain injury using a variety of exploratory histological protocols to investigate abnormalities in neurons, microglia, astrocytes, and blood vessels. Specifically, Tau protein, a biomarker found in the cerebrospinal fluid and in neurodegenerative lesions, was used to detect any cellular consequence of brain trauma related to chronic or acute head clashing. Microglial morphology appeared normal and the MRI scan revealed no abnormal neuropathological changes. However, in the bull's brain, tau antibodies AT8 and CP13 highlighted the presence of neuronal plaques and damaged neurons on the surface of the white matter and in sulcus depths. The presence and distribution of these abnormalities resembles that of early chronic traumatic encephalopathy (CTE) in humans. Although our small sample size does not allow us to make sweeping assumptions, these preliminary findings lead us to believe that muskoxen may suffer from chronic or acute brain trauma after head clashing despite their imposing headgear. If TBI occurs frequently in these animals, it has consequences for sexual selection and evolutionary strategies. Furthermore, if widespread, this type of injury would be an interesting as a model to compare to human TBI and CTE.

Abstract: The effect of darkness on recovery from traumatic brain injury (TBI).Ancona Martínez Isis Monserratt[1], Córdova Balcázar Dania Nayeli[1], Monroy Matamoros Danna Paola[1], Niño Carbajal Salvador Usiel[1], Navarro Luz[2], Martínez Tapia Ricardo de Jesús[2] and Estrada Rojo Francisco[2]1.- Escuela Nacional Preparatoria, Plantel No.5 “José Vasconcelos” UNAM2.- Lab. de Neuroendocrinología, Departamento de Fisiología, Facultad de Medicina, UNAM Traumatic brain injury (TBI) is a severe health problem that involves people's death and disability, with high costs for society and health systems.When a TBI occurs, brain mechanisms are activated, leading to further damage to the brain and mechanisms that protect it from injury (neuroprotection); the latter should be favored to establish a better and speedy recovery. Several investigations look for therapeutic strategies that increase neuroprotection. Recently in animal models, it has been reported that exposure to darkness for several days allows the recovery of damaged visual pathways, even at the visual cortex level. This work proposes to explore this approach as a therapy for recovery from TBI.Mus musculus, CD1 strain (50 gr) were used, acclimatized first for 8 days to a 12:12 light/dark cycle with lights on at 8 AM, later they were randomly divided into 4 groups: 1, control 12:12 light/dark; 2, control in continuous darkness; 3, TBI 12:12 light/dark; 4, TBI in continuous darkness. These conditions were maintained for 10 days after TBI, during which food intake, weight, and water consumption were measured, and a neurobehavioral scale was applied. The TBI was produced by means of a "weight drop" type model in the motor cortex with lateral coordinates of 2 mm and anteroposterior coordinates of -1.4 mm. Subsequently, the individuals were sacrificed, and their brains were extracted to make histological sections stained with Hematoxylin-Eosin. Cell counting was made in the damaged area. Cell counting, behavior, and metabolic data were statistically analyzed. Our data show that the TBI maintained in continuous darkness had a better behavioral and histological recovery than the 12:12 light/dark cycle TBI group. Project supported by PAPIIT IN228320

Title: Projectile Concussive Impact as a Preclinical Model for Traumatic Brain Injury

Authors: *L. T. MICHALOVICZ, K. A. KELLY, J. P. O'CALLAGHAN;
CDC-NIOSH, Morgantown, WV

Abstract: Traumatic brain injury (TBI) is as a major cause of death and disability experienced by nearly 3 million people per year. These injuries can be experienced in any environment and can result from falls, vehicular accidents, or from being struck by or against an object. While TBIs can be severe and/or fatal, the majority of injuries are considered to be mild. However, even mild TBI has the potential to have long-lasting neurological effects including headaches, cognitive/memory impairments, mood dysfunction, and fatigue. By using animal models of TBI, we can investigate the underlying pathophysiology that can lead to neurological dysfunction in the absence of serious trauma (i.e. penetrating injuries). Here, we used a projectile concussive impact (PCI) model of mild TBI developed at Walter Reed Army Institute of Research, where a ball bearing is propelled at the head by air pressure. While several studies using PCI have employed helmets to mitigate direct damage from impact, we needed to utilize a non-helmeted model of PCI-induced TBI to evaluate the protective nature of different helmet materials for the mitigation of work-related TBI. Adult male Sprague-Dawley rats were evaluated for neurobehavioral, neuroinflammatory and neural damage end points up to 72 hours post-TBI using different types of ball bearings. Animals that received TBI using aluminum or steel ball bearings took approximately 1.7 and 7.3 times longer, respectively, to recover from anesthesia compared to sham controls. While rats impacted with aluminum were behaviorally normal even 1 hr following TBI, those impacted with the steel ball bearing had an impaired neurobehavioral score for up to 24 hrs post-TBI which correlated with the presence of subdural hematoma, neurodegeneration, and significant markers of neuroinflammation including increased brain inflammatory cytokine mRNA expression and gliosis. Interestingly, while rats impacted with the aluminum ball bearings did not display markers of neurodegeneration or changes in brain cytokine mRNA expression, they did display minor activation of astrocytes and microglia. These data support the use of this non-helmeted variation of the PCI model for the future evaluation of helmet materials and demonstrates that even minor TBI can produce measurable brain cellular changes.

Title: Proteomic and Phosphoproteomic Identification of Upregulated Mechanisms in Two Mouse Models of r-mTBI and in Human CTE, and Their Response to Delayed Treatment with the Potential Therapeutic Anatabine

Authors: *A. MORIN[1,2], R. DAVIS[1], T. DARCEY[1], B. MOUZON[1,2], M. BROWNING[1], N. SALTIEL[1], S. FERGUSON[1,2], D. PARIS[1,2], M. MULLAN[1], F. CRAWFORD[1,2];
[1]The Roskamp Inst., Sarasota, FL; [2]James A Haley Veterans Admin., Tampa, FL

Abstract: Heterogeneity of mild traumatic brain injury (mTBI) is recognized as a factor that hinders the development of efficient therapeutic strategies. At the preclinical phase, this heterogeneity is driven by high variability across animal models of mTBI; at the translational stage - by differences between animal and human physiological responses. Our study attempted to bridge these gaps by conducting phospho- and total proteomics of cortical tissue from two well-characterized mouse models of repetitive mTBI (r-mTBI) and identifying the overlapping mechanisms. Mice with 5 (over 9 days) or 24 (over 90 days) repetitive closed-head hits were euthanized at 6 months after the last injury to target chronic aspects of mTBI pathology. Their proteomic profiles were further compared to results from human samples of chronic traumatic encephalopathy (CTE, n=11) (Proteome Central: PXD007694). We identified 5 biological functions that were upregulated in the two preclinical models and all human samples of CTE - *Transport, RNA splicing, Axonogenesis, Glycolytic processes, GTPase signaling*. In the second part of our study, we introduced a delayed treatment with an anti-inflammatory compound anatabine, an agonist of α7 nicotinic acetylcholine receptors, which has previously exhibited therapeutic properties in models of r-mTBI and neurodegeneration. Mice of both r-mTBI models (5 and 24 hits) were treated with anatabine starting at 6 months after the last injury to explore the therapeutic potential of its late administration, to mimic typical treatment interventions in human mTBI. Anatabine treatment was successful at suppressing the 5 biological processes triggered by r-mTBI. The delayed treatment with anatabine also improved cognitive functions, however the relationship of this to proteomic responses requires additional research. Identification of the mechanism of action of anatabine in these models will identify novel therapeutic targets for the chronic consequences of r-mTBI. Overall, our study revealed 5 mechanisms common to two preclinical models of r-mTBI and to human CTE that could be claimed to be validated targets for further investigation.

Title: Tbi-induced functional deficits associated with inflammation are augmented by secondary immune challenges and ameliorated by forced turnover of microglia

Authors: *C. E. BRAY[1], K. G. WITCHER[1], D. ADELKUNLE-ADEGBITE[1], E. HANS[1], F. ZHAO[1], T. CHUNCHAI[3], J. E. DZIABIS[4], Z. M. TAPP[1], C. ASKWITH[1], D. S. EIFERMAN[2], J. P. GODBOUT[1], J. P. GODBOUT[1];

Abstract: Traumatic brain injury (TBI) induces microglia mediated neuroinflammation that leads to acute symptoms and dysfunction. Though acute complications often resolve, cognitive and psychiatric impairments may develop or persist years after injury. Chronic microglial priming/reactivity may be a major issue that sets the stage for exaggerated responses to secondary challenges that augment inflammation and neuropathology. Our goal was to induce forced turnover of microglia after TBI and determine the degree to which reactive microglia profiles were reversed. Here, mice were injured by midline fluid percussion injury and 7 d later microglia were subjected to forced turnover. At 30 dpi, cortical gene expression was determined using NanoString's Neuropathology gene expression assay (760 genes). Many inflammatory genes that persisted at 30 dpi in the cortex (C1qc, Tlr2) were reversed following microglia turnover. Moreover, microglia repopulation attenuated TBI associated astrocyte gene expression (Aqp4, Gfap, S100b). Deficits in neuronal connectivity (N1 and N2 compound action potentials) in the corpus callosum were rescued by microglia forced turnover. Cognitive dysfunction 30 dpi was reversed by microglia turnover. Additionally, repopulation of microglia eliminated chronic TBI-induced depressive-like behavior. Next, we investigated if functional responses to a secondary immune challenge through intraperitoneal injection of LPS were attenuated. As expected, LPS caused exacerbated sickness behavior 30 dpi in mice subjected to TBI. Forced Microglia turnover after TBI alleviated prolonged sickness behaviors associated with microglial priming. Together, these data indicate that post-injury turnover of microglia attenuates persistent inflammatory effects and functional deficits sustained by TBI.

Abstract: Intimate partner violence (IPV) is a world-wide epidemic that affects 1 in 4 women in their lifetime. The COVID-19 pandemic has restricted personal movement and confined people to their homes, which elevated IPV incidence and severity. As a result of IPV, upwards of 90% of victims receive assaults directed towards the head, neck, or face that likely induce traumatic brain injury (TBI). And, incidence and prevalence of IPV rises for pregnant women, with unknown consequences on fetal development. Here, we studied the impact of gravida TBI (gTBI) on cortical circuitry, cognition, depressive- and anxiety-like behavior, inflammation, and gut histology on the offspring of pregnant mice who suffered a TBI. We expected that gTBI would lead to altered cognition, increased depressive- and anxiety-like behavior, susceptibility to infection, dysbiosis in gut microbiome, and distorted brain circuitry in offspring. Pregnant dams received either diffuse TBI or sham injury 12 days post-coitum. After giving birth, a subset of mixed-sex pups from TBI and sham control mothers were assessed for cortical circuitry using laser scanning photostimulation (LSPS) at post-natal day (PND) 28. All other pups were assessed for cognitive, anxiety-like, and depressive-like behaviors from PND30-80. At PND80, pups received LPS (1 mg/kg, i.p.) to induce an immune response and blood was drawn 6hrs post-LPS. After 24hrs, pups were euthanized and blood and tissue were harvested. Litter size was similar between gTBI and control offspring. Male gTBI offspring had significantly lower body weights at weaning compared to male control offspring. LSPS functional circuit mapping revealed significantly weaker intralaminar connectivity onto layer 5 pre-frontal pyramidal neurons in male gTBI offspring compared to male control offspring. At PND42 and PND58, circulating neutrophil and monocyte populations were significantly lower in male gTBI offspring than male control offspring. And, after an LPS injection, gTBI offspring had significantly smaller

neutrophil populations. Analysis of gut histology failed to reveal significant differences in mucosal layer thickness. Moreover, there were no overt behavioral differences on depressive-like or cognitive behavior tests. However, during the open field (OF) task to measure anxiety-like behaviors, male gTBI offspring spent more time in the OF center and crossed into the OF center more often than male controls. This study is the first to show that gTBI in mice leads to altered cortical functional connectivity and altered immune response in offspring. The social impact of gTBI necessitates further investigation to aid recovery in mothers and children.

Title: Characterizations and Targeting of the Endocannabinoid System in Traumatic Brain Injury.

Authors: *T. BLACK;
Univ. of Saskatchewan.

Abstract: Traumatic Brain Injuries (TBI) are considered one of the leading causes of death and disability worldwide. One emerging area of TBI research is the involvement of the endocannabinoid system (ECS) in response to brain injury. The ECS is modulated by exogenous cannabinoids such as Δ^9-tetrahydrocannabinol (THC) found in *Cannabis sativa.* THC is a partial agonist of both cannabinoid receptors CB1R and CB2R. CB1R activation contributes to analgesia and anxiolytic effects, whereas CB2R activation reduces inflammation. In the wake of *Cannabis* legalization in Canada, and as awareness surrounding post-traumatic complications increases, the need for research examining this intricate relationship between exercise, the ECS, and TBI is apparent. To date there has been a lack of research into the effects of TBI and exercise on the ECS, pre-clinical or otherwise. We **hypothesized that treatment of rats subjected to TBI with THC post-injury will restore locomotor function and improve behavioral and molecular profiles of injured rats.** **Methods:** 4-5 Sprague-Dawley rats of both sexes aged 8-12 weeks at the time of TBI were randomly assigned to: 1) No TBI + Vehicle; 2) No TBI + 1 mg/kg THC *i.p.*; 3) 300 g weight drop TBI + Vehicle; or 4) 300 g weight drop TBI + 1 mg/kg THC *i.p*. Rats were trained on the rotarod 4 days pre-injury, and tested for 7 days post-injury, with a break from rotarod at days 5 and 6. Behavioral and physiological changes were assessed using the tetrad battery: catalepsy, body temperature, open-field, and antinociception.

Y-maze was used to assess spatial learning and memory. Inflammatory cytokine profiles and CB1R receptor quantity were performed post-mortem on samples from the cortex. **Results:** 1 mg/kg of THC decreased male, but not female, rotarod performance between TBI treatment groups, and non-TBI controls. However, THC had no significant effect on catalepsy, temperature regulation, or tail-flick across all treatments. There were no significant differences between treatment groups in the open field or Y-maze. According to the post-mortem analysis, there were no significant differences in inflammatory cytokine profiles or CB1R concentrations between groups.
Conclusions: According to the results, 1 mg/kg THC exhibited a significant decrease in locomotor performance in male TBI and non-TBI rats in comparison to controls across the test period. These locomotor differences were not reciprocated in female rats and were not mirrored by any other behavioural or molecular differences. Therefore, 1 mg/kg THC may limit motor coordination in male rats following TBI, but the underlying mechanisms for this deficit remain unclear.

Title: Effect of the estrous cycle on motor recovery from a traumatic head injury (TBI)

Authors: *L. NAVARRO, **F. ESTRADA-ROJO**;
UNAM, CDMX, Mexico

Abstract: The estrous cycle involves a series of events in various female systems regulated by the hypothalamic-pituitary-gonad axis. The various phases of this cycle involve considerable changes in the release of hormones such as FSH, LH, estradiol, and progesterone. Relatively a few years ago, it was known that women had lower mortality compared to men of the same age in the event of a head injury (TBI) of similar magnitude, which suggested that the presence of estradiol and progesterone provided some neuroprotection before the damage. Additionally, it is known that in animal models, the administration of both hormones after a TBI is associated with a reduction in apoptosis and neuronal death and better behavioral recovery after the damaging event. This work analyzes the motor recovery of rats subjected to TBI at different phases of the estrous cycle. Female Wistar rats of between 250 and 300 grams were used, divided into four groups (n = 6), one group for each phase of the estrous cycle. The estrous cycle was monitored by vaginal smears. Once the phase had been established, a TBI was induced through a weight drop model at the motor cortex level; the site of damage was chosen using a stereotaxic system and coordinates established in the Paxinos atlas (2010). Subsequently, a neurobehavioral test of

21 points was applied during the following eight days. The results were statistically analyzed. Our data show that the group in which TBI was induced during the diestrus, had a better recovery than the control group, followed by the group in the proestrus phase. In both cases, this coincides with peaks of progesterone release.

Title: Influence of repetitive brain trauma on extracellular tau elimination at the blood brain barrier

Authors: *M. EISENBAUM, J. OJO, F. CRAWFORD, C. BACHMEIER;
Roskamp Inst., Sarasota, FL

Abstract: Introduction. Exposure to repetitive head injuries sustained in the military or contact sports has been associated with the accumulation of extracellular tau in the brain, which may contribute to the pathogenesis of neurodegenerative tauopathies. Several studies have observed an interaction between extracellular tau and neurovascular damage in the context of repetitive mild traumatic brain injury (r-mTBI). What remains unclear is the effect of neurovascular dysfunction on the elimination of tau from the brain following head trauma. These studies will investigate the role of the cerebrovasculature in the elimination of extracellular tau from the brain, and the influence of r-mTBI on these processes. **Aims.** 1) Evaluate cerebrovascular tau uptake in the context of repetitive mild traumatic brain injury (r-mTBI), 2) examine the influence of r-mTBI on exogenous tau elimination from the brain, and 3) interrogate the role of the blood brain barrier (BBB) in tau elimination. **Methods.** *In vivo,* TBI was administered to wild-type mice 2 times per week for 12 weeks using a of closed head injury model. To determine the interaction between cerebrovascular cells and extracellular tau, tau uptake and caveolin-1 expression was evaluated in isolated r-mTBI cerebrovessels at 24 hours, 3, and 6 months post injury. Tau elimination from the brain was examined following stereotaxic injection of exogenous tau in mice 6 months post last r-mTBI. Tau transcytosis across the blood-brain barrier (BBB) was examined in the presence of a caveolin-1 modulator in an *in vitro,* BBB model. **Results.** Cerebrovascular tau uptake and caveolin-1 expression progressively decreased in r-mTBI cerebrovessels relative to r-sham animals. Exogenous tau levels residing in the brain following intracranial injection were increased in r-mTBI mice compared to r-sham mice. Caveolin-1 inhibition significantly decreased the basolateral-to-apical transit of tau across the BBB model. **Discussion.** Cerebrovascular uptake of extracellular tau is mediated by caveolin-1

and represents a mechanism for tau elimination across the BBB. In the chronic phase following r-mTBI, cerebrovascular caveolin-1 levels progressively decrease, which may contribute to the accumulation of tau in the brain following head trauma.

Title: Altered Orexin Function Following Mild Traumatic Brain Injury

Authors: *R. T. SOMACH[1], I. JEAN[2], M. LIM[3], A. S. COHEN[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Children's Hosp Philadelphia, UPENN, Bala Cynwyd, PA; [3]Dept. of Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Every year, approximately 2 million people in the United States alone will experience a Traumatic Brain Injury (TBI). Between 30-70% of patients that have a TBI will also develop a sleep disorder. These can include hypersomnia and narcolepsy, where patients have difficulty staying awake. While prior research on TBI induced sleep disorders have identified potential treatments of the symptoms, the underlying causes of these disorders are not known. The neuropeptide orexin is critical in regulating arousal and is decreased in non-TBI occurrences of hypersomnia and narcolepsy. Studies in humans and rodents have shown that following TBI, there is a decrease in the levels of orexin in the blood and brain. To further study this, our lab employed the lateral fluid percussion injury (LFPI) method to induce a mild injury in mice 6-8 weeks of age. We recorded sleep behavior in mice 1 week after injury and found that the animals had an inability to maintain wakefulness. We used immunohistochemical staining to count the number of orexin neurons after injury to determine if orexin cell death was the cause of excessive sleepiness. We found that there was no meaningful reduction in the number of orexin neurons after a mild TBI. We stained for the immediate early gene cFOS to determine the activity of orexin neurons after injury. We found that there was a smaller percentage of active orexin neurons in the injured animals. To directly assess the activity of orexin neurons after TBI, we used slice electrophysiology to measure their activity. To locate orexin neurons within the lateral hypothalamus, we used a mouse model with an orexin-EGFP reporter and confirmed their identity using immunohistochemical methods. Once identified, we used whole cell patch clamp to record synaptic currents and action potential dynamics in orexin neurons. This research will greatly improve our understanding of the cellular mechanisms of TBI induced sleep disorders.

Title: Sex differences in neurobehavioral responses to mild and moderate traumatic brain injury (TBI) in rats

Authors: *O. N. AL YACOUB, M. P. BAIER, K. M. STANDIFER, H. O. AWWAD;
Dept. of Pharmaceut. Sci., Univ. of Oklahoma- Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: Traumatic Brain Injury (TBI) is a condition of disruption of normal brain function due to an impact, penetration or jolt to the head. Male bias in clinical and preclinical studies is a pressing issue in neuroscience and TBI research. Sex differences in pathophysiology and recovery following TBI of varying severity are poorly understood, which limits delivery of efficient care and development of successful therapeutics for TBI. The goal of this study was to investigate sex differences in response to either mild TBI (mTBI) or moderate TBI (ModTBI) by assessing neurological, behavioral and nociceptive responses. Wistar male (9-16 weeks) and female (12-13 weeks) rats received either a sham craniotomy, mTBI or modTBI controlled cortical impact to the left cerebral hemisphere. Injury severity and recovery were assessed using modified neurological severity scores (mNSS) on days 1 and 8 post-TBI. Vestibulomotor function was determined using the rotarod. Nociceptive sensitivity was assessed by measuring hind paw withdrawal threshold (PWT) from mechanical pressure and tail flick latency (TFL) from radiant heat on days 2, 4, and 7 post TBI. The presence of anxiety-like symptoms was assessed using the elevated plus maze (EPM) on day 7 post-TBI. Two-way ANOVA with or without repeated measures (as appropriate) was performed on data from each sex. Results: Both male and female rats displayed similar neurological deficits per TBI severity; with validated mNSS scores on day 1 post-TBI (mTBI: 1-6 and modTBI: 7-12). Both sexes showed full neurological recovery on day 8 following mTBI (mNSS <1) and partial neurological recovery from ModTBI (mNSS, mean ± SD, M : 4.07 ± 2.2, F: 2 ± 1.3; n=5-7). mTBI induced transient vestibulomotor deficits on days 1 - 4 post-TBI in both sexes and rats recovered by day 8 post-TBI. However, modTBI induced vestibulomotor deficits from day 1 with no recovery by day 8 post-TBI in male rats, and full recovery in females. Female rats showed impaired rotarod performance on days 1-4 after mTBI and 1-7 after ModTBI compared to sham rats. mTBI, modTBI and sham groups were significantly different from each other on all days tested in male rats. Female rats with mTBI and ModTBI were equally impaired, with no statistical difference between them on days 1-8. mTBI and ModTBI induced significant thermal hyperalgesia and mechanical allodynia compared to sham rats in both sexes to a similar extent. No differences in anxiety-like behaviors between sham and TBI groups were detected on day 7 post-TBI in either

sex. In conclusion, mTBI and ModTBI produced similar deficits in neurological functions and pain sensitivity, but different patterns of vestibular deficits in male and female rats.

Title: Conditional ablation of ApoE in astrocytes reduces hippocampal newborn neuron complexity and impairs spatial learning and memory following traumatic brain injury.

Authors: ***T.-S. YU**, Y. TENSAOUTI, E. STEPHANZ, E. RAFIKIAN, M. YANG, S. KERNIE;
Columbia Univ. Med. Ctr., New York City, NY

Abstract: Polymorphisms in the apolipoprotein E (APOE) gene confer a major genetic risk for the development of late-onset Alzheimer disease (AD), with the APOE4 allele providing an increased risk relative to the more common E3 allele. Despite its clinical implications, the function for APOE in the brain remains largely unknown but is believed to be critical for repair and remodeling lipid membranes, organelle biogenesis, and dendritogenesis because of its role in cholesterol and lipid transport and metabolism. We have recently demonstrated that APOE is critical in both dendritogenesis and spine development of adult hippocampal newborn neurons in naïve and injured brains using conventional APOE null mice.
In the adult brain, APOE is synthesized by astrocytes, microglia, and pericytes. Among them, the major source of APOE is the astrocyte. To reveal the specific role of APOE synthesized by astrocytes, we generated astrocyte-specific ablation of ApoE using floxed ApoE mice crossed to Aldh-Cre transgenic mice to allow for inducible ablation of APOE in astrocytes.
Mice received tamoxifen at 3-weeks of age and then underwent controlled cortical impact (CCI) to mimic traumatic brain injury 3 weeks later. At the time of injury, a GFP-expressing retrovirus (MMLv) was injected into the dentate gyrus to allow for visualization of newborn neurons and subsequent analysis of morphology. Four weeks after surgery, an approximately 80% reduction in APOE-expressing cells in the hippocampus was observed in conditional knockouts. Using the Golgi-Cox method, stained cells in the dentate gyrus in the absence of astrocytic APOE had unchanged dendritic structures when compared with controls in both sham-operated and injured brains. In hippocampal newborn neurons, no difference was observed in the sham-operated mice despite the reduction in astrocytic APOE. However, in the injured mice, reduction of astrocytic APOE resulted in less complex newborn neurons revealed by Sholl analysis. The deficits in newborn neurons in the dentate gyrus resulted in impairments in hippocampal-dependent

behavioral tasks. Using a reversal learning version of Morris water maze, the injured conditional knockout mice learned to reach the hidden platform in the learning phase, but failed at retrieving the location of the hidden platform. This demonstrates that astrocytic ApoE is required for functional injury-induced neurogenesis following traumatic brain injury.

Title: The nicotinic acetylcholine receptor modulator AVL-3288 attenuates hippocampal-based cognitive deficits following repeated mild TBI in adolescent rats

Authors: *T. A. MCCORKLE[1], R. RAGHUPATHI[2];
[2]Neurobio. and Anat., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sports-related concussions (SRC, a subset of mild Traumatic Brain Injury) in adolescents is a leading cause of long-term cognitive deficits. We have developed an age-appropriate and clinically-relevant model of SRC in adolescent (35-day old) male and female Sprague Dawley rats by subjecting them to 3 separate episodes over 7 days of an impact to the intact skull (2.0mm depth at 5.5m/s velocity). Rats were tested for hippocampal-dependent cognition at 4 weeks post-injury in the Morris Water Maze (MWM) and Novel Object Location (NOL) tasks. Male and female brain-injured animals exhibited significant deficits in locating the hidden platform in the MWM over the 5-day testing period compared to the uninjured (sham) rats. Similarly, both male and female brain-injured rats had significant difficulty recognizing the new location of an object they had been familiarized with in an earlier trial. Based on previous studies, we hypothesized that impaired cholinergic transmission may be a mechanistic basis for these cognitive deficits. Positive allosteric modulation of nicotinic acetylcholine receptors (nAChR) via AVL-3288 was reported to diminish spatial learning deficits in brain-injured adult male rats. Male and female rats underwent injury or sham surgery in adolescence and then were injected with AVL-3288 at 30 minutes prior to testing the animals in either the MWM or NOL tasks at 4 weeks post-injury. Preliminary data indicate that treatment with AVL-3288 attenuated injury-induced cognitive deficits in both tasks suggesting that reduced activity of the nAChR may underlie post-traumatic cognitive deficits.

Title: The role of hippocampal glucocorticoid receptor dysfunction in long term outcomes of pediatric Traumatic Brain Injury

Authors: *D. LENGEL[1], J. W. HUH[2], R. RAGHUPATHI[3];
[1]Drexel Univ., Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Children that sustain a Traumatic Brain Injury (TBI) during preschool-age (younger than 4 years old) are more likely to suffer from cognitive and psychosocial deficits that can emerge during adolescence/adulthood. We evaluated the effects of pediatric TBI in 11-day-old rats on cognitive and emotional behaviors between 4-6 weeks post-injury (adolescence). Brain-injured animals exhibited more open arm time in the elevated plus maze (EPM) at 4-weeks post-injury. Pediatric TBI also resulted in impairments in spatial learning in the Morris water maze at 6-weeks post-injury along with deficits in long-term potentiation in the hippocampal CA1 field. Prior studies have demonstrated that suppression of glucocorticoid receptors (GR) within the hippocampus impairs spatial learning and hippocampal synaptic plasticity, and results in more active behaviors in the EPM. Thus, we investigated whether pediatric TBI influences the expression and function of hippocampal GRs at 4-weeks post-injury by exposing sham and brain-injured animals to the EPM and measuring corticosterone, corticotropin-releasing hormone (CRH), and the mRNA expression of GRs and GR target gene, serum- and glucocorticoid-inducible kinase 1 (sgk1). Pediatric TBI did not influence corticosterone reactivity to the EPM, but resulted in an impairment in the transcriptional activity of GRs within the dorsal and ventral hippocampus at 4 weeks post-injury, as evidenced by an attenuation of the stress-induced increase in skg1. In order to determine whether impaired function of GRs influences LTP function, we bath-applied corticosterone (100nm) onto hippocampal slices during recording. Corticosterone restored short-term but not long-term potentiation, further pointing to impaired function of GRs. These results demonstrate that pediatric TBI results in long-term deficits in GR function within the hippocampus, which may underlie the cognitive and behavioral deficits observed following injury. Future directions include investigating whether GR overexpression in the hippocampus can reverse these cognitive and behavioral deficits following TBI.

Title: Quantitative PCR validation of plasma microRNAs as potential diagnostic biomarkers of epileptogenesis after traumatic brain injury

Authors: M. HEISKANEN, S. DAS GUPTA, X. EKOLLE NDODE EKANE, N. LAPINLAMPI, N. PUHAKKA, A. PITKÄNEN;
Univ. of Eastern Finland, Kuopio, Finland

Abstract: Over 50 million people suffer traumatic brain injury (TBI) each year, and it is a major cause of death and disability. Patients with TBI often suffer from comorbidities, such as post-traumatic epilepsy (PTE). There is an urgent need for molecular biomarkers to improve prediction of TBI outcome. We studied plasma microRNA (miRNA) expression in an animal model of PTE. We hypothesized that expression levels of specific plasma miRNAs at acute post-TBI time point will predict epileptogenesis. We present our preliminary results of plasma miRNA validation by PCR methods.
RT-qPCR validation: Tail vein plasma was sampled at 48 h after lateral fluid-percussion injury (LFPI)-induced TBI (n=16) or sham operation (n=4). TBI group included 7 rats that during a 6-months follow-up developed epilepsy (TBI+) and 9 that did not (TBI-). Based on DESeq2 analysis (TBI vs. sham) of small-RNA sequencing data from the present and two other cohorts, we selected 5 miRNAs for RT-qPCR validation using miRCURY LNA RT-qPCR assays.
Droplet digital PCR (ddPCR) validation: Four miRNAs validated in qPCR, and 3 miRNAs selected from sequencing data were measured in plasma of 5 TBI (48 h post-injury) and 5 naïve rats by ddPCR using miRCURY LNA miRNA assays with EvaGreen chemistry.
RT-qPCR showed upregulation of miR-9a-3p (FC=9.3, $p<0.001$), miR-434-3p (FC=4.2, $p<0.01$), miR-323-3p (FC=4.6, $p<0.05$), and miR-136-3p (FC=4.4, $p<0.01$) in TBI animals as compared to sham. Difference in miR-129-5p expression did not reach statistical significance (FC=1.9, $p=0.09$). RT-qPCR found no difference in miRNA expression between TBI+ and TBI- rats.
ddPCR showed upregulation of miR-9a-3p (FC=27.7, $p<0.01$), miR-434-3p (FC=14.6, $p<0.01$), miR-323-3p (FC=34.9, $p<0.01$), miR-136-3p (FC=10.6, $p<0.01$), miR-124-3p (FC=5.5, $p<0.05$), miR-212-3p (FC=1.5, $p<0.01$) and miR-132-3p (FC=3.5, $p<0.01$) in TBI animals as compared to naïve.
We validated 7 differentially expressed plasma miRNAs after TBI, indicating them as potential biomarkers for injury effect. RT-qPCR analysis did not find differences in miRNA expression

between TBI+ and TBI- rats, however, miR-124, miR-212, and miR-132 remain to be analyzed. Next, we will measure the 7 potential miRNA biomarker candidates in a larger EPITARGET cohort, including 115 TBI, 23 sham, and 13 naïve rats, using ddPCR. We will also investigate if miRNA expression is linked to epileptogenesis, or histopathological and behavioral outcome measures after TBI.

Title: Effects of Traumatic Brain Injury on Neural Signatures Mediating Impulse Control in Rats Performing a Probabilistic Reversal Learning Task.

Authors: M. J. FRANCOEUR[1], L. FAKHRAEI[1], T. TANG[2], S. HULYALKAR[2], D. RAMANATHAN[1];
[1]Psychiatry, UC San Diego, La Jolla, CA; [2]UC San Diego, San Diego, CA

Abstract: Traumatic brain injury (TBI) has been linked with chronic behavioral impairments seen in disorders such as depression, anxiety and addiction. Poor impulse control is a central feature of many psychiatric disorders and a common symptom post-TBI, yet the manifestation of impulsivity in TBI animals and its underlying neural mechanisms remain unknown. Impulsivity generally describes acting prematurely without consideration of behavioral consequences and can be debilitating to everyday life. Here, we examine chronic behavioral deficits resulting from bilateral frontal controlled cortical impact during a probabilistic reversal learning (PRL) task while simultaneously recording “brain-wide” local field potentials (LFPs). In the PRL task rats choose to respond in one of two noseports: one leads to a high-probability reward (“target“) and the other to a low-probability reward (“non-target”). Rewards are probabilistically delivered at an 80:20 ratio and a reversal of “target” and “non-target” noseports occurs when the rat makes 80% correct responses over a 10 trial moving window. Following recovery from TBI surgery, we implant electrodes across 30 brain regions to record LFPs from sensorimotor, attention, visual, reward, limbic, and cognitive brain regions, allowing for an unbiased sampling across neural networks. Comparing the behavior and physiology of control (N=10) and TBI (N=12) rats, we hypothesize that rats with injury will demonstrate dysregulated impulse control on the PRL task and show neural signatures associated with this impairment. Rats with injury overall perform fewer reversals and take longer to correctly respond to contingency changes. We found that reward-related beta-oscillations in orbitofrontal cortex signal a match in expected and actual reward on the PRL task. Specifically, reward-related beta activity is greater for “targets” compared to “non-targets” in both the initial block and subsequent reversal blocks. Similarly, theta activity in medial prefrontal cortex provides a neural signature for errors (“non-target”) that

switches to the new "non-target" after reversal. This activity likely mediates optimal win-stay behavior for the "target" while allowing animals to ignore misleading feedback from probabilistic reward delivery and may serve as a bio-marker for disrupted impulse control in rats with brain injuries.

Title: Linking brain and serum lipidome alterations following mild traumatic brain injury

Authors: *A. PULLIAM[1], E. GIER[2], D. GAUL[2], F. FERNANDEZ[2], M. C. LAPLACA[1]; [1]Wallace H. Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. and Emory Univ., Atlanta, GA; [2]Sch. of Chem. and Biochem., Georgia Inst. of Technol., Atlanta, GA

Abstract: Traumatic brain injury (TBI) is an extremely heterogeneous disease, which makes clinical diagnosis challenging, especially for mild TBI (mTBI). Current methods to diagnose mTBI rely heavily on self-reported subjective symptoms. Serum-based lipid biomarkers may be a more objective tool to diagnose and discriminate between different injury phenotypes because of the relative ease with which lipids transport across the blood brain barrier into systemic blood flow compared to protein biomarkers. In this study, we aimed to identify a lipid biomarker panel that is both brain-specific and TBI-specific using a clinically relevant closed head injury model. Male (n=14) and female (n=18) rats obtained sham-procedures (n=9), a single impact (n=10; head displacement= 5 mm), or 3 impacts (2 min interval; head displacement= 5 mm, 2 mm, 2mm) (n=11) by a controlled cortical impact device (velocity = 5 m/s). Whole blood was collected at baseline, 30 min, 4 hrs, and 24 hrs post-injury and brains were collected 24 hrs post-injury. Untargeted ultra-performance liquid chromatography (UPLC-MS) in negative and positive modes was used to analyze lipidome changes after injury in serum and brain samples. UPLC-MS of serum in both positive and negative modes yielded 14,119 features. Principal component analysis showed separation between uninjured and injured serums and clustering of pooled quality control samples. Welch's t-tests were conducted and features with q-values below 0.05 and fold change above 1.5 were identified as features of interest for further MS/MS experiments. Twenty-one candidate lipid biomarkers were selected with genetic algorithms for discriminating injured from uninjured samples in female and male sexes independently, including phosphatidylcholine and

sphingomyelin. These features were used in a binary comparison of injured versus uninjured serum and performed with high sensitivity, specificity, and accuracy (94.1%, 97.1, 93.6%) for males and (91.7%, 93.8%, 92.7%) for females, respectively. Orthogonalized partial least squares discriminant analysis with venetian blinds cross validation and modeling of each timepoint as a separate class showed 77% proper class assignment over all four timepoints. Most misclassified samples were collected at baseline and 30 mins post-injury, which may suggest minimal lipidome changes at early time points. These results show the ability of serum lipids to differentiate between TBI and uninjured rodents. Comparison to brain lipids is ongoing. Together, these results will indicate if dysregulated lipids in the serum reflect brain-specific changes following TBI and guide further refinement of a novel biomarker panel.

Title: Computational prediction of vascular injury after traumatic brain injury

Authors: S. F. KHOSROSHAHI, C. K. DONAT, A. MCGARRY, O. PORAT, M. SASTRE, D. SHARP, ***M. GHAJARI**;
Imperial Col. London, London, United Kingdom

Abstract: Introduction: Mechanical forces acting on vessels during traumatic brain injury (TBI) often damage blood-brain barrier (BBB) and cause haemorrhage. A key question is how mechanical forces disrupt the vascular network. We hypothesised that large tensile forces acting on vessels can produce BBB disruption. To test this, we combined finite element (FE) modelling with quantitative histopathology in a controlled cortical impact (CCI) model of TBI in rats. **Methods:** High resolution synchrotron images of a Sprague Dawley (SD) rat brain (Zhang et al., Sci. Rep., 2015) was used to develop a detailed FE model incorporating vascular network (Fig. A-C). The model was used to predict maximal tensile strain in vessels during CCI. CCI was performed on SD male rats (sham n=4, CCI n=8). Three days post-injury, sections from the contusion core were stained for fibrinogen. The staining was quantified in 5 segments in the ipsilateral corpus callosum (CC) and cortex (Fig. F). Linear mixed effects modelling was used to test the relationship between strain in vessels and fibrinogen extravasation. **Results:** The FE model predicted large strains in ipsilateral vessels particularly in the cortex and near the edges of the impactor (Fig. E). The empirical data also showed pronounced vascular damage, as indicated by a strong increase of Fibrinogen cortex and subcortical structures (Fig. F). Quantification of Fibrinogen optical density showed an increase of 150% in the cortex and 90% in CC (Fig. G). A

linear mixed effects model incorporating strain and ROI (CC and cortex) as the fixed effects predicted 30% of the variation in Fibrinogen optical density (Fig. H). Removing strain from the model slightly reduced the prediction to 28%. **Conclusion:** We found a link between mechanical strain in vessels and BBB disruption post-injury. Our results show that fibrinogen extravasation increases by increasing strain. They also show more BBB disruption in the cortex than CC when we control for strain.

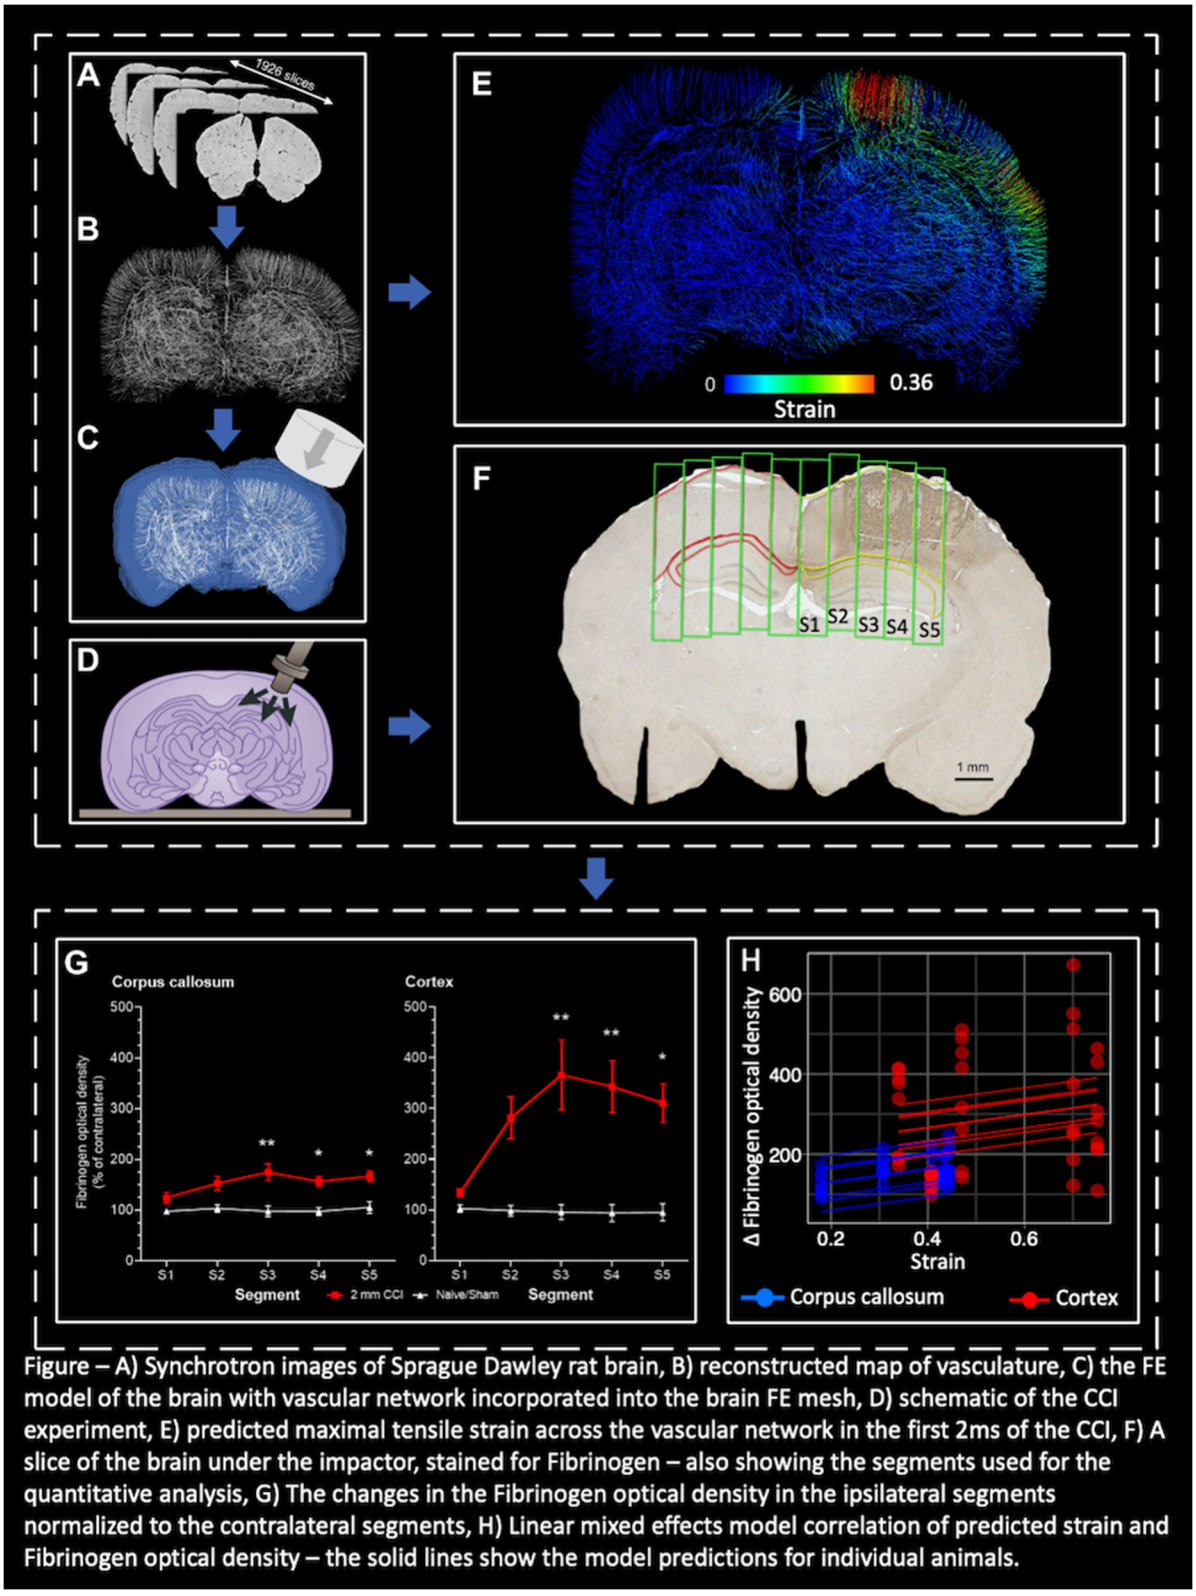

Figure – A) Synchrotron images of Sprague Dawley rat brain, B) reconstructed map of vasculature, C) the FE model of the brain with vascular network incorporated into the brain FE mesh, D) schematic of the CCI experiment, E) predicted maximal tensile strain across the vascular network in the first 2ms of the CCI, F) A slice of the brain under the impactor, stained for Fibrinogen – also showing the segments used for the quantitative analysis, G) The changes in the Fibrinogen optical density in the ipsilateral segments normalized to the contralateral segments, H) Linear mixed effects model correlation of predicted strain and Fibrinogen optical density – the solid lines show the model predictions for individual animals.

Title: Using an Elevated Plus Maze assay to measure anxiety-like behaviors in a mouse model following mild traumatic brain injury

Authors: ***M. MOJENA**[1], K. M. BEST[2,4], H. METHENY[6], A. S. COHEN[3,5];
[1]Col. of Arts and Sci., Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Nursing and Clin. Care Services, [3]Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Ctr. for Sleep and Circadian Neurobio., [5]Dept. of Anesthesiol. and Critical Care Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [6]Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Every year in the United States traumatic brain injury (TBI) results in 2.5 million emergency department visits, hospitalizations, and deaths. Millions more may be affected that do not seek care. Victims of TBI can suffer from a multitude of chronic symptoms including sensory and motor deficits and neuropsychiatric symptoms, such as anxiety. The neurobiology underlying the symptoms of anxiety disorders after TBI remains largely unknown. Since anxiety disorders have such a high prevalence and lead to prominent reductions in productivity and quality of life for TBI sufferers, it is important to investigate their causes and manifestations. Modeling these symptoms in animal models of TBI affords the opportunity to determine mechanisms underlying behavioral pathologies and to test potential therapeutic agents. This study examined the effect of mild TBI on anxiety-like behaviors in a mouse model. Mild lateral fluid percussion injury (LFPI), or sham surgery, was induced in 8-week-old male C57B/L6 mice. An Elevated Plus Maze (EPM) protocol was adapted and performed at 24 hours, 3 days, and 2 weeks after injury in separate cohorts of mice. The EPM is an elevated, 1 meter high platform divided into four equal quadrants arranged in a plus sign. Two opposing quadrants are open while the remaining two closed quadrants are surrounded by dark, opaque walls. As a test of anxiety-like behavior, the EPM relies on a rodent's natural tendency to avoid exposed, bright areas where they may be vulnerable to predators. Each mouse was placed in the center of the EPM apparatus and allowed to freely explore for 5 minutes. ANY-maze software was used for mouse tracking and videos were analyzed for the number of entries and amount of time spent in

each quadrant by each mouse. Our results demonstrated increased anxiety behaviors in the sham (non-injured) compared to the injured animals. However, injury condition was significantly correlated with total distance traveled and average speed, suggesting that motor deficits must be examined as a potential confounding factor. Further research is needed to determine if the observed behavioral alterations have electrophysiological correlates in brain structures mediating anxiety.

Title: Pain sensitivity and aversion after traumatic brain injury (TBI): A behavioral and histological analysis

Authors: *K. M. BEST[1,3], M. M. MOJENA[5], H. METHENY[6], A. S. COHEN[2,4];
[1]Dept. of Nursing and Clin. Care Services, [2]Dept. of Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Ctr. for Sleep and Circadian Neurobio., [4]Dept. of Anesthesiol. and Critical Care Med., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [5]Col. of Arts and Sci., Univ. of Pennsylvania, Philadelphia, PA; [6]Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Traumatic brain injury (TBI) affects more than 2.5 million people in the United States each year and is associated with multiple long-term sequelae that impact functional ability and quality of life. Chronic pain is a significant morbidity after TBI, with up to 90% of veterans reporting chronic headache and a similar incidence in civilian populations. Pain may occur in other body areas not affected by the primary head trauma, including neck, back and limb pain, and is hypothesized to arise from TBI-induced neuroplasticity and central sensitization. This study examined the effect of mild TBI on pain sensitivity and pain-related aversive behaviors in a mouse model of brain injury, lateral fluid percussion injury (LFPI). Under anesthesia, mild LFPI was induced in 6- to 8-week-old male C57B/L6 mice and behavioral experiments were performed at one or two weeks after injury. A three-day conditioned place aversion (CPA) protocol was adapted from Cunningham et al. (2006), using 1% formalin injection as the aversive stimulus, to allow for simultaneous assessment of evoked pain behaviors and aversion. Following completion of behavioral testing, animals underwent live perfusion with 4% paraformaldehyde (PFA), and fixed brains were sliced into 50 μm thick sections. Immunohistochemical (IHC) staining for cFos was performed to identify brain regions activated

by the CPA protocol. All experiments were carried out under protocols approved by the Institutional Animal Care and Use Committee. Mouse tracking during CPA was performed using ANY-maze software (Wood Dale, IL), and evoked pain behaviors were manually coded in 10 second epochs each minute for 60 minutes after formalin injection. Data were analyzed with two-way repeated measures ANOVA and Sidak's multiple comparison test in order to evaluate for effects by injury condition and test duration. Our results showed increased pain-related aversion at one week following TBI. Further research is needed to determine whether the observed behavioral alterations have electrophysiological correlates in brain structures mediating nociceptive processing and aversion.

Abstract: Background: The symptoms of coronavirus disease 2019 (COVID-19) are highly variable, ranging from minor to potentially life threatening - the latter requiring intensive critical care medical response at prevalence levels that can strain healthcare systems. Significant concern is also emerging over the potential for lingering symptoms in COVID-19 survivors. In particular, numerous cases of hospitalized COVID-19 patients with neurological symptoms are being reported, including deficits in sensation, cognition and consciousness, as well as vascular and inflammatory lesions observed by magnetic resonance imaging (MRI). Very little is known about how these brain effects persist or resolve - and the extent of the effects in the much larger population of COVID-19 survivors, who self-isolated while infectious.
Objectives: To fill this knowledge gap, we have created NEUROCOVID19: a multidisciplinary study involving neuroimaging scientists and academically-oriented clinicians, that aims to: **1.** Test whether COVID-19 survivors have incident brain lesions compared to matched COVID-19 negative controls; **2.** Evaluate neuroanatomy and neurophysiology, clinical, sensory, and

behavioural findings when COVID-19 survivors are no longer infectious (at baseline) and at follow-up; **3.** Test for multivariate relationships between these measurements across COVID-19 survivors, including associations with risk variables such as age and indices of cerebrovascular health. **Methods:** The study involves ongoing recruitment of COVID-19 survivors in two groups: those that were hospitalized, and those that self-isolated; and a control group of participants that tested negative for COVID-19 and self-isolated consequent to cold or flu-like symptoms. NEUROCOVID19 measurements include comprehensive, state-of-the-art brain MRI at 3 Tesla, including acquisitions and associated metrics probing brain anatomy and physiological function, lung MRI, olfactory and behavioural (NIH toolbox) assessments, and electroencephalography. Baseline measurements are undertaken within 3 weeks after hospital discharge or leaving quarantine, with 3-month follow-up. **Significance:** Our initial pilot data (20 cases, 10 controls) strongly support our hypothesis that neuroinvasion occurs and produces brain lesions in some COVID-19 survivors with and without hospitalization. Knowledge translation of our protocol and findings to radiology, neurology and COVID-19 recovery clinics will help to address on-going health needs of COVID-19 survivors, and will help to understand the mechanisms that underpin the heterogeneous brain symptoms.

Abstract: Motivation/problem statement: We have recently discovered autism/intellectual disability somatic mutations in postmortem brains, presenting higher frequency in Alzheimer's disease subjects, compared with the controls. We further discovered high impact cytoskeletal gene mutations, coupled with potential cytoskeleton-targeted repair mechanisms (Ivashko-Pachima, Hadar⋯Gozes, Molecular Psychiatry, 2019 EPUB). One of the identified genes/proteins exhibiting somatic mutations was activity-dependent neuroprotective protein (ADNP), also linked with stress (Sragovich⋯Gozes, 2019, Transl Psychiatry. 9(1):235). We now investigate if somatic mutations in brain diseases are specific to the brain, or phenocopied in the blood in Alzheimer's disease risk populations, such as posttraumatic stress syndrome (PTSD) individuals, toward potential diagnostics and preventative measures. **Methods/ approach:** To identify high and moderate impact somatic potential mutations, we performed variant calling analyses on an RNA-seq database including peripheral blood samples from 85 soldiers (58 controls and 27 with symptoms of PTSD (Boscarino et al., 2019, G3 (Bethesda) 9, 463-471). **Results:** High (e.g. protein truncating) as well as moderate impact (e.g. single amino acid change) putative somatic mutations in thousands of genes as well as germline mutations were identified. Further crossing the mutated genes with databases including genes driving autism, intellectual disability, cytoskeleton, inflammation and DNA repair (Venn diagrams), identified the highest number of cytoskeletal-mutated genes (187 high and 442 moderate impact). Most of the mutated genes were not specific to PTSD. However, the inflammation database exhibited a larger number of putative high impact mutated genes specific to the PTSD-symptom cohorts vs. the controls (14 vs. 13), highlighting tumor necrosis factor specifically in the PTSD-symptom cohort. **Conclusion/implications:** With microtubules and neuro-immune interactions playing essential roles in brain neuroprotection and Alzheimer-related neurodegeneration, these findings contribute to mechanistic understanding of PTSD and brain protection, as well as provide future diagnostics toward personalized military deployment strategies and drug design.

Title: Can alternative medical methods evoke neuro-functional somatosensory responses? A case study suggesting functional improvement.

Authors: A. OTAIF[1], M. E. ALSHAMMARI[2], ***C. G. GERIN**[3];
[1]Life Sci., Texas A&M, Corpus Christi, TX; [2]Sci., King Khalid Military Acad., Riyadh, Saudi Arabia; [3]Neurosci., UTRGV, Edinburg, TX

Abstract: Somatosensory pathways act as the avenue in transferring information concerning the body and its interaction with the external environment to the brain. We aim to demonstrate that through studying somatosensory, motor cortical and subcortical networks, we can explain functional recovery after stimulations applied as an alternative medical treatment. Those stimulations might have evidenced neural pathways and networks important in recovery of function. Materials and methods: The de-identified medical reports of nine patients with initial presentations of cerebral trauma or stroke inducing paralysis were studied.These included the alternative treatments they received and other available materials such as videos and photographs. Patients were either males or females and their ages ranged from 20 to 95-year old. All patients, were first treated through conventional medical interventions, including physical therapy. Patients consulted for alternative medical treatment, one year or more, after the initial diagnosis**.** The alternative medical treatment consisted in multiple points stimulations. Twelve points of stimulation on the skull were used. Additional 4 points of stimulation were located at the right and left calves and at the right and left forearms. All stimulations had nociceptive and proprioceptive components. The stimulations were applied successively one by one (legs, arms, skull). The treatment consisted in a one-time (exceptionally two) session. The duration of each stimulation was about 0.5 s. Results show that in all 9 cases, patients had improvement in their motor skills, including gain of weight support and unassisted small walks, independent and voluntary movements of limbs. Improvement was steady over a period of one to several years. We believe that whether lesions included prefrontal cortical areas, or motor and sensory areas, the alternative treatment triggered existing or new neuronal networks as well as synaptic efficiency or reactivation, through highly increased, sensory nociceptive coupled to proprioceptive, afferences. Those results highlight the need to further investigate neural function of cortical and subcortical areas through non-invasive and indirect pathways stimulations, during a stable chronic phase after a CNS insult.

Title: Loss of consciousness in National Football League players is associated with high strain in the thalamus and brainstem.

Authors: *K. A. ZIMMERMAN[1], J. COURNOYER[2], C. KARTON[2], T. B. HOSHIZAKI[2], M. GHAJARI[1], D. SHARP[1];
[1]Imperial Col. London, London, United Kingdom; [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background: Sports traumatic brain injury (TBI) can produce transient neurological signs such as loss of consciousness (LOC) and dystonic posturing. However, it is unknown why impacts produce a range of neurological effects. Video surveillance allows the biomechanics of impacts to be calculated from impact reconstructions. The biomechanics can then be used to estimate the patterns of strain produced in different brain regions. Here we use a 3D model of brain injury biomechanics to investigate the strains produced by National Football League impacts that produce mild TBI leading either to LOC, dystonic posturing, or producing no neurological signs. We test the hypotheses that LOC is associated with high strain within the brainstem and thalamus, whereas dystonic posturing is association with high strain in the motor cortex and/or corticospinal tracts.

Methods: 82 videos of mild TBIs in the NFL were classified as showing either LOC (20), posturing (21) or no neurological signs (No Signs - 41). Methods are highlighted in Fig A & B. The estimated magnitude and location of mechanical strain in specific brain regions were then statistically compared across the groups. Results: Impacts leading to LOC had significantly higher impact kinematics and whole brain measures of brain deformation compared to No Signs impacts. A voxelwise analysis of brain deformation corrected for the magnitude of strain showed regions of disproportionately higher strain in the thalamus, brain stem and cerebellum in impacts leading to LOC compared to No Signs (Fig C). Impacts leading to posturing also showed regions of higher strain, however these areas were constrained to the cortical regions including the motor cortex.

Conclusions: We show that strains are particularly high in the thalamus and brain stem in those players who lose consciousness. In contrast, impacts leading to posturing appear to disproportionately affect cortical regions, including the motor cortex. These results provide evidence that loss of consciousness is produced by head impacts that produce high strain in the brainstem and thalamus.

Hosp., Florence, Italy

Abstract: Background: Outcomes after traumatic brain injury (TBI) are highly variable, with many survivors affected by persistent disability, including cognitive problems. Axonal injury is thought be a significant determinant of outcome, which can be assessed using novel techniques such as fluid biomarkers and advanced MRI assessment. Poor long-term outcomes post-TBI may also relate to progressive neurodegeneration, which can be assessed using serial volumetric MRI to quantify brain atrophy longitudinally.
Methods: BIO-AX-TBI (Developing and Validating Blood and Imaging BIOmarkers of AXonal Injury Following Traumatic Brain Injury, NCT03534154) is a large multi-centre cohort study of patients after acute moderate-severe TBI. Patients admitted to major trauma units underwent baseline clinical followed by serial blood biomarker and MRI assessments over the course of a year, with detailed functional outcome ascertainment. Single molecule array assays quantified blood concentrations of neurofilament light (NFL), S100-B, ubiquitin carboxy-terminal hydrolase L1 (UCHL1), glial fibrillary acidic protein (GFAP) and tau.
Results: 197 patients after TBI underwent acute blood biomarker assessment. Clinical outcomes were ascertained at 6 and 12 months. Several control groups were assessed: 95 healthy participants with imaging and blood biomarker assessments, 28 healthy controls with longitudinal neuroimaging and 24 trauma patients with extracranial injuries (non-TBI trauma, 'NTT', London). TBI patients had significant elevations of blood biomarkers compared with

controls and NTTs. GFAP, S100B, Tau and UCH-L1 were elevated rapidly post injury. NFL peaked more gradually and remained chronically elevated. Diffusion tensor imaging (DTI) assessment showed reduced fractional anisotropy in TBI patients, which remained abnormal into the chronic phase. Early cortical atrophy was predicted by acute plasma tau concentration and chronic white matter atrophy was predicted by NFL levels. Cognitive function at 12 months, and functional outcomes at 6 and 12 months were predicted by the acute blood biomarker levels and DTI MRI measures.
Conclusions: In this multi-centre longitudinal of acute moderate-severe TBI, blood assessment of neuronal and glial breakdown products provided a reliable readout of injury severity, predicting functional outcomes at 6 and 12 months. Blood NFL and DTI MRI were particularly sensitive to traumatic white matter injury and predicted accelerated white matter atrophy in the chronic phase.

Abstract: Background: Over the last decade, almost 250,000 US service members and veterans (SMVs) have sustained a traumatic brain injury (TBI). Biomarkers that can diagnose TBI and discriminate injury severity, and are associated with long-term neurobehavioral symptom reporting, may shed light on underlying pathological mechanisms and improve clinical care. This study examines the diagnostic utility of blood levels of protein biomarkers linked to brain injury in SMVs with a history of traumatic brain injury (TBI), and examines their relationship with neurobehavioral symptom reporting following TBI. **Methods:** Participants (n=481) were enrolled in the 15-Year Longitudinal TBI Study (Defense and Veterans Brain Injury Center [DVBIC]) from 2011 to 2019, following an uncomplicated mild TBI (n=215), complicated mild TBI (n=49), moderate or severe TBI (Moderate/Severe TBI group, n=69), or orthopedic or soft-tissue injury without TBI (Injured Control group, n=148). Concentrations of neurofilament light chain (NfL), tau and glial fibrillary acidic protein (GFAP) in serum samples were measured using an ultrasensitive assay (SIMOA™). **Results:** Participants were mostly male (93%) and white (73%) with a median age of 36 (IQR=29-44). Within one year after injury, we observed higher levels of NfL in the Moderate/Severe TBI group when compared to the Injured Control ($p < 0.0001$, $d = 1.1$), Uncomplicated mTBI ($p < 0.0001$, $d = 1.02$) and Complicated mTBI ($p = 0.0333$, $d = 0.75$) groups, which was confirmed in logistic regression analysis controlling for demographics, number of TBIs and time since injury. NfL also discriminated the Moderate/Severe TBI group from Injured Control (AUC = 89.8% [95% CI: 81.2-97.9%, $p < 0.0001$), and Uncomplicated mTBI (AUC = 86.6% [95% CI: 77.4-0.94%], $p < 0.0001$) groups with high accuracy. In addition, logistic regression analysis also showed higher levels of GFAP in the Moderate/Severe TBI group when compared to Injured Control and Uncomplicated mTBI groups. One or more years post-injury, GFAP levels were higher in the Moderate/Severe TBI group in comparison to the Injured Control ($p = 0.0093$, $d = 0.66$) and Uncomplicated mTBI groups ($p = 0.0002$, $d = 0.91$). We found no significant group differences for tau at either timepoint. **Conclusion:** Blood levels of NfL, a neurofilament protein predominantly in axons, are elevated in moderate and severe TBIs in the first year after injury, but not one or more years post-injury. GFAP, an astrocytic protein, is elevated within the first-year post-injury, as well as one or more years post-injury. Our results suggest the potential of NfL and GFAP as diagnostic biomarkers in TBI.

Title: Exosomal microRNA is associated with sleep quality in military personnel with traumatic brain injury

Authors: *S. MITHANI[1], J. LEETE[1], J. PUCCI[2], V. GUEDES[1], K. KENNEY[2], J. WERNER, Jr.[2], J. GILL[1];
[1]NIH, Bethesda, MD; [2]Uniformed Services Univ. of Hlth. Sci., Bethesda, MD

Abstract: Traumatic brain injury (TBI) is highly prevalent among military personnel and commonly co-occurs with disturbed sleep and leads to adverse health outcomes. The potential of using exosomal microRNA (exomiRs) as a biomarker is of particular interest in the context of TBI, as it may aid in diagnostics, prediction of patient outcomes, patient stratification for clinical trials, and further understanding of underlying pathophysiology. We used a convenience sample from the baseline measurements of 130 post-9/11 era military personnel and veterans from the Chronic Effects of Neurotrauma Consortium Multicenter Prospective Longitudinal Study (control; *n*=22; TBI poor sleep, *n*=58; TBI good sleep, *n*=50). Participants included in this cross-sectional analysis had clinical sleep data and plasma for exomiR analysis. Sleep quality was assessed using the global score on the Pittsburgh Sleep Quality Index (PSQI) with a cut-off score of >10 to distinguish poor sleepers from good sleepers. ExomiR profiling analysis was performed using nCounter Human v3 miRNA Expression Panels with 798 miRNA probes. Kruskal-Wallis tests followed by the Dunn test and the Benjamini-Hochberg procedure for false discovery rate to correct for multiple comparisons was performed to compare exomiR between groups. Additionally, Spearman's correlations were used to determine the relationship between exomiR and behavioral/psychological scores. After normalization, exomiR expression profiled revealed a total of 8 differentially expressed exomiR among the three groups and the PSQI global score positively. Within the TBI group, the expression levels of 4 exomiRs were significant: hsa-miR-1250-5p (r=0.229, p=0.017); hsa-miR-139-5p (r=0.236, p=0.014); hsa-miR-211-3p (r=0.206, p=0.033); and hsa-miR-4516 (r=0.212, p=0.028). Overall, differentially expressed exomiRs have been reported to play a role in psychiatric disorders, progressive neurodegeneration, and vascular physiology, all of which have been associated with the remote TBI.

Med., [4]CENC Biorepository, [5]Dept. of Neurol., Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [6]CENC Imaging Core, Univ. of Utah, Salt Lake City, UT; [7]Dept. of Physical Med. and Rehabil., Virginia Commonwealth Univ., Richmond, VA; [8]Dept. of Neurol., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA

Abstract: Symptoms of post-traumatic stress disorder (PTSD) are frequently associated with history of combat-related mild traumatic brain injury (mTBI) in military populations. Finding biomarkers that relate to PTSD symptoms may aid in the identification of therapy targets for those most at risk for poor outcomes following a mTBI. This study examined relationships between levels of exosomal proteins and miRNAs in the peripheral blood and severity of PTSD symptoms in a cohort of combat-exposed service members and Veterans (SMs/Vs) with and without chronic mTBI(s). Participants (n = 141) were all enrolled in the Chronic Effects of Neurotrauma Consortium (CENC) Multicenter Prospective Longitudinal Study, now housed in the Long-Term Impact of Military Brain Injury Consortium (LIMBIC). Participants were divided into four groups based on TBI history and severity of PTSD symptoms as measured by the PTSD Checklist for DSM-5 (PCL-5). We isolated peripherally circulating exosomes and analyzed exosomal levels of 798 miRNAs (miRNAs) with nCounter® Analysis Technology, as well as exosomal levels of neurofilament light chain (NfL), tau, phosphorylated tau (p-tau), Amyloid beta (Aβ) 42, Aβ40, interleukin (IL)-10, IL-6, tumor necrosis factor-alpha (TNFα), and vascular endothelial growth factor (VEGF) by using a Simoa HD-1 analyzer. We observed group differences for exosomal NfL, a protein marker of axonal injury and degeneration ($p = 0.0082$). Pairwise comparison showed higher levels of exosomal NfL in participants with both mTBI

history and more severe PTSD symptoms (PCL-5 scores higher or equal to 50) when compared to those with mTBI and lower PCL-5 scores (p= 0.0110), as well as the control group (no mTBI and no PTSD, p = 0.0221). NfL was also positively correlated with PCL-5 scores (p = 0.0040, r = 0.407573). Pairwise comparisons also revealed 14 differentially expressed miRNAs. Specific miRNAs linked to severity of PTSD symptoms included hsa-miR-139-5p, hsa-miR-103a-3p, hsa-miR-33a-5p, hsa-miR-520f-3p, which have been associated with neurodegenerative diseases. We observed that levels of hsa-miR-139-5p (p = 0.005817, r = 0.254591), hsa-miR-2278 (p = 0.01543, r = 0.2244367), hsa-miR-1827 (p =0.01219, r = 0.2320489) and hsa-miR-11851-3p (p = 0.01014, r = 0.2378501) correlated with PCL-5 scores. Our findings suggest the potential of exosomal NfL and specific miRNAs as prognostic biomarkers in TBI, while also shedding light on possible mechanisms underlying the development of persistent PTSD symptoms in military populations.

Title: Validation of a clinical guideline to identify traumatic brain injury patients at risk for in-hospital mortality: Utility of the guideline for prediction of patient disposition.

Authors: *J. E. OLSON[1], C. FALANK[3], D. SEDER[4], J. RAPPOLD[3], M. MCCARTHY[2]; [1]Emergency Med., [2]Surgery, Wright State Univ. Sch. of Med., Dayton, OH; [3]Surgery, [4]Critical Care Med., Maine Med. Ctr., Portland, ME

Abstract: Over 2.5 million traumatic brain injury (TBI) patients are treated in the United States each year. Rapid diagnosis of TBI and subsequent application of definitive care lead to better outcomes. We previously developed a clinical guideline using patient age, referral status, initial values of systolic blood pressure, heart rate, Glasgow Coma Scale (GCS), and injury severity score (ISS) and CT evidence of contusion and brain edema to calculate in-hospital mortality risk with a logistic regression model (J Emerg Med, 53:18-59, 2017). We now validate this guideline using patient data from Ohio, Maine, and the National Trauma Data Bank (NTDB) and demonstrate the model's utility to predict discharge disposition to home, rehabilitation, nursing home, hospice, or morgue.
TBI patient data for 2017-2019 were obtained from trauma registries at Miami Valley Hospital (Dayton, Ohio, N=2,008), Maine Medical Center (Portland, Maine, N=1,043) and the 2015 NTDB (N=189,907) under IRB-approved protocols. Statistical comparisons were made with SigmaPlot 13 using Chi Square, ANOVA, and t-test. Receiver Operating Curve (ROC) and Hosmer-Lemeshow analyses were performed using R. Significance was indicated for $p<0.05$.

Comparisons of patient data used in the clinical guideline model revealed differences between Ohio and Maine TBI populations. The Maine population was older on average than that of Ohio. The average systolic blood pressure for Maine patients was higher, but the average heart rate was equivalent to that of Ohio patients. Maine patients were more likely to arrive directly from the accident scene. Ohio and Maine populations had different distributions of GCS, ISS, and contusion while the fraction of patients with brain edema was similar. Nevertheless, the mortality rate was equivalent for Ohio, Maine, and NTDB patients (2.8%, 4.2%, 3.4%, respectively).
The guideline predicted in-hospital death with equivalent areas under the ROC (95% CI) of 0.88 (0.84-0.93), 0.91 (0.88-0.96), and 0.91 (0.91-0.92) for Ohio, Maine, and NTDB, respectively. Within ventiles of calculated risk, the model predicted observed rates of mortality. Ohio, Maine, and NTDB populations had different distributions of discharge disposition. The calculated mortality risk was different for each discharge disposition but for each disposition, the risks calculated from Ohio, Maine, and NTDB populations were similar.
We conclude our clinical guideline for calculating in-hospital mortality risk of TBI patients is valid and generalizable across a spectrum of patient populations. The guideline provides early indication of patients at risk for death and can be a tool for predicting patient disposition.

Title: Investigating the Effects of Sport-Related Concussion on Structural Brain Connectivity: Evidence for Altered Local and Global Network Efficiency During Acute Symptom Management

Authors: *E. D. ANDERSON[1], D. SCHULTZ[2], Y. WANG[3], E. CARLSON[2], L. ALBERS[2], J. TUTTLE[2], M. MEYER[2], M. NETA[2], C. R. SAVAGE[4], A. K. BARBEY[5];
[1]Univ. of Illinois At Urbana-Champaign, Urbana, IL; [3]Special Educ. and Communication Disorders, [4]Ctr. for Brain, Biol. and Behavior, [2]Univ. of Nebraska-Lincoln, Lincoln, NE; [5]Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Accumulating evidence indicates that mild traumatic brain injury (mTBI) alters the structural brain connectome by reducing network efficiency at a local and global scale. However, conflicting reports exist as to the time course of these connectivity changes throughout symptom management and initial recovery. Here, we report longitudinal structural connectivity data acquired in 30 student athletes who experienced a concussion while playing NCAA Division I football. Diffusion tensor imaging (DTI) was acquired prior to the athletic season, immediately following exposure to mTBI, and after symptomatic recovery (immediately before return to play). Performing DTI tractography, we identified reliable changes in structural connectivity

between these three timepoints. We find that acute mTBI exposure is initially associated with decreased clustering and local brain network efficiency, followed by a return to baseline after injury management and clearance for return to play ($p < 0.01$; FDR-corrected). However, measures of global network efficiency do not exhibit this pattern of recovery to baseline, instead demonstrating persistent decreases even after injury management and return to play. Our results support a novel dissociation between local and global network efficiency measures of mTBI, suggesting that acute symptomatic recovery is associated with return to baseline in measures of local network efficiency, while alterations to global network efficiency may persist following injury assessment, symptom management, and return to play.

Abstract: Background: Traumatic brain injury (TBI) affects both young and elderly populations and results in a significant global healthcare burden. TBI patients often suffer from costly long-term neurological and cognitive problems that reduce their quality of life and ability to work, including motor deficits such as gait abnormalities, memory impairments and anxiety. Current clinical practice for TBI patients is largely supportive, centred on non-specific endpoints such as management of tissue oxygenation, cerebral perfusion pressure and intracranial pressure[1]. At present there are no clinically validated drug treatments aimed specifically at preventing neuronal loss following TBI[2]. Xenon is a noble gas used medically as a general

anesthetic and in MRI imaging[3]. We have previously shown that xenon-treatment improves short and long-term outcomes, prevents late-onset cognitive impairments and improves survival after moderate TBI in mice[4, 5]. The aim of this study is to evaluate the efficacy of xenon in a second species, rats, and in a severe injury model.
Methods: Adult male Sprague Dawley rats (N=22) underwent controlled cortical impact (CCI) brain trauma or sham surgery. Animals were randomised to receive either 50%Xe:25%O_2:25%N_2 or 75%N_2:25%O_2. Locomotor function (CatwalkXT) and histological outcomes [lesion volume, neuronal cell count (NeuN), microglia (Iba1) and astrocytes (GFAP)] were assessed at 24 h by blinded observers.
Results: The xenon-treated group exhibited a reduction in locomotor deficits. Lesion volume was reduced in the xenon-treated group. Xenon-treatment resulted in preservation of neurons in cortical and subcortical regions that was associated with increases in numbers of resting microglia and reactive astrocytes.
Conclusions: We show for the first time that xenon is neuroprotective after severe TBI in rats. Functional improvement and neuronal preservation was associated with a xenon-induced enhancement of resting microglial cell numbers and astrocyte activation. These findings are consistent with a role for early beneficial neuroinflammation in xenon's neuroprotective effect. Xenon may be of benefit in the treatment of clinical brain trauma.

Title: Core-cross-linked nanoparticles reduce oxidative stress and cell death following traumatic brain injury in mice

Authors: *A. W. TARUDJI[1], A. M. PRIESTER[2], A. J. CONVERTINE[2], F. M. KIEVIT[1]; [1]Biol. Systems Engin., Univ. of Nebraska, Lincoln, NE; [2]Material Sci. & Engin., Missouri Univ. of Sci. and Technol., Rolla, MO

Abstract: Following a traumatic brain injury (TBI), cell death from the initial injury releases excess reactive oxygen species (ROS) and lipid peroxidation products (LPoX). ROS and LPoX induce mitochondrial and cell membrane damage in surrounding cells causing secondary cell death and release of ROS and LPoX. There is currently no clinically available treatment shown to reduce secondary injury, which might be due to poor retention of small molecule drugs in TBI. However, the blood-brain barrier permeability following TBI opens the opportunity for improved retention of nanoparticles (NPs). Here, we used a controlled cortical impact (CCI) mouse model of TBI (4 m/s impact velocity, 2.5 mm impact depth) on 6-wk old male C57BL/6J mice; animal procedures were approved by IACUC. We immediately administered core-cross-linked NPs (ANPs, 0.2 mg IV) with similar properties to our previously reported NPs (24 nm) synthesized through thiol-ene and thiol-Michael reactions and dialysis-purification that rely on their thioether bond to scavenge ROS (9.93 μmol/mg NPs). MnTMPyP (0.5 mg IP), an antioxidant small molecule drug and no additional treatment were used for comparisons. To compare ROS levels following CCI, we administered dihydroethidium (DHE, 625 μg IV) at 3 h post-CCI and harvested the brain at 4 h post-CCI for confocal microscopy. The DHE fluorescence mean intensity at the perilesional was normalized to the contralateral hemisphere. We found a significant increase in ROS in the CCI mice (mean ± SEM: 1.44 ± 0.06) compared to the CCI+MnTMPyP mice (1.19 ± 0.05, $p<0.05$) and the CCI+ANP mice (1.03 ± 0.07, $p<0.01$), as determined by one-way ANOVA and Tukey's post hoc test; n = 3 for each treatment group. To compare cell death following CCI, we performed Western blot of α-II-spectrin breakdown products (SBDPs) that correlate to total cell death (150 kDa), necrosis (145 kDa), and apoptosis (120 kDa) from perilesional brain lysate at 3 d post-CCI; SBDPs were normalized to β-actin and SBDPs in the control mice. We found a significant increase in 150 and 145 kDa SBDPs of the CCI mice (2.31 and 5.11-fold increase) compared to the CCI+ANP mice (1.42 ($p<0.001$) and 3.76-fold increase ($p<0.05$)), while there was no significant difference of 120 kDa SBDP across the treatment groups, as determined by two-way ANOVA and Tukey's post hoc test; n = 3 for each treatment group. Our results suggest that ANP treatment reduces ROS and necrosis in the CCI mouse model of TBI likely because of better ANPs retention in TBI. ANPs are a promising candidate to reduce ROS, LPoX, and secondary injury in TBI.

Title: Positive allosteric modulation of alpha7 nicotinic acetylcholine receptors enhances sustained attention and decreases anxiety-like behavior after experimental traumatic brain injury

Authors: *E. H. MOSCHONAS, R. REDDY, C. SUNLEAF, T. RANELLONE, A. BENBOURENANE, A. PATEL, S. BALAJI, T. MAGDELINIC, S. SHA, J. CHENG, C. O. BONDI;
Safar Ctr. for Resuscitation Res., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Introduction: Traumatic brain injury (TBI) is a leading cause of cognitive disability. Although long-term impairments in higher-order executive functioning such as sustained attention and goal-directed behavior are common clinically, they are not well established in preclinical models of TBI. Additionally, TBI-associated psychopathologies like anxiety and depression can further exacerbate cognition. Moreover, decreased acetylcholine (ACh) after TBI is known to cause cognitive impairment and thus pharmacological strategies that enhance ACh may ameliorate cognitive disruptions. Hypothesis: NS-1738, a novel positive allosteric modulator at the α7 nicotinic ACh receptors will restore sustained attention and reduce affect after TBI. Methods: Anesthetized adult male rats received either a controlled cortical impact of moderate severity (2.8 mm cortical deformation at 4m/s) or sham injury and then were randomly assigned to NS-1738 (3 mg/kg; i.p.) or vehicle (1.0 mL/kg; i.p.). Treatments began 24 h post-surgery and were given once daily for 7 days. Behavioral assessments were evaluated utilizing a complex and novel battery of paradigms. Specifically, assessment of sustained attention and impulsivity was carried out on post-operative days 14-24 using the 3-choice serial reaction time task (3-CSRT), which is analogous to the Continuous Performance Test often used in the clinical setting. Anxiety-like responses (open field test; OFT) and passive/active avoidance (shock probe defensive burying test; SPDB) were conducted on post-operative days 28 and 29, respectively. Results: The preliminary data suggest that NS-1738 ameliorates TBI-induced deficits in the 3-CSRT and the OFT, while also enhancing measures of active coping in the SPDB, which supports the hypothesis and promotes a novel pharmacotherapy for attenuating cognitive deficits and affect disorder for TBI patients. Statistical analyses comprise of repeated measures ANOVAs followed by Newman-Keuls post hoc tests, where appropriate. Conclusion: Subacute augmentation of cholinergic function after TBI may be efficacious at restoring neurobehavioral performance. Significance: Integrating animal models of higher-order attention, motivation, and anxiety in the battery of laboratory tests after TBI, as well assessing cholinergic regulation in cortical regions mediating these outcomes is critical for developing novel treatment approaches that can be successfully translated to the clinic.

Title: Systems biology-based drug repurposing to improve recovery from traumatic brain injury: in vitro and in vivo validation

Authors: *N. P. T. KAJEVU[1], A. LIPPONEN[1], N. PUHAKKA[1], T. NATUNEN[2], M. HILTUNEN[2], A. PITKÄNEN[1];
[1]Epilepsy Res. Lab., AIV Inst. For Mol. Sciences, UEF, Kuopio, Finland; [2]Sch. of Medecine, Inst. of Biomedicine, Kuopio, Finland

Abstract: Background: Almost 50 million people suffer from traumatic brain injury (TBI) each year and over 40% TBI survivors develop long-term post-TBI complications such as epileptogenesis. To date, no treatment can alleviate progression of TBI sequalae, and identification of novel treatments to improve post-TBI outcome is a major unmet medical need. Hypothesis: Systems biology approach will offer an unbiased approach to identify and select drugs for repurposing to enhance recovery from TBI by promoting neuroprotection and alleviating inflammation. Objective: This study aims at mitigating the severity of pathological and functional post─TBI outcomes by using systems biology -identified drugs. Methods: Selected drugs were tested in cortical neuron-BV2 microglia co-cultures to assess in vitro efficacy of the drugs on: (a) Neuronal survival using microtubule associated protein 2—based neuronal survival assay (b) Neuroprotective potential from nitric oxide mediated neurotoxicity using Griess reagent-nitrite assay (c) Anti-inflammatory effect using tumour necrosis factor alpha ELISA. Preliminary results: Our in vitro results revealed that 50 nM of trichostatin and 100 µM of FBA improved neuronal survival by 72.9% (p=0.000) and 50.6% (p=0.0007) respectively. At 50 nM trichostatin reduced nitrite levels to 27.6% (p=0.000) and 100 µM FBA reduced nitrite levels to 47% (p=0.000). Neuroinflammation was reduced to -139% (p=0.000) by 50 nM trichostatin and to -23.2% (p=0.0084) by 100 µM FBA. Conclusion and prospects: Our in vitro findings suggest that systems biology approach helps identification of drugs that have a potential to treat post-TBI complications. In vivo experiments in a clinically relevant rat model of TBI are currently ongoing to assess the therapeutic effect of drugs that showed the best efficacy in in vitro testing. If effective, these drugs could promote the recovery of TBI patients and prevent post-traumatic epileptogenesis.

Title: A Rodent Model of Traumatic Brain Injury Impairs Object-Place Paired-Associates Learning

Authors: *S. M. SMITH[1], N. FEREKIDES[1], A. HERNANDEZ[2], S. LOVETT[1], J. F. ABISAMBRA[1], S. N. BURKE[1];
[1]Neurosci., Univ. of Florida, Gainesville, FL; [2]UAB, Fultondale, AL

Abstract: Approximately 2.8 million Americans suffer from a traumatic brain injury (TBI) each year. As a result, TBI disables six times more people annually than breast cancer, multiple sclerosis, spinal cord injuries, and HIV/AIDS combined (Colantonio et al., 2009). Animal models continue to be of paramount importance in elucidating the mechanisms of dysfunction following TBI. Here, we used a rodent model of closed cortical impact (CCI) to assess cognitive dysfunction following either frontal (n=6) or parietal (n=6) cortical injury, and frontal (n=2) or parietal (n=2) sham. Importantly, our assessment of cognitive dysfunction is through a rodent adaptation of a clinically relevant task: object-location paired-associates learning (PAL) (Bussey et al., 2008). PAL is a part of the Cambridge Neuropsychological Test Automated Battery (CANTAB), which uses a variety of assessments to examine cognitive dysfunction in disease states (Robbins & Sahakian, 1994). In humans, the CANTAB PAL task is used to assess cognitive deficits in object and spatial recognition in diseases such as schizophrenia, Alzheimer's, and TBI. To date, our rodent version of PAL has not yet been employed in a rodent model of TBI, and its usage will be important for understanding clinical consequences of cognitive impairment post-injury and for testing the efficacy of potential treatments and rehabilitation strategies. We found that parietal injury impaired performance on PAL compared to sham controls, but frontal injury did not. This was indicated by a greater number of days to criterion (t_6= 3.56; p = 0.01) as well as a larger number of errors post-surgery on the PAL task (t_6 =3.61; p = 0.01). An in-depth trial-by-trial analysis of bias (tendency to stick with an object/place regardless of correctness) and strategy usage (tendency to utilize heuristics such as staying with an object that was correct in a previous trial even though it is no longer correct) was also performed. There was no significant difference in place or object bias between injury groups (frontal vs. parietal, injury vs. sham control), indicating that performance decreases in the parietal injury group were not due to differences in bias. The current data show the utility of PAL for quantifying TBI-related cognitive dysfunction and future studies will test intervention strategies for mitigating TBI-induced cognitive decline.

Title: Loss of mammalian target of rapamycin in NG2 cells reduces acute white matter sparing and locomotor recovery after spinal cord injury

Authors: *N. PUKOS[1], M. A. JEFFRIES[2], T. L. WOOD[3], D. M. MCTIGUE[4];
[1]Dept. of Neurosci., The Ohio State Univ., Columbus, OH; [2]Rutgers Univ., Newark, NJ; [3]Dept Pharmacology, Physiol. & Neurosci., New Jersey Med. Sch, Rutgers Univ., Newark, NJ; [4]Dept Neurosci, Ohio State Univ. Col. of Med., Columbus, OH

Abstract: Chronic demyelination slows conduction velocity and impairs recovery after spinal cord injury (SCI), and is partially due to the loss of oligodendrocytes (OLs). Surviving OLs are post-mitotic and thought to not remyelinate spared axons; thus, the robust endogenous repair that occurs after SCI is mainly from NG2+ glial cells that proliferate then differentiate into mature OLs. Since NG2 cells are the primary source of new myelin, it is critical to understand the mechanisms that regulate NG2 cell function post-injury. Previous work from developmental and chemical demyelination studies show that the mammalian target of rapamycin (mTOR) is necessary for OL differentiation and myelination. However, whether mTOR impacts NG2 cell function and recovery after SCI is unknown. Here, we tested the hypothesis that **mTOR activation in NG2 cells promotes OL differentiation and myelination after SCI.** In rat and mouse SCI models, we show mTOR activation in NG2 cells rises for 7-14 days post-injury (dpi) and declines to baseline thereafter. Using conditional transgenic mice, mTOR deletion in NG2 cells resulted in fewer mature OLs, decreased white matter sparing, and worse locomotor recovery at 14 dpi. However, if mice were allowed to survive to 35 d or 84 dpi, chronic OL genesis equalized the ultimate number of OLs, extent of myelination, and locomotor recovery compared to controls. Overall this work suggests that mTOR signaling is important in the acute SCI setting for maintaining OLs and myelin, but it is dispensable for long-term OL genesis and remyelination. These data highlight that cellular mechanisms driving cell repair after SCI fluctuate over time and suggest mTOR-directed therapies should be cognizant of possible effects on myelination in the acute SCI setting.

Title: Tlr4 signaling in spinal cord injury contributes to neuroinflammation, alterations in extracellular matrix, and reduced locomotor recovery.

Authors: *F. RYAN[1], E. J. BRADBURY[2], S. DAVID[1];
[1]McGill Univ. Hlth. Ctr., Montreal, QC, Canada; [2]King's Col. London, London, United Kingdom

Abstract: Tissue damage after spinal cord injury (SCI) triggers inflammation and alteration in extracellular matrix (ECM). Toll-like receptors (TLRs) are key mediators of innate immunity. They respond to molecules released by damaged tissue, which trigger and subsequently amplify inflammation that may cause further damage to cells and ECM. We studied the role of TLR4 on inflammation and ECM composition after SCI by comparing wildtype (WT) and TLR4 knockout (KO) mice. We also aimed to find whether TLR4 has effects on neuronal survival, myelination and locomotor recovery. To do this, spinal cord contusion injuries were done in female TLR4 KO and WT mice using the Infinite Horizon impactor. mRNA levels of proinflammatory chemokines and cytokines showed no differences between genotypes at 7 d post injury (PI) but they were reduced in KO mice at 8 weeks PI. Immunofluorescence staining of chondroitin sulfate proteoglycans (CSPG), a key component of the ECM, showed a small but significant reduction in TLR4 KO mice. In addition, CSPG deposition is located in closer proximity to macrophages than to microglia. We also observed significant increase in labeling with Wisteria floribunda agglutinin (WFA), a marker of perineuronal nets (PNN), and Aggrecan, a major constituent of PNNs, in TLR4 KO mice at 8 weeks after SCI. These changes were accompanied with significant decrease in mRNA and protein expression of matrix metallopeptidase 9 (MMP9). In addition, there was a significant reduction of neuronal and myelin loss in TLR4 KO mice at 8 weeks PI. mRNA and protein expression of key necroptotic markers were notably reduced in KO mice at this timepoint. There was a significant improvement of locomotor recovery in TLR4 KO mice at 8 weeks. Taken together, our results highlight that TLR4 signaling is detrimental to recovery at later time points after SCI.

Title: Modulating the EphB2-NMDA receptor interaction in the superficial dorsal horn attenuates neuropathic pain following cervical spinal cord injury

Authors: *N. M. HEINSINGER, W. ZHOU, J. L. WATSON, A. FALNIKAR, R. CAIN, G. SPAGNUOLO, R. V. ALLAHYARI, D. JAFFE, T. FOX, E. V. BROWN, B. A. CHARSAR, M. B. DALVA, A. C. LEPORE;
Thomas Jefferson Univ., Philadelphia, PA

Abstract: A large percentage of spinal cord injury (SCI) patients suffer from chronic neuropathic pain (NP). Importantly, pharmacological therapies for NP often are ineffective or have severe adverse effects, highlighting the critical need to identify novel, effective treatments. Central sensitization, or the hyperexcitability of dorsal horn circuitry, is a major substrate for SCI-induced NP. Studies have shown that NP is linked to EphB/ephrinB signaling through potentiation of NMDAR function, suggesting that the EphB-NMDAR interaction may be an important therapeutic target for NP. We previously reported that EphB2 activation stimulates a direct interaction between EphB2 and the NMDAR via the extracellular Y504 residue of EphB2, thus promoting NMDAR synaptic localization and excitatory synapse function. We hypothesized that modulating the EphB2-NMDAR interaction via knockdown of EphB2 would attenuate NP by preventing EphB2-NMDAR localization at excitatory synapses. Our rodent model of unilateral cervical contusion shows a persistent NP phenotype in the form of forepaw thermal hyperalgesia and mechanical allodynia, as well as spontaneous, supraspinal aspects of pain as assessed by the grimace test. Using this model, we find increased EphB2 expression in the dorsal horn two weeks post-injury, as well as increased colocalization of EphB2 and GluN1 (NMDAR subunit) at vGlut2-positive synapses in dorsal horn neurons after cervical SCI, indicating an enhanced interaction between EphB2 and NMDARs at putative excitatory glutamatergic synapses. Furthermore, RNAscope *in situ* hybridization analysis revealed upregulated EphB2 mRNA expression in neurons 2 weeks post-SCI, and specifically upregulated EphB2 mRNA in *tacr*1+ neurons in the superficial dorsal horn. When we knockdown expression of EphB2 7 days post-SCI using an shRNA-EphB2 lentivirus delivered via intraspinal DH injections, we are able to reverse the already-established NP-like phenotype of thermal hyperalgesia. Collectively, these findings suggest that enhanced EphB2-NMDAR interaction underlies alterations in excitatory synaptic transmission in the dorsal horn and consequently persistent NP following SCI.

Title: Transneuronal delivery of hyper-interleukin-6 enables functional recovery after severe spinal cord injury in mice

Authors: M. LEIBINGER, C. ZEITLER, P. GOBRECHT, A. ANDREADAKI, G. GISSELMANN, *D. FISCHER;
Cell Physiol., Ruhr Univ. Bochum, Bochum, Germany

Abstract: Spinal cord injury (SCI) often causes severe and permanent disabilities due to the regenerative failure of severed axons. Here we report significant locomotor recovery of both hindlimbs after a complete spinal cord crush. This was achieved by the unilateral transduction of cortical motoneurons with an AAV expressing hyper-IL-6 (hIL-6), a potent designer cytokine stimulating JAK/STAT3 signaling and axon regeneration. We find collaterals of these AAV-transduced motoneurons projecting to serotonergic neurons in both sides of the raphe nuclei. Hence, the transduction of cortical neurons facilitates the axonal transport and release of hIL-6 at innervated neurons in the brain stem. Therefore, this transneuronal delivery of hIL-6 promotes the regeneration of corticospinal and raphespinal fibers after injury, with the latter being essential for hIL-induced functional recovery. Thus, transneuronal delivery enables regenerative stimulation of neurons in the deep brain stem that are otherwise challenging to access yet highly relevant for functional recovery after SCI.

Title: Expression of gastrin releasing peptide receptors in the spinal ejaculation generator and associated lumbosacral autonomic and motor nuclei after chronic spinal cord injury in male rats.

Authors: W. A. NOFTZ, S. GAIKWAD, T. ETTEY, E. MAUPIN, L. M. COOLEN;
Biol. Sci., Kent State Univ., Kent, OH

Abstract: Spinal cord injury (SCI) in men is commonly associated with sexual dysfunction, including anejaculation, and chronic mid-thoracic contusion injury in male rats also impairs ejaculatory reflexes. Ejaculation is controlled by a spinal ejaculation generator (SEG) consisting of a population of lumbar spinothalamic (LSt) neurons, which control ejaculation through release of neuropeptides including galanin and gastrin releasing peptide (GRP) and axonal connections with lumbar and sacral autonomic neurons in sympathetic and parasympathetic nuclei and motor neurons within the sacral nucleus of the bulbocavernosus. In addition, LSt cells are interconnected, while the functional significance of these interconnections is unknown. It was recently demonstrated that mid-thoracic spinal contusion injury in male rats caused reduction of GRP-immunoreactivity and mRNA in LSt cells, while GRP-containing axon projections were unaffected. Moreover, intrathecal infusions of GRP can facilitate ejaculation in SCI males with similar or even greater effects in SCI males compared to sham controls. The current study examined the expression of GRP receptors (GRPR) within LSt cells and autonomic and motor targets and tested if SCI affects GRPR expression. Male rats received mid-thoracic contusion or sham injury and spinal cords were collected and sectioned 4 weeks later. *Galanin, ChAT* and *GRPR* mRNA were visualized in the lumbar spinal cord using fluorescent in situ hybridization using RNAscope. Preliminary analysis showed higher expression of *GRPR* in LSt neurons compared to autonomic and motor targets. Expression of *GRPR* was observed in 25-56% of *ChAT* cells in autonomic and motor targets, where SCI had no effect on *GRPR* or *ChAT* mRNA, except transcript levels in the central autonomic nucleus. *GRPR* was expressed in 90-100% of LSt neurons, where SCI reduced *galanin* but not *GRPR* transcript levels. These results suggest that GRP released from LSt cells can influence ejaculation via actions on subpopulations of lumbosacral autonomic and motor nuclei, and on the LSt cell population. In addition, lack of changes of GRPR receptors after SCI further support development of GRP as a potential novel treatment for sexual dysfunction after SCI.

[2]BIOINFORMATICS, [1]CENTRO DE INVESTIGACION PRINCIPE FELIPE, VALENCIA, Spain

Abstract: Spinal cord injury (SCI) is a devastating condition that leads to the loss of locomotor function. Currently, there are no effective treatment for SCI and the subsequent paralysis [1]. The search of an efficient treatment is a challenging task due to the intricated nature of the pathological processes derived from SCI. In order to understand the time-depending transcriptional profile changes after SCI, we performed an analysis of the transcriptome of the spinal cord tissue of rats subjected to severe traumatic SCI. The animals were sacrifice at 4 different time points: 1 week (considered as acute stage), 2 weeks (sub-acute stage) and at 4 and 8 weeks (chronic stages). Moreover, we explored the beneficial molecular mechanism driven by neural progenitor cells (NPCs) transplantation through the analysis of the transcriptome of transplanted animals. We found that several genes belonging to the cAMP signaling pathway (such as EPAC2, BDNF or CAMKK2) are severely downregulated along the different stages after SCI. Interestingly, the NPCs transplantation is able to achieve an increase in mRNA levels of EPAC2, in the area immediately rostral to the injury, and BDNF and CAMKK2 at the injury site. These transcriptional changes enlightened by the microarray analysis were further validated by RT-qPCR. In order to explore the functional relevance of EPAC2 functions over the therapeutical effect of the NPCs therapy we performed an in vivo experiment combining NPCs transplantation with intrathecal administration of EPAC2 agonist/antagonist (S-220/ESI-05). Animals that received NPCs+DMSO, NPCs+S-220 or NPCs+ESI-05 had significantly increased levels of cAMP rostral to the lesion ($p<0.05$) compared to untreated or S-220 treated animals, what suggests that cAMP augmentation is caused solely by NPCs therapy. Additionally the histological quantification of ED-1 showed that NPCs+S-220 treated animals had a reduced ED1+ area what suggest that the NPCs transplantation combined with the activation of EPAC2 lead to a reduced microglia and macrophage infiltration/activation in the injured spinal cord.

Title: Chronic contusion injury decreases glutamatergic axonal inputs to spinal ejaculation generator in rats: Time course

Authors: N. P. RITCHEY[1], N. J. MUDRAK[2], L. M. COOLEN[1];
[1]Kent State Univ., Kent, OH; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Chronic spinal cord injury (SCI) results in sexual dysfunction in men and rats, including anejaculation. Ejaculation is controlled by a spinal reflex generator in the lumbosacral spinal cord. This generator consists of a population of lumbar spinothalamic (LSt) cells, located in spinal levels L3-4 and which convert the sensory inputs during sexual activity into a coordinated autonomic and motor output required for ejaculation. Sensory inputs require glutamate-induced activation of NMDA receptors in LSt cells. We previously demonstrated that contusion spinal injury at T5-6 severely disrupted ejaculatory reflexes triggered by stimulation of the dorsal penile nerve in male rats. Therefore, we hypothesize that SCI impaired relay and processing of sensory signals required to trigger ejaculation. Indeed, we showed that contusion injury significantly reduced glutamatergic inputs to LSt cells, evidenced by a significant reduction of axon terminals expressing vesicular glutamate transporter 1 or 2 (VGlut1 or VGlut2). In the current study, we tested the time course by which SCI caused reduction in glutamatergic inputs to LSt cells. Male Sprague Dawley rats received a contusion injury at spinal levels T6 and were perfused 1 day, 1, 2, or 4 weeks later. Controls consisted of animals with sham surgery or no surgery and were perfused at the same time intervals. Spinal cords were immuno-stained for galanin (LSt cell marker) and VGlut1 or VGlut2. Quantitative confocal analysis of putative synaptic inputs to LSt cells showed that SCI significantly reduced VGlut1- and VGlut2-inputs to LSt cells at all time points with increasing further loss of VGlut2-inputs with each time point, while loss of VGlut1 reached statistical significance only at the later time points. In addition, it was determined that loss of glutamatergic inputs wasn't specific to LSt cells, and reductions of VGlut1- and VGlut2-axons were noted throughout the medial laminae at lumbar 3-4 spinal levels. These reductions were again noted at all time points for VGlut2-axons, while reaching statistical significance only at the later time points for VGlut1-axons. Together, these data demonstrate an immediate and long-lasting impact of SCI on glutamatergic inputs to LSt cells and neighboring cells, which may in turn contribute to sexual dysfunction following SCI.

Title: The Evoked-Potential Operant Conditioning System (EPOCS)

Authors: ***N. HILL**[1], A. EFTEKHAR[2], K. LUU[1], T. FAKE[1], J. NORTON[1], S. DEVETZOGLOU-TOLIOU[1], J. CARP[1], T. VAUGHAN[1], J. R. WOLPAW[1], A. K. THOMPSON[3];

Abstract: The Evoked Potential Operant Conditioning System (EPOCS) is an experimental system for improving muscle control in people who have neuromuscular disorders—for example, to improve gait in people who have difficulty walking following an incomplete spinal-cord injury. It works by monitoring the state of specific target muscles (via EMG signals if standing, or by gait cycle measurements if walking on a treadmill), and automatically triggering electrical or mechanical stimulation when the conditions are conducive. It provides two forms of feedback that a researcher or therapist can use to train a patient to increase or decrease the size of the resulting evoked response (for example, the soleus H-reflex). The first feedback channel continuously monitors the amplitude of the ongoing EMG in the target muscle, guiding the patient into a consistent state that is conducive to stimulation; the second channel provides immediate trial-by-trial feedback of the reflex size, relative to the distribution of previous reflexes and the session target. The approach has been shown to be able to improve walking in people with spastic gait due to incomplete spinal-cord injury (Thompson et al., J. Neurosci. 2013).

EPOCS consists of custom-written software paired with carefully chosen and configured hardware. The software is based on BCI2000 (Schalk et al., IEEE Trans. Biomed. Eng. 2004), a widely-used open-source software platform that allows biological signals to be measured and processed in real time for applications in research and in translational clinical neurotechnology. EPOCS replaces BCI2000's usual graphical user interface with a "skin" more suitable for a clinical research workflow. The hardware consists of a biopotential amplifier and data acquisition board capable of delivering surface-electromyography signals together with an auxiliary input, and a constant-current electrical stimulator that can deliver a brief pulse transcutaneously to a peripheral nerve to elicit a reflex. The system can also be configured to trigger a mechanical stimulator (for conditioning natural stretch reflexes) or a transcranial magnetic stimulator (for investigating the role of responses generated by the brain rather than reflexes from the spinal cord).

The software is offered by the National Center for Adaptive Neurotechnologies as part of our NIH-funded core mission to disseminate neurotechnology. It is available without charge to clinical researchers who possess compatible equipment, in conjunction with training. Further information is available at https://neurotechcenter.org/epocs .

Title: Alterations in motor output of multisegmental spinal responses in individuals with SCI after transspinal-transcortical paired associative stimulation combined with locomotor training

Authors: *T. S. PULVERENTI[1], M. ZAAYA[1], E. GRABOWSKI[1], M. GRABOWSKI[1], M. A. ISLAM[1], M. KNIKOU[1,2];

Abstract: Activity-based rehabilitation combined with other therapeutic strategies can promote more robust recovery of sensorimotor function after spinal cord injury (SCI). Transspinal-transcortical paired associative stimulation is a promising neuromodulation strategy that can alter both spinal and corticospinal excitability. In this study, we investigated the changes in the phase-dependent modulation of transspinal stimulation-evoked potentials (TEPs) over multiple spinal segments following transspinal conditioning stimulation, as well as the phase-dependent modulation pattern of the transspinal evoked potentials (TEPs) during robot-assisted stepping in individuals with SCI. In this study, we delivered paired transspinal and transcortical stimuli at an interstimulus interval in which TMS was delivered after transspinal stimulation in seven individuals with chronic motor incomplete and complete SCI (n=1 AIS A, n=1 AIS B, n=2 AIS C, n=2 AIS D) during Lokomat robotic gait training. Paired stimuli were delivered during the stance phase of the step cycle, triggered based on foot switches. Participants received at least 20 sessions (1h/day, 5 days/week) of locomotor training (avg.=25.6). For transspinal stimulation, the cathode electrode was placed over T10-L1, and two anode electrodes were placed bilaterally on the abdominal muscles, while for transcortical stimulation a double cone coil was placed over M1. Both stimuli were delivered at threshold intensities that evoked cortical or spinal motor responses in the soleus muscle. TEPs were recorded bilaterally from locomotor muscles during Lokomat stepping before and after the intervention. TEPs were recorded randomly across the step cycle, which was divided equally into 16 bins with bin 1 corresponding to heel contact, and bins 9 and 16 corresponding approximately to stance-to-swing and swing-to-stance transition, respectively. TEPs during walking were normalized to the homonymous maximal TEP recorded during stepping. The TEPs of the right medial gastrocnemius and medial hamstrings were depressed in the swing phase and the right soleus was depressed during heel contact. In addition,

TEPs from the left soleus, peroneus longus, and vastus lateralis were facilitated in the swing phase while the vastus lateralis was facilitate during the stance phase. We conclude that transspinal-transcortical paired associative stimulation combined with locomotor training may be utilized as a means to alter spinal motor output in people with SCI.

Title: Isolating stimulation artifact to identify motor response during walking

Authors: *K. MOMENI[1], R. PILKAR[2], M. RAVI[1], F. ZHANG[1], G. F. FORREST[1];
[1]Tim and Caroline Reynolds Ctr. for Spinal Stimulation, [2]Ctr. for Mobility and Rehabil. Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Non-invasive spinal cord targeted transcutaneous spinal stimulation (scTS) is applied to one or multiple spinal segments for neuromodulation targeting spinal circuitry. Surface electromyography (sEMG) provides a sensitive technique for analyzing motor activity during scTS. However, the overpowering presence of artifact in the electromyography signal due to scTS limits the ability to measure motor response during different neuromodulation techniques. Recent advances in biomedical signal processing have yielded specific detailed algorithms to successfully remove electrical stimulation artifacts from EMG signals during stimulation. We have previously shown the effectiveness of a custom-developed computational algorithm, utilizing empirical mode decomposition (EMD) and notch filtering, to remove the neuromuscular electrical stimulation artifact from sEMG recordings. In this investigation, we extend our analysis to demonstrate the effectiveness of our custom-developed computational algorithm to isolate the scTS artifact during walking overground in an individual with incomplete spinal cord injury. Our group has been piloting the intervention of scTS with overground and/or exoskeleton training and showing that modulation of spinal networks leads to increased inter-limb reciprocal lower-limb muscle activation. This investigation will help with the modification of individualized scTS parameters to achieve task-specific neuromodulatory effects.

Title: Analysis of Transcutaneous Spinal Stimulation induced EMG responses during spinal mapping after SCI.

Authors: *M. RAVI, K. MOMENI, F. ZHANG, R. PILKAR, G. F. FORREST;
Kessler Fndn., West Orange, NJ

Abstract: Activity based training therapies have shown recovery for individuals with SCI. However, more recently, researchers have shown that combining electrical stimulation with the training therapies can lead to significant functional recovery for tasks such as standing and walking. More studies have shown recently that even after an SCI, the spinal sensorimotor networks can be activated when electrical stimulation is applied on the corresponding spinal cord segments. One challenge in using non-invasive spinal stimulation techniques is finding the optimal parameters of stimulation - specifically, frequency and amplitude. We systematically applied non-invasive spinal cord Transcutaneous Spinal Stimulation (scTS) at various locations between C4/5 and Coccyx with anodes placed on the anterior iliac crests and EMG was recorded from lower limb and abdominal muscles. Stimulation waveforms were either monophasic, biphasic or rectified. Carrier-wave frequency was set at 5 kHz for monophasic and biphasic modes of stimulation whereas there was no carrier frequency in the rectified mode. Systematic modulations of amplitude and frequency induced specific EMG responses for different spinal roots. The responses were analyzed by latency - Early Responses (<5ms after stimulation pulse), Middle Responses (5-15ms) and Late Responses (>15ms). Maximum Peak to Peak amplitude (averaged across a time period of at least 3 seconds) was used to compare different muscles and roots. Data was analyzed both normalized and non-normalized. Results show that analyzing the stimulation induced EMG responses during a spinal mapping session, especially the late responses, could be beneficial in finding optimal scTS parameters of stimulation to target specific muscles through existing sensorimotor networks after SCI.

Title: Trunk M1 plasticity differences between rehabilitation assisted recovery and spontaneous recovery after SCI

Authors: *B. NANDAKUMAR[1], G. H. BLUMENTHAL[2,3], K. A. MOXON[4];
[1]Biomed. Engin., UC Davis, Davis, CA; [2]Biomed. Engin., Drexel Univ., Philadelphia, PA;
[3]Biomed. Engin., [4]UC Davis, Davis, CA

Abstract: Trunk M1 plays a critical role in the recovery of weight supported stepping after complete mid-thoracic spinal cord injury. After partial SCI, there is a spontaneous recovery of weight supported stepping that can be further enhanced by physical rehabilitation. The difference in cortical plasticity associated with rehabilitation and spontaneous recovery of function is unknown. Hence, we examined trunk M1 reorganization in a clinically relevant injury model where there is scope for substantial spontaneous recovery of function. In this study, the role of physical rehabilitation on locomotor recovery and cortical reorganization was assessed in female Sprague Dawley rats (n=31) with a T10 mid-thoracic contusion (150 Kilodynes). In a subset of animals (SCI-EX, n=15), quadrupedal treadmill exercise therapy was initiated 1-week post-injury for 30 min, five days/week for five weeks post SCI. Locomotor recovery (BBB) was assessed once a week for five weeks post-injury. At week 6, all animals underwent motor cortex mapping (ICMS). The likelihood to activate trunk musculature was evaluated through visual observation and EMG recordings within the trunk and hindlimb M1, at the threshold and suprathreshold currents (100μA). Exercise therapy significantly improved locomotor recovery such that the injured animals could take weight supported steps with consistent co-ordination. SCI shifted trunk M1 Caudal and lateral towards HLM1 with a higher likelihood to activate trunk musculature in HL M1, regardless of therapy. After SCI, there was a loss of cortical control of trunk muscles in putative lower thoracic trunk M1 (LTM1). This loss was rescued by exercise therapy. In LTM1, the likelihood to recruit lower thoracic trunk muscles with ICMS was similar regardless of therapy. However, the recruitment strategy differed. In SCI-EX animals, ICMS exclusively activated lower thoracic trunk musculature below the lesion. In contrast, animals that did not receive therapy (SCI-NX) had a higher likelihood to co-activate with mid-thoracic musculature. Within LTM1, SCI-NX animals also had a higher probability of activating mid-thoracic trunk musculature with ICMS, more than both SCI-EX and Naïve animals. EMG amplitude in the lower thoracic ventral trunk muscles was higher in SCI-EX animals. In contrast, EMG in dorsal mid-thoracic, ventral upper thoracic trunk muscles was higher in SCI-NX animals. These results suggest that cortical plasticity associated with physical rehabilitation is not a mere enhancement of plasticity associated with spontaneous recovery but is relatively novel and relying on establishing cortical control of muscles below lesion rather than muscles above.

Title: Effects of epidural kilohertz frequency spinal cord stimulation on lower urinary tract function

Authors: *C. J. STEADMAN, C. L. LANGDALE, W. M. GRILL;
Duke Univ., Durham, NC

Abstract: Spinal cord injury (SCI) leads to bladder dysfunction, including neurogenic detrusor overactivity (NDO), detrusor-sphincter dyssynergia (DSD), and impaired bladder emptying. Novel approaches are necessary to promote continence and efficient bladder emptying after SCI. Epidural kilohertz frequency spinal cord stimulation (KHF SCS) successfully treats chronic pain, and considering the parallels between the pathophysiology of chronic pain and post-SCI bladder dysfunction, we hypothesized that KHF SCS would treat bladder dysfunction after SCI. The purpose of this study was to determine the parameters of KHF SCS that suppress both NDO and DSD by measuring changes in bladder capacity (BC), voiding efficiency (VE), non-voiding contractions (NVC), and external urethral spincter (EUS) electromyography (EMG) during KHF SCS in anesthetized rats with and without acetic acid cystometry. In the first cohort of healthy male (n=7) and female (n=7) rats, we performed continuous-fill saline cystometry while measuring bladder pressure, EUS EMG, and voided and residual volumes. A two-contact epidural paddle electrode was placed over the S1 cord segment. The effects of KHF SCS were measured using three frequencies {1 kHz, 5 kHz, 10 kHz} and three amplitudes {20, 40, 80% of motor threshold (MT)}, as well as trials with no stimulation (intra-block control) and with 50 Hz SCS at 80% of MT. In the second cohort of healthy male (n=7) and female (n=7) rats, cystometry was performed using 0.1% acetic acid to induce bladder hypersensitivity. BC during saline cystometry was increased with SCS at 1 kHz 80% MT, 5 kHz 20% MT, 10 kHz 80% MT, and 50 Hz 80% MT compared to control. VE was increased with SCS at 5 kHz 20% MT and 5 kHz 80% MT compared to control. Average EUS EMG activity during voiding was significantly increased with SCS at 5 kHz and 10 kHz 20%, 40%, and 80% MT, and there were no changes in EUS burst duration. BC decreased with acetic acid, and the number of NVC increased, but there were no differences in VE, average EUS EMG activity, or burst duration. SCS did not alter BC, and VE was increased with 1 kHz 80% MT SCS. The number of NVC was decreased by SCS at 1 kHz 20% MT, 1 kHz 40% MT, 5 kHz 20% MT, 5 kHz 80% MT, 10 kHz 40% MT, and 10 kHz 80% MT compared to acetic acid control, and the NVC area under the curve was increased with SCS at 5 kHz 20% and 80% MT and 10 kHz 80% MT. Average EUS EMG activity was increased with SCS at 10 kHz 20% and 40% MT. The results suggest that epidural KHF SCS may be a viable approach to modulate lower urinary tract function. SCS at 5 kHz 20% MT, 5

kHz 80% MT, and 10 kHz 80% MT altered bladder function in both healthy and hypersensitive animals, with SCS at 5 kHz 20% MT being the most effective stimulation parameters.

Title: Comparison of Self-Reported Neurological Status to Evaluated International Standards for Neurological Classification of Spinal Cord Injury (ISNCSCI) Outcomes in People with Chronic Spinal Cord Injury.

Authors: *N. DATTA, D. C. CILIEN, K. L. GANT;
The Miami Project To Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: International Standard for Neurological Classification of Spinal Cord Injury (ISNCSCI) has long been the most reliable screening tool for classification of spinal cord injuries (SCI). The ability to predict ISNCSCI status without performing an in-person ASIA (American Spinal Injury Association) exam can be useful to researchers. This study aims to develop a numerical framework to reasonably predict Neurological status with only information from self-reported SCI levels, including Motor, Sensory, Neurological levels, and ASIA Impairment Scale (AIS) Grade. To this end, a comparison between self-reported levels and those obtained by ASIA certified evaluators was made with data collected over 9 years (2012 -20) from 581 consenting participants. After exclusions (n=567), median distribution and Kruskal-Wallis Tests were studied. We found that (1)94.4% of the study population had an idea about the neurological level of injury component of an ASIA Exam, however only 32.3% had any idea about AIS grade. Further, only 18.9% had any idea about Motor Level, and only 15.6% about sensory level. (2) Overall, participants reported their neurological level of injury as being 1 level below the evaluator rated level. Majority of those with cervical injury (C group) reported their Level accurately, however, majority of those with thoracic injury (T group) reported their Level as being 1 level below the evaluator rated level, and those with lumbar injury (L group) reported their level as being 3 levels below the evaluator rated level. (3) 75^{th} percentile of participants who self-reported their motor level, did so accurately. Among them, C group reported their motor level accurately. T group reported their motor Level as being 1 below the evaluator rated level. None in the L group reported their motor level. (4) 50^{th} percentile of participants who self-reported their Sensory level, did so 1 Level below the evaluator rated sensory level. Among them, C group reported their sensory level accurately, T group reported their Sensory Level as being 1 level below the evaluator rated level. None in the L group reported their sensory level. (5) Self-reported AIS grade can be used to predict complete and incomplete injuries (Sensitivity=

92.15% Specificity= 75.95%) but not sensory incomplete or motor incomplete injuries. The study of the data leads us to surmise that it is possible for an investigator to make a reasonable assumption about the ISCNSCI status of a person with SCI from self-reported data alone. This can significantly impact prescreening protocols, by reducing the need for preliminary in-person visits for ASIA exam, which would benefit both the investigator and the SCI community at large.

Title: Differential Activation of Dorsal Horn Neuron Subtypes in a Mouse Model of Spinal Cord Injury Induced Neuropathic Pain

Authors: *E. V. BROWN, M. A. DEMARCO, A. MALIK, N. M. HEINSINGER, L. CHENG, A. C. LEPORE;
Thomas Jefferson Univ., Philadelphia, PA

Abstract: Neuropathic pain is the most common co-morbidity of spinal cord injury (SCI); it is highly debilitating and due to an incomplete understanding of its underlying mechanisms is often refractory to current treatments. SCI induces cellular changes in the CNSthat alters the excitability dorsal horn involved in pain transmission. Primary nociceptors synapse into a complex network of dorsal horn inhibitory and excitatory interneurons, the output of which regulates signaling to supraspinal pain processing areas. The dorsal horn is heterogeneous, with unique microcircuits regulating specific modalities of nociception. To investigate activity changes in the neuron populations that comprise these microcircuits, we are using a clinically relevant C5 hemi-contusion mouse model of SCI. This model induces persistent neuropathic pain-like behavior including mechanical allodynia, and thermal hyperalgesia. Using the immediate early gene c-FOS as a marker, we have spatiotemporally characterized neuronal activity in several general or modality-specific neuronal subtypes of the dorsal horn, including $NK1R^+$ projection neurons, $Pax2^+$ inhibitory interneurons, and $Calretinin^+$ and $PKC\gamma^+$ excitatory interneurons. In addition to immunohistological assessment, we used a c-fos driven transgenic mouse line, to induce fluorescent reporter expression in active populations of neurons. We have initially found that $PKC\gamma^+$ excitatory interneurons become hyperactive following SCI, even without peripheral sensory stimulation. As these neurons are not typically involved in pain circuitry, we hypothesize that this activation may be contributing to the development of neuropathic pain-like behaviors in our SCI model. Further, we are exploring how reduced activation of dorsal horn inhibitory interneurons may contribute to SCI induced mechanical

allodynia. We are continuing to identify activity changes in additional dorsal horn neuron populations following SCI.

Title: Drug Repurposing: Delayed Administration of High Dose Human Immunoglobulin G for Treatment of Traumatic Cervical Spinal Cord Injury

Authors: *J. CHIO[1], J. WANG[1], V. SURENDRAN[1], L. LI[1], M. ZAVVARIAN[1], K. PIECZONKA[1], M. FEHLINGS[2];
[1]Div. of Exptl. and Translational Neurosci., Krembil Res. Inst., Toronto, ON, Canada; [2]Div. Neurosurg., Toronto Western Hosp., Toronto, ON, Canada

Abstract: Purpose: Neuroinflammation exacerbates damage caused by initial trauma from spinal cord injury (SCI). Severity of neuroinflammation depends on integrity of the blood-spinal cord-barrier (BSCB), as a compromised BSCB enhances neuroinflammation by facilitating immune cell infiltration. By targeting neuroinflammation, immunosuppressants are used to treat SCI patients. However, as patients experience immune suppression, immunomodulation is more effective than immunosuppression. Human Immunoglobulin G (hIgG) is used in clinic as an immunomodulatory treatment for inflammation. Although we have shown that administration of hIgG (2g/kg) is beneficial after SCI, the optimal time window of administration and mechanism of hIgG are unknown. We hypothesize that hIgG is beneficial when administered at extended time points post-SCI by stabilizing the BSCB. **Methods**: With a clinically-relevant rat model of clip compression-contusion SCI at cervical level 7/thoracic level 1, a single bolus of hIgG (2g/kg) or control buffer was administered intravenously at 15 minutes, 1 hour or 4 hours post-SCI. Spinal cord, serum and spleens were collected to evaluate hIgG's effects. **Results:** Demonstrated by immunohistochemistry, hIgG co-localized with BSCB astrocytes, pericytes and endothelial cells. At 24 hours post-SCI, relative to control buffer, hIgG (2g/kg) significantly enhanced BSCB integrity when administered at delayed time points. This is indicated by Western blot, with greater protein expression of tight junction proteins (ZO-1, occludin) and reduced presence of albumin. In addition, there is reduced extravasation of Evan's Blue. A stronger BSCB was associated with reduced spinal cord neuroinflammation as assessed by cytokine assay. Despite reducing spinal cord inflammation, hIgG (2g/kg) increased levels of

inflammatory cytokines in serum and spleen. With flow cytometry, it was demonstrated that hIgG (2g/kg) reduced neutrophil counts in blood, but increased splenic neutrophil population. Short-term benefits of delayed hIgG (2g/kg) administration correlate with enhanced white and gray matter preservation, higher counts of spinal cord motor neurons and improved sensory and motor function at eight weeks post-injury. **Conclusions:** As a clinically-relevant immunomodulatory treatment, hIgG (2g/kg) shows promise as a therapeutic approach for SCI. The anti-inflammatory effects mediated by hIgG (2g/kg) might be two-fold; enhancing BSCB integrity and trafficking neutrophils to the spleen. To promote clinical translation, future steps include determining which fragment of hIgG mediates the aforementioned immunomodulatory effects.

Abstract: Mitochondrial dysfunction is a well-characterized consequence of spinal cord injury (SCI). We previously reported that treatment with the FDA-approved β_2-adrenergic receptor agonist formoterol beginning 8h post-SCI induces mitochondrial biogenesis (MB) and improves body composition and locomotor recovery in female mice. To determine the time-to-treatment window of formoterol, female mice were subjected to 80 kDyn contusion SCI and daily administration of vehicle or formoterol (0.3 mg/kg) beginning 24h after injury. This delayed treatment paradigm improved body composition in female mice by 21 DPI, returning body weight to pre-surgery weight and restoring gastrocnemius mass to sham levels; however, there was no effect on locomotor recovery, as measured by the Basso-Mouse Scale (BMS), or lesion volume. To assess the cross-sex potential of formoterol, injured male mice were treated with vehicle or formoterol (0.3 or 1.0 mg/kg) beginning 8h after SCI. Formoterol also improved body composition post-SCI in male mice, restoring body weight and muscle mass regardless of dose. Interestingly, however, improved BMS scores and decreased lesion volume was observed only in

male mice treated with 0.3 mg/kg. Additionally, 0.3 mg/kg formoterol induced MB in the gastrocnemius and injured spinal cord, as evidenced by increased MB protein expression and mitochondrial number. These data indicate that formoterol treatment improves recovery post-SCI in both male and female mice in a dose- and initiation time-dependent manner. Furthermore, formoterol-induced functional recovery post-SCI is not directly associated with peripheral effects, such as muscle mass and body weight.

Title: Mu Opioid Receptor Activation Restores Sexual Dysfunction After Chronic Spinal Cord Injury in Male Rats

Authors: *T. ETTEY[1], S. GAIKWAD[3], L. COOLEN[2];
[1]Sch. of Biomed. Sci., [2]Dept. of Biol. Sci., Kent State Univ., Kent, OH; [3]Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Spinal cord injury (SCI) significantly affects urogenital functions, including severe deficits in ejaculation in men and male rats, but development of treatment options is limited by a lack of knowledge of effects of SCI on the spinal control of sexual reflexes. The spinal ejaculation generator (SEG) consists of a population of lumbar spinothalamic cells (LSt) that control ejaculation via axonal projections to autonomic and motor centers in the lumbosacral spinal cord upon stimulation of sensory inputs via the dorsal penile nerve (DPN). LSt cells control ejaculation via release of neuropeptides, including enkephalin acting via mu and delta opioid receptors. It was previously shown that in control male rats, intrathecal infusions of mu opioid receptor agonist DAMGO strongly facilitated ejaculatory reflexes, while antagonists prevent ejaculation triggered by stimulation of the DPN. Here, we test the hypothesis that DAMGO infusions may restore ejaculatory reflexes in SCI males. In a first study, male Sprague Dawley rats received either mid-thoracic spinal contusion or sham treatment (n=11 each). Four weeks later, animals received an acute spinal transection to remove remaining supraspinal influence on the SEG and subsequent intrathecal infusions (10 µl) of saline and DAMGO (0.1 nmol) while parameters of ejaculatory reflexes were recorded. In addition, DPN was stimulated at frequencies that normally trigger ejaculation in control males and reflexes were recorded. Findings indicated that DAMGO, but not saline triggered ejaculatory reflexes and facilitated DPN-stimulated reflexes equally in sham and SCI groups. In a second study, the procedures were repeated, but without the acute spinal transection prior to infusions. In this study, DAMGO

triggered and facilitated ejaculatory reflexes in SCI groups, but not in sham males. These results indicate that removal of supraspinal inhibitory inputs is required for facilitatory effects of enkephalin within the SEG and that contusion SCI may at least partially remove such inputs. Together the findings support the hypothesis that Mu opioid receptor agonists may be a target for development of treatment options for sexual dysfunction following SCI.

Title: Blocking inhibitory RGMa promotes tissue preservation and axonal plasticity after cervical spinal cord injury

Authors: *A. J. MOTHE[1], P. B. JACOBSON[2], C. H. TATOR[1];
[1]Krembil Res. Inst., Toronto, ON, Canada; [2]AbbVie, North Chicago, IL

Abstract: After traumatic spinal cord injury (SCI) degenerative events including cell death, axonal damage, and the upregulation of inhibitory molecules limit regeneration and recovery. Repulsive Guidance Molecule A (RGMa) is a potent inhibitor of axonal growth and is rapidly upregulated after SCI in both rodents and in humans. Recently, we showed that delayed administration of human monoclonal antibodies that block inhibitory RGMa signaling promote neuroprotective and regenerative effects in a clinically relevant rat model of thoracic SCI. However, it is unknown whether RGMa blocking antibodies are effective for cervical SCI. Also, as the majority of SCI cases are cervical, and spinal cord level-specific heterogeneity in response to surgical and pharmacological interventions have been observed clinically, this warrants investigation. In the present study, we also examined whether systemic administration of RGMa antibodies could be delayed to 3h, a therapeutically relevant time window after cervical SCI. Using a clinically relevant rat model of cervical (C6/7) impact-compression SCI, human RGMa monoclonal antibodies were intravenously injected either immediately following SCI (acute), or 3h, or 24h post-injury, and then weekly for 9 weeks. Control rats received human IgG (hIgG) isotype antibodies recombinantly produced from CHO cells. Plasma levels of antibody were assessed longitudinally, and recovery was examined with weekly behavioral tests and histological analyses at 12 weeks post-SCI. Pharamacokinetic analysis showed human antibodies in rat plasma and in spinal cord injured tissue immunostained with hIgG at all time intervals after administration. Rats with cervical SCI showed improvement in motor function and gait parameters when treated acutely and at 3h post-injury with anti-RGMa antibodies. Lesion analysis showed that inhibition of RGMa promoted tissue preservation, and a 2-fold sparing of

perilesional motoneurons at 12 weeks after cervical SCI in all treated groups. Prior to endpoint, BDA tracer was injected into the sensorimotor cortex for anterograde labelling of motor axons. Rats treated with RGMa antibodies showed a significantly greater density of BDA labeled fibers in the gray matter adjacent to the dorsal corticospinal tract in segments rostral to the cervical lesion. RGMa inhibition also increased serotonergic innervation in the ventral horns caudal to the cervical lesion. These results show that administration of anti-RGMa monoclonal antibodies may be delayed to a therapeutically relevant time window following cervical SCI to promote neuronal and tissue sparing and axonal plasticity to facilitate repair.

Title: Aav-mediated delivery of constitutively active pfn1 induces axon regeneration and functional recovery after spinal cord injury

Authors: *D. MACHADO[1], R. PINTO-COSTA[1], J. NOGUEIRA-RODRIGUES[1], T. SILVA[2], P. BRITES[2], M. SENA-ESTEVES[3], M. M SOUSA[1];
[1]Nerve Regeneration Group, [2]NeuroLipid Biol. Group, i3s - Inst. de Inovação e Investigação em Saúde, Porto, Portugal; [3]Dept. of Neurol., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: In mammals, axon growth capacity declines after synapse formation, and the CNS fails to regenerate after trauma, causing unrecoverable neurologic deficits. Despite progress in rehabilitative care, no efficient treatment has yet been developed for spinal cord injury (SCI) patients. Using models with different regenerative capacities, we identified profilin1 (PFN1) as a key player in axon elongation and regeneration. *In vitro* results demonstrated that increased expression of constitutively active human PFN1 (S138AhPFN1) tunes the growth cone cytoskeleton towards axon regeneration. Here we present *in vivo* evidence that using AAV.PHP.eB-mediated delivery of S138AhPFN1 to rodents, prior to lesion, promotes axon regeneration, maturation of neuromuscular junctions and functional recovery of injured sciatic nerves and increases the ability of regenerating CNS axons to penetrate the inhibitory spinal cord fibrotic/glial scar. Therapeutic potential of S138AhPFN1 delivery was then assessed at an acute timepoint after injury (2-3 hours) using AAV9-mediated delivery. *In vivo* intravenous delivery of

AAV9.S138AhPFN1 successfully targeted the spinal cord. Spinal cord injured mice injected with AAV9.S138AhPFN1 presented total recovery of mechanical nociception at 16 weeks post-injury. Furthermore, some animals of the treated group were able of gain total weigh support and plantar stepping at the end of the recovery period, in contrast to control animals which were not able to support their own weight during the entire recovery period. At the histological level, sensory axons of the dorsal column tract, traced using cholera toxin, regenerated for longer distances. In summary, our results show that AAV9.S138AhPFN1 intravenous administration presents a very good therapeutic potential for SCI, leading to increased axon regeneration and gain of function.

Title: Gastrin releasing peptide alleviates sexual dysfunction after chronic spinal cord injury in male rats.

Authors: *S. S. GAIKWAD[1], T. ETTEY[2], L. M. COOLEN[3];
[1]Univ. of Mississippi Med. Ctr., Jackson, MS; [3]Biol. Sci., [2]Kent State Univ., Kent, OH

Abstract: Spinal cord injury (SCI) has devastating effects on urogenital functions, including severe deficits in ejaculatory function in men and male rats. Surveys among SCI men place recovery of sexual function as high priority, but development of treatment options is limited by a lack of understanding of effects of SCI on the spinal ejaculation generator (SEG). The SEG comprises of a population of lumbar spinothalamic cells (LSt) that regulate ejaculation via release of neuropeptides from axonal projections to autonomic and motor nuclei in the lumbosacral spinal cord upon sensory stimulation of the dorsal penile nerve (DPN). A critical LSt peptide for the control of ejaculation reflex is gastrin releasing peptide (GRP), as intrathecal infusions of GRP facilitate ejaculatory reflexes, while antagonists prevent ejaculation triggered by stimulation of the DPN in control male rats. SCI causes reduction in GRP mRNA and peptide levels in LSt, leading to the hypothesis that this lack of GRP contributes to ejaculatory dysfunction following SCI. Here, we test this hypothesis by studying the effects of GRP infusions on restoration of ejaculatory reflexes in SCI male rats. In a first study, male Sprague Dawley rats received either mid-thoracic spinal contusion injury (n=11) or sham surgery (n=8). Four weeks later, animals received an acute spinal transection to remove remaining supraspinal influences on the SEG and subsequent intrathecal infusions (10 µl) of saline and GRP (0.2 nmol) while parameters of ejaculatory reflexes were recorded. Subsequently, DPN was stimulated and

reflexes were recorded. Findings indicated that GRP, but not saline triggered ejaculatory reflexes and facilitated DPN-stimulated reflexes equally in sham and SCI groups. In a second study, the procedures were repeated, but without acute spinal transection prior to infusions. GRP again triggered and facilitated ejaculatory reflexes but with greater effects in SCI compared to sham groups. In a third study, lower dosages of GRP (0.08 or 0.03 nmol) were shown to have less effect on ejaculation. Together these results support the hypothesis that impairment of ejaculation may be partially due to disruption of GRP synthesis in LSt cells and suggest that GRP may be a potential therapeutic target for sexual dysfunction following SCI.

Title: Maturation of the amygdala subnuclei in children and adolescents with Autism Spectrum Disorder and the association with social and repetitive behaviors

Authors: *D. SEGUIN[1], S. PAC[2], J. CHEN[3], R. NICOLSON[4], J. MARTINEZ-TRUJILLO[1], E. G. DUERDEN[5];
[1]Physiol. & Pharmacol., [2]Neurosci., [3]Biomed. Engin., [4]Psychiatry, [5]Fac. of Ecuation, Western Univ., London, ON, Canada

Abstract: The amygdala plays a key role in regulating emotional processes, including emotional recognition and some aspects of fear and anxiety responses. Dysregulated amygdala development has been reported in young children with ASD, while less is known about amygdala maturation in later childhood and adolescence, a sensitive window for social skill development. In this longitudinal magnetic resonance imaging (MRI) study, we assessed macrostructural development of the amygdala subnuclei in older children and adolescents with (n=23) and without ASD (n=15) at 2 timepoints 3 years apart. At the first session, participants were scanned with MRI at a median age of 12 years, with a second scan at a median age of 15 years. The volumes of seven subnuclei (basolateral, central, medial, cortical, paralaminar, corticoamygdaloid area and anterior amygdaloid area)were extracted using an automatic segmentation algorithm for the two timepoints, to examine growth. In adolescents with ASD only, amygdala subnuclear volumetric changes were assessed in relation to ASD symptomology. Participants with ASD were diagnosed using the Autism Diagnostic Observation Schedule, General (ADOS-G) and the Autism Diagnostic Interview, revised (ADI-R). Amygdala subnuclei growth was compared between the participant groups and revealed larger BLA nuclei volumes in adolescents with ASD compared to neurotypical participants (B=46.8, p=0.04). When examining ASD symptomatology in relation to the growth of the amygdala subnuclei, reciprocal social interaction scores on the ADI-R were positively associated with increased growth of the BLA nuclei (B=8.3, p=0.001). Growth in the medial nucleus predicted the communication (B=-46.9,

p=0.02) and social (B=-47.7, p<0.001) domains on the ADOS-G. Growth in the right cortical nucleus (B=26.14, p=0.02) predicted ADOS-G social scores. Central nucleus maturation (B=29.9, p=0.02) was associated with the repetitive behaviors domain on the ADOS-G. Larger BLA volumes may be due to increased neuronal density, consistent with postmortem studies. These findings reveal an association between amygdala subnuclei volumes and ASD symptoms, which may reflect activity-dependent plasticity. Improved understanding of amygdala subnuclei growth trajectories in youth may aid in identifying key windows for targeted interventions, particularly for social communication in adolescents with ASD who display social impairments.

Title: Autistic Traits and the Aging Brain

Authors: *A. JOB SAID[1], B. BLAIR BRADEN[2], B. K. WOODRUFF[3], R. J. CASELLI[3], G. L. WALLACE[1];
[1]George Washington Univ., Washington, DC; [2]Arizona State Univ., Phoenix, AZ; [3]Mayo Clin. Arizona, Phoenix, AZ

Abstract: Introduction: Knowledge of middle and older adulthood in autism spectrum disorder (ASD) is nearly non-existent. The few studies of aging in ASD that have been completed to date are plagued by cohort effects, presenting confounds to understanding contributions of autistic behavior to brain-based outcomes in later adulthood. In three recent studies we have shown that the presence of the Broader Autism Phenotype (BAP), elevated subclinical autistic traits occurring in approximately 5-10% of the population, is associated with increased executive function problems and social cognitive difficulties compared to those without the BAP during older adulthood (60-91 years). The current study, for the first time, examines brain-based associations with the BAP during middle and older adulthood.
Method: 166 community dwelling adults (76% female) ranging in age from 49-81 (M=64) years completed a neuropsychological battery and provided a Magnetization Prepared-RApid Gradient Echo (MP-RAGE) magnetic resonance imaging (MRI) scan. The BAP was assessed using self-ratings from the Autism Quotient (AQ). Brain volumes were quantified using FreeSurfer and compared between the highest quartile of AQ scorers (BAP; n=47) and the other 72% of the sample (non-BAP; n=119) using multivariate analysis of covariance (MANCOVA) accounting

for the effects of age, gender, and total intracranial volume (ICV). In complementary analyses, multiple linear regressions examined links between continuous AQ ratings and brain volumes using the same covariates.
Results: BAP adults had decreased brain volume compared to the non-BAP group in the bilateral hippocampus, right amygdala, left thalamus, and left cerebellar cortex (Fs>5.32, ps<.03), after co-varying the influences of age, gender, and ICV. Similarly, linear regression analyses revealed that increasing continuous autistic traits were predictive of decreased volumes in bilateral hippocampus, left thalamus, and left cerebellar cortex (ts>2.24, ps<.04, $\blacktriangle R^2$s$\geq$.02) after accounting for covariates.
Discussion: This study provides the first evidence that the BAP conveys potential risk to brain health through decreased subcortical (i.e., hippocampal, thalamic, and cerebellar) brain volumes during a period of development (middle and older adulthood) when tissue loss is already occurring. Similar findings of brain volumetric reductions have been shown in studies of children and young adults and middle age adults with ASD. This convergence across subclinical (BAP) and clinical (ASD) samples lends validity to the investigation of the BAP in adult development to inform neurobiological effects of aging in ASD.

Title: Longitudinal Functional Connectivity of Cognitive Brain Networks in Older Men with Autism

Authors: *M. WALSH[1], B. PAGNI[2], N. GUERITHAULT[1], A. NESPODZANY[3], L. BAXTER[4], C. SMITH[5], B. BRADEN[1];
[1]Arizona State Univ., Arizona State University, AZ; [2]Arizona State Univ., Tempe, AZ; [3]UCSD, San Diego, CA; [4]Mayo Clin., Phoenix, AZ; [5]Southwest Autism Res. and Resource Ctr., Phoenix, AZ

Abstract: ***Background***: Emerging cross-sectional research on cognitive aging in ASD shows some evidence of poorer cognitive control in older adults with ASD. Brain functional connectivity may reveal early biomarkers of cognitive aging. In our prior cross-sectional work, we showed age-group differences suggesting exacerbated reductions in functional connectivity affecting the fronto-parietal network (FPN) in adults with ASD (Walsh et al., 2019). This

current, preliminary study extends these findings by longitudinally examining changes in functional connectivity of canonical cognitive brain networks over a two-year follow-up period in a sample of mid to older adults with and without ASD. ***Methods***: Participants included men ages 40-64 years at the start of the study (mean: 50.7[7.1]) of average intellectual ability (IQ>80) with and without ASD (ASD: *n*=13; NT: *n*=18). Follow-up intervals were two years on average. Using a six-minute, eyes closed resting-state fMRI scan, group-ICA was used to identify the FPN, dorsal attention (DAN), default mode (DMN), and salience networks (SN) and main effects of time and group by time interactions were modeled at the whole-brain level with FDR-correction ($p<.05$, cluster-level) with age as a covariate in SPM12. Baseline and follow-up performance on the Wisconsin Card Sorting Task (WCST; Total Errors) was used to examine associations with cognitive control for participants with ASD. ***Results****:* For the right lateralized FPN, a significant time by diagnosis interaction was observed, such that adults with ASD showed declines in connectivity between the left inferior frontal gyrus (IFG; pars triangularis portion) and the rest of the FPN that were not observed in NT participants ($p=.018$, FDR-corrected, cluster level). No other main effects of time or group by time interactions were observed for the right lateralized FPN or other networks investigated (left FPN, DMN, DAN, or SN). No significant effects of time or group by time interactions were found for the Wisconsin Card Sorting Task. However, poorer baseline ($r_9=0.579$, $p=0.062$) and follow-up ($r_9=0.621$, $p=0.042$) WCST performance was marginally and significantly associated, respectively, with larger decreases in FPN-IFG connectivity over time for participants with ASD. ***Conclusions****:* FPN-prefrontal connectivity decreases with age in mid to older adults with ASD, but not NT adults, and this decreasing connectivity predicts poorer follow-up performance on a cognitive control task. Despite the small sample included in this preliminary analysis, these findings suggest a trend toward worse brain aging in ASD, which may predict poorer cognitive outcomes.

Abstract: EEG complexity measures of cognitive states distribute heterogeneously to ASD risk measures with some hierarchical sequence clustering.AuthorsS. S. Wolfson, I. Kirk, K. Waldie, S. King; The University of Auckland, Auckland NZDisclosuresS. S. Wolfson: None, I. Kirk: None, K. Waldie: None, S. King: NoneAbstractAutism spectrum disorder is an increasingly

prevalent and debilitating neurodevelopmental condition and an EEG diagnostic challenge. Despite large amounts of electrophysiological research over many decades, an electroencephalogram biomarker for ASD has not been found. We hypothesized that reductions in complex dynamical system behavior in the human central nervous system as part of the macroscale neuronal function during cognitive processes might be detectable in whole EEG for higher risk ASD adults. We compared the medians of correlation dimension, largest Lyapunov exponent, Higuchi's fractal dimension, multiscale entropy, multifractal detrended fluctuation analysis and Kolmogorov complexity during resting, cognitive and social skill tasks in 20 EEG channels of 39 adults over a range of ASD risk. We found heterogeneous complexity distribution with clusters of hierarchical sequences pointing to potential cognitive processing differences but no distinction based on ASD risk.

Title: Sensory brain responses alterations as translational biomarkers for SYNGAP1 haploinsufficiency

Authors: *M. CARRENO-MUNOZ[1,2], B. CHATTOPADHYAYA[1], K. AGBOGBA[1], V. COTE[1,3], S. WANG[4], M. LEVESQUE[4], M. AVOLI[5], J. L. MICHAUD[1], S. LIPPE[1,3], G. DI CRISTO[1,2];
[1]CHU Sainte-Justine Res. Ctr., Montreal, QC, Canada; [2]Neurosciences, [3]Psychology, Univ. of Montreal, Montreal, QC, Canada; [4]Neurol. and Neurosurg., [5]Neurol. and Neurosurgery, and Physiol., Montreal Neurolog. Institute-Hospital, Montreal, QC, Canada

Abstract: Autism-spectrum disorder (ASD) is a range of neurodevelopmental disorders characterized by impaired social interaction, stereotyped behaviours, cognitive impairments and sensory deficits. While there are hundreds of genes involved in ASD, SYNGAP1 gene is particularly gaining attention because of the frequency and penetrance of loss-of-function variants found in patients as well as the wide range of co-morbid brain disorders associated with SYNGAP1 pathogenicity. In both human patients and animal models, SYNGAP1 haploinsufficiency leads to cognitive and social problems, altered neural circuit excitability, spontaneous seizure and unadaptative behaviours. Until now, most of the research on the deficits caused by SYNGAP1 haploinsufficiency has focused on cognitive problems but recent works point to the possibility that altered sensory processing may strongly contribute to cognitive problems and other altered behaviours associated with ASD. Indeed, sensory symptoms are

becoming an important early biomarker, since they are often documented as early as 6 months of age in infants later diagnosed with ASD (considerably earlier than development of other higher cognitive functions as attention). Although sensory processing and sensitivity problems have been largely reported in ASD, whether auditory and visual perception and processing are altered in SYNGAP1 haploinsufficiency is not known. Here we study different aspects of auditory and visual perception in patients and a mouse model of SYNGAP1 haploinsufficiency. Our preliminary results reveal altered electrophysiological activity underlying both auditory and visual perception in both patients and mice, and suggest these could be used as strong and translational biomarkers for SYNGAP1 haploinsufficiency.

Abstract: Normal 0 false false false EN-US X-NONE X-NONE /* Style Definitions */ table.MsoNormalTable {mso-style-name:"Table Normal"; mso-tstyle-rowband-size:0; mso-tstyle-colband-size:0; mso-style-noshow:yes; mso-style-priority:99; mso-style-parent:""; mso-padding-alt:0in 5.4pt 0in 5.4pt; mso-para-margin:0in; mso-pagination:widow-orphan; font-size:12.0pt; font-family:"Calibri",sans-serif; mso-ascii-font-family:Calibri; mso-ascii-theme-font:minor-latin; mso-hansi-font-family:Calibri; mso-hansi-theme-font:minor-latin; mso-bidi-font-family:"Times New Roman"; mso-bidi-theme-font:minor-bidi;} **Background:** Autism spectrum disorder (ASD) is characterized by repetitive behaviors and impaired social communication. Differences in neural excitability/inhibitory ratios have been previously reported in ASD. Magnetic Resonance Spectroscopy (MRS) has been shown as an effective technique to measure concentrations of the neurotransmitter glutamate, which general causes increases in neural excitability. It is therefore possible that this may be used as a predictor for the efficacy of pharmacological interventions in ASD. **Method:** MRS data from adult participants with ASD was processed to determine differences in glutamate concentration in the cerebellum and dorso-lateral prefrontral cortex (DLPFC). Social behavior was assessed before and after a 12 week trial of Memantine using the Clincal Global Impression (CGI) scale. Changes in social behavior were compared to concentrations of glutamate in both ROIs to determine if glutamate concentration

may serve as a predictor of changes in social behavior due to Memantine. **Results:** A positive correlation was discovered between glutamate concentration in left DLPFC and changes in CGI scores related to social interaction. There was no relationship between glutamate concentration in either cerebellum or DLPFC with regard to aberrant or abnormal behavior, repetitive behavior, verbal or nonverbal communication, hyperactivity, anxiety, hypo or hyper sensitivity, or restricted interest. **Conclusions:** More work is needed to further assess the efficacy of biomarkers acquired using MRS in predicting treatment response to Memantine, but the current results indicate that it may be possible that these biomarkers can predict changes in social interaction. <!--EndFragment-->

Abstract: Phelan-McDermid Syndrome (PMS) is a rare genetic condition characterized by deletion or mutation of region 22q13.3, which includes the *SHANK3* gene. Clinical descriptions of this population include mildly dysmorphic features, epilepsy, neonatal hypotonia, severely impaired or absent expressive language, developmental delays, and intellectual impairments. Among these characteristics, individuals with PMS may have autistic-like traits, which include abnormal reactivity to sensory stimuli. However, the neural underpinnings of these sensory processing abnormalities are unknown. This study focuses on comparisons of event-related potential (ERP), event-related spectral perturbation (ERSP), and inter-trial coherence (ITC) between PMS and typically developing (TD) individuals in a standard auditory gating task

measuring attenuation of neural activity to repetitive auditory stimuli. A total of 38 participants, 23 PMS (14 females, age range 96-216 months) and 15 TD (7 females, age range 98-178 months) were included in data analysis. Analysis included a series of general linear models using a region-specific and global (whole head) approach to characterize neural activity between PMS and TD by age, gender, and group. The most notable findings between PMS and TD were in regional analyses, where PMS showed weaker gating than TD for P50 and N1 amplitudes, N1 latency, lower delta ERSP, and lower theta to beta ITC. Within PMS, larger deletion sizes were associated with increased auditory processing abnormalities for P50 and N1 amplitudes and beta, gamma frequencies. Specifically, larger deletion sizes showed greater gating impairment for the P50 in younger individuals and for the N1 in older individuals, suggesting the possibility for developmentally regulated involvement of additional genes in this region. Larger deletion sizes were additionally associated with higher beta and gamma ERSP, in which larger deletions tended toward higher beta for males and toward higher gamma for females, suggesting potential differential effects of deletion size by gender. Results suggest that individuals with PMS exhibit auditory processing abnormalities with complex variation by deletion-size, gender, and age with congruency to impaired early recognition and redundancy attenuation (P50), feature processing (N1), theta to beta synchronization (ITC), information integration (delta), and inhibitory modulation of repeated auditory stimuli (beta, gamma). Findings may provide valuable insight into clinical characterization of sensory and speech behaviors in future studies.

Title: Investigating the role of the striatum in the link between noise-induced hearing loss and age-related cognitive decline

Authors: *S. V. PATEL, A. L. SCHORMANS, C. M. DECARLO, S. H. HAYES, S. N. WHITEHEAD, B. L. ALLMAN;
Western Univ., London, ON, Canada

Abstract: Hearing loss is a chronic and prevalent health condition, affecting ~466 million people worldwide. In addition to age-related hearing impairment, excessive exposure to loud noise is a leading cause of hearing loss. Beyond the devastating effects of hearing impairment itself,

epidemiological studies have identified hearing loss as a major risk factor for age-related cognitive decline, including dementia. At present, the brain regions mediating the link between hearing loss and cognitive decline remain elusive, and it is unclear which brain regions beyond the auditory pathway are particularly susceptible to noise exposure. Although previous studies on rodents have shown that noise exposure alters neurotransmitter systems within the striatum—a brain region involved in stimulus-response habit-learning—it is not known whether such changes contribute to cognitive decline following noise-induced hearing loss. In order to investigate this possibility, we developed a rodent model of noise-induced hearing loss to reliably track cognitive function across aging. To that end, we exposed 6-month old male Fischer 344 rats to broadband noise (100 dB SPL, 4 hours/day x 30 days) or silence. Hearing sensitivity was assessed using the auditory brainstem response; an electrophysiologically-measured evoked potential from the brain in response to sound. Separate cohorts of rats then underwent cognitive-behavioral testing at 7, 10, and 13 months of age on an operant-conditioning based visuomotor associative learning task that relies on normal function of the dorsal striatum. Over 18 consecutive days, rats performed ~150 daily trials of the task in which they received a food pellet upon correctly choosing the left feeder trough when the cue light was steady, and the right feeder trough when the cue light was flashing. Consistent with our effort to model hearing loss often experienced by humans who are exposed to occupational noise, our protocol resulted in a mild, high-frequency hearing loss in the rats. Overall, in contrast to our prediction, noise exposure did not cause deficits in stimulus-response habit-learning at any age. In fact, compared to age-matched shams, the noise-exposed rats performed more accurately on the visuomotor associative learning task at 10 months old, requiring fewer correction trials than the sham-exposed group, and at 13 months old, the noise-exposed rats had faster reaction times for correct responses. Ultimately, the absence of significant noise-induced cognitive deficits on this visuomotor associative learning task suggests a role for brain regions other than the striatum in mediating the link between hearing loss and cognitive decline.

Title: The functional organization of somatosensory and cortical pathways in the dorsal column nuclei

Authors: *A. UPADHYAY[1], F. IMAI[2], A. YONK[1], D. J. MARGOLIS[1], S. J. BENSMAIA[3], Y. YOSHIDA[2], V. E. ABRAIRA[1];

Abstract: The brainstem dorsal column nuclei (DCN) are the first supraspinal regions for the integration of ascending tactile and proprioceptive information, making them an enticing target to understand precortical sensory processing as well as novel neural prostheses to restore sensory function following injury. However, the underlying cellular and synaptic architecture of the DCN and how they facilitate somatosensory function remains underexplored. Here, we describe the ascending and descending somatosensory pathways of the DCN. We utilized mouse genetic and viral tracing strategies to reveal distinct sensory and cortical projections within the DCN, and used c-fos to investigate the functional role of these nuclei. We show that sensory and cortical pathways primarily converge in the gracile (Gr) and cuneate (Cu) nuclei, which receive primary afferent input from the lower and upper body, respectively. Of the VGlut1+ afferents that define this region, we find that primary afferents (71% of inputs in Gr, 81% of inputs in Cu) make up the majority of inputs to the DCN, with the remainder coming from cortical structures. Given the significance of presynaptic inhibition within the spinal cord, we explored whether sensory and cortical pathways in the DCN also receive axoaxonic contacts. We show that primary afferent terminals more frequently receive axoaxonic contacts than cortical terminals, and have more axoaxonic contacts per terminal. Furthermore, we show that cortical projections to the DCN mainly originate in the primary somatosensory cortex (S1) in a somatotopic manner. Preliminary evidence suggests these cortical projections target both excitatory and inhibitory neurons in the DCN. We used c-fos to investigate the functional role of these nuclei during predominantly sensory or motor behaviors. We found that both punctate stimulation of the hindpaw (44% increase in Gr) and treadmill walking (50% increase in Gr) evoked an increase in c-fos labeling, suggesting these nuclei are recruited during both tactile sensation and locomotion. Finally, we show the DCN project reciprocally to the spinal cord dorsal horn, suggesting a cortico-DCN-spinal pathway for modulating tactile and proprioceptive information. Collectively, these results identify the DCN as a nexus for the processing and distribution of somatosensory information and offers an alternative site for therapeutic intervention to restore sensorimotor function.

Abstract: The functions of the brain arise from the connections between neurons and the formation of neural circuits. Pain and its processing, proprioception, and motivated behaviors are some examples of the result of the activity of these circuits. It is relevant to understand the molecular mechanisms leading to the formation of neural circuits; to identify potential modulators that serve as a foundation for therapeutic approaches for pain management and motivated behavior disorders such as addiction, obesity, and eating disorders. Therefore, it is fundamental to find markers that can track specific neural circuits. In this work, we show that the transcription factor Early B-Cell Factor 2 (Ebf2) is a marker of circuits responsible for somatosensory processing, and motivation and reward systems of the brain. By using genetically engineered 129Sv$^{Ebf2/Tau-GFP}$ mice, which express the reporter gene green fluorescent protein fused to Tau protein (TGFP) under the control of the *Ebf2* gene promoter, we detect the expression of Ebf2 in the mouse brain at different stages of development, from late embryonic stage (E14.5) to adult mice (P56) (n=25 individual brains). At all these stages, we observe expression of Ebf2-TGFP in various components of the somatosensory system including, the substantia gelatinosa (SG) of the spinal cord and the central nervous system: the ventral posteromedial nucleus of the thalamus (VPM), the principal trigeminal (PrV) nucleus and the trigeminal lemniscus, and the parabrachial nucleus (PBN) of the pons. The latter has a role in pain and somatosensory processing but, additionally, it participates in the regulation of motivated behaviors. Related to this motivation system of the brain, we also observe Ebf2-TGFP signals in components of the Dorsal Diencephalic Conduction System; such as the bed nucleus of the stria terminalis (BNST), the stria medullaris (sm), the dorsomedial habenula (dMHb), and the interpeduncular nucleus (IPN) of the midbrain. Ebf2-TGFP axons also connect the IPN to the dorsal tegmental nucleus (DTg). Moreover, we can detect Ebf2-TGFP axons arising from the periaqueductal gray matter (PAG) and innervating the ventral forebrain. Another set of Ebf2 axons originate from the lateral hypothalamic area (LHA); and connects it to the amygdala, which suggests these populations have a role in regulating motivation and reward.

Title: The parabrachial complex processes dura inputs through a direct trigeminal ganglion to parabrachial connection

Authors: *O. UDDIN[1], M. ANDERSON[1], R. MASRI[2], J. SMITH[1], A. KELLER[3];
[1]Anat. and Neurobio., [2]Dept. of Advanced Oral Sci. and Therapeut., Univ. of Maryland, Baltimore, MD; [3]Anat. & Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Migraines cause significant disability and contribute heavily to healthcare costs. Irritation of the meninges' outermost layer (the dura mater) and trigeminal ganglion activation contribute to migraine initiation. Maladaptive changes in central pain-processing regions are also important in maintaining pain. The parabrachial complex (PB) is a central region that mediates chronic pain. Specifically, amplified PB activity is causally related to increased pain (PMID 32217613, PMID 29862375). PB receives diverse sensory information, including a direct input from the trigeminal ganglion (PMID 29184209). We hypothesized that PB processes inputs from the dura. Using *in vivo* electrophysiology recordings from single units in 22 anesthetized male and female adult rats, we identified 58 neurons in lateral PB that respond reliably and with short latency to electrical dura stimulation. After injecting tracer into PB, anatomical examination reveals retrogradely labeled cell bodies in the trigeminal ganglion. Neuroanatomical tract-tracing revealed a population of neurons in the trigeminal ganglion that innervate the dura and project directly to PB. Based upon these findings, we hypothesize that amplified activity of dura-responsive PB neurons underlies migraine-associated pain. To model the trigeminal sensitization associated with migraine, we applied low pH (4.8) solution to the dura, recording spontaneous and pinch-evoked activity of dura-responsive PB neurons. In preliminary experiments conducted several hours after applying low pH to the dura, we have identified dura-stimulus-responsive PB neurons in which either receptive field or neural activity is increased compared to baseline. These data indicate that PB is strategically placed to process dura inputs and suggest that it is directly involved in the pathogenesis of migraine headaches.

Title: The neurokinin-1 receptor is expressed with gastrin-releasing peptide receptor in spinal interneurons and modulates itch

Authors: *T. SHEAHAN[1], C. WARWICK[1], L. FANIEN[1], S. ROSS[2];
[2]Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The neurokinin-1 receptor (NK1R, encoded by *Tacr1*) is expressed in spinal dorsal horn neurons and has been suggested to mediate itch. However, previous studies relied heavily on neurotoxic ablation of NK1R spinal neurons, which limited further dissection of their function in spinal itch circuitry. Thus, we leveraged a newly developed $Tacr1^{CreER}$ mouse line to characterize the role of NK1R spinal neurons in itch. We show that pharmacological activation of spinal NK1R and chemogenetic activation of $Tacr1^{CreER}$ spinal neurons increases itch behavior, whereas pharmacological inhibition of spinal NK1R suppresses itch behavior. We use fluorescence *in situ* hybridization to characterize the endogenous expression of *Tacr1* throughout the superficial and deeper mouse dorsal horn, as well as the lateral spinal nucleus of mouse. Notably, *TACR1* expression was evolutionarily conserved in the human spinal cord dorsal. Retrograde labeling studies from the parabrachial nucleus show that less than 20% of superficial $Tacr1^{CreER}$ dorsal horn neurons are spinal projection neurons, and thus the majority of $Tacr1^{CreER}$ are local interneurons. We then use a combination of *in situ* hybridization and *ex vivo* two-photon Ca^{2+} imaging of the spinal cord to establish that NK1R and the gastrin-releasing peptide receptor (GRPR) are coexpressed within a subpopulation of excitatory superficial dorsal horn neurons. These findings are the first to describe a role for NK1R interneurons in itch and extend our understanding of the complexities of spinal itch circuitry.

Title: Gastrin releasing peptide receptor signaling from endosomes: a key source of itch signaling.

Authors: *D. D. JENSEN;
NYU Col. of Dent..

Abstract: Chronic pruritus is a major unmet clinical problem with one in four adults experiencing chronic pruritus in their lifetime. G-protein coupled receptors (GPCRs) are key receptors driving itch signaling and are the major therapeutic target for itch relief. The newly discovered ability of GPCRs to signal from endosomes in cells provides new challenges for understanding GPCR signaling regulation, how endosomal signaling of GPCRs contributes to disease states like chronic pruritus, and opens new targets for therapeutic development. The Gastrin releasing peptide receptor (GRPR) is a key mediator of pruritis in the spinal cord and is rapidly internalized upon activation. Yet, little is known about the molecular mechanisms regulating GRPR signaling in pruritus, if GRPR can signal from endosomes or the role of endosomal GRPR in the development of pruritus. Aims: Determine the importance of internalization and endosomal signaling of GRPR in pruritus. Methods: The endosomal inhibitors (PitStop2 & Dyngo4a) and dominant-negative forms of dynamin were used to inhibit endocytosis and trafficking of GRPR in cell lines and in mouse models for pruritus. GRPR internalization and trafficking to endosomes were quantified using BRET and fluorescent microscopy. Endosomal-mediated ERK signaling and gene expression were measured in cell lines using FRET biosensors and luciferase gene expression assays. pH-sensitive mesoporous silica nanoparticles (MSN) were used to deliver RC-3095, a GRPR antagonist, specifically to endosomes to block endosomal signaling of GRPR. Chloroquine (CQ) and deoxy-cholic acid (DCA) invoked itch responses following intrathecal injections of endosomal inhibitors were measured and neuronal activation was quantified using phospho-ERK1/2 immunofluorescence. Results: In HEK cells clathrin and dynamin disruption attenuated GRP-induced GRPR internalization and trafficking to endosomes, which blocked cytosolic and nuclear ERK signaling and the increased expression of the serum response element reporter gene. Pre-incubation of the cells with pH-sensitive nanoparticles containing GRPR antagonists also blocked the ERK signaling in the cells. CQ and DCA injections resulted in an increase in phosphor-ERK immunolabeling in spinal neurons in mice. While intrathecal injection of endosomal inhibitors attenuated scratching responses to CQ and DCA in mice. Discussion: Our results demonstrate a critical role for GRPR endosomal signaling in the transmission of itch. These results highlight the ability of endosomal released antagonist to inhibit GRPR signaling and provide a new target for developing therapeutics that block GRPR mediated pruritus.

Title: Visualizing the itch-sensing skin arbors

Authors: *Y. XING, H. R. STEELE, H. B. HILLEY, K. LAWSON, T. NIEHOFF, L. HAN;
Georgia Inst. of Technol., Atlanta, GA

Abstract: Diverse sensory neurons exhibit distinct neuronal morphologies with a variety of axon terminal arborizations subserving their functions. Due to its clinical significance, the molecular and cellular mechanisms of itch are being intensely studied. However, a complete analysis of itch-sensing terminal arborization is missing. Using a novel *MrgprC11*^{CreERT2} transgenic mouse line, we labeled a small subset of itch-sensing neurons that express multiple itch-related molecules including MrgprA3, MrgprC11, histamine receptor H1, IL-31 receptor, 5-HT receptor 1F, natriuretic precursor peptide B, and neuromedin B. By combining sparse genetic labeling and whole-mount PLAP histochemistry, we found that itch-sensing skin arbors exhibit free endings with extensive axonal branching in the superficial epidermis and large receptive fields. These results revealed the unique morphological characteristics of itch-sensing neurons and provide novel insights into the basic mechanisms of itch transmission.

Title: Mrgprc11^{+} DRG sensory neurons mediate glabrous skin itch

Authors: *H. R. STEELE, Y. XING, Y. ZHU, H. HILLEY, K. LAWSON, Y. NHO, T. NIEHOFF, L. HAN;
Georgia Inst. of Technol., Atlanta, GA

Abstract: Despite being the most common reason for visiting the dermatologist, chronic itch has very few effective treatments. Additionally, the most deliberating form of itch, glabrous skin (palms and soles) itch, has attracted virtually no attention within the field due to a lack of methodology. This is despite glabrous skin itch arising from many medical conditions (plantar and palmar psoriasis, dyshidrosis, and cholestasis). Therefore, to identify which neuronal populations mediate glabrous skin itch we examined the central and peripheral innervation pattern of three previously identified itch-sensing neurons (MrgprA3^{+}, MrgprD^{+}, and MrgprC11^{+}). We found that both MrgprD^{+} and MrgprC11^{+} sensory neurons densely innervate glabrous skin, while MrgprA3^{+} sensory neurons do so only very sparsely. Consistently, glabrous skin-innervating neurons identified by retrograde tracing showed very weak neuronal responses to MrgprA3 agonist chloroquine. These results indicate, for the first time, the potential

mechanistic differences that exist between hairy and glabrous skin itch. As MrgprC11$^+$ neurons have not previously been characterized, we used immunostaining and RNAscope *in situ* hybridization to determine that MrgprC11 is expressed in a subset of small-diameter peptidergic neurons that constitute ~18% of DRG sensory neurons, including the majority of both MrgprA3$^+$ and NPPB$^+$ itch-sensing neurons. To investigate the mechanisms of glabrous skin itch, we developed novel acute and chronic mouse behavioral assays to examine itch sensation arising from the glabrous skin of the plantar hindpaw. We found that mice exhibit specific biting behavior in response to pruritogens and licking in response to algogens. Using this assay, we demonstrated that chemogenetic activation of MrgprA3$^+$ and MrgprD$^+$ nerves in the glabrous skin do not induce biting behavior, suggesting that they do not mediate glabrous skin itch. In contrast, we found that activation of MrgprC11$^+$ neurons using both chemogenetic activation and the MrgprC11 agonist Bam8-22 induced significant dose-dependent biting behaviors in glabrous skin. Finally, we found that ablation of MrgprC11$^+$ neurons almost completely abolishes both acute (Bam8-22) and chronic glabrous skin itch. These results suggest that MrgprC11$^+$ neurons are a major mediator of glabrous skin itch. In summary, our findings reveal new avenues for future glabrous skin itch study and the development of glabrous-skin specific anti-itch therapies.

Title: The role of NPY2R$^+$ neurons in the amygdala on non-histaminergic itch

Authors: *D. PAVLENKO, T. AKIYAMA;
Dermatol., Univ. of Miami, Miami, FL

Abstract: Title: The role of NPY2R$^+$ neurons in the amygdala on non-histaminergic itchA major part of the itch neural pathway is the amygdala. Previous work has shown that activating itch-responsive neurons in the amygdala causes an increase in itch- and anxiety-related behaviors. In contrast, activation of the $GABA_A$ receptor in the amygdala causes a decrease in itch-related behavior. Neuropeptide Y receptor type 2 (NPY2R) has been found primarily in the amygdala and hypothalamus. It has been categorized as a presynaptic GCPR whose activation leads to a downstream inhibition of glutamate. In the present study, we tested the role of NPY2R-expressing amygdala neurons on itch.To manipsulate the activity of NPY2R-expressing neurons, we prepared NPY2R-cre mice and injected a cre-dependent AAV into the amygdala of these mice. The cre-dependent AAV contained tdTomato and chrimsonR, which allowed us to use

light to activate NPY2R-expressing neurons and map the projection patterns of NPY2R-expressing amygdala neurons in the brain. Prior to surgery, mice had intradermal injections of the nonhistaminergic itch mediator chloroquine to see their base level scratch response to the chemical. After surgery, the intradermal injections were repeated in a light on and light off condition. When the light is on, the NPY2R neurons are activated, and there was a suppression of itch-related behavior. To further validate the role of NPY2R-expressing neurons in itch, we injected an NPY2R agonist peptide YY 3–36 (PYY3–36) into the amygdala in naïve mice and videotaped their behaviors. PYY3-36 dose-dependently elicited itch-related behavior. Based on these findings, we concluded that NPY2R-expressing amygdala neurons are involved in the regulation of itch.

Title: NIH HEAL Initiative: NINDS Preclinical Screening Platform for Pain (PSPP)

Authors: *S. A. WOLLER, A. TAMIZ, S. IYENGAR;
Div. of Translational Res., NINDS, Rockville, MD

Abstract: The National Institute of Neurological Disorders and Stroke (NINDS) aims to enhance pain management and accelerate the discovery and development of new non-addictive pain therapeutics as part of the recently launched Helping to End Addiction Long-term (HEAL) Initiative, a trans-agency effort to provide scientific solutions to the opioid crisis. With HEAL support, the NINDS Preclinical Screening Platform for Pain (PSPP) has been set up to accelerate identification of novel approaches to treat both acute and chronic pain conditions. Under NINDS direction, preclinical testing of submitted agents is performed by contract facilities on a blinded and confidential basis at no cost to the PSPP participants. Test candidates are evaluated in a suite of *in vivo* pain-related assays following *in vitro* receptor profiling, pharmacokinetic, and side-effect profile assessment. Importantly, test candidates are also evaluated in models of abuse liability. In vivo pain-related assays include models of acute to chronic pain and persistent pain mechanisms, as well as specific models of neuropathic, nociceptive and neuroplastic pain, including e.g. chemotherapy-induced neuropathic pain, osteoarthritis pain, and migraine. A key feature of the PSPP is the flexibility to continuously acquire and validate innovative new models and endpoints that more closely represent human pain conditions. Towards that end, test systems and endpoints amenable to evaluating devices can also be incorporated. PSPP provides researchers from academia and industry, in the US and internationally, an efficient, rigorous, one-stop *in vivo* screening resource to identify and profile novel non-opioid, non-addictive therapeutic candidates, including small molecules, biologics, natural products and devices for the treatment of pain. This presentation will elaborate on this novel non-opioid, non-addictive pain

therapeutic discovery and development program and its efforts to engage the drug discovery and device development community.

Title: The pharmacological interaction of gabapentin and sulforaphane relief pain in a fibromyalgia like pain model.

Authors: *I. Y. ZAMORA DIAZ[1], F. J. LOPEZ MUNOZ[2], M. E. GÓNZALEZ-TRUJANO[3]; [1]CINVESTAV, CDMX, Mexico; [2]CINVESTAV, Mexico, Mexico; [3]Inst. Nacional de Psiquiatría "Ramón De la Fuente Muñiz", CDMX, Mexico

Abstract: The current management of fibromyalgia represents an important challenge for therapeutics in the control of this type of pain. Drugs of the α2-δ ligand family, characterized by blocking the activity of voltage-gated calcium channels, have shown some utility for this condition. Pregabalin belongs to this group and is one of the FDA-approved drugs for the treatment of fibromyalgia-like pain. Gabapentin, although it belongs to the family of α2-δ ligands, is a drug with less application for this condition due in part to the lack of studies that reinforce its efficacy. On the other hand, sulforaphane is an isothiocyanate derived from glucosinolate-type compounds found in cruciferous vegetables. This has been related to effects on the central nervous system as an antinociceptive, anxiolytic-antidepressant and anticonvulsant, associated in part with its modulating role in the activity of calcium channels and its neuroprotective action as an antioxidant. The objective of this study was to evaluate the antinociceptive effects of the individual administration and in combination of different doses of gabapentin and sulforaphane in two of the most important painful manifestations of fibromyalgia, using the reserpine-induced fibromyalgia pain model in rats. The antiallodynic effects were analyzed by mechanical and thermal stimulation; and the anti-hyperalgesia by mechanical stimulus. Time-course curves were made for both molecules recording behavior every 30 min and during a period time of 4 hours. The dose-response effects were obtained. Our results demonstrated that both sulforaphane and gabapentin administered individually produced significant antiallodynic and anti-hyperalgesic effects and in a dose-dependent manner in the fibromyalgia-type pain model. Additionally, it was determined that the combination of intermediate doses, but not lower doses, of both drugs facilitated antiallodynic and/or anti-hyperalgesic activities but producing the same level of effect using only 1/3 of the individual dose of each case. This study provides evidence of the potential of gabapentin and sulforaphane for the relief of fibromyalgia-type pain alone or in combination of certain doses.

Abstract: Aging leads to adaptations in the human somatosensory system with older individuals reporting changes in perception of odor, high and low pitch sounds, and taste. Age-related changes have also been reported in the systems that process pain with quantitative sensory testing (QST) showing that older individuals report increases in pain threshold (PTh) and decreases in pain tolerance (PTo). QST testing has improved our understanding of pain processing at the bottom and top of a range, while also providing evidence that individuals with chronic pain show increased pain sensitivity. However, conventional QST approaches tell us little about how age and chronic pain influence the calibration of the pain system across different levels of stimulus intensity. To directly address this gap in the literature, we assessed pain ratings across a heat-pain stimulus-response curve in a total of 159 participants. Participants were grouped based on age and chronic pain status; 75 healthy controls (young pain -free: 22.9 years), 25 young participants with chronic jaw pain (young pain: 35.9 years), 26 older healthy controls (old-pain-free: 66.5 years), and 33 older individuals with chronic low back pain (old pain: 66.5 years). Participants received 4 second bouts of heat stimulation to their right, volar forearm at 9 different temperatures ranging from 40°C to 48°C. Participants received each temperature twice in a pseudo-randomized order. Participants were asked to rate their pain to each stimulus on a scale from 0 to 100 (0 being no pain, 100 being intolerable pain). We used linear mixed models to quantify the relationship between temperature, pain rating, age and pain status. To further quantify associations between temperature and pain rating we ran four Pearson's Product Correlations and performed a one-way analysis of variance test using each participants R^2 value. We report 2 novel findings. First, both age and chronic pain were separately associated with a flatter slope in the heat-pain stimulus-response curve. Second, we found that age was also associated with greater variability in pain ratings across the range of temperatures. Previously reported central and peripheral pain mechanisms alone cannot account for our findings, suggesting that age and chronic pain alter the heat pain stimulus-response curve via multiple mechanisms.

Title: Dim Light at Night Exacerbates Chemotherapy-Induced Peripheral Neuropathy in Mice

Authors: *J. R. BUMGARNER, W. H. WALKER, II, J. A. LIU, H. MELENDEZ-FERNANDEZ, J. C. WALTON, C. DEVRIES, R. J. NELSON;
West Virginia Univ., Morgantown, WV

Abstract: Chemotherapy-induced peripheral neuropathy (CIPN) is a debilitating disease associated with numerous chemotherapeutic agents used in cancer treatment. Despite its prevalent and severe effects on both patient quality of life and treatment outcome, there is currently no accepted treatment for CIPN. Considering that disruption of circadian rhythms is known to alter immune function, induce peripheral and central inflammation, alter metabolism, and even directly exacerbate pain behavior in rodents, we sought to examine the relationship between disrupted circadian rhythms and CIPN. We hypothesized that exposure to dim light at night (dLAN; 5 lux) exacerbates pain behavior associated with chemotherapy treatment. To test this hypothesis, pain behavior was assessed in female ovariectomized CFW mice before and after treatment with paclitaxel. Thermal withdrawal thresholds were tested using the hot and cold plates, and mechanical withdrawal thresholds were tested using an electric von Frey instrument. Starting on the first night of either dLAN or dark night housing conditions, mice received a 5-day i.p. treatment regimen of either paclitaxel (2 mg/kg/day) or vehicle. We observed that dLAN exposure exacerbated mechanical allodynia associated with paclitaxel treatment starting in and persisting in the third week of dLAN housing. Using qRT-PCR, we observed that paclitaxel-treated mice housed in dLAN demonstrated upregulated expression of *Il-6* in the rostral ventromedial medulla of the descending-regulatory system. Together, these data suggest harmful effects of dLAN exposure on pain behavior associated with CIPN. Future non-pharmacological therapeutic interventions for CIPN should consider mitigating circadian rhythm disruption to improve patient health and treatment outcome.

Title: Evaluation of recombinant gene therapy with serine-histogranin and endomorphin-1 in a model of phantom limb pain in rats

Authors: A. PACHECO-SPIEWAK, A. EESWARA, F. BORJA, S. GROSS, M. HERNANDEZ, S. JERGOVA, *J. SAGEN;
Univ. of Miami, Miami, FL

Abstract: Limb amputation frequently results in emergence of phantom limb pain (PLP). This perception of pain from the missing extremity is poorly understood and current therapeutic options are marginally effective. To mimic PLP, we have developed a rodent model in which inflammation and peripheral nerve constriction injury is followed by axotomy of the sciatic nerve. This replicates complex extremity injuries that frequently occur prior to medically indicated amputation. The occurrence of prior pain has been clinically observed to predict quality and severity of subsequent PLP. Previous studies in our lab have shown alleviation of pain-like behavior induced by peripheral nerve injury or spinal cord injury by NMDA receptor antagonist serine-histogranin (SHG). Further analgesic potential was explored through combination of SHG gene with mu-opioid peptide endomorphin-1 (EM1). The current study investigates the potential of SHG and SHG/EM1 gene constructs in reducing or preventing development of PLP-like behavior. Our model aims to discover the most efficient route and best timing of delivery of the therapeutic gene constructs. Using male Sprague-Dawley rats, AAV_SHG, AAV_SHG/EM1 or AAV_GFP constructs were administered via dorsal root ganglion injection, intrathecally, or intraspinally either on the same day as the transection or one week later, with pre-amputation injury induced at 1 to 14 days prior to the transection. Autotomy onset, severity, and location were monitored daily as indicators for PLP-like behavior. Upon completion of in vivo studies, CSF and tissue were collected for neurochemical and immunocytochemical analysis. Our data shows significant attenuation in the severity and onset of the PLP-like behavior in animals treated with SHG and SHG/EM1 gene constructs compared to GFP. The most robust effect of both constructs was observed after intraganglionic injection. Comparison of SHG and SHG-EM1 outcomes showed that animals treated with SHG/EM1 displayed lower autotomy scores compared to SHG alone, suggesting that the inhibition of glutamate signaling by SHG and the simultaneous activation of mu-opioid receptor by EM1 may generate more potent PLP alleviation. Recombinant SHG and EM1 peptides were detected in the spinal tissue of treated animals. Analysis of CSF samples and immunocytochemistry showed downregulation of inflammatory mediators IL-1β and TNF-α and reduction in reactive glial markers GFAP and Iba-1 in animals treated with gene constructs compared to GFP controls. These data demonstrate the potential beneficial effect of targeted gene therapy in the prevention or attenuation of PLP.

Title: Importance of the prefrontal cortex-bed nucleus of the stria terminalis pathway in visceral nociception

Authors: ***A. C. JOHNSON**[1,2], C. O. LIGON[2], B. GREENWOOD[2,1];
[1]Res. Admin. 151, VA Hlth. Care Syst., Oklahoma City, OK; [2]Physiol., Univ. of Oklahoma Hlth. Sci. Ctr., Oklahoma City, OK

Abstract: *Introduction:* Corticolimbic brain circuits demonstrate abnormal activity in patients with stress-induced visceral pain disorders, such as irritable bowel syndrome (IBS), characterized by colonic hypersensitivity. The prefrontal cortex (PFC) has been shown to participate in both pain and stress modulation. We have previously found that the pathway from the central amygdala to the bed nucleus of the stria terminalis (BNST) modulates colonic sensitivity in the rat. The BNST also receives signals from the PFC, but the role of the PFC in the modulation of stress-induced colonic nociception is unknown. The hypothesis for this study was that activation of PFC-BNST pathway could induce colonic hypersensitivity. *Methods:* To test the role of PFC-BNST signaling, we infected the PFC with viral vectors to express channelrhodopsin (ChR2) or halorhodopsin (HR3.0) and implanted fiber optic cannula at the BNST in male Fischer 344 rats (n=4/group). To model a chronic stressor, a different cohort had a single micropellet (30 μg) of the stress hormone, corticosterone (CORT) or cholesterol (CHOL) control implanted in the PFC (n=8/group). Graded, isobaric colorectal distension (20-60 mmHg, 10 min) was used to assess colonic sensitivity, quantified as the number of abdominal muscle contractions in freely moving rats. In rats with opsins, colonic sensitivity was assessed with and without laser stimulation after 10 weeks to allow for opsin expression. In rats with micropellets, colonic sensitivity was measured after 8 days at the peak diffusion of the micropellet. Results were analyzed with a repeated measure two-way ANOVA with Bonferroni's post-hoc analysis (mean ± standard deviation). *Results:* We first found that inhibition of the PFC-BNST pathway in via HR3.0 did not affect colonic sensitivity in non-stressed rats (60 mmHg: 22.0 ± 2.8 vs. 21.5 ± 3.3, p=0.99). In contrast, activation of the PFC-BNST pathway with ChR2 induced colonic hypersensitivity (60 mmHg: 36.0 ± 8.8 vs. 28.5 ± 6.5, $p<0.05$. Finally, to evaluate the role of the PFC-BNST pathway to modulate stress-induced colonic hypersensitivity, we implanted CORT in the PFC and found that the rats developed colonic hypersensitivity compared to CHOL-implanted controls (60 mmHg: 37.9 ± 4.6 vs. 24.3 ± 2.7, $p<0.01$). *Conclusions:* Both ChR2

activation and CORT-induced signaling from the PFC to the BNST induced colonic hypersensitivity. These results support the role of the PFC-BNST pathway as part of a corticolimbic circuit that modulates visceral sensation in response to stress. Modulation of the PFC-BNST pathway could represent a valid target for novel therapies to treat disorders such as IBS.

Title: Female mice exhibit persistent hyperalgesia while housed with CFA-treated conspecifics or their bedding.

Authors: *Y. ZHANG, A. E. RYABININ;
Dept. of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: It has become a well-documented observation in literature that an animal's pain experience can be altered by another's pain state depending on their social relationship. However, the neural mechanisms of such modulation of pain by social interactions is still far from understood. Our lab has previously reported that naïve mice housed in the same room with mice experiencing alcohol withdrawal-induced hyperalgesia also exhibited hypersensitivity to pain. We showed that exposure to the beddings of mice experiencing alcohol withdrawal-induced hyperalgesia was sufficient to cause hypersensitivity in co-housed naïve mice, demonstrating that olfactory signaling played an important role in the transferred pain experience. The aim of the present study was to examine whether our observation of persistent transferred pain from exposure to beddings of affected conspecifics was specific to alcohol withdrawal-induced hyperalgesia or common in other painful conditions. Female C57BL/6J mice were singly housed in separate cages. After baseline testing, one group of mice received an intra-plantar injection of CFA (CFA-primary) and were housed with a group of untreated mice (CFA-bystander) in separate cages in the same room for the rest of the testing period. Another group of naïve mice were housed in a different room (CFA-olfactory), exposed to only the bedding from CFA mice that were transferred over daily in small portions and distributed evenly outside of the cages of CFA-olfactory mice. Female mice receiving intra-plantar saline injections (Saline-primary), co-housed with Saline-primary (Saline-bystander), as well as only exposed to Saline-primary beddings (Saline-olfactory) were used as control groups. Results showed that both CFA-bystander and CFA-olfactory female mice exhibited a decrease in von Frey mechanical threshold compared to baseline. Their mechanical threshold recovered 7 days following removing CFA-primary mice or the beddings from CFA-primary mice. On the other hand, we did not detect

meaningful difference in nociceptive threshold for thermal nociception between groups in the Hargreaves test. In conclusion, we demonstrate that the olfactory stimulation from the bedding of mice experiencing CFA-induced persistent inflammatory pain contributes to development of significant allodynia in that bystander mice housed in the same room for a prolonged period. Together with our previous finding, this study provided evidence for a role of olfaction in social communication of individual's pain state.

Title: Standardization of Preclinical Models for Pain

Authors: *M. A. VARNEY[1], E. LEAHY[1], D. BUDAC[1], E. DUGAN[1], M. URBAN[1], Q. CHANG[1], H. FERNANDES[1], J. GRESACK[1], S. A. WOLLER[2], S. IYENGAR[2], T. HANANIA[1]; [1]Psychogenics, Paramus, NJ; [2]NINDS, Rockville, MD

Abstract: Under the NIH Helping to End Addiction Long-term[SM] (HEAL) Initiative, PsychoGenics was awarded a contract to screen and profile novel therapeutics within the Preclinical Screening Platform for Pain (PSPP). The main goal of this platform is to accelerate the preclinical development of non- starting opioid, non-addictive therapies for acute and chronic pain.
In collaboration with NINDS and experts in the field, PsychoGenics evaluates assets through *in vitro* cell-based functional assays to rule out opioid receptor activity and to assess *in vitro* abuse liability, *in vivo* pharmacokinetic studies to guide the dose range and pretreatment times for the side effect profile, *in vivo* efficacy and abuse liability studies. *In vivo* efficacy studies that are used in evaluating assets include the plantar incision model and L5/L6 spinal nerve ligation model. Disease specific pain models as well as novel endpoints that may increase translation are also being evaluated and optimized. Examples include models of neuropathic pain, osteoarthritis pain, deep muscle pain and migraine. Non-evoked endpoints being developed in these models include gait, guarding and place escape avoidance paradigm (PEAP). All studies are performed in a blinded fashion in both sexes. Data are reported consistent with ARRIVE Guidelines.
This presentation will show examples of the tiered approach used to evaluate assets and the efforts to enhance novelty, rigor and reproducibility in pain research to support the NINDS PSPP program within the HEAL Initiative.

Abstract: Peripheral neurons of the dorsal root ganglia (DRG) are at the forefront of integrating and transmitting sensory information to the central nervous system. In the context of acute, chronic or neuropathic pain, DRG's are considered a primary target for treatment. One current challenge is the identification of the cellular activities most relevant to pain control. Recent advances in our understanding of the physiology and pathophysiology of DRG neurons point to voltage-gated sodium channels (Nav) as a promising target, arousing great interest in the pharmaceutical industry. Nav channels give rise to the upstroke of an action potential and are thus the ultimate checkpoint of cell excitability. Of the 10 Nav channel alpha subunits isoforms, which forms the core of the channel, a single amino acid substitution in the S5-S6 linker renders Nav1.5, Nav1.8, and Nav1.9 resistant to tetrodotoxin (TTX), making them a TTX-resistant (TTX-R) specific subgroup implicated in heart, muscle and dorsal root ganglion excitability. Furthermore, TTX-resistant Nav channel expression has been suggested to characterize selective populations of DRG neurons. Using primary cultures of DRG neurons isolated from adult non-human primates (NHP) and rodents, we performed whole cell electrophysiology using current-clamp and voltage-clamp protocols. We found that TTX-resistant Nav channels can be engaged for action potential initiation of small diameter DRG neurons (< 30 pF), but totally absent from large diameter ones (> 50 pF) in rodents. However small, as well as large, diameter DRG neuronal populations express TTX-resistant Nav channels in NHPs. This may help define species-specific context for therapeutic relevance. In addition, action potential threshold and biophysical characterization of the Nav currents from acutely isolated adult DRGs demonstrated species differences relevant to the design of *ex vivo* neuropharmacology assays.

Title: A Free Open-Source Method of Image Cytometry in Rat Dorsal Root Ganglia with Fluorescent Immunohistochemistry

Authors: *M. B. ANDERSON;
Anat. & Cell Biol., Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Immunohistochemistry (IHC) is a valuable tool in clinical and biological research for evaluating proteins and other antigens in spatially bound tissue. In neuroinflammatory pain research, primary afferent neurons of the dorsal root ganglion (DRG) are studied to understand molecular signaling mechanisms involved in nociception (pain) and inflammation. Measuring IHC immunofluorescence in DRG neurons require manual hand tracing of nuclear and somatic boundaries, which is laborious, error-prone, and can require several weeks to collect the appropriate sample size with a mouse or pen-input display monitor. To overcome these limitations and increase standardization of sampling and measurement, we employed a reliable neuronal cytoplasmic reporter, exclusive to DRG neuronal soma, in a semi-automated algorithm-based approach of Image Cytometry in rat Dorsal Root Ganglion (IC-DRGs). The resulting output images are binary nuclear and somatic masks of DRG neurons, defining boundaries of measurement for CellProfiler and manually scored at 94% accurate. Herein, we successfully show a novel approach of automated image analysis for DRG neurons using a robust ImageJ/FIJI script, overcoming morphological variability and imaging artifacts native to imaging frozen tissue sections processed with fluorescent IHC.

Title: Dorsal root ganglion neurons assemble an axon initial segment which can initiate spontaneous activity in neuropathic pain

Authors: *A. I. NASCIMENTO[1], L. L. LUZ[2], F. MAR[3], P. AGUIAR[2], B. SAFRONOV[2], M. M. SOUSA[2];
[1]ICBAS - Inst. de Ciências Biomédicas Abel Salazar, i3S - Inst. de Investigação e Inovação em Saúde, Univ. do Porto, Porto, Portugal; [2]i3S, Univ. do Porto, Porto, Portugal; [3]ICBAS, Univ. do Porto, Porto, Portugal

Abstract: Most CNS neurons have a multipolar morphology and a specialized structure - the axon initial segment (AIS), which initiates action potentials, maintains neuronal polarity and modulates excitability *via* structural and molecular alterations. In contrast, dorsal root ganglion (DRG) neurons have a pseudounipolar morphology and it is unclear whether they possess an AIS *in vivo*. We established an *in vitro* model in which DRG neurons recapitulate their physiological morphology and assemble an AIS-like segment at the stem axon enriched in the AIS-specific protein Ankyrin-G (AnkG). This prompted us to investigate the existence of this structure *in vivo*. Strikingly, we observed that most adult myelinated DRG neurons have an AIS in the proximal stem axon, which becomes enriched in AnkG and voltage-gated sodium (Nav) channels during embryonic development. The physiological role of this segment is not clear, as action potentials are initiated in the peripheral axon terminals of DRG neurons. However, in peripheral neuropathic pain, DRG neurons develop spontaneous activity initiating in an unknown cellular compartment inside the ganglion. We decided to investigate if this newly-discovered AIS of DRG neurons is the source of such pathological activity using the chronic constriction injury (CCI) model. Immunofluorescence data show that the AIS is located in a more proximal position 4 days after CCI, and in all timepoints analyzed after injury the relative enrichment of Nav channels in the AIS with respect to the cell body is greater than in naïve animals. To investigate the contribution of the AIS and its alterations to DRG neuron excitability, we have created a detailed biophysical model of an Aδ-fiber DRG neuron based on our morphological and physiological data. Computer simulations demonstrate that the observed AIS alterations have a negligible effect on the excitability of DRG neurons, but the existence of the AIS itself facilitates the initiation of spontaneous activity. Additionally, we established a mouse model to provide a time-controlled abolition of AnkG expression in adult DRG neurons, leading to AIS disassembly. Using calcium imaging of DRG explants from these mice, we have observed that the AIS contributes to the spontaneous activity associated with CCI. Our discovery of the AIS of DRG neurons and its contribution to pathological hyperexcitability creates a new path for the development of therapeutic options for chronic pain management.

Title: Long lasting pain relief and shift of dorsal root ganglia transcriptome in chronic nerve injury treated with nanomedicine; attenuating cyclooxygenase-2 has widespread influence on gene expression

Authors: *B. S. DEAL[1], A. STEVENS[1], M. SALEEM[1], L. REYNOLDS[1], J. JANJIC[1], J. A. POLLOCK[2];
[1]Duquesne Univ., Pittsburgh, PA; [2]Duquesne Univ. Dept. of Biol. Sci., Pittsburgh, PA

Abstract: Neuroinflammatory pain can transition to chronic pain through molecular mechanisms that are poorly understood. In order to discern how immune cells, neurons, and glial cells influence one another throughout this process, one strategy is to turn a specific cellular communication pathway off with targeted cyclooxygenase 2 (COX-2) inhibiting nanotherapeutic (CXB-NE) delivered directly to macrophages at the site of injury. Because this nanotherapeutic CXB-NE is specific to macrophages, we can probe the molecular cell biology and transcriptomic components that are influenced by the attenuation of the production of prostaglandin E2 (PGE2). A result of this treatment is a significant reduction in hypersensitivity and pain-like behavior. Using Chronic Constriction Injury (CCI) as well as total RNAseq, this study shows that attenuating the local production of PGE2 not only influences the transcriptome of macrophages but other cell types such as neutrophils and neurons. We also demonstrate that the changes that occur during pain relief caused by the CXB-NE nanotherapeutic affect not only the local cell types at the site of injury in the sciatic nerve, but also influences gene expression profile changes at the dorsal root ganglion (DRG). Some of the key findings reveal that critical molecular pathways active during pain relief include transducer activity, G-protein coupled receptor activity, neutrophil degranulation, and transmembrane signaling receptor activity. Increased expression of factors contributing to neuronal regeneration such as fibronectin leucine-rich transmembrane neuronal protein 3 (Flrt3) and leucine-rich repeat transmembrane neuronal proteins (LRRTM1, LRRTM2, and LRRTM3) are also enriched with CXB-NE nanotherapeutic compared to drug free nanoemulsion (DF-NE). These findings as well as others, demonstrate that the pain relief achieved by this nanotherapeutic not only influence COX2 production of PGE2, but rather have widespread influence of gene expression locally and at the corresponding DRG.

Title: Contribution of peripheral changes in CD137-mediated sciatic nerve crush-induced neuropathic pain

Authors: *L. CAO, A. A. WAKLEY, H. JACOBS, E. JORDAN, E. BARTLETT;
Univ. of New England, Biddeford, ME

Abstract: We have previously shown that the costimulatory molecule CD137L is involved in the development of neuropathic pain following sciatic nerve crush (SNC). CD137L knockout (KO) mice displayed reduced sensory sensitivity and faster recovery of sensory and motor functions following SNC. CD137L was found to be mediating its effects at the spinal cord level. In this study, we sought to identify potential CD137L-mediated changes in the peripheral nervous system that could contribute to the reduced neuropathic pain-like behaviors in B6.CD137L KO mice. First, inflammation-related markers within lumbar (L3-L6) dorsal root ganglia (DRG) were examined via real-time quantitative PCR (RT-qPCR) in a time course study (days 0, 3, 7, 14, 28, and 56; n=8/group). SNC induced notable upregulation of several pro-inflammatory cytokines (including CCL2, CCL3, CCL5, and TNF-alpha) in the B6 wild type (WT) but not the CD137L KO mice, while CD137L KO mice showed notable increases in the expression of the anti-inflammatory factors IL-10 and arginase-1 (Arg-1) following SNC. Second, we assessed whether CD137L KO mice showed faster regeneration of the injured sciatic nerve. A segment of sciatic nerve containing the injury site was analyzed via whole mount immunohistochemistry in a time course study (days 0, 3, 7, 14, 28, and 56; n=4/group). The sciatic nerve segments were classified as neurofilament 200 (NF200) positive (non-nociceptive fibers), calcitonin gene-related peptide (CGRP) positive (peptidergic c-fibers), and isolectin B4 (IB4) positive (non-peptidergic c-fibers). No significant differences were observed between WT and CD137L KO mice in terms of the three types of fibers or the volume of the traumatic neuroma formed at the injury site. On the other hand, in the pin prick behavioral assay (days 0-77, n=15-17/group), both WT and CD137L KO mice showed sensory recovery from the proximal to the distal end, with CD137L KO mice recovered faster at all testing sites compared to WT mice. Altogether, a proclivity for an anti-inflammatory state within the DRG in CD137L KO mice may contribute to the reduced neuropathic pain-like behaviors in CD137L KO mice.

Title: Latent Pain Sensitization unmasked byμ-δ opioid receptor heteromer in neuropathic and inflammatory pain

Authors: *K. E. INYANG[1], G. O. LAUMET[2], S. R. GEORGE[3];
[2]Physiol., [1]Michigan State Univ., East Lansing, MI; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Title: Latent Pain Sensitization unmasks μ-δ opioid heteromer in neuropathic and inflammatory painAuthors: Kufreobong E Inyang[1], Susan R George[2], Geoffroy Laumet[1]1 Department of Physiology, Michigan State University, East Lansing, MI, USA2 Department of Medicine and Pharmacology, University of Toronto, Toronto, Ontario, CanadaAbstract: Rodent models of latent pain sensitization can be used to study the episodic nature that chronic pain can exhibit. At pain remission, central sensitization is countered by the activity of endogenous opioid receptors. In animal models, latent pain sensitization can be unmasked by antagonizing opioid receptors resulting in pain relapse. Due to previous studies have focused predominantly on inflammatory pain, the presence of latent pain sensitization in animal model of chemotherapy-induced peripheral neuropathic pain and in female mice is unknown. This study investigates whether μ- and δ-OR suppress latent pain sensitization in model of chemotherapy-induced neuropathic pain in both sexes.There is significant evidence suggesting that μ-and δ-ORs form a heteromer that is capable of modulating pain sensitivity. The potential implication of the μ-δ OR heteromer in latent pain sensitization has not been fully explored due to a lack of tools to effectively modulate the heteromer. In this study, we were able to specifically target the μ-δ OR heteromer using a novel peptide to prevent its heteromerization. We then investigated whether disruption of the μ-δOR heteromer, after remission, reinstates pain hypersensitivity. At remission from cisplatin-induced neuropathic pain, antagonism of μOR and δOR reinstates pain hypersensitivity in both sexes. Disruption of the μ-δOR heteromer reinstates pain hypersensitivity in both sexes after remission from cisplatin-induced neuropathic and postsurgical pain. Taken together our findings suggest that the μ-δOR heteromer plays a crucial role in remission in various pain models and may represent a novel therapeutic target to prevent the relapse to pain and the transition to chronic pain.Acknowledgements: This study has been supported by the American Pain Society and the Rita Allen Foundation (G.L.).Competing interests: The authors except declare no competing interests.

Title: Role of calcitonin gene related polypeptide (CGRP) in diabetic neuropathic pain model dorsal root ganglion

Authors: *Z. HUMA[1], S. JADOON[2], K. RAUF[3];
[1]IBMS, Khyber Med. Univ., Peshawar, Pakistan; [2]Ayub Med. Col., Abbottabad, Pakistan;
[3]COMSATS Univ., Abbottabad, Pakistan

Abstract: Prolonged, uncontrolled diabetes mellitus patients are prone to develop injuries to peripheral nervous system. These lead to cellular and molecular alterations throughout the nociceptive pathway. Though pro-nociceptive neuronal and non-neuronal cellular alterations in the dorsal root ganglion (DRG), have been identified the molecular mechanisms in DRG are complicated and link several signaling pathways to induce and maintain NP culminating in release of Calcitonin Gene Related Polypeptide (CGRP). Metformin is postulated to have an indirect pro-neuropathic effect via reduction of Vitamins B6 and B12 via the Adenosine Monophosphate-activated Protein Kinase (AMPK). Studies have shown that activation of AMPK reverses NP effects by negatively regulating these signaling events and decreases the excitability of dorsal root ganglion neurons via calcium channels. Thus, the rationale of this study is to understand the pathways of nociceptive pain in diabetic neuropathy and the complex interplay of the disease and its drugs as hyperglycemia may lead to a down regulation of AMPK expression. Following ARRIVE guidelines and after approval from University ethical board, 32 Balb/c male and female mice, 8 to 10 weeks age and weighing 25 to 35gms were given Alloxan (200mg/kg) to establish an animal diabetic model. These Diabetic mice were then divided into three groups. Group A were observed for three weeks for neuropathy and then given i/p normal saline for 7 days while Group B similarly observed were given i/p Metformin (200 mg/kg) for 7 days. Group C were further subdivided into C1 and C2 with C1given i/p Metformin (200 mg/kg) for initial 7 days while Group C2 were given the same days. Both mechanical and thermal hyperalgesia and allodynia were weekly recorded in each group. Mice were dissected and their DRG isolated. Immunohistochemistry was done to observe the expression of CGRP. Analysis of the data was done using MS Excel, Graph Pad Prism software version 5.0, SPSS version 22.0 and ImageJ analyzer. Neuropathic pain was validated in all the groups by significantly developed ($p<0.001$) hyperalgesia and allodynia. Earlier Metformin administration reduced the developing hyperalgesia in both Group C1 ($p< 0.01$) and C2 ($p< 0.05$) as compared to control (Group A).The IHC parameters of CGRP expression showed $p < 0.0001$ in reducing CGRP expression in DRG slides of Group C1 and Group C2 as compared to Group A (control). CGRP is one of the key neuromodulators expressed in DRG in diabetic neuropathic pain. Earlier administration of Metformin, a cAMPK activator significantly reduces the developing hyperalgesia and the up regulated CGRP expression in DRG sections of diabetic neuropathic model.

Title: An unbiased approach to identifying changes in the gene expression profile of sensory neurons in painful diabetic neuropathy

Authors: ***D. GEORGE**, N. JAYARAJ, D. REN, R. MILLER, D. MENICHELLA; Northwestern, Chicago, IL

Abstract: Painful diabetic neuropathy (PDN) is a debilitating and intractable disease and characterized by neuropathic pain and small-fiber degeneration. Given the prevalence of the disease, there is a pressing need to identify new targets for the development of non-opioid, non-addictive, disease-modifying therapeutics for PDN. In patients with PDN, nociceptors within the dorsal root ganglion (DRG) become hyperexcitable and eventually degenerate, but the molecular mechanism underlying the phenomenon is still widely unknown. Our aim is to identify changes in the gene expression profile of the DRG neurons in PDN pathology to facilitate the discovery of novel druggable targets. Using a well-established mouse model of PDN, mice were either fed a regular diet (RD, 11% fat) or a high-fat diet (HFD, 42% fat) for 10 weeks during which these mice become obese, develop glucose intolerance, exhibit mechanical allodynia and show a decrease in the intra-epidermal nerve fiber density. We then used a single-cell RNA (scRNA-seq) sequencing approach using the 10X platform to capture the changes in the DRG in an unbiased fashion. As expected, analysis of the scRNA-seq identified both neuronal and non-neuronal clusters and several differentially expressed genes. Interestingly, we saw two closely related non-peptidergic clusters expressing a Mas-related G protein-coupled receptor (Mrgprd). While there were no differences in the expression of Mrgprd in one of the clusters (NP1 Type1), there seemed to be a significant increase in the expression of Mrgprd in a cluster we refer to as the NP1 Type2. To determine the functional relevance of the overexpression of Mrgprd, we used *in vivo* 2-photon calcium imaging with $Na_v1.8$ Cre-GCaMP6 animals fed an RD or HFD and examined whether administration of β-alanine (a known agonist of Mrgprd) in the hind paw would directly activate Mrgprd positive DRG neurons. We observed an increase in the number, as well as an increase in the magnitude of response in the HFD indicating the hyperexcitability of neurons expressing Mrgprd. Taken together, our data highlights an important role of the Mrgprd receptor in the generation and maintenance of hyperexcitability in a mouse model of PDN.

Title: Mitochondrial Calcium Uniporter Deletion Prevents Painful Diabetic Neuropathy by Restoring Mitochondrial Morphology and Dynamics

Authors: *N. JAYARAJ[1], D. GEORGE[1], S. HACKELBERG[1], D. REN[1], S. EDASERRY[1], C. RATHWELL[1], R. MILLER[2], J. SAVAS[1], R. MILLER[1], D. M. MENICHELLA[1];
[1]Northwestern Univ., Chicago, IL; [2]Rush Univ., Chicago, IL

Abstract: Painful diabetic neuropathy (PDN) is an intractable complication affecting 25% of diabetic patients. PDN is characterized by neuropathic pain accompanied by dorsal root ganglion (DRG) nociceptor hyperexcitability, resulting in calcium overload, axonal degeneration, and loss of cutaneous innervation. However, the underlying molecular pathways responsible for these effects are unknown. Using highly stringent quantitative proteomic analyses, we found that mitochondrial proteins are differentially expressed in DRG neurons from mice with PDN caused by a high fat diet (HFD). In particular, mitochondrial fission proteins were overexpressed. Electron microscopy demonstrated fragmented mitochondrial morphology in DRG nociceptors. *In vivo* calcium imaging revealed increased calcium signaling in $Na_V1.8$-expressing DRG neurons of HFD mice. Selectively deleting the mitochondrial calcium uniporter from these neurons restored normal mitochondrial morphology and dynamics, prevented axonal degeneration, and reversed mechanical allodynia. Hence, we propose that targeting calcium entry into nociceptor mitochondria may be a promising therapeutic approach for PDN patients. Moreover, these results may illuminate other neurodegenerative diseases involving similar underlying events.

Title: Activation of KeratinocyteGq-linked G-Protein Coupled Receptors Regulates Degeneration of Cutaneous Nerves

Authors: *A. BELMADANI, N. JAYARAJ, D. REN, D. GEORGE, C. RATHWELL, R. J. MILLER, D. MENICHELLA;
Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Painful diabetic neuropathy (PDN) is one of the most common complications of diabetes, affecting 25% of diabetic patients. DPN is characterized by small-fiber degeneration, which can progress to complete loss of cutaneous innervation and is accompanied by neuropathic pain. Uncovering the mechanisms underlying degeneration of cutaneous nerves in PDN remains a major challenge to finding effective and disease-modifying therapy. Keratinocytes are closely juxtaposed to cutaneous nerve terminals potentially enabling communication between keratinocytes and cutaneous afferents. Our aim is to identify mechanisms by which keratinocytes communicate with cutaneous afferents and how this signaling regulates axonal degeneration underlying neuropathic pain in PDN. In this study, we utilized a chemogenetic approach using DREADD receptors, synthetic receptors based on the structure of human muscarinic receptors that can be activated by the synthetic ligands clozapine and clozapine N-oxide (CNO). We genetically expressed stimulatory DREADD (hM3Dq) into K14 basal keratinocytes (K-14) in mice as a tool for mimicking the activation of Gq-linked G protein-coupled receptors (GPCRs) in K14-expressing basal keratinocytes. Histological characterization of the skin from mice expressing hM3Dq in K-14 positive cells revealed a clear thickening of the epidermis (as shown by H&E staining) due to K-14 expressing cell hyperproliferation (as shown by BrdU incorporation). Additionally, we observed reduced innervation of the epidermis (as shown by PGP9.5 staining), indicating that activation of K-14 Gq-linked GPCRs drives nerve fibers degeneration in the epidermis. Furthermore, transcriptional profiling of activated K-14 from the skin of K14-hM3Dq mice revealed downregulation of genes involved in neuronal survival and neurite outgrowth, including Nerve Growth Factor (NGF), artemin, a member of the Glial Cell-Derived Neurotrophic Factor (GDNF) ligand family, and Semaphorin 3D. Our results suggest that basal keratinocyte Gq-linked GPCRs could represent highly “druggable” and easily accessible targets for the development of therapeutics that by reversing axonal degeneration of cutaneous nerves in pathological conditions such as PDN could ameliorate the associated neuropathic pain.

Title: Differential keratinocyte expression of topical pain medication targets from patients with neuropathic pain: implications for personalized medicine

Authors: *P. J. ALBRECHT[1], Y. LIU[2], G. HOUK[1], B. RUGGIERO[1], D. BANOV[2], M. DOCKUM[1], M. CARVALHO[2], A. DAY[2], F. RICE[1], G. BASSANI[2];
[1]Integrated Tissue Dynamics, LLC, Rensselaer, NY; [2]Professional Compounding Centers of America, Houston, TX

Abstract: The overall objective of this study was to investigate potential cutaneous targets for topically applied active pharmaceutical ingredients, commonly utilized as a singularly delivered active or in combination with other actives, as a personalized medicine strategy for treating chronic pain. We set out to identify quantifiable, objective biomarkers in chronic painful skin to provide a tissue basis for directing individualized compounded topical preparations aimed to optimize the efficacy on a patient-by-patient basis. The intent of this preliminary, small-scale investigation was to demonstrate the potential for a larger proof-of-principle clinical trial of topical compounded formulations, which have seen an increase in use for various pain syndromes, including those of a neuropathic etiology, including post-herpetic neuralgia (PHN). Referencing 5 of the most common actives used in these formulations (ketamine, gabapentin, clonidine, baclofen, lidocaine), and 3 well-established cutaneous mediators (neuropeptides, cannabinoids, vanilloids), the study set out to determine if these neural signaling systems were present in epidermal keratinocytes from painful skin associated with PHN. A comprehensive immunolabeling platform was used to quantify each biomarker in skin biopsy epidermal keratinocytes taken from ipsilateral (pain) and contralateral (nonpain) dermatomes of an enriched cohort of PHN patients. Results demonstrate significant differential labeling among the cohort for each biomarker, consistent with mechanisms of action among keratinocytes. Importantly, the total biomarker panel indicates that the enriched cohort contains distinct subgroups. The heterogeneity of the cohort differences may explain studies that have not shown statistical group benefit from topically administered compounded therapies. Rather, the essential need for individual tissue biomarker evaluations is evident, particularly as a means to direct a more accurately targeted topical approach and generate positive clinical results.

Title: Heterogeneity of burst discharge in adult thalamic reticular nucleus neurons

Authors: *L. HARDING-JACKSON, J. BEATTY, C. COX;
Michigan State Univ., East Lansing, MI

Abstract: Long studied for its role in epilepsies and sensory processing disorders, the thalamic reticular nucleus (TRN) is an integral regulator of sensory processing circuits between thalamus and cortex. Most, but not all TRN neurons produce action potentials (APs) in two modes: burst-discharge when hyperpolarized, and tonic-discharge when depolarized. Burst discharge varies greatly in the frequency and duration of the transient AP discharge. We investigated potential mechanisms that may account for burst frequency variation and potential functional significance of these distinct populations. Whole-cell TRN neuron recordings from adult male and female C57BL6 mice revealed a broad range of burst frequencies ranging from 4-342 Hz (n=92). In neurons with high frequency discharge (>100Hz), the burst was composed of 8±7 APs (n=54), whereas slower burst discharges (50-100 Hz) had fewer APs (3±1, n=26). In tetrodotoxin nearly all neurons (n=47/48) produce a transient low threshold spike (LTS) which underlies the burst discharge. This depolarization was blocked by low concentrations of $NiCl_2$, suggestive of the role of T-type calcium current. The amplitude of the LTS was positively correlated with the burst discharge frequency and the number of APs/burst. The small conductance calcium-activated potassium (SK) channel antagonist, Apamin, increased number of APs/burst and the LTS amplitude indicating the role of SK current in regulating burst discharge. Prior studies suggest that T-type calcium channels are distributed throughout the dendrites in neurons with high frequency burst discharge. We investigated if this was similar in neurons with lower burst discharge frequencies. Using 2-photon laser scanning microscopy and a calcium indicator, we quantified calcium signals in response to transient somatic depolarization at proximal (10-50µm), intermediate (100-150µm) and distal (200-300µm) dendritic regions. Calcium signals were smaller in slow bursting neurons at proximal and intermediate regions compared to high frequency bursting neurons. There was no significant difference at distal locations. Addition of Apamin significantly increased calcium signal in proximal and intermediate regions of the high frequency bursting neurons, but not in slow bursting neurons. These data reveal that heterogeneous TRN burst discharge frequencies may represent cell populations with different dendritic ion channel composition and distribution. With these results, we aim to understand the consequence of TRN-dependent thalamic inhibition and provide greater insight into how perturbations within the region may lead to various neurological disorders.

Title: Rapid sensory adaptation in the mouse thalamocortical circuit, and the relative contribution of thalamic state

Authors: N. C. WRIGHT[1], P. Y. BORDEN[1], Y. LIEW[1], M. F. BOLUS[1], W. M. STOY[2], C. R. FOREST[2], G. B. STANLEY[1];
[1]Coulter Dept. of Biomed. Engin., [2]Mechanical Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Rapid sensory adaptation describes the interaction between the perception of a given sensory stimulus and recent stimulus history, spanning milliseconds to seconds. Despite its profound, complex, and widely-reported effects across all across sensory systems, the mechanistic basis of rapid sensory adaptation is poorly understood. A wide range of studies primarily in in-vitro and anesthetized preparations have pointed to the emergence of adaptation effects at the level of primary sensory cortex, with only modest signatures in earlier stages of processing. Yet the nature of rapid adaptation and how it shapes sensory representations during wakefulness, and thus the potential role in adaptive changes in perception, are unknown, as are the mechanisms that underlie this phenomenon. To address these knowledge gaps, we recorded spiking activity in primary somatosensory cortex (S1) and the upstream ventral posteromedial (VPm) thalamic nucleus in the vibrissa pathway of the awake mouse, and quantified responses to whisker stimuli delivered either in isolation or embedded in an adapting sensory background. We found that during wakefulness, cortical sensory responses were indeed adapted by persistent sensory stimulation; mean feature-evoked rates and synchronous spiking of S1 putative excitatory neurons were profoundly adapted, and inhibitory neurons only modestly so. Recordings in VPm and further optogenetic manipulation experiments suggest this largely reflected changes in thalamic spike timing, with little contribution from thalamocortical or intracortical synaptic depression. A network model supports this conclusion, and further suggests that robust feedforward inhibition serves to dampen excitatory firing in the adapted condition. Taken together, these results suggest that cortical adaptation results from changes in the timing of thalamic input, and the way in which this differentially impacts cortical excitation and feedforward inhibition, pointing to a prominent role of thalamic gating in rapid adaptation of primary sensory cortex.

Title: Role of PBN projecting CeA^{pdyn} amygdala neurons in nociception

Authors: H. FUNAHASHI, D. PAVLENKO, K. SAKAI, *T. AKIYAMA;
Univ. of Miami, Miami, FL

Abstract: The role of the amygdala in the processing of pain and itch has been studied. A recent study revealed that the parabrachial nucleus (PBN) projecting central nucleus (CeA) amygdala neurons regulate pain. The neuronal subpopulations in the CeA include prodynorphin (Pdyn)-expressing neurons. In this study, we investigated whether the optogenetic stimulation of Pdyn+ amygdala neurons and PBN projecting CeA^{pdyn} amygdala neurons altered pain and itch sensitivity in mice. To modulate the activity of Pdyn+ amygdala neurons, we used Pdyn-cre transgenic mice. An AAV encoding a Cre-dependent fast opsin (ChrimsonR) fused to the red fluorescent protein (rAAV5/Syn-FLEX-ChrimsonR-tdTomato; Addgene) was bilaterally injected into the CeA. The injection volume was 0.25 µl, injected over 1 min using a glass needle and plunger. An optic fiber (200 µm diameter) was implanted directly above each injection site or PBN and fixed to the skull with dental cement. Mice were allowed three weeks to recover from surgery before behavior testing. For scratching behavior test, histamine (50 µg/10 µl; Sigma-Aldrich) or chloroquine diphosphate salt (100 µg/10 µl; Sigma-Aldrich) was injected intradermally into the shaved rostral back skin. Behavior was video recorded for 30 min. For optogenetic stimulation, light pulses were delivered at constant intensity and frequency (3 mW, 2 Hz) via an LED driver connected to a waveform generator. Optogenetic stimulation of Pdyn+ amygdala neurons or PBN projecting CeA^{pdyn} amygdala neurons inhibited histamine- and chloroquine-evoked scratching. Additionally, optogenetic stimulation of Pdyn+ amygdala neurons suppressed the number of Fos positive neurons increased by intradermal injection of chloroquine. For thermal pain sensitivity, paw withdrawal latencies were measured by Hargreaves plantar test. Hindpaw heat withdrawal latency was increased by optogenetic stimulation of Pdyn+ amygdala neurons and PBN projecting CeA^{pdyn} amygdala neurons. For mechanical pain sensitivity, paw withdrawal thresholds were determined by von Frey filament test. Optogenetic stimulation of PBN projecting CeA^{pdyn} amygdala neurons, but not Pdyn+ amygdala neurons, increased the mechanical withdrawal threshold. Our data indicate that PBN projecting CeA^{pdyn} amygdala neurons regulate nociception.

Abstract: The nodose and jugular vagal ganglia supply sensory innervation to the airways and lungs. Jugular vagal airway sensory neurons wire into a brainstem circuit with ascending projections into the submedius thalamic nucleus (SubM) and ventrolateral orbital cortex (VLO), regions known to regulate the endogenous analgesia system. Here we investigate whether the SubM-VLO circuit exerts descending regulation over airway vagal reflexes in male and female rats using a range of neuroanatomical tracing, reflex physiology and chemogenetic techniques. Anterograde and retrograde neuroanatomical tracing confirmed connectivity of the SubM and VLO. Laryngeal stimulation in anesthetized rats reduced respiration, a reflex that was potently inhibited by activation of SubM. Conversely, inhibition of SubM potentiated laryngeal reflex responses, while prior lesions of VLO abolished the effects of SubM stimulation. In conscious rats, selective chemogenetic activation of SubM neurons specifically projecting to VLO significantly inhibited respiratory responses evoked by inhalation of the nociceptor stimulant capsaicin. Jugular vagal inputs to SubM via the medullary paratrigeminal nucleus were confirmed using anterograde transsynaptic conditional herpes viral tracing. Respiratory responses evoked by microinjections of capsaicin into the paratrigeminal nucleus were significantly attenuated by SubM stimulation, whereas those evoked via the nucleus of the solitary tract were unaltered. These data suggest jugular vagal sensory pathways input to a nociceptive thalamocortical circuit capable of regulating jugular sensory processing in the medulla. This circuit organization suggests an intersection between vagal sensory pathways and the endogenous analgesia system, potentially important for understanding vagal sensory processing in health and mechanisms of hypersensitivity in disease.

Title: A-fiber sensation strongly contributes to pleasantness of deep pressure and CT-fiber mediated pleasant touch

Authors: *L. K. CASE[1,2], N. J. MADIAN[2], M. V. MCCALL[2], M. BRADSON[2], J. LILJENCRANTZ[2,3], A. T. CHESLER[2], M. C. BUSHNELL[2];

[1]Anesthesiol., UC San Diego, La Jolla, CA; [2]Natl. Ctr. for Complementary and Integrative Health, NIH, Bethesda, MD; [3]Sahlgrenska Acad., Univ. of Gothenburg, Gothenburg, Sweden

Abstract: C-tactile (CT) afferents are unmyelinated sensory afferents in hairy skin with a maximal response to slow, gentle stroking. Firing of CT afferents strongly correlates with ratings of touch pleasantness, leading to the labelling of the CT pathway as a social-affective sensory pathway (Loken, Wessberg et al. 2009). Patients with AB deafferentation and consequent loss of light touch sensation still perceive slow gentle stroking as pleasant, corroborating its C-fiber origin (Olausson, Lamarre et al. 2002). Recently, however, ablation of the spinothalamic pathway (by which C-fiber sensations ascend to the thalamus) was found to impair all C-fiber mediated sensations of pain, temperature, and itch *without* any effect on pleasant touch perception (Marshall, Sharma et al. 2019). This finding suggests that integration of A and CT fiber input occurs prior to its projection to the thalamus. However, it remains unclear how A fiber sensory input contributes to CT-associated pleasant sensation. In addition, the reliance of pleasant pressure perceived in deeper tissues on A or C fibers is unknown. We conducted pressure nerve blocks in 5 healthy human volunteers (3 males and 2 females, ages 21-25) to eliminate A fiber input and tested the pleasantness of gentle stroking and deep pressure before appreciable loss of C-fiber function. Our findings show that once A-fiber sensation is eliminated, the perceived intensity and pleasantness of *both* gentle stroking and deep pressure are nearly abolished. In contrast, intensity and pleasantness of stroking and pressure are maintained in the unaffected arm. These findings demonstrate for the first time that perceiving the pleasantness of deep pressure critically depends on A fibers. In addition, A-fiber input appears to play a strong role in the pleasantness of CT-optimal gentle brushing. We extend the conclusion of Marshall and colleagues to suggest that in typical individuals, both A and C sensory afferents are important contributors to CT pleasant sensation.

Title: The potential clinical utility of cuff-pressure versus heat-based paradigms to measure conditioned pain modulation: an exploratory study in healthy individuals and those with chronic pain

Authors: *R. EL-SAYED[1], C. FAUCHON[2], L. B. KISLER[3], J. A. KIM[3], S. FIROUZIAN[3], N. R. OSBORNE[3], K. D. DAVIS[4];

[1]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [2]Univ. Hlth. Network, Toronto, ON, Canada; [3]Krembil Res. Inst., Toronto, ON, Canada; [4]Krembil Res. Inst, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Background: Conditioned pain modulation (CPM) is a physiological measure thought to reflect an individual's endogenous pain modulation system. CPM refers to the reduction of pain evoked by a painful test stimulus (TS) applied to one body region due to a painful conditioning stimulus (CS) applied to another region. CPM varies across individuals and provides insight into chronic pain pathophysiology. There is growing evidence that CPM may help predict individual pain treatment outcome. However, paradigm variabilities and practical issues have impeded widespread clinical adoption of CPM assessment. The aim of this exploratory study was to compare two different CPM paradigms in healthy controls (HCs) and those with chronic pain. **Methods:** All participants provided informed consent to REB approved protocols. CPM was evaluated in 11 people with chronic pain and 9 HCs. Each participant underwent two CPM paradigms: one used heat stimuli (Q-Sense, Medoc Inc) and the other used pressure cuff stimuli (Nocitech). Stimulus intensities were individually set to evoke pain intensity rated at ~50/100. The TS were applied before and during a CS applied to a contralateral limb. The CPM effect was calculated as a %change of pain evoked by the TS with vs without the CS, with negative scores indicating pain inhibition. **Results:** The pressure paradigm required less time to administer than the heat paradigm. In the chronic pain group, most individuals exhibited inhibitory CPM using either the heat (*N*= 5 CPM<0%, 3 CPM=0%, 3 CPM>0%) or pressure (*N*= 7 CPM<0%, 1 CPM=0%, 3 CPM>0%) paradigms. Heat- and pressure- evoked CPM was correlated (r=0.48) in those with chronic pain. In contrast, in the HC group, CPM evoked by pressure stimuli (-52%+/-39%) was more pronounced than from heat stimuli (0.5%+/-32%). Most HCs (7 of 9) did not exhibit inhibitory CPM using the heat paradigm (CPM 0-43%) but did exhibit strong inhibitory CPM evoked by the pressure paradigm (CPM -20% to -90%). **Conclusion:** These findings highlight that compared to heat-based, a pressure-based paradigm can assess CPM in chronic pain with the advantages of producing consistent findings to the literature in HCs, using a simpler system, a shorter test time and lower cost; important factors for both research and clinical use.

Title: Circuit-targeted fMRI of brain-wide inputs to posterior medial thalamic nucleus

Authors: *N. LI, S. GHOSH, M. SCHWALM, W. ZHENG, A. JASANOFF;
Biol. Engin., MIT, Cambridge, MA

Abstract: The posterior medial thalamic nucleus (POm) plays critical roles in modulating somatosensory perception, motor behavior, and well-learned sensorimotor habits. The circuit mechanisms underlying such modulatory functions involve pathways from both cortical and subcortical brain regions, but the process whereby these disparate inputs combine to influence POm function in sensory perception is poorly understood. Here we study the integration of brain-wide inputs to POm during somatosensory processing using a novel neural activity indicator called NOSTIC, which transduces neuronal calcium signals into fMRI responses. NOSTIC is targeted to POm inputs using a retrograde trans-synaptic herpes viral vector, enabling selective functional imaging of monosynaptic POm afferents. Our results reveal several clustered POm input regions engaged by stimulation of the rat forepaw. The activated POm input regions are located not only in the primary somatosensory cortex and secondary somatosensory cortex but also in additional deep brain regions, such as superior colliculus and zona incerta. Our findings suggest mechanisms by which multisensory information impinges on somatosensory processing and provide a basis for further investigation of the subcortical pathways involved in thalamic modulatory roles.

Title: Single-cell RNA sequencing defines distinct populations of microglia after peripheral nerve injury

Authors: S. TANSLEY[1,2], S. UTTAM[1], ***A. UREÑA GUZMÁN**[1,3], M. YAQUBI[4], L. HEALY[4], J. S. MOGIL[1,2,5], A. KHOUTORSKY[1,5];
[1]Dept. of Anesthesia and Fac. of Dent., [2]Dept. of Psychology, [3]Div. of Exptl. Med., McGill Univ., Montreal, QC, Canada; [4]Neuroimmunology Unit, Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [5]Alan Edwards Ctr. for Res. on Pain, McGill Univ., Montreal, QC, Canada

Abstract: Microgliosis in the spinal dorsal horn caused by peripheral nerve injury contributes to the development of neuropathic pain. Interestingly, microglia inhibition reverses mechanical allodynia caused after peripheral nerve injury only in male mice. Microglia from the brain present transcriptional sex-differences as well as distinct subpopulations in health and disease. To further study the potential mechanisms by which microglia promote pain, and to investigate

changes in their transcriptional states, we performed microglia single-cell RNA-seq (scRNA-seq) following spared nerve injury (SNI) in male and female mice at different phases of pain development. We collected the lumbar spinal cord of male and female naive C57BL/6 mice as well as mice of both sexes at day 3 (developmental phase), day 14 (early chronic phase), and 5 months (chronic phase) post-SNI and sham controls. One biological sample consisted of four pooled lumbar segments. Unsupervised clustering analysis of single-cell RNA sequencing data revealed eleven distinct microglia clusters, with uniquely expressed genes identified in seven of them. Differentially expressed genes (DEGs) were found across time points and between both sexes, with a higher number of DEGs present in male mice. Gene ontology enrichment analysis pointed to clusters involved in proliferation, immune response, and signal transduction. Microglia belonging to each cluster were present in both SNI and sham groups. However, males showed a higher proportion of microglia belonging to clusters with high expression of proliferation-related genes when compared to female mice. To confirm differences in proliferating microglia, we labeled cells with Ki67, a proliferation marker, and Iba1, a microglia marker. Quantification of Ki67-positive microglia in the dorsal horn spinal cord three days post-SNI showed a significantly higher number of proliferating microglia in males as compared to females (68.85 ± 5.89, and 46.6 ± 1.83, respectively, $p<0.011$), with no differences in total microglia (82.81 ± 5.52 in males, and 76.41 ± 1.84 in females, $p=0.313$). We also identified a male-specific microglia cluster with an inflammatory profile restricted to the early time point. Our findings are consistent with previous studies showing that male microglia display stronger inflammatory responses as compared to female microglia. The results of this study have the potential to contribute to the identification of subsets of microglia involved in the development and establishment of chronic pain, as well as providing evidence for sex-specific responses of microglia to peripheral nerve injury.

Title: Spinal cMyc and SIRT3 plays important role in HIV gp120 with morphine-induced neuropathic pain.

Authors: X. ZHU, K. HAYASHI, H. YI, J. GU, K. TAKAHASHI, Y. KASHIWAGI, S. LIU, ***S. HAO**;
Univ. of Miami, Miami, FL

Abstract: Opiate use disorder and human immunodeficiency virus (HIV) infection are two major public health problems. Chronic morphine use up-regulates HIV entry into immune cells. Emerging clinical data suggests that repeated use of opioid pain medications can increase neuropathic pain (NP) in people living with HIV. Thus, it is significant to elucidate the exact mechanisms of chronic pain. HIV gp120 increases the expression of transcription factor c-Myc in mesangial cell proliferation. Sirtuins 3 (Sirt3) deacetylates MnSOD and thereby activates it for scavenging $mtO_2^{\bullet-}$. In the present study, we investigated the role of cMyc and Sirt3 in a HIV coat glycoprotein gp120 with morphine (gp120/M)-induced neuropathic pain state. HIV-related neuropathic pain was induced by repeated administration of intrathecal recombinant HIV-1 gp120 and morphine. Mechanical allodynia was assessed using von Frey filaments. Protein expression of spinal cMyc, EZH2, and SIRT3 was examined using Western blots. Intrathecal administration of antisense oligonucleotides against cMyc, GSK126 (EZH2 inhibitor), mito-Tempol (Mito-T, a $mtO_2^{\bullet-}$ scavenger) or recombinant Sirt3 (rSIRT3) was given intrathecally. The image of $mtO_2^{\bullet-}$ in the spinal dorsal horn was examined using MitoSox Red (mitochondrial superoxide indicator) image assay. HIV-gp120 with morphine induced mechanical allodynia lasting for over 3 weeks. HIV-gp120/M upregulated the expression of cMyc, EZH2, and down-regulated Sirt3 in the spinal dorsal horn. Intrathecal administration of antisense oligonucleotides against cMyc, GSK126 (EZH2 inhibitor), Mito-T, or recombinant Sirt3 (rSIRT3) reduced mechanical allodynia in the gp120/M neuropathic pain model. Using ChIP assay, **the enrichment of** H3K27me3 binding to SIRT3 gene promoter region was increased in gp120/M treated rats compared to that in control group. These results suggest that spinal transcriptional factor cMyc, epigenetic writer EZH2, and Sirt3 play an important role in the HIV gp120-related neuropathic pain state, and provide evidence for a novel approach to treating chronic pain due to HIV/opioid.

Title: Computational modeling predicts dorsal columns are involved in fast-acting sub-perception spinal cord stimulation (SCS)

Authors: *J. E. GILBERT[1], N. D. TITUS[1], T. C. ZHANG[3], R. ESTELLER[3], W. M. GRILL[2]; [1]Biomed. Engin., [2]Biomed. Engineering, Electrical and Computer Engineering, Neurobiology, and Neurosurg., Duke Univ., Durham, NC; [3]Neuromodulation Res. and Advanced Concepts, Boston Scientific Neuromodulation, Valencia, CA

Abstract: Sub-perception SCS has emerged as a successful therapy for chronic neuropathic pain that provides therapeutic efficacy, but unlike conventional SCS does not elicit paresthesia. Sub-perception SCS at high frequencies (1-10 kHz) typically has a slow (hours – days) onset of analgesia, but recent studies of sub-perception SCS at lower frequencies (≤150Hz) demonstrated pain relief with a more rapid onset (minutes) following placement corresponding to paresthesia-pain overlap and titration of the pulse width and frequency. Although some sub-perception SCS mechanisms of action may involve dorsal horn effects, ≤150Hz sub-perception SCS may also engage dorsal column (DC) axons, given that the electrode placement and analgesic timing are consistent with conventional SCS, which activates DC axons. We quantified how SCS parameters (placement, pulse width, frequency, and amplitude) influenced activation of DC axons and subsequent neural responses in the dorsal horn using an integrated computational model. We calculated potentials generated by a bipolar SCS electrode in the rat spinal cord using a finite element model and applied the potentials to an axon model tuned to match measured DC axon responses. The outputs of the DC axon models were inputs to a validated network model of the spinal dorsal horn that includes representations of center and surround peripheral receptive fields. We measured the firing rate of the model center receptive field wide-dynamic range (WDR) projection neuron as a proxy for pain. SCS applied at amplitudes as low as 60% of the predicted sensory threshold with appropriately titrated pulse widths activated model DC axons and subsequently reduced WDR firing rates across all tested frequencies. However, WDR firing increased with SCS amplitude, creating a non-monotonic response curve with maximal suppression at 75-85% of the sensory threshold. Minimizing WDR firing rate required spatially targeting stimulation to include surround receptive fields. While all tested frequencies generated reductions in model WDR firing rates, the greatest reductions occurred between 50Hz and 90Hz. High frequency (1.2kHz and 10kHz) SCS produced small and transient reductions in model WDR firing rates suggesting different underlying mechanisms of action. Our results support the hypothesis that sub-kHz, sub-perception SCS generates rapid analgesia by activating a small number of dorsal column axons. Furthermore, our results demonstrate the importance of spatial targeting and appropriate selection of amplitude and pulse width for maximum suppression of model WDR neuron firing rate.

Title: Terpenes Found in Cannabis sativa are Potential Novel Therapeutics for Chemotherapy-Induced Neuropathic Pain

Authors: *R. HECKSEL, A. KERESZTES, J. M. STREICHER;
Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: *Cannabis sativa* has been cultivated and used both medically and recreationally for thousands of years. However, there continues to be a lack of literature on some potentially therapeutic compounds found in the cannabis plant called terpenes. Terpenes are a class of organic chemicals that give plants, including cannabis, their distinct odors and flavors. Anecdotally, terpenes are thought to enhance the cognitive and therapeutic effects caused by certain cannabis strains; however there is very little, if any, empirical evidence for this claim. We previously found that some of the major terpenes found in *Cannabis sativa*, namely α-humulene, β-pinene, geraniol, and linalool, induce tetrad effects (analgesia, hypothermia, hypolocomotion and catalepsy) at high doses in mice. These tetrad behaviors could be blocked by cannabinoid receptor type 1 (CB1) and adenosine A2a antagonists, suggesting CB1 and A2a receptor mediated mechanism. In our current study, we sought to extend these findings to determine if these terpenes could be novel treatments for neuropathic pain using a mouse model of chemotherapy-induced peripheral neuropathy (CIPN). We also investigated the rewarding or aversive effects of terpenes using a Conditioned Place Preference (CPP) mouse model. Our results indicate that acute terpene administration in CIPN induced efficacious anti-nociception and dose-dependently induced analgesic tolerance upon chronic treatment. CPP results indicated significant aversive behavior for animals treated with α-humulene, β-pinene, and β-caryophyllene. Interestingly, administration of geraniol and linalool produced neither aversion nor preference. These findings suggest that geraniol and linalool could be novel efficacious therapies for CIPN with no aversive or rewarding side effects. Seeking a mechanism for these results, we used an *in vitro* model of BV-2 microglia cells expressing an NFκB-luciferase

reporter stimulated with lipopolysaccharide. This model demonstrated dose-dependent decreases in NFκB activation for all terpenes with full blockade by α-humulene, β-pinene, and geraniol, suggesting these to be the most efficacious anti-inflammatory agents. Using CHO cells expressing a human CB1 receptor, we also found that all terpenes produced rimonabant-sensitive CB1 activation, suggesting that all terpenes act as CB1 agonists. Anti-inflammatory and CB1 activity could thus be mechanisms for the anti-nociception observed in CIPN, which will be tested in future studies. Translationally, this research could help identify specific cannabis terpenes beneficial for medical *Cannabis* strains used to treat pain or inflammatory conditions.

Title: Widespread pressure conferred by a weighted blanket reduces chronic pain in adults with high trait anxiety

Authors: *J. N. BAUMGARTNER[1], D. QUINTANA[1], L. LEIJA[2], L. CASE[1];
[1]Anesthesiol., Univ. of California San Diego, La Jolla, CA; [2]Psychological Sci., Univ. of San Diego, San Diego, CA

Abstract: Deep pressure is an affective touch stimulus that has been found to increase pleasantness ratings and decrease anxiety. Recent work has also demonstrated analgesic effects of deep pressure on experimentally evoked pain. However, the effect of deep pressure on *chronic* pain and the mechanisms underlying its pain-relieving effects are unknown. Emerging evidence suggests that weighted blankets (WB) – blankets sewn with weighted materials to provide deep widespread pressure to the body – reduce anxiety and insomnia, factors known to influence pain. We hypothesized that wearing a WB would reduce ratings of chronic pain, mediated by improvements in anxiety and sleep. In a remote, smartphone-based ecological momentary assessment (EMA) study, 93 adults with chronic pain diagnoses (79% female; age $M = 43.54$ $SD = 12.32$) were randomized (stratified by sex) to wear a heavily WB ($n = 49$; 15 pounds) or a lightly (placebo control) WB ($n = 44$; 5 pounds) once for 15-minutes and then overnight for seven days. Participants were blinded to the manipulation of blanket weight. Participants rated their initial expectation for pain relief from their blanket and made daily ratings of pain, anxiety, and sleep quality on visual analog scales. Chronic pain, trait anxiety, and sleep disturbance were

assessed from before wearing the WB to after the week-long intervention using validated questionnaires. After controlling for trait anxiety, we obtained a significant time x group interaction (p = .04, Cohen's f = .18) demonstrating reductions in chronic pain from before to after the intervention in the heavily WB group relative to the lightly WB group. This effect was maintained after controlling for expected pain relief (p = .04, Cohen's f = .19). Post-hoc analyses revealed that individuals reporting high trait anxiety obtained greater pain reductions from the heavily WB than the lightly WB (p < .01, Cohen's f = .56), even after controlling for expected pain relief (p < .01, Cohen's f = .60). In contrast, there were no significant differences in pain reductions between the two blankets for individuals low in trait anxiety (p = .16). Blanket-related pain reductions were not mediated by reported changes in anxiety or sleep, suggesting direct sensory effects on pain perception. We propose effects of sensory gating and/or changes in interoceptive sensibility as candidate mechanisms to be investigated in future studies. Overall, these results demonstrate that widespread deep pressure from a WB may be an effective and low-cost therapeutic tool for highly anxious adults living with chronic pain.

Title: Recombinant GABAergic progenitors releasing conopeptide MVIIA alleviate hypersensitivity in rat models of neuropathic pain

Authors: *B. MARIN, M. HERNANDEZ, J. SAGEN, S. JERGOVA;
Univ. of Miami, Miami, FL

Abstract: Chronic pain is a debilitating condition affecting quality of life. Treatment of chronic pain is clinically challenging due to the development of tolerance and addiction to analgesic drugs, such as opioids. Recombinant cell-based therapy provides a new avenue for the management of chronic pain because it can continually produce and secrete analgesic substances at local pain sites in the spinal cord. One of the hallmarks of neuropathic pain is a reduction of GABAergic inhibitory signaling in the spinal cord that leads to exaggerated hyperexcitability of spinal dorsal horn neurons. Transplantation of GABAergic neuronal cells may restore the inhibitory potential in the spinal cord and replace dysfunctional interneurons. Grafted cells may also release analgesic peptides by means of genetic engineering to further enhance the benefits of cell-therapy approach. The omega-conopeptide, MVIIA, an N-type Ca2+ channel blocker, was one of the earliest tested treatments for severe pain in animal models and is in clinical use marketed as FDA approved Prialt (Ziconotide). However, due to its poor penetration through the blood brain barrier it must be delivered intrathecally. The goal of this project is to develop

transplantable recombinant GABAergic cells releasing MVIIA that can alleviate pain-like behavior following peripheral and spinal cord injury. Rat models of chronic constriction of the sciatic nerve for peripheral neuropathic pain and spinal clip compression for spinal cord injury were used to induce chronic pain. Animals were tested weekly for the presence of tactile, cold and heat hypersensitivity. Rat embryonic E14 neuronal progenitors were harvested from medial ganglionic eminence and transfected with p_lenti_MVIIA. Their viability, proneuronal phenotype, and the ability to release recombinant MVIIA were confirmed via immunostaining and FLISA analysis. Recombinant, naive cells or saline were intraspinally injected into animals when signs of chronic pain were detected. An analgesic effect of both recombinant and naive grafts was observed in both pain models compared to saline injected animals, with more robust effect in the recombinant graft group, with hypersensitivity in recombinant graft groups showing progressive decline over several weeks. Conditioned place preference with gabapentin revealed significant reduction of ongoing pain in both graft groups, with stronger effect in the recombinant graft group. Inflammatory biomarkers Iba-1, IL1-β, and TNF-α were reduced in treated animals compared to controls. Our results demonstrate the enhanced beneficial effect of targeted recombinant cell-based therapy in the management of chronic pain.

Title: Identification of cannabinoid receptor ligands within the Conus venom.

Authors: *S. JERGOVA[1], K. LIEBMAN[1], N. CHANDNANI[1], S. C. GROSS[1], J. IMPERIAL[2], B. M. OLIVERA[2], J. SAGEN[1];
[1]Univ. of Miami, Miami, FL; [2]Univ. of Utah, Salt Lake Cty, UT

Abstract: Chronic neuropathic pain is a clinically challenging condition insufficiently controlled by current pharmacotherapy. Cannabinoid (CB) receptors have been recently recognized as valuable targets for various clinical indications. Several preclinical studies showed strong analgesic effects of CB1 receptor agonists. However, most of the drugs used therapeutically that interact with CB receptors are derived from cannabis and due to their psychoactive components are not be widely used for pain management. Therefore, selective ligands of CB receptors that do not induce side effects are of clinical interest. The venom of marine snail genus Conus represents a natural source of various peptides with potent antinociceptive activity. We have previously screened several Conus venoms for their ability to induce CB1 receptor internalization using HEK293 cells expressing CB1 receptor. The most potent samples were further fractionated by HPLC and screened in vitro and in vivo. C. Textile venom samples were selected as the best

candidate to search for CB1 receptor ligand. The aim of this study was to identify the CB1 ligand(s) withing the C. Tex HPLC venom fractions that can be further developed for pain therapies, and to conduct similar screening to identify CB2 receptor ligands. HEK 293 cells expressing CB1 or CB2 receptors were incubated with venom fractions, CP55,940 or WIN55,212-2 as positive controls and confirmed by selective CB1 and CB2 antagonists. Internalization of CB receptor was evaluated by immunofluorescence. Analgesic effects of the most potent subfractions were evaluated in the formalin model and peripheral and central pain via intrathecal delivery using Alzet pumps for chronic infusion. After each set of in vitro and in vivo evaluations, the most potent samples were further fractionated and evaluated. Immunoprecipitation was conducted to isolate possible CB1 receptor ligand from the C. Tex subfraction and the sample was analyzed by mass spectrometry. Results showed C. Geo venom fractions were the most potent inducing CB2 receptor internalization. Their effect was reduced by proteolytic enzymes, suggesting a peptidergic component. The selected C. Tex subfraction showed analgesic effects in animal models and stability when administered via intrathecal pumps for 4 weeks. The search for CB1 receptor ligand was successful in identifying the possible sequence of the active fraction. These findings indicate that CB-active conopeptide derivatives have potential for development as a chronic pain therapy.

Abstract: Pain syndromes such as small fiber neuropathy (SFN) can be linked to mutations in voltage-gated sodium channels (Na_vs). Several Na_V mutations are described, and many were shown by manual patch-clamping to display gain-of-function characteristics. In some very rare individual cases, approved drugs were identified that specifically interact with the mutations and make the channel more sensitive e.g. for a specific local anesthetic. Such rare constellations can support the patients' clinical treatment , which is often insufficient, leaving the patient with severe untreated symptoms over years.Within the framework of the Sodium Channel Network Aachen (SCN^{Aachen}) we aim to (i) identify mutation-induced patient-specific Na_V gating changes, and (ii) systematically screen for US/EU-approved drugs, which specifically target mutation-induced Na_V malfunctions in a favorable manner. To this end, we use stable cell lines and HEK/ND7 cells transiently expressing Nav1.7 and Nav1.8 variants to comprehensively characterize mutation-induced functional changes in activation and inactivation gating and to screen a compound library of approved drugs on the SyncroPatch, a high-throughput electrophysiology robot. In addition to several known Na_v mutations, we will characterize variants identified in a cohort of SFN patients at the RWTH Aachen University Hospital with respect to their biophysical effects, temperature dependence and pharmacological profiles. We will present the results of this extensive work and thus provide a high-throughput approach for the identification of personalized treatment options for pain patients.

Title: Genetic deletion of neuronal F2rl1 gene and pharmacological inhibition of protease-activated receptor-2 attenuates oral cancer nociception in mice.

Authors: ***N. H. TU**[1], K. INOUE[1], D. H. KIM[1], H. D. TRAN[1], Y. TAGUCHI[2], J. C. DOLAN[1], S. YAMANO[1], L. E. EDGINGTON-MITCHEL[3], N. W. BUNNETT[1], B. L. SCHMIDT[1]; [1]NYU Col. of Dentistry, Bluestone Ctr. for Cli, New York, NY; [2]Dept. of Periodontology, Osaka Dent. Univ., Osaka, Japan; [3]Bio21 Inst., Univ. of Melbourne, Melbourne, Australia

Abstract: Oral squamous cell carcinoma (SCC) secretes proteases into the cancer microenvironment. These secreted proteases cleave protease-activated receptor-2 (PAR_2) which in turn initiate nociceptive signaling. PAR_2 is upregulated in the lingual nerve of patients with tongue cancer (oral SCC). We hypothesize that genetic deletion of *F2rl1* (the gene that codes for PAR_2), or pharmacological inhibition of PAR_2, attenuates oral cancer nociception. To test this hypothesis, we undertook experiments with *Par2 Nav1.8* knockout mice (the *F2rl1* gene is knocked out in $Na_v1.8$-positive neurons); wild type C57BL/6J mice were used as a control. Over the course of 16 weeks, 100 µg/mL of the carcinogen 4-Nitroquinoline 1-oxide (4NQO) was administered in the mouse drinking water to induce oral SCC. Simultaneously, mice were trained weekly in a dolognawmeter®, a validated operant assay of orofacial nociception. The dolognawmeter® assay was performed once a week for 28 weeks to quantify orofacial dysfunction secondary to oral cancer nociception. In a second experiment, *F2rl1* RNAi was injected into the tongue of wild type mice with 4NQO-induced oral SCC. In a third experiment, human oral SCC (HSC-3) supernatant was injected into the paw of *Par2 Nav1.8* and wild type mice with and without administration of the PAR_2 antagonist GB88. We observed attenuated nociception at 28 weeks in *Par2 Nav1.8* mice with 4NQO-induced oral SCC [83.4 ± 173.8 (%) in *Par2 Nav1.8* versus 221.2 ± 238.7 (%) in wild type]. Similarly, we found attenuated cancer nociception 28 weeks after the first administration of 4NQO in mice in which the *F2rl1* gene was genetically deleted through RNAi [271.6 ± 448.5 (%) in *F2rl1* RNAi versus 580.9 ± 391.6 (%) in random RNAi]. *Par2 Nav1.8* mice exhibited attenuated nociception in the paw secondary to HSC-3 supernatant injection at 1, 3, and 6 hour(s) post-injection [0.3 ± 0.1 (g) in *Par2 Nav1.8* versus 0.1 ± 0.05 (g) in wild type at 6 hours]. Pharmacological inhibition of PAR_2 by GB88 attenuated nociception in the paw following injection of HSC-3 supernatant in wild type mice at 1, 3, 6, and 12 hour(s) post-injection [0.4 ± 0.1 (g) in GB88 versus 0.05 ± 0.05 (g) in control at 6 hours]. We infer from these findings that PAR_2 is a central component of the nociceptive signaling mechanism responsible for oral SCC pain. Our findings may open new avenues for the development of genetic or pharmacological approaches for treating oral cancer pain by targeting PAR_2.

Title: Early life pain experience alters pain behaviour and pain related activity in the somatosensory and the medial prefrontal cortices in adulthood

Authors: *P. CHANG, L. FABRIZI, M. FITZGERALD;
Univ. Col. London, London, United Kingdom

Abstract: Background and Aims: Early life painful experiences have long-lasting effects upon adult behavioural pain sensitivity but it is not known whether cortical activity related to pain perception is also affected. Here we recorded pain related neural activity in the somatosensory cortex (S1) and the medial prefrontal cortex (mPFC) in awake adult rats, following early life skin incision. We hypothesised that functional connectivity between these two cortical areas would be altered following neonatal skin injury, resulting in altered pain perception. Methods: Simultaneous pain behaviour and electrophysiological local field potential activity was recorded in S1 and mPFC in awake male Sprague-Dawley rats. Data was collected at baseline (BL) and at 0 (2hrs), 1, 4 and 10 days after unilateral hindpaw skin incision in a control group and a 'primed' group (exposed to skin incision at postnatal day 3) (n=8-10 per group). Behavioural pain sensitivity (paw withdrawal threshold, PWT) and S1-mPFC functional connectivity (phase locking value, PLV) were measured following electronic von Frey (vF) stimulation of the hindpaw. Experiments were regulated by the Home Office Animal (Scientific Procedures) Act, 1986. Results: Primed rats displayed heightened behavioural pain sensitivity to mechanical von Frey (vF) stimulation of the hindpaw following adult skin injury compared to controls (2 way ANOVA, $P < 0.001$). Skin injury also elicited an increase in mPFC-S1 PLV in the theta range, relative to baseline, in both groups on the D0 (permutation t-test, mean difference between BL and D0: primed= 0.11 [95%CI 0.05, 0.20], p=0.01; control=0.14 [95%CI 0.05, 0.25], p=0.03). The adult skin injury evoked increase in theta mPFC-S1 PLV was correlated with behavioural pain sensitivity in both groups (PLV increase inversely related to PWT, $R^2 =0.26$, P=0.003) indicating that the PLV is a measure of pain related cortical connectivity. Importantly, the theta mPFC-S1 PLV increase was significantly prolonged in primed rats compared to controls, and still present at day 4 post injury (permutation t-test, mean difference between BL and D4: Primed =0.13 [95%CI 0.04, 0.23], p=0.01; control =0.15 [95%CI -0.03, 0.19], p=0.15). Conclusion: Painful experience in early life has a significant effect on both behavioural pain sensitivity and the function of pain related cortical circuits in adults. Long-lasting changes in pain related functional S1 and mPFC connectivity follow postnatal skin incision, supporting the hypothesis that brain circuits underlying pain perception are altered.

Title: A neuronal mechanism of spinal hyperexcitability is sexually dimorphic in rodent and human models of pathological pain

Authors: ***A. DEDEK**[1,2], J. XU[3], C. M. KANDEGEDARA[1,2], J. A. LANDRIGAN[1], C. DEDEK[1], P. J. LOMBROSO[3], E. C. TSAI[4,2,5], M. E. HILDEBRAND[1,2,5];
[1]Carleton Univ., Ottawa, ON, Canada; [2]The Ottawa Hosp. Res. Inst., Ottawa, ON, Canada; [3]Yale Univ., New Haven, CT; [4]The Ottawa Hosp., Ottawa, ON, Canada; [5]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Clinical and epidemiological evidence suggest a sex difference in the mechanisms underlying chronic pain, with female chronic pain patients outnumbering their male counterparts by 2:1. Despite this, the neurobiological underpinnings of sexually dimorphic pain signaling remain unclear in rodents and are virtually unexplored in human preclinical models. Within the nociceptive system, the superficial dorsal horn (SDH) is a critical site of pain modulation. Pathological pain arises when there is an imbalance between excitation and inhibition in neurons of the SDH. We have recently characterized a pathological pain pathway in male rat and human SDH neurons where brain-derived neurotrophic factor (BDNF) mediates a loss of inhibition through the downregulation of chloride co-transporter 2 (KCC2), driving downregulation of the phosphatase $STEP_{61}$ and a subsequent potentiation of GluN2B-containing N-methyl D-aspartate receptors (NMDARs) (Dedek, Xu et al., Brain, 2019). Here, we investigated whether molecular mechanisms of spinal hyperexcitability and pathological pain are conserved between sexes in both rodents and humans. Our models of pathological pain included *ex vivo* BDNF pain pathology models in rodent and human spinal cord and the *in vivo* complete Freund's adjuvant (CFA) rodent model of inflammatory pain. For the human tissue translational pain models, we collected human spinal cord samples from male and female organ donors 1 to 3 hours post-aortic cross-clamping. We paired patch-clamp electrophysiological recordings of synaptic NMDAR responses with *ex vivo* pharmacology, biochemical approaches, and behavioral testing. In

contrast to male rodents, we find that in female rats, NMDAR responses at lamina I SDH synapses are not potentiated by spinal cord *ex vivo* treatment with BDNF nor in the *in vivo* CFA model of inflammatory pain. Parallel biochemical evidence suggests that active $STEP_{61}$ and KCC2 are not downregulated and active Fyn and GluN2B are not upregulated at SDH synapses in female rodent (CFA inflammatory pain and *ex vivo* BDNF) as well as human (*ex vivo* BDNF) models of pathological pain. Electrophysiological recordings and biochemical investigations in ovariectomized rats suggest hormonal mediation of this sex difference. We conclude that neuronal mechanisms of SDH hyperexcitability are sexually dimorphic in both rats and humans, with a BDNF/$STEP_{61}$/Fyn-dependent potentiation of GluN2B-containing NMDARs in males but not females. This sexual divergence in underpinning neurobiological mechanisms of chronic pain has profound implications for the development of novel pain therapeutics.

Title: Persistent pain after traumatic brain injury: pain symptoms, sensory signs, neuropsychological and psychosocial impact

Authors: *L. E. ROBAYO[1], V. GOVIND[2], *L. FLEMING[3], D. NILANJANA[4], E. WIDERSTROM-NOGA[3];
[1]Miller Sch. of Med. - Neurosci. Dept., [2]Radiology, [4]Miami Project to Cure Paralysis, [3]Univ. of Miami, Miami, FL

Abstract: Persistent pain develops in approximately 50% of people who experience a traumatic brain injury (TBI), yet effective treatment is still lacking mainly because pain symptoms, sensory signs, psychosocial and neuropsychological factors associated with this condition have not been fully characterized. For this, we assessed and compared these factors in people with TBI without persistent pain (N=23, age: 29.74 ± 7.90), with TBI-related persistent pain (N=26, age: 34.35 ± 11.10) and healthy controls (N=38, age 28.68 ± 7.54). Pain was characterized using the International SCI Basic Pain Dataset version 2 modified for TBI and the neuropathic pain diagnostic questionnaire DN4. Sensory function was measured in three standard sites during a quantitative sensory testing (QST). Neuropsychological tests and questionnaires evaluated cognitive and emotional functions, and the multidimensional pain inventory (MPI) determined the impact of pain in people's life. Participants with TBI-related pain reported mean pain intensity of 7.65 ± 1.71 (0-10 scale) during the last 7 days and 92.3% of these participants had more than one pain problem commonly located in the head (76%), shoulders and neck (67%),

and back (43%) with a neuropathic nature in 42.31% of the participants (DN4 total score ≥3 out of 7). Kruskal-Wallis (DF=2, Bonferroni-adjusted *P*) test was used to determine differences between groups. As predicted, the pain group presented significant higher anxiety (Beck's anxiety inventory, *H*=26.399, *P*=0.000, *P*=0.000), higher depression (Beck's depression inventory, *H*=26.102, *P*=0.004, *P*=0.000), and lower total recall (Hopkins Verbal Learning Test, *H*=9.448, *P*=0.029, *P*=0.17) compared to the TBI without pain and AB control groups correspondingly. QST lower graphesthesia scores (*H*=8.954, *P*=0.010), forehead lower cool (*H*=7.008, *P*=0.026), lower warm (*H*=6.323, *P*=0.038) and higher vibration (*H*=10.670, *P*=0.004); and right medial calf higher vibration (*H*=6.427, *P*=0.034) detection thresholds were found between the pain group and AB control group suggesting abnormal sensory function. Additionally, MPI scores (0-6 scale) of pain severity (3.76 ± 1.41), life interference (3.64 ± 1.71) and affective distress (3.09 ± 1.45) indicate the negative impact of the persistent pain in the participants, although most of them feel support (4.21 ± 1.77) and life control (4.27 ± 1.17). Collectively, our findings contribute to our understanding of the sensory, neuropsychological and psychosocial factors associated with the TBI-related persistent pain. Nevertheless, future work is required to fully characterize the nature of the pain and the mechanisms undergoing this condition.

Title: Oral squamous cell carcinoma supernatant sensitizes TRPV4 in trigeminal ganglia neurons through PAR_2

Authors: *E. W. CHEN[1], S. NICHOLSON[1], K. INOUE[1], L. EDGINGTON-MITCHELL[2], N. BUNNETT[3], B. L. SCHMIDT[1];
[1]NYU Oral Cancer Center, Col. of Dentistry, New York Univ., New York, NY; [2]Biochem. and Mol. Biol., The Univ. of Melbourne, Parkville, Australia; [3]Dept. of Mol. Pathobiology, Col. of Dentistry, New York Univ., New York, NY

Abstract: Pain is the worst symptom experienced by oral cancer patients. The transient receptor potential vanilloid 4 (TRPV4) ion channel may play a role in mechanical stimulus-induced oral cancer nociception. In this study, we asked the question whether oral cancer cells release mediators that activate PAR_2 which then sensitize TRPV4 channels in trigeminal ganglia (TG) neurons. We collected supernatant from a cell line of human oral squamous cell carcinoma (HSC-3). We then incubated TG neurons in this supernatant. Using calcium imaging, we measured calcium transient response to TRPV4 agonist GSK1016790A in TG neurons treated with either supernatant or vehicle (DMEM media). We found that HSC-3 supernatant treatment yielded a greater percentage of small and medium-sized TG neurons that responded to GSK 1016790A in C57BL/6J mice. Calcium transient amplitudes in HSC-3 supernatant treated neurons were greater than those in neurons treated with DMEM media.
We utilized *Par2*$^{-/-}$ mice to determine the role of PAR_2 in HSC-3 supernatant induced TRPV4 sensitization. We found that the percentage of neurons responding to GSK 1016790A after treatment with HSC-3 supernatant was similar to the percentage responding to DMEM media. HSC-3 supernatant sensitization of TRPV4 was diminished in TG neurons with PAR_2 deletion. From our findings we infer that HSC-3 supernatant sensitizes TRPV4 in TG neurons and that PAR_2 is required for sensitization.

Treatment	TG responded to GSK (%)		Δf/f (mean ± SEM)	
	C57BL/6J	*Par2*$^{-/-}$	C57BL/6J	*Par2*$^{-/-}$
DMEM	13.93	5.45	0.40 ± 0.03	0.27 ± 0.02
HSC-3	29.11	6.43	0.77 ± 0.12*	0.37 ± 0.14

*$P < 0.05$, vs. DMEM media (unpaired student's *t*-test)

Title: Excitatory chloride physiology discriminately encodes noxious cold in a multimodal sensory neuron

Authors: *N. J. HIMMEL, A. SAKURAI, J. M. LETCHER, M. N. BENSON, T. R. GRAY, D. N. COX;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: *Drosophila* larvae detect both noxious cold and innocuous touch using Class III (CIII) dendritic arborization neurons, a class of sensory neuron which tiles the larval barrier epidermis. The ability to differentiate between harmful and innocuous stimuli is key to organism survival, but is also relevant to human health, as the inability to discriminate between painful and non-painful stimuli underlies many neuropathic pain conditions. It is therefore important to elucidate generalizable mechanisms by which multimodal pain sensors (nociceptors) operate. CIII nociceptors are thought to function via a high-low filter, whereby high levels of activation drive cold-associated behaviors (primarily full-body contraction; CT), and low levels of activation drive a complex suite of touch-associated behaviors. Both modalities make use of Transient Receptor Potential channels, but it remains unknown what other molecular factors contribute to the activity required to selectively drive cold-evoked behaviors. Transcriptomic analysis of CIII neurons reveals enriched expression of TMEM16/anoctamin family genes, which often function as calcium-activated chloride channels. Loss-of-function disruptions of the anoctamins *subdued* and *CG15270* result in a reduced capacity to CT, and reduced cold-evoked CIII activity, but not reduced touch sensitivity, suggesting a modality-specific and excitatory function. Although Cl^- currents in archetypal neurons are hyperpolarizing, genetic, *in vivo* manipulations of Cl^- physiology (via knockdown and overexpression of SLC12 channels) and *ex vivo* manipulations of extracellular [Cl^-] indicate that CIII Cl^- currents are depolarizing. Consistent with this, Cl^- optogenetics, which are more often inhibitory, instead activate CIII neurons, and can be used to initiate CT behavior *sans* cold. Moreover, overexpression of the SLC12 *ncc69* (related to *NKCC1/2*) results in nociceptive sensitization and increased spontaneous CIII activity, a genotype-phenotype relationship consistent with some types of neuropathic pain. These results collectively indicate a conserved, excitatory role for SLC12 and TMEM16 channels in animal sensory neurons, and present a genetically-tractable system in which to study mechanisms relevant to neuropathic pain.

Title: Cancer cell-derived exosomes mediate oral cancer pain

Authors: *Z. A. DUBEYKOVSKAYA, T. H. NGUYEN, B. L. SCHMIDT, D. G. ALBERTSON;
Blue Stone Ctr. For Clin. Res. of New York, New York, NY

Abstract: Oral cancer patients experience pain at the site of the cancer prior to treatment. Pain is initiated and maintained in the tumor microenvironment by mediators that sensitize primary afferent nociceptors. Anti-nociceptive therapy with opioids does not adequately manage pain. Patients no longer experience pain after removal of the tumor. Intraplantar injection of conditioned media from HSC-3 (RRID:CVCL_1288) cancer cells induces mechanical allodynia and thermal hypersensitivity, while conditioned media from noncancer (dysplasia) DOK (RRID:CVCL_1180) cells do not evoke nociception. Conditioned media contain soluble substances and exosomes. Exosomes are 30-150 nm extracellular vesicles. They are formed within the endosomal system as intralumenal vesicles of multivesicular bodies and are released into the extracellular space. Here, we investigated whether exosomes derived from nociceptive cancer cells conditioned media mediate mechanical and thermal nociception in a mouse model. **Methods**. We isolated exosomes from conditioned media of cancer cell lines HSC-3 and OSC-20 and noncancer DOK cells by differential centrifugation. Morphology, size and purity of exosomes were validated by transmission electron microscopy, nanoparticle tracking analysis and western blot. We separated exosome-positive and exosome-depleted fractions from conditioned media by size-exclusion chromatography. Exosome-positive and exosome-depleted fractions were combined to generate a reconstituted fraction. We injected cell line media DMEM, conditioned media, the exosome-depleted and the reconstituted fractions into the right hind paws of male mice (n=5 per group). Paw withdrawal was measured in response to mechanical (von Frey filaments) and thermal stimulation. **Results**: Intraplantar injection of HSC-3 cell conditioned media induced nociception. Depletion of exosomes from HSC-3 cell conditioned media reduced or abolished mechanical allodynia and thermal hypersensitivity. Nociceptive behaviors were restored in response to the conditioned media reconstituted with the HSC-3 exosome fraction, but not with DOK cells-derived exosomes. By contrast, nociceptive behavior was not observed when mice received intraplantar injections of DOK cell conditioned media, DOK cell conditioned media depleted of exosomes or exosome depleted media reconstituted with the DOK cells exosomes. Nociceptive responses were induced when the DOK conditioned media was reconstituted with HSC-3 cells exosomes. **Conclusions:** Oral cancer pain mediators are released in exosomes.

Title: The calcium sensor stim1 senses pain, not itch

Authors: ***Y. MEI**[1], D. WEI[5], I. ZHANG[2], F. WANG[2], H. ZHAO[2], D. LI[2], T. ROHACS[3], Y.-X. TAO[4], H. HU[4];
[1]Rutgers New Jersey Med. Sch., ; [3]Dept. of Pharmacology, Physiol. & Neurosci., [4]Dept. of Anesthesiol., [2]Rutgers New Jersey Med. Sch., Newark, NJ; [5]New York Univ. Sch. of Med., New York, NY

Abstract: Stromal interaction molecule 1 (STIM1) is an endoplasmic reticulum (ER) calcium sensor that can sense a calcium drop in ER and reacts to extracellular stimuli. STIM1 is expressed and functional in nociceptive neurons in the dorsal root ganglion (DRG). We wonder whether sensory STIM1 can sense peripheral stimuli such as alogenic agents and pruritogens. Here we show that peripheral inhibition of STIM1 or deletion of STIM1 in sensory neurons (SN-STIM1 knockout) significantly reduces noxious mechanical-, cold-, capsaicin-, AITC- and bradykinin-induced nociception. Activation of STIM1 by thapsgargin (an ER Ca^{2+}-ATPase inhibitor) triggers spontaneous nociceptive behavior and induces pain hypersensitivity, which is significantly attenuated in SN-STIM1 knockout (KO) mice. These effects are confirmed by L3/4 DRGs STIM1 knockdown mice. Interestingly, pruritogens (histamine (His), the peptide Ser-Leu-Ile-Gly-Arg-Leu (SLIGRL) or chloroquine (CQ)-induced itch behavior is not altered in SN-STIM1 KO mice. Moreover, activation of STIM1 induces pain but not itch via inhibition of potassium currents and increase in neuronal excitability. Consistently, capsaicin-, AITC- or bradykinin-induced calcium entry is significantly decreased while CQ- or His-induced calcium influx is intact in SN-STIM1 KO neurons. Activation of TRPV1 triggers STIM1 translocation and SOC entry, suggesting a novel link between STIM1 and pain targets. Strikingly, STIM1 is expressed and functional in most TRPV1+ neurons but is not functional in His- responding neurons. Our findings reveal that STIM1 distinguishes pain and itch, two distinct sensory modalities.

Title: Evolutionarily ancient roles for TRPA1 in cold-evoked nociceptive behavior

Authors: ***J. M. LETCHER**, N. J. HIMMEL, A. SAKURAI, M. HOLGUIN-LOPEZ, D. N. COX;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Thermosensory nociception alerts organisms to potential environmental dangers, thereby serving as a protective mechanism for driving adaptive behavioral responses to safeguard against incipient damage. Transient receptor potential (TRP) channels play a key role in thermosensation and can be activated directly or indirectly by changes in temperature. However, less is known regarding how TRPs mechanistically function in regulating noxious cold detection and whether there is molecular conservation across phyla. TRPA1 has a functional role in chemical sensing that predates the protostome-deuterostome split (>550 mya), yet it remains unknown whether TRPA1 thermal sensing is equally ancient. Protostome, and many deuterostome, TRPA1s have been associated with high-temperature sensing, while some deuterostome TRPA1s (including those of mice and humans) have been identified as noxious cold sensitive. Among invertebrates, *C. elegans* TRPA1 is implicated in detecting cool (sub-noxious) temperatures, however, it is unknown if this holds for noxious cold. Conversely, in *Drosophila* TRPA1 is known to function in class IV (CIV) polymodal nociceptor neurons for mechanical and high heat nociception. Our previous studies identified class III (CIII) multidendritic sensory neurons as cold nociceptors that are required for noxious cold-evoked contraction (CT) behavior in larvae. We further demonstrate via CIII-specific neurogenomic studies that TRPA1 is enriched in these neurons, suggesting it may contribute to noxious cold sensing. Analyses of multiple TRPA1 whole-animal mutants revealed severe impairment of cold-evoked CT behavior, which we likewise observed with CIII-specific TRPA1 knockdown. Behavioral studies of TRPA1 mutations revealed isoform-specific requirements for noxious cold sensing that are distinct from isoforms linked to noxious heat sensing or UV sensing via CIV neurons. Electrophysiological recordings demonstrate that TRPA1 is required in CIII neurons for cold-evoked electrical activity. TRPA1 appears to function in cold-evoked sensory transduction, however physiological and behavioral defects are independent of alterations in CIII neuronal morphology. CIII-specific expression of TRPA1 rescued nocifensive behavior in whole animal TRPA1 mutants. Further, behavior deficits were also rescued by ectopic expression of human TRPA1. Collectively, these findings shed new light on evolutionarily ancient properties of TRPA1 in thermal sensing and raises interesting questions regarding the molecular and mechanistic underpinnings of TRPA1 polymodality.

Title: Tools for efficient 3D cell and projection analysis and atlas registration of whole mouse spinal cord

Authors: *F. FIEDERLING, L. A. HAMMOND, C. A. MASON, J. DODD;
Zuckerman Inst., Columbia Univ., New York, NY

Abstract: The spinal cord (SC) contains a remarkable and complex variety of interconnected cells that relay and process somatosensory information and execute movement. Classic research on the embryonic and adult SC has identified major classes of neurons, based on embryonic markers, morphology and position within the SC. But recent advances in transcriptional profiling have revealed that the extent of spinal cell diversity far exceeds previous assumptions.
To achieve better characterization of spinal cell types and the detailed connectivity between cells that form functional circuits, it is necessary to map the spatial relations of neurons and projections. To date, however, unbiased approaches to map positional information in the context of the whole SC are severely limited by a lack of tools for efficient data collection and analysis. Moreover, the absence of a standardized 3D reference atlas for the mouse SC complicates anatomical mapping of data and comparison between samples and results across the field.
Here we present tools for practicable analysis of labelled cells and projections in whole mouse SC in the context of a novel 3D anatomical atlas. We have designed soluble, 3D-printed, 'Spine Racks' that guide oriented and parallel embedding of serial tissue segments of the entire SC within a single block for synchronous cryo-sectioning. Spine Racks precisely position tissue pieces within each block section array, permitting automated imaging of slides and rostro-caudal sorting of section images. Additionally, we have developed "SpinalJ", a user-friendly plugIn for ImageJ, to register section images and to map the reconstructed data to a prototype 3D reference atlas. SpinalJ further combines various tools for manual and automated cell and projection analysis, as well as for data visualization.
Together, these tools capacitate high-throughput comparative analyses of neurons and their projections in whole SC.

Title: Effects of thrust magnitude and duration of spinal manipulation on immediate muscle spindle response in an animal model.

Authors: *C. R. LIMA[1], A. LAW[2], P. LI[1], W. REED[1];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Lawson State Community Col., Birmingham, AL

Abstract: Rationale: High velocity low amplitude spinal manipulation (HVLA-SM) is a non-pharmacological approach commonly used by chiropractors, physical therapists and osteopaths to treat acute and chronic back pain, but little is known about the relationship between HVLA-SM biomechanical characteristics and its subsequent neurophysiological effects. **Objective:** To characterize trunk muscle spindle responses immediately after high velocity, low amplitude (HVLA-SM) delivered at various thrust magnitudes and thrust durations.**Methods:** Secondary analysis from multiple studies involving anesthetized adult male/female cats (n = 70; 2.3-6.0 kg) receiving L6 HVLA-SM. Muscle spindle afferent recordings were obtained from L6 dorsal rootlets prior to, during, and immediately after HVLA-SM. L6 HVLA-SM was delivered posterior-to-anterior using a feedback motor with peak thrust magnitudes of 25, 55, 85% of cat body weight (BW) and thrust durations of 25, 50, 75, 100, 150, 200, and 250ms. Time to 1st action potential (AP; ms) and muscle spindle discharge frequency during 1 and 2s post-HVLA-SM (Hz) were determined.**Results:** A significant association between HVLA-SM thrust magnitude and immediate muscle spindle response was found ($p < 0.001$). For non-control thrust magnitude pairwise comparisons (25%, 55%, 85%BW), 55%BW thrust magnitude had the most consistent impact on post-HVLA-SM discharge outcomes particularly at a thrust duration of 50ms (False Discovery Rate < 0.05). No significant association was found between thrust duration and immediate post-HVLA-SM muscle spindle response ($p > 0.05$).**Conclusion:** HVLA-SM thrust magnitudes delivered at 55%BW are more likely to impact immediate (≤ 2s) post-HVLA-SM muscle spindle response, particularly when HVLA-SM is delivered at shorter thrust durations (≤ 50ms).

Figure 1. An example recording of a trunk muscle spindle response during an L6 HVLA-SM. The immediate post-HVLA spindle response outcomes (time to 1st action potential, 1s post-HVLA-SM activity, and 2s post-HVLA-SM) that were measured in this study are illustrated.

Title: Spinal cord reflexes in a brain iron-deficient model of restless legs syndrome: Role of dopamine and adenosine receptor modulators

Authors: *S. WOODS[1], S. CLEMENS[2];
[1]Brody Sch. of Med., Greenville, NC; [2]Physiol., East Carolina Univ., Greenville, NC

Abstract: Restless Legs Syndrome (RLS) is a sensorimotor disorder that severely disrupts sleep. RLS patients regularly present with a condition known as brain iron deficiency (BID), and BID is commonly associated with altered dopamine (DA) and adenosine (ADE) neurotransmission. We here tested if a diet-induced brain iron-deficient animal model mimics the increased spinal cord excitability reported in other RLS animal models, and the responsiveness of this model to treatment with DA and ADE receptor modulators.
Following previously established protocols, newly-weaned C57Bl/6 mice were separated into two cohorts that were fed control iron (CTRL ID, ~ 48 ppm Fe, 8 males and 8 females) and two cohorts that were fed iron-reduced diets (ID, 4-6 ppm Fe, 10 males and 10 females). Blood analyses after 10 weeks revealed that the ID diet did not induce an anemic phenotype. To assess spinal excitability, we measured thermal pain reflex (TPRs) withdrawal latencies, starting at one week after diet exposures. At 3 weeks on their respective diets, both male and female ID cohorts showed significantly lower TPR latencies than their respective CTRL ID cohorts, and this difference remained stable over time. Based on the current standard treatment for patients with RLS, all cohorts were then administered DA D3 receptor (D3R) agonist (pramipexole, PPX, 0.5 mg/kg, i.p.). PPX did not significantly alter spinal reflex latencies but led to strongly increased locomotor and rearing activities in both ID cohorts. Next, we tested the effects of the DA D1 receptor (D1R) antagonist ecopipam (SCH 39166, 0.5 mg/kg, i.p.). SCH 39166 had no effect on TPRs in CTRL ID animals, but it rescued the hyperexcitable phenotype in male ID animals and slightly improved the outcome in female ID animals. Finally, we tested in week 9 the effects of the ADE A1 receptor (A1R) agonist N6-cyclpentyladenosine (CPA, 1 mg/kg, i.p.) and the ADE receptor antagonist caffeine (50 mg/kg, i.p.). CPA increased TPR latencies in the ID cohort, while caffeine reduced them in CTRL ID animals.
Together, our data show that diet-induced iron-deficiency leads to a decrease in TPR latencies and that, in this model, increased spinal cord excitability is unresponsive to D3R modulation but is responsive to D1R and A1R receptor modulation. As RLS patients present with BID and are responsive to D3R-based treatment in the clinic, these findings suggest that D3R effect in the clinic is not congruent with the ID animal model. Instead, our data point to the possibility that ID-induced changes in reflex excitability may be linked to an altered D1R/A1R system in the spinal cord.

Title: Identifying the Spinal Cord Neuronal Circuit through which Heat Shock Protein 90 Regulates ERK MAPK Signaling and Opioid Anti-Nociception

Authors: *B. ROMAN[1], K. GABRIEL[2], J. M. STREICHER[2];
[1]Univ. of Arizona, ; [2]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Heat shock protein 90 (Hsp90) has been studied and recognized as a vital regulator of protein biochemistry; recent studies from our lab have shown that Hsp90 is also a crucial regulator of opioid-induced pain relief through several molecular mechanisms in the nervous system. Through past testing, Hsp90 inhibitors like 17-AAG have shown to affect anti-nociception oppositely when applied to either the brain or spinal cord. When 17-AAG was injected in the spinal cord, anti-nociception was enhanced rather than reduced like in the brains of mice. Our previous work further found that signaling proteins including ERK and RSK1/2 mediate the enhanced anti-nociceptive effects of Hsp90 inhibition in spinal cord. Though this circuit is normally suppressed through the Hsp90 protein, by inhibiting it with 17-AAG and applying a co-treatment of the opioid agonist morphine, the circuit is activated to promote the enhanced anti-nociception seen in mice. Through the same study, and utilizing immunohistochemistry analysis of the spinal cords, phosphorylated ERK was found to overlap with the dendrite marker MAP2. Though not a complete overlap, the imaging suggests that activation of the ERK mechanism, and thus the RSK mechanism and anti-nociception, occurs in the post synaptic dendrites, located in the dorsal horn of the spinal cord. Uncovering the neuronal circuit in which these molecular mechanisms take place will bring more insight into the organization of Hsp90 and Mu opioid receptors (MOR) in the spinal cord. Our proposed study will identify spinal cord neuronal circuits that mediate anti-nociception when Hsp90 proteins are inhibited. We report on our progress using double-labeling of Hsp90 or phospho-ERK with different neuronal markers to place these signaling events in a circuit context; pre- vs. post-synaptic, ascending vs. descending modulation, interneurons vs. projection neurons, and similar circuit analysis. These markers include synapsin I or synaptophysin to determine pre-synaptic localization; PSD95 or SHANK3 to determine post-synaptic localization; if pre-synaptic localization is observed, alpha2 adrenergic receptor (descending modulation) or IB4 (ascending modulation); if post-synaptic localization is observed, NK1 or CGRP. Through these studies we aim to illuminate a novel neuronal circuit through which Hsp90 promotes enhanced opioid pain relief.

Title: Determination of the proprioceptive organs of the rat larynx

Authors: *I. HERNANDEZ-MORATO[1], V. X. YU[1], S. BRENNER-MORTON[2], M. PITMAN[1];
[1]Otolaryngology-Head & Neck Surgery, Columbia Univ., New York, NY; [2]Columbia Univ., Columbia's Zuckerman Institute, NY

Abstract: Introduction: The larynx is a group of muscles, cartilages, and mucosa in the upper airway that plays a vital role in respiration, airway protection, and phonation. These functions rely on the precise opening, closing, and vibration of the vocal folds (VF), key structures within the larynx, which in turn are controlled by the intrinsic laryngeal muscles (ILM). Exquisite ILM coordination is required for proper VF movement, which often entails near-instantaneous microadjustments. Any defect in ILM coordination can result in defective VF movement and subsequent functional impairment, such as the dysfunctional voice observed laryngeal dystonia. Such precise coordination requires a well-calibrated proprioceptive apparatus. However, controversy remains over whether canonical proprioceptive organs - muscle spindles and Golgi tendon organs - are present in the intrinsic laryngeal muscles. In this exploratory work, we seek to identify the proprioceptive organs of the larynx.
Methods: Sixty-two Sprague-Dawley rats were distributed across 5 age groups post-birth: P3, P8, P11, P14-15, and adult. Larynxes were sectioned and immunostained for VGLUT1, a marker of primary afferent sensory nerve endings used to identify muscle spindles in other muscle groups, and beta-tubulin III to identify and visualize laryngeal sensory structures. S46, GNAT3, PLCβ, S100b, and CGRP were used as corroborative markers to classify identified sensory structures. Extrinsic laryngeal muscle and leg muscles were used as positive controls.
Results: Using VGLUT1 staining, muscle spindles were rarely observed in the ILM and were identified only in the lateral thyroarytenoid muscle of three P8 animals. S46 staining demonstrated no muscle spindles in the ILM. In contrast, rich staining for VGLUT1, beta-tubulin III, and S100 was observed in the laryngeal mucosa overlying the arytenoid cartilages in all laryngeal specimens. In addition, VGLUT1-positive intramuscular receptor-like entities were observed in nearly all ILM samples. Finally, VGLUT1 was not found to colocalize with CGRP, GNAT3, PLCβ, ruling out nociceptive and gustatory functions for VGLUT1-positive structures.
Conclusion: The study findings suggest rat ILM rarely contain muscle spindles. The larynx may exhibit a non-canonical proprioceptive mechanism comprised of VGLUT1-positive nerve endings in the arytenoid mucosa and intramuscular receptors. A future study of laryngeal proprioception will further define the afferent arm identified here, providing insights required to advance treatment for VF disorders such as spasmodic dysphonia.

Title: Heat shock protein 90 inhibition in spinal cord enhances opioid anti-nociception by suppressing AMPK signaling

Authors: ***K. GABRIEL**;
Univ. of Arizona, Tucson, AZ

Abstract: Opioid misuse is a prevailing problem for chronic pain treatment that is accompanied by sideeffects such as constipation, tolerance, and addiction. Mu opioid receptor (MOR) signalmodulation has been heavily studied in an attempted to optimize opioids and to decrease theirside effects. Our lab has demonstrated an important role for the chaperone protein Heat shockprotein 90 (Hsp90) in regulating ERK MAPK signaling and pain relief downstream of the MOR.When 17-AAG, an Hsp90 inhibitor, is administered to the spinal cord (intrathecally, IT), there isan augmentation in morphine induced antinociception in mice. This signifies that Hsp90 acts torepress ERK MAPK signaling to reduce antinociception in the spinal cord. This led us to performquantitative proteomic analysis on the spinal cords of male and female CD-1 mice treated with0.5 nmol 17-AAG, in order to elucidate the signaling network that activates opioid anti-nociceptionin the spinal cord. Network analysis of this data revealed that 5'-AMP-activated protein kinasesubunit beta-1 (AMPK) was downregulated by 1.4-fold. Previous studies have implicated AMPKactivation as a target of interest in the opioid field because it seems to reduce or preventpathological pain. This result suggested that a reduction in AMPK activity could lead to enhancedopioid signaling and pain relief. We first tested this in female mice using the AMPK agonist AICAR(100 nmol, IT), which we found decreased 0.5 nmol 17-AAG's enhanced morphine (3.2 mg/kg,subcutaneous, SC) antinociception in the 52°C tail flick test, with no effect on the vehicle/morphinegroup. In contrast, AICAR not only decreased 17-AAG's enhanced antinociception, it alsodecreased morphine's effect in the vehicle group in male mice. Conversely, when using the AMPKinhibitor dorsomorphin (20 nmol, IT), we were able to see an enhancement of morphineantinociception greater than 17-AAG alone in female mice. Our data supports our hypothesis thatHsp90 inhibition in spinal cord enhances opioid pain relief by decreasing AMPK signaling. Thisleads to the enhanced opioid antinociception, which can be reversed when an AMPK agonist isadministered. We have thus elucidated a key molecular mechanism by which Hsp90 is regulatingopioid signaling in the spinal cord, which helps us stablish the basic science foundation of howHsp90 inhibition leads to enhanced opioid antinociception. We have also discovered a novelAMPK signal transduction role in the spinal cord downstream of acute opioid treatment that variesbetween male and female mice.

Title: Parallel ascending spinal pathways for affective touch and pain

Authors: *S. CHOI[1], J. HACHISUKA[2], M. A. BRETT[1], A. R. MAGEE[1], H. R. KOERBER[2], S. E. ROSS[2], D. D. GINTY[1];

Abstract: Each day we experience myriad somatosensory stimuli: hugs from loved ones, warm showers, a mosquito bite, and sore muscles after a workout. These tactile, thermal, itch, and nociceptive signals are detected by peripheral sensory neuron terminals distributed throughout our body, propagated into the spinal cord, and then transmitted to the brain through ascending spinal pathways. Primary sensory neurons that detect a wide range of somatosensory stimuli have been identified and characterized. In contrast, very little is known about how peripheral signals are integrated and processed within the spinal cord and conveyed to the brain to generate somatosensory perception and behavioral responses. We tackled this question by developing new mouse genetic tools to define projection neuron (PN) subsets of the anterolateral pathway, a major ascending spinal cord pathway, and combining these new tools with advanced anatomical, physiological, and behavioral approaches. We found that *Gpr83*$^+$ PNs, a newly identified subset of spinal cord output neurons, and *Tacr1*$^+$ PNs are largely non-overlapping populations that innervate distinct sets of subnuclei within the lateral parabrachial nucleus (PBN_L) of the pons in a zonally segregated manner. In addition, *Gpr83*$^+$ PNs are highly sensitive to cutaneous mechanical stimuli, receive strong synaptic inputs from primary mechanosensory neurons, and convey tactile information bilaterally to the PBN_L in a non-topographically organized manner. Remarkably, *Gpr83*$^+$ mechanosensory limb of the anterolateral pathway controls behaviors associated with different hedonic values (appetitive or aversive) in a scalable manner. Our study reveals a dedicated spinal cord output pathway that conveys affective touch signals to the brain as well as parallel ascending circuit modules that cooperate to convey tactile, thermal and noxious cutaneous signals from the spinal cord to the brain. Furthermore, our study provides an

insight into the new therapeutic opportunities for developing treatments for neurological disorders associated with pain and affective touch.

Nacional Autónoma de México, Ciudad de México, Mexico; [5]De Fisiología, Biofísica y Neurociencia, Cinvestav, CInvestav, Mexico

Abstract: In the spinal cord there are sensory-motor regulation nerve circuits that actively participate in maintaining posture or performing locomotion. In the spinal cord, specifically at the lumbosacral levels (L6-S2) are integrated somatic and visceral reflexes. After of spinal cord injury produced a muscular deterioration and the unrest in the sensation of balance. These injuries compress, stretch or break (avulsion) the roots of the spinal cord causing sensory, motor and autonomic dysfunctions. The separation of the nerve roots occurs as a result of the traction force on the spinal cord, when this injury occurs in the anterior root is called ventral root avulsion (VRA). The studies that exist on this injury have determined the poor survival of motor neurons. A first approach was to characterize the afferent information of the lumbosacral region during the electro-stimulation of five lumbosacral nerves in intact rabbits. For this purpose, 4 virgin rabbits of the Chinchilla breed (6 months old) were used. The females were anesthetized with 20% urethane (diluted in distilled water) and placed in a dorsal position to make a sagittal incision in the dorsal-caudal skin from segment L5 to S3. Under a stereomicroscope, a longitudinal incision was made in the dura mater to expose the dorsal roots. Each one of the roots was placed on a silver electrode to record the DRPs. Five nerves were identified from the lower left extremity. Electrical stimuli of variable intensity and voltage were applied to each of the nerves. In addition, to observe the changes produced by VRA, 4 virgin rabbits divided in 2 groups (n=2) were used: a) Sham and b) VRA. All the rabbits were anesthetized with ketamine and sodium pentobarbital. A sagittal incision was made in the dorsal skin from segment L5 to L7, the vertebral segments were discovered to locate the right ventral root of the medullary segment L6 under a stereomicroscope. The Sham group was only located the roots and sutured again. Meanwhile, the roots of the VRA group were located and with the help of an avulsion hook, one of the ventral roots of the right medullary segment L6 was broken. The results obtained show that at level S1, for the sciatic nerve, there is a greater amplitude and quantity of components (3 to 4); for the pudendal nerve the number of components decreases, showing records of only one or two waves. This may be due to the fact that the sciatic nerve is a large nerve and the amplitude of the DRPs is related to the degree of facilitation of axon excitability at the site of stimulus.

Title: The impact of neural activity on immune cell profile in the mouse colon

Authors: *A. Y. EPOUHE[1], B. M. DAVIS[2], K. M. ALBERS[3];
[2]Dept. of Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept Neurobio., Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: Pain detecting sensory neurons are now recognized as contributors to the body's immune response under normal physiological and pathological conditions. In the colon, dysregulation of this communication is thought to contribute to the chronic and recurring inflammatory conditions of the gut evident in inflammatory bowel disorders (Crohn's and colitis). In this exploratory study we are using optogenetic strategies to probe how nerve activity impacts immune cell populations in the distal colon. Recent studies using pharmacological agonism and chemical ablation strategies have demonstrated the capacity of visceral nociceptors to sense bacteria and modulate the inflammatory response. These approaches provide new but limited insight into whether sensory afferents have a direct or indirect role in these processes. To address this issue, we are using mice that express the light-activated channelrhodopsin (ChR2) protein under control of the TRPV1 promoter. Targeted optogenetic activation of sensory afferents that innervate the distal colon is done *in situ* using a fiberoptic probe inserted into the distal colon. Colon tissue is then isolated from stimulated mice and analyzed using immunolabeling of sectioned and whole mount colon tissue to determine the relative number and location of MHCII+ antigen-presenting cells and CD3+ T cells in the colon tissue. Comparison of three groups of mice is being done: Group 1 mice express ChR2 in TRPV1+ neurons and receive optogenetic stimulation, Group 2 mice that express ChR2 in TRPV1+ neurons and but do not receive optogenetic stimulation and Group 3 mice are control mice that do not have ChR2 expression. Mice utilized for these experiments were on a C57/Bl6 background and were between 8-24 weeks old. Both male and female mice were included for analysis, but sex differences were not assessed. Mice were stimulated for two 30 min sessions over 6 hours prior to tissue collection. Initial results indicate that light stimulation of TRPV1+ colon afferents decreases the number of MHCII+ cells in the lamina propria of the colon with little or no change in CD3+ cell number. These studies were supported by NIH grant 5R01AR069951.

Title: The role of ExPAN to myenteric neuron communication in colon dysmotility following inflammation

Authors: *K. A. MEERSCHAERT[1], K. SMITH-EDWARDS[1], K. M. ALBERS[3], B. M. DAVIS[2];
[2]Dept. of Neurobio., [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept Neurobio., Univ. of Pittsburgh Dept. of Neurobio., Pittsburgh, PA

Abstract: Colitis is thought to lead to colon dysmotility by altering the intrinsic and extrinsic neural circuits of the enteric nervous system. The colon receives extrinsic primary afferent neuron (ExPAN) input from thoracolumbar (TL; T10-L2) and lumbosacral spinal levels (LS; L5-S1) and the nodose ganglion. ExPAN processes course throughout the myenteric ganglia of the enteric nervous system, where data suggests that they can have local effector functions through the release of glutamate and/or neuropeptides (e.g. CGRP, substance P) or act indirectly through autonomic reflexes. However, there is little known on how different ExPANs modulate myenteric activity, nor how this may change in inflammatory states. To determine the effects of inflammation on colon motility patterns, we recorded colonic migrating motor complexes (CMMC) in isolated colon preparations. To model colitis, we used 3% dextran sodium sulfate (DSS) for 5 days or vehicle treated male and female mice. To visualize activity in myenteric neurons, we used the calcium indicator GCaMP. We first established if colitis changes baseline myenteric neuron activity in an isolated colon preparation. Next, we used an *ex vivo* colon, pelvic nerve, and L6 dorsal and ventral root preparation to determine how colitis modulates LS ExPAN and/or parasympathetic efferent communication to myenteric neurons.This model of colitis caused a 21% increase in the frequency (p=0.03) and 20% increase in the speed of CMMC (p=0.02). Interestingly, we did not find changes in the percentage of myenteric neurons with spontaneous or evoked activity in isolated colons, suggesting that dysmotility after colitis may be due to changes in extrinsic populations that are also known to regulate motility (e.g. ExPANs, sympathetic, or parasympathetic input). To test this, we used our *ex vivo* preparation to electrically stimulate either the L6 dorsal or ventral root to activate the LS ExPANs or parasympathetic efferents, respectively. Previous work from our lab has shown ventral root stimulation activates myenteric neurons, but dorsal root stimulation does not activate myenteric neurons unless the spinal cord remains intact. We confirmed this result in our vehicle treated animals and tested whether ExPANs may be able to directly activate these cells after colitis. DSS treatment did not cause myenteric activation in response to dorsal root stimulation. Furthermore, we found no change in the percentage of responsive myenteric neurons to ventral root

stimulation after colitis. This suggests that the LS level may not be involved in the dysmotility seen after colitis leaving the possibility that a different neuraxis level (TL or nodose) may be involved.

Title: Uncovering the role of sleep and exercise in the transition from acute to persistent pain

Authors: D. M. KLYNE[1], B. A. HILLIARD[2], M. Y. HARRIS[2], M. AMIN[2], C. TESTA[2], L. J. HOBSON[2], G. E. CRUZ[2], P. W. HODGES[1], *M. F. BARBE[2];
[1]NHMRC Ctr. of Clin. Res. Excellence in Spinal Pain, Injury & Hlth., The Univ. of Queensland, Brisbane, Australia; [2]Anat. and Cell Biol., Lewis Katz Sch. of Medicine, Temple Univ., Philadelphia, PA

Abstract: Emerging evidence suggests that sleep is not only affected by pain, but also influences pain, with poor sleep increasing pain. The question remains, however, whether poor sleep contributes to pain chronicity. Exercise is thought to evoke pain relief via inflammation-reducing mechanisms, similar to those attributed to “healthy” sleep. This raises a further question as to whether exercise could protect against the negative effects of poor sleep. This study aimed to test these questions in a clinically relevant rat model of acute overuse-induced nerve injury. Twenty-five young adult female Sprague-Dawley rats performed a high-repetition high force lever-pulling task for 4 weeks. Rats were then split into 3 groups and exposed for 3 weeks to either: (1) voluntary exercise via access to a running wheel (from 1800-600, 5 d/wk, Ex), (2) sleep disturbance (from 600-1800, 4 random d/wk, SD), or (3) both (Ex+SD). Forepaw mechanical sensitivity was assessed by monofilament testing methods. Tail vein blood draws was performed, and serum assayed for inflammatory cytokines, brain-derived neurotrophic factor (BDNF) and corticosterone. Data were longitudinally compared between groups using mixed-effects models with repeated measures, followed by Tukey post-hoc tests (means and SEM are presented). Post-injury exercise was associated with forepaw hypersensitivity; this sensitivity improved with exercise with and without sleep disturbance, but worsened with sleep disturbance alone (Fig. 1A). With respect to serum biomarkers (Fig. 1B-D), sleep disturbance enhanced BDNF and interleukin-6 (IL-6), but suppressed the potent anti-inflammatory interleukin-10 (IL-10), relative to exercise with and without sleep disturbance. Corticosterone decreased with each intervention. The findings provide preliminary evidence for a role of poor sleep in the transition from acute to

chronic pain, and the potential for exercise to counter these sleep-induced effects. Changes in BDNF and inflammation may be a common underlying mechanism for these relationships.

Title: Early life pain exposure alters fever response to adult immune challenge

Authors: *M. G. GOMEZ, C. SEARLES, L. HANUS, A. Z. MURPHY;
Georgia State Univ., Atlanta, GA

Abstract: Infants born prematurely are significantly more likely to be admitted to the Neonatal Intensive Care Unit (NICU) where they experience upwards of 10-18 painful procedures each day, often with no anesthesia or analgesia. Pre-clinical studies have shown that early exposure to pain disrupts the normal development of the CNS in multiple ways that persist into adulthood. Similar findings are reported clinically as well. The present study aims to explore the effects of neonatal injury on the response to an immune challenge in adulthood. Male and female rats were exposed to a short-term inflammatory insult induced by intraplantar administration of 1% carrageenan (CGN) on the day of birth (P0). In adulthood (P60-P90), rats were implanted with Thermicron iButtons to monitor core body temperature; 14 days later, rats were injected with lipopolysaccharide (LPS) to elicit an immune response. Animals were sacrificed after 24 hours or at their peak fever point and brain tissue collected for immunohistochemical analysis of VGAT, VGLUT, Fos and prostaglandin receptor within the median preoptic area (MnPO), a critical CNS site for the fever response. Analysis of LPS-induced febrile response at 24 hours show a trend in both males and females exposed to early life pain to have higher peak fever temperature than controls. Fever duration was also longer in pain exposed females. Immunohistological analysis of MnPO tissue is currently in progress. Together, these studies may elucidate a mechanism through which children experiencing unresolved pain during the perinatal period show an increased severity of sickness behavior and attenuated immune signaling.

Title: Validation of a custom-built thermal grill to generate the perception of pain in healthy human subjects

Authors: *R. M. CASTON, T. S. DAVIS, E. H. SMITH, J. D. ROLSTON;
Neurosurg., Univ. of Utah, Salt Lake City, UT

Abstract: The thermal grill illusion (TGI) is an experimental pain model consisting of interlaced warm and cool bars. The temperature difference between the bars increases the perceived illusory pain. However, bars that are too cold or hot conflates the pain generated solely from the

bar arrangement with thermal pain. Temperature perception also varies among individuals. To account for individual variation and maximize temperature difference between bars without causing thermal pain, we built a custom-thermal grill. We validated the illusion with a rigorous psychophysical paradigm. **Methods**: We recruited 20 healthy human participants between the ages of 18-65. We incorporated a tree-structured classification algorithm into our thermal grill software to determine each subject's hot pain threshold (HPT) and cold pain threshold (CPT). Thresholds were used to generate three temperature settings: 1) all the bars set 1°C < HPT, 2) all the bars 1°C > CPT, and 3) alternating warm and cool (TGI). Categories were randomly presented 15 +/- 0.4 times per subject for 10 seconds each. Subjects rated discomfort, pain, hot, and cold on a sliding scale from 0-10 (none to worst). Subjects were classified as responders if their TGI discomfort rating was different than both the cool and warm stimuli (Tukey-Kramer post hoc pairwise comparison, a=0.05). **Results**: Across all responders, a Kruskal-Wallis H test showed a difference in discomfort and for pain between the TGI, cool, and warm settings (discomfort: $X^2(2) = 19.14$, $p < 0.005$, mean rank score of 27.18 for TGI, 13.77 for cool, and 10.05 for warm; pain: $X^2(2) = 14.04$, $p < 0.005$, mean rank score of 23 for TGI, 14 for cool, and 14 for warm). Using a Tukey-Kramer post hoc pairwise comparison on the mean ranks (a=0.05), we found that for discomfort: the TGI was significantly different from cool ($p < 0.01$) and from warm ($p < 0.001$); similarly, for pain: the TGI was significantly different from cool ($p < 0.01$) and from warm ($p < 0.01$). The normalized pain rating for cool and warm was 0 +/- 0 and 1.03 +/- 0.38 for the TGI. We found that 11 subjects experienced the TGI. **Conclusion**: Here we report the validation of our novel thermal grill and psychophysical paradigm. All software and hardware schematics are open source and freely available to promote this classic psychological illusion's reproducibility. Our responder rate is slightly lower than previous reports, which may be due to our stringent responder criteria or because our protocol eliminates the conflating effects of thermal pain shown by none of our responders reporting warm or cool as painful. Our custom-built thermal grill and software can be used as an experimental paradigm to study human subjects' pain processing.

Title: Abnormal brainstem trigeminal fiber microstructure as a key feature of treatment non-response across trigeminal neuralgia subtypes: a DTI study

Authors: *S. TOHYAMA[1], M. R. WALKER[1], J. Y. ZHANG[1], J. C. CHENG[2], M. HODAIE[3]; [1]Krembil Res. Inst., Toronto, ON, Canada; [2]Stony Brook Univ. Sch. of Med., Stony Brook, NY; [3]Neurosurgery, Toronto Western Hosp., Univ. of Toronto, Toronto, ON, Canada

Abstract: Background & Aims: Trigeminal neuralgia (TN) is a highly disabling chronic neuropathic facial pain condition. TN is classified into several different subtypes based on the etiology and pathogenesis, including classical TN (CTN), TN secondary to multiple sclerosis (MS-TN), and TN associated with a solitary pontine lesion (SPL-TN). While the differing treatment response rates across the subtypes of TN is well-established, the rationale behind this spectrum is not well understood. Using diffusion tensor imaging (DTI), we aimed to determine whether alterations in the brainstem trigeminal fibers are associated with surgical response in TN and whether the degree of microstructural alterations predicts the likelihood of response across subtypes of TN. **Methods**: We retrospectively studied 98 TN patients (39 males and 59 females, mean age +/- SD: 58.3 +/- 13.8 years), consisting of 61 CTN, 26 MS-TN, and 11 SPL-TN patients. All patients underwent neurosurgical treatment for TN and based on clinical follow-up data, were identified as responders or non-responders. Responders were those that achieved greater than 75% pain relief at 12 months post-treatment. Each patient underwent a 3 Tesla MRI session before treatment to acquire a T1-weighted anatomical scan and a 60 directions diffusion-weighted imaging scan. Diffusivity metrics of fractional anisotropy (FA), mean diffusivity (MD), radial diffusivity (RD), and axial diffusivity (AD) were obtained from the proximal brainstem segment of the trigeminal nerve pathway. Age- and sex-matched healthy individuals and the contralateral, unaffected side served as controls. **Results**: Overall, treatment non-responders (n=47) showed significantly decreased FA and AD, and increased RD in the brainstem trigeminal fiber microstructure, compared to responders (n=51) and healthy controls (n=50). There was also a statistically significant difference between the subtypes of TN non-responders for FA, MD, and RD on the affected side. SPL-TN non-responders (n=10) demonstrated the greatest degree of microstructural alterations, characterized by decreased FA, and increased MD and RD, followed by MS-TN non-responders (n=15), and CTN non-responders (n=22). No significant diffusivity differences were observed for the responder subgroups of CTN (n=39) and MS-TN (n=11). **Conclusions**: We find that abnormal brainstem trigeminal fiber microstructure is a key feature of treatment non-response in TN. Furthermore, the degree (or extent) of these alterations predicts the likelihood of surgical response across the different types of TN. Thus, DTI may serve as an important tool in the clinical setting to aid treatment decision making.

Title: Modulating Brain Rhythms of Pain using Transcranial Alternating Current Stimulation (tACS)

Authors: E. MAY[1], V. D. HOHN[1], M. M. NICKEL[1], L. TIEMANN[1], C. GIL AVILA[1], H. HEITMANN[1], P. SAUSENG[2], *M. PLONER[1];

Abstract: Pain protects the body. However, pain can also occur for longer periods without serving protective functions. Such chronic pain conditions are associated with substantial changes of brain structure and function and are difficult to treat. Thus, a better understanding of the underlying brain mechanisms and new approaches for the treatment of pain are urgently needed. Here, we therefore investigated a causal role of oscillatory brain activity for pain and explored the potential of transcranial alternating current stimulation (tACS) as a new treatment approach for pain. To this end, we investigated whether tACS can modulate pain and pain-related autonomic activity in 29 healthy human participants using a tonic heat pain paradigm as an experimental model of chronic pain. In 6 recording sessions, participants received tACS over prefrontal or somatosensory cortices at alpha or gamma frequencies or sham tACS. During tACS, pain ratings and autonomic responses were collected. Using the present setup, tACS did not modulate pain intensity, the stability of pain ratings or the translation of the noxious stimulus into pain. Likewise, tACS did not change autonomic responses. Bayesian statistics further indicated a lack of tACS effects in most conditions. The only exception was alpha tACS over somatosensory cortex where evidence for tACS effects was inconclusive. Taken together, the present study did not find significant tACS effects on tonic experimental pain in healthy human participants. However, considering the conceptual plausibility of using tACS to modulate pain and the urgent need for novel pain treatments, further tACS studies are warranted. Based on the present and previous findings, such studies might apply refined stimulation protocols targeting alpha oscillations in somatosensory cortices.

Title: Reduced left hippocampal volume and decreased hippocampal n-acetylaspartate post acute stress in a mouse model of early life stress: an magnetic resonance study

Authors: *A. D. BRAKE[1], X. YANG[1], C.-Y. LEE[2], P. LEE[2,3], P. KESELMAN[2], O. ELLER[1], I.-Y. CHOI[2,4], J. HARRIS[2,1], J. CHRISTIANSON[1];

Abstract: Early life stress (ELS) exposure is a significant risk factor for developing chronic pain syndromes, psychiatric disorders including depression and anxiety, and metabolic disorders later in life. Dysregulation of the hypothalamic pituitary adrenal (HPA) axis has been shown to contribute to these outcomes. The hippocampus is negative limbic regulator of the HPA axis and is sensitive to increased glucocorticoids during early development. We have previously described that ELS in mice, in the form of neonatal maternal separation (NMS), results in suppressed hippocampal neurogenesis, dysregulated corticosterone production, metabolic syndrome, and urogenital hypersensitivity. This study aimed to determine whether NMS mice have decreased hippocampal volumes using magnetic resonance imaging (MRI), similar to what has been observed in patients with depression and/or a history of ELS. We also measured the spectral contents of the hippocampus prior to and after an acute stress exposure (water avoidance stress) using magnetic resonance spectroscopy (MRS). In order to determine if metabolic changes contribute to these observations, body weight was correlated with hippocampal spectral contents after WAS. NMS was performed by separating entire litters for 3 hours/day from postnatal day (P) 1 to P21. At nine months of age, body weight and composition of naïve (n=5) and NMS (n=9) female mice was assessed using qMRI. Mice then underwent MRI and MRS both prior to and 1 day after a 1h exposure to water avoidance stress (WAS). Whole brain volumetric analysis was performed using Voxel Base Morphometry. MRS was analyzed in a single voxel over the right hippocampus and MRS analysis was performed with LCModel software. The left hippocampus of NMS mice was 0.038 mm^3 smaller compared to naïve mice ($p<0.005$). No significant differences in hippocampal spectral contents were observed between naïve and NMS mice prior to WAS. However, at 1 day after WAS, NMS mice showed significantly lower N-acetyl-aspartate (NAA), pCreatine, and pCholine, and a trend toward decreased glutathione levels, compared to naïve mice. NMS mice showed a trend toward increased body weight and body fat percentage compared to naïve mice. Interestingly, a significant negative correlation was observed between body weight and pCreatine content post-WAS in NMS mice, as well as a positive correlation between body weight and Glutamine for both naïve and NMS mice.

Together, these data suggest that NMS in mice reduces left hippocampal volume and disrupts stress-induced neurochemical responses in adulthood, which may also be related to whole body metabolic changes.

Abstract: Pain modulatory network is influenced by sex and age in a healthy state and during osteoarthritis progression in rats.Joyce T. Da Silva [1,2]*, Youping Zhang[1], Amir Tofighbakhsh[1], David A. Seminowicz[1x], Jin Y. Ro[1x].
[1] Department of Neural and Pain Sciences, School of Dentistry, University of Maryland Baltimore, Baltimore, United States of America. [2] Department of Psychiatry, School of Medicine, Johns Hopkins University, Baltimore, United States of America.[X] Senior authors.
Old age and female sex are risk factors for the development of osteoarthritis (OA) and chronic pain. We investigated the effects of sex and age on pain modulatory networks in a healthy state and during OA progression. We used functional MRI to determine the effects of sex and age on periaqueductal gray functional connectivity (PAG FC) in a healthy state (pre-OA) and during the early and late phases of monosodium iodoacetate (MIA)-induced OA in male and female Fischer 344 rats (young, 3-6 mo / old, 20-24 mo). For functional MRI, rats were scanned using a Bruker 7T MRI (TR = 1500 ms, in plane resolution = 400 μm, slice thickness 1 mm, acquisition time: 15 minutes) and under isoflurane anesthesia ≤ 1.5%. We then examined how sex and age affect longitudinal changes in PAG FC in OA. In a healthy state, females exhibited more widespread PAG FC than males, and this effect was exaggerated with aging. Young males had moderate PAG FC changes during the early phase but recruited additional brain regions, including the rostral anterior cingulate cortex (ACC), during the late phase. Young females exhibited widespread PAG FC in the early phase, which includes connections to insula, caudal ACC, and nucleus accumbens (NAc). Older groups had strong PAG FC with fewer regions in the early

phase, but they recruited additional brain regions, including NAc, in the late phase. Overall, our findings show that PAG FC is modulated by sex and age in a healthy state. A widespread PAG network in the early phase of OA pain may contribute to the transition from acute to chronic OA pain and the increased risk of developing chronic pain for females. Enhanced PAG FC with the reward system may represent a potential mechanism underlying chronic OA pain in elderly patients.

Title: Modulations of ongoing oscillations exerted by sustained painful heat and non-painful cold stimuli recorded from the human insula using intracerebral EEG

Authors: *G. LIBERATI[1], D. MULDERS[1], L. LEBRUN[1], A. COURTIN[1], S. FERRAO SANTOS[2], J.-G. RIBEIRO VAZ[2], C. RAFTOPOULOS[2], A. MOURAUX[1];

Abstract: The human insula is a target for spinothalamic input, but there is still no consensus on its role in pain perception. Using intracerebral electroencephalography (iEEG), we recently observed that sustained periodic warm nociceptive stimuli selectively modulated theta- and alpha-band ongoing oscillations recorded from the insula. These modulations, however, are not necessarily pain-specific, as they could be simply related to the activation of the spinothalamic system, and/or to the conveyance of thermal information. The aim of the present study was to disentangle these aspects by comparing the effects of sustained periodic painful heat stimulation and sustained periodic non-painful cold stimulation on insular ongoing oscillatory activity.
6 patients undergoing iEEG (34 insular contacts) participated in the experiment (Fig. 1). Each patient received 2 blocks of sustained periodic stimuli (painful heat and non-painful cold stimuli; frequency: 0.2 Hz). The order of the blocks was randomized across participants.
Whereas both heat and cold stimuli elicited an increase of EEG power at the frequency of stimulation (0.2 Hz), only heat stimuli exerted a 0.2 Hz modulation of ongoing oscillations in the theta frequency band (Fig. 2). These findings suggest that the modulation of theta oscillations exerted by painful heat stimuli is not merely related to the activation of the spinothalamic system and/or to the conveyance of thermal information, but could be more strongly related to pain perception.

Title: The Hsp90 Isoform-Selective Inhibitor KUNG65 Enhances Opioid Anti-Nociception while Reducing Tolerance

Authors: *K. CHOU[1], S. MISHRA[3], B. S. J. BLAGG[3], J. M. STREICHER[2];
[1]Univ. of Arizona, ; [2]Pharmacol., Univ. of Arizona, Tucson, AZ; [3]Chem., Univ. of Notre Dame, Notre Dame, IN

Abstract: Opioids are the gold standard for pain management, however, adverse side effects like respiratory depression and addiction limit their viability. One approach to improve opioid therapy focuses on a dose-reduction strategy by amplifying opioid analgesia without boosting side effects, so that less opioid can be given. To this end, we've focused on Heat shock protein 90 (Hsp90), a central protein regulator in the cell; ongoing studies from our lab have shown that inhibition of Hsp90 in the spinal cord improves morphine anti-nociceptive potency by 2-3 fold in acute and chronic pain while reducing tolerance, rescuing established tolerance, and not changing reward and constipation, enabling a dose-reduction strategy. However, our results also showed that non-selective Hsp90 inhibitors given systemically (intravenous, IV) have the opposite effect, blocking opioid pain relief. Seeking a means to surmount this roadblock, we determined which Hsp90 isoforms regulate opioid pain relief in brain and spinal cord in mice using selective small molecule inhibitors and CRISPR/Cas9 gene editing. We found that Hsp90α alone regulated opioid signaling and pain relief in the brain. However, in the spinal cord,we found that the isoforms Hsp90α, Hsp90β, and Grp94all regulated opioid signaling and pain relief. This led to our hypothesis that targeting spinal cord Hsp90 with isoform-selective inhibitors given IV could boost opioid pain relief without altering side effects, enabling a dose-reduction strategy. We tested this hypothesis with the novel Grp94-selective inhibitor KUNG65, given at a 1mg/kg dose IV in male and female CD-1 mice, followed by a 24hr treatment time, then analysis of opioid anti-nociception and side effects. We found that systemic (IV) KUNG65 treatment resulted in a 1.9 fold increase in morphine potency to relieve tail flick pain, consistent with our earlier studies injecting inhibitor directly into spinal cord. We also found that KUNG65 boosted morphine efficacy in paw incision pain, with dose/response analysis in progress. Additionally, we found that KUNG65 injection could rescue established morphine tolerance in the tail flick assay, again as we found for direct spinal cord injection. These results support our hypothesis that isoform-selective Hsp90 inhibitors can selectively engage Hsp90 in the spinal cord when given systemically, resulting in improved opioid anti-nociception and side effects. These results strongly suggest that Hsp90 isoform-selective inhibitors could be a powerful new tool to improve opioid therapy through a dose-reduction strategy, and further show that this effect can be achieved through a translationally relevant dosing route.

Title: The impact of advanced age and sex on Mu Opioid Receptor signaling in the midbrain periaqueductal gray: implications on analgesia

Authors: *E. F. FULLERTON[1], M. C. KAROM[1], M. RUBAHARAN[1], J. M. STREICHER[2], A. Z. MURPHY[1];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Chronic pain is exceedingly prevalent in individuals over 65 years of age, but is under-managed in this population due in large part to a dearth of knowledge regarding the impact of age on opioid efficacy for chronic pain management in the elderly. We have previously shown that advanced age and sex alter morphine modulation of persistent inflammatory pain (induced by intraplantar administration of Complete Freund's adjuvant (CFA)), such that morphine potency is highest in adult male rats (2mos), with EC_{50} values 2-fold higher in aged males (18mos) and females regardless of age. Age induced changes in morphine EC_{50} values were accompanied by a reduction in mu opioid receptor (MOR) expression in the ventrolateral periaqueductal gray (vlPAG), a CNS region critical in pain modulation. The present studies further explore the impact of sex and age on opioid signaling within the PAG. MOR affinity, availability, and G-protein activation were assessed using radioligand binding assays and GTPγS assays in vlPAG tissue from adult and aged, male and female rats collected 72h following CFA administration. Regulation of opioid induced G-protein signaling was assessed using RNAscope to analyze mRNA expression of Regulator of G-Protein Signaling (RGS) family members RGS4 and RGS9-2. We find that aged males and females (adult and aged) exhibit reduced vlPAG MOR binding potential (radioligand binding assay) and reduced G-protein activation efficiency (GTPγS assay) compared to adult males, suggesting that age- and sex- induced alterations in MOR machinery contribute to reduced opioid potency. Our analyses of RGS mRNA revealed increased expression of RGS4 and RGS9-2 in the vlPAG of aged animals compared to adults, indicating that MOR signaling is subject to greater negative regulation in the aged vlPAG. The observed age-related reductions in vlPAG MOR expression, MOR agonist binding, and opioid induced G-protein activation, along with the observed increase in vlPAG RGS4 and RGS9-2 have significant implications in pain management in the aged population. Our novel findings elucidate several mechanisms responsible for reduced morphine potency in aged animals, and identify potential therapeutic targets to improve pain management in the elderly.

Title: The Src kinase signaling pathway: a potential regulator of intermittent fasting-induced enhancement in morphine antinociception

Authors: *F. HANAK[1], P. LANGLAIS[2], J. M. STREICHER[1];
[1]Pharmacol., [2]Med., Univ. of Arizona, Tucson, AZ

Abstract: The opioid epidemic is a public health crisis in the United States, marked by high levels of abuse and poor quality of life for chronic pain patients requiring continuous use of opioids. In an effort to find a non-pharmacological alternative or adjunct therapy to opioid medication, we previously showed that daily intermittent fasting (IF) in mice improved morphine efficacy in acute and chronic pain, while mitigating reward, tolerance and constipation. The present study aimed to characterize the molecular mechanism by which IF enhances morphine-induced antinociception. Male and female CD-1 mice were subjected to 7 days of IF or *ad libitum* control (AL), with daily 18-hour periods of fasting, followed by 6-hour periods of feasting on standard chow. Spinal cords were harvested from male and female mice, and protein extraction was performed. Using quantitative proteomic analysis, we found that the expression levels of 654 proteins were significantly altered in IF mice compared to AL controls. In the present study, we chose to examine the role of Src Kinase Signaling Inhibitor 1 (SRCIN1) in modulating IF effects. SRCIN1 protein expression was downregulated 32% by IF, suggesting an increase in Src signaling. We thus subjected male and female CD-1 mice to 7 days of the aforementioned IF regimen, then treated them with the Src kinase inhibitor Src-1I (10 nmol, intrathecal injection) or Vehicle, 10 minutes, followed by morphine (3.2 mg/kg, subcutaneous injection), and assessed antinociception using the thermal tail flick assay. The previously seen IF-induced increase in thermal latency was eliminated by Src inhibition in male mice, and this effect was less pronounced in females. These data suggest that the antinociceptive effects of IF are promoted by Src kinase signaling, with a potential sex difference in the molecular mechanism of IF. Further discoveries in this mechanism could result in the development of improved pain management therapies, as well as uncover novel molecular circuits linking IF to changes in opioid antinociception.

Title: Loss of SUR1 subtype K_{ATP} channels alters antinociception and locomotor activity after opioid administration

Authors: *A. H. KLEIN, G. SAKAMAKI, K. JOHNSON, M. MESINGER, E. HMU;
Univ. of Minnesota, Duluth, MN

Abstract: There are several classes of opioids targeting the mu opioid receptor, each with various functional selectivity of downstream pathways including K_{ATP} channels. As part of an on-going investigation into differences between synthetic, semi-synthetic, and non-synthetic opioids and their downstream effects on potassium channel signaling, we hypothesize there are differences in K_{ATP} channel activation between buprenorphine, fentanyl, and [D-Ala2, N-MePhe4, Gly-ol]-enkephalin (DAMGO). To test this hypothesis, male and female mice lacking the SUR1-K_{ATP} channel subunit (SUR1 KO) were behaviorally tested against wild-type (SUR1 WT) using modified Hargreaves and von Frey methods to measure thermal and mechanical antinociception, respectively. Latency and force measurements were taken before and after drug injection (DAMGO, 10 mg/kg; fentanyl, 0.25 mg/kg; buprenorphine, 5.83 mg/kg) at 3 min., 15 min., 30 min., 45 min., 60 min., and 120 min., post subcutaneous injection. Potassium channel flux was measured using a fluorescence intensity plate reader in cultured primary dorsal root ganglia and dorsal horn cells in SUR1 KO and WT mice. In addition, we also tested if loss of SUR1 would affect locomotor activity of mice administered buprenorphine, fentanyl, or DAMGO at the same doses tested for thermal/mechanical antinociception. Mice with a global loss of SUR1 have significantly attenuated thermal and mechanical paw withdrawal latencies/forces compared to SUR1 WT mice. Potassium flux decreased in after fentanyl and buprenorphine exposure in cultured dorsal root ganglia and spinal cord neurons from SUR1 KO mice compared to WT mice. Hyperlocomotion was significantly attenuated in SUR1 KO mice after buprenorphine administration, similar to morphine, but was not affected after fentanyl or DAMGO administration. We conclude that there are differences in K_{ATP} channel dependent activity between fentanyl, buprenorphine, and DAMGO from our behavioral assays and fluorescence intensity data. Future experiments will possibly investigate the K_{ATP} channel contribution of analgesia in the central nervous system, utilizing tissue cultures from higher order brain regions

Title: Intrathecal Knockdown of Adenylyl Cyclase 1 Attenuates Morphine Tolerance and Withdrawal in Mice

Authors: *A. DOUCETTE[1], K. JOHNSON[1], V. WATTS[2], A. H. KLEIN[3];
[1]Pharm. Practice and Pharmaceut. Sci., Univ. of Minnesota, Duluth, MN; [2]Purdue Univ., West Lafayette, IN; [3]Pharm. Practice and Pharmaceut. Sci., Univ. of Minnesota Duluth, Duluth, MN

Abstract: Opioids are clinically used to alleviate pain, accomplishing analgesia by inhibiting neuronal signal transmission. Chronic opioid use for pain management leads to tolerance and dosage escalation, potentially increasing substance dependence. Opioid tolerance and opioid induced hyperalgesia during repeated opioid administration and chronic pain are associated with upregulation of adenylyl cyclase activity. The objective of this study was to test the hypothesis that a reduction in adenylyl cyclase 1 (AC1) activity would attenuate morphine tolerance and hypersensitivity, and inflammatory pain. Mice were subjected to twice daily treatments of saline, 15 mg/kg morphine, for 5 days. Trigeminal ganglia, dorsal root ganglia, sciatic nerves, spinal cord, and brain stem were collected from mice in each treatment group for Quantitative PCR. mRNA expression of adenylyl cyclase (Adcy) 1, 2, 3, 5, 6, 8; Epac 1 (Rapgef 3) and Epac 2 (Rapgef 4); and PKA subunits A and B (Prkaca and Prkacb) were compared to controls. Adcy1 was upregulated in the spinal cord, dorsal root ganglia, and sciatic nerves of morphine tolerant mice. Short-hairpin RNA (shRNA) gene knockdown of Adcy1 in the spinal cord and dorsal root ganglia was accomplished using a lumbar injection of an associated adenovirus viral vector (AAV9-GFP-U6-m-Adcy1-shRNA) and negative controls (AAV9-GFP-U6-m-scrambl-shRNA). Behavioral testing such as open field testing, rotarod testing, burrowing, thermal and mechanical paw withdrawal latencies were tested after injection. Morphine tolerance (15mg/kg, sc, 5 days and 10-40mg/kg escalation over 4 days) and opioid-induced hypersenstivity were also assessed after inoculation. Lumbar intrathecal administration of a vector incorporating short-hairpin RNA against Adcy1 did not affect baseline parameters such as open field testing, rotarod testing, and burrowing testing, nor did it affect C-fiber compound action potentials. Pharmacological inhibition of AC1, also attenuated morphine induced hypersensitivity. Morphine tolerance and withdrawal were attenuated in Adcy1 shRNA mice compared to control vector mice. Gene knockdown of Adcy1 decreases morphine tolerance and opioid-induced hypersensitivity, which could form the basis for novel therapeutics in the future.

Title: Investigating the role of G-protein bias in the antinociceptive and side effect profiles of two novel mu opioid receptor agonists kurkinorin and kurkinol.

Authors: A. F. ALDER[1], S. KASKA[2], D. LUO[2], T. E. PRISINZANO[2], ***B. M. KIVELL**[1]; [1]Victoria Univ. of Wellington, Wellington, New Zealand; [2]Univ. of Kentucky, Lexington, KY

Abstract: Current pain medications that activate mu-opioid receptors (MOPr) have high abuse potential and overdose risk due to respiratory depressive effects. One mechanism that has been proposed to generate safer MOPr agonists for the treatment of pain is the development of G-protein biased agonists. Here we evaluate two novel MOPr agonists with different G-protein signalling bias properties, in preclinical models of pain and side-effects to determine whether G-protein bias correlates to improved side effects. We found that both kurkinorin (a weak G-protein biased MOPr agonist), and kurkinol (a strong G-protein biased MOPr agonist) had a similar duration of action to morphine in the tail-withdrawal and hotplate anti-nociceptive assays in male and female C57BL/6J mice. We also show that G-protein bias correlated to reduced tolerance in the tail-withdrawal assay of acute nociception. Furthermore, the antinociceptive potency and tolerance of kurkinorin and morphine were reduced in male β-arrestin2 knockout mice in the tail-flick anti-nociceptive assay, confirming that anti-nociceptive tolerance is β-arrestin2 dependent in this assay. In contrast, in the chemotherapy-induced model of neuropathic pain, tolerance to kurkinol and kurkinorin developed at the same rate as morphine. The strong G-protein biased MOPr agonist Kurkinol induced similar respiratory depression effects in whole-body plethysmography tests as morphine. Kurkinol, but not kurkinorin induced constipation in assays of small intestine transit time and faecal accumulation. Kurkinol showed increased motor coordination impairment compared to the less bias kurkinorin in the accelerating rotarod assay. Moreover, the respiratory depressive and constipation effects of kurkinol were not reversed in β-arrestin2 knockout mice, indicating that both respiratory depression and gastrointestinal effects of MOPr agonists act via G-protein signalling pathways. In conclusion, we have identified that kurkinorin, a weakly G-protein biased MOPr agonist induces antinociception with reduced respiratory and gastrointestinal side effects, whereas kurkinol, the highly selective G-protein biased MOPr agonist induced potent antinociceptive effects with a worse side effect profile, indicating an inverse relationship between G-protein bias and side effect profile.

Title: Antinociceptive synergistic interaction between palmitoylethanolamide and morphine in the mouse formalin test

Authors: *M. DECIGA-CAMPOS[1], F. J. LÓPEZ-MUÑOZ[2];
[1]SEPI. Escuela Superior de Medicina, Inst. Politécnico Nacional, Ciudad de México, Mexico;
[2]Dept. de Farmacobiología, Cinvestav, Ciudad de México, Mexico

Abstract: Pharmacological synergism has been used to obtain higher efficacy at drug concentrations at which side effects are minimal. In this study, the pharmacological antinociceptive interaction between *N-palmitoylethanolamide* (PEA) and morphine was investigated. Individual concentration-response curves of PEA (0.1-100 μg/paw) and morphine (0.3-56.2 μg/paw) were evaluated in mice in which nociception was induced intraplantarly with 2% formalin. Different nociceptive responses counted flinches and licking behavior. Thus, we establish two EC_{50} according to the behavior analyzed; in flinches, behavior PEA generated EC_{50}= 11.61 ± 2.13 μg/paw and morphine produce EC_{50} = 3.96 ± 0.2 μg/paw. However, in licking behavior PEA generated EC_{50} = 29.39 ± 4.2 μg/paw and morphine produce EC_{50} = 10.94 ± 0.2 μg/paw. Flinching behavior was used to determine the experimental combinations according to the isobolographic method in a fixed 1:1 ratio. The isobologram demonstrates that the combinations investigated in this study produced a synergistic interaction; flinching experimental values (Z_{exp}= 2.72 ± 0.17 μg/paw) were significantly smaller than those calculated theoretically (Z_{add}= 7.78 ± 1.07 μg/paw) and licking experimental values (Z_{exp}= 6.28 ± 0.89 μg/paw) were significantly smaller than those calculated theoretically (Z_{add}= 19.71 ± 2.13 μg/paw). The antinociceptive mechanisms of the PEA and morphine combination involve PPAR-α receptors. These findings suggest that PEA and morphine could be interesting to treat inflammatory pain.

Title: Comparative analysis of human mesenchymal stem cells from bone marrow, adipose and umbilical cord as sources of anti-inflammation therapy

Authors: *Q. FAN, C. AKESSON, J. LI, J. CHENG;
Cleveland Clin., Cleveland, OH

Abstract: Objective: Human mesenchymal stem cells (hMSCs) have come to the forefront as a potential treatment for chronic pain and opioid tolerance due to their trophic and immunomodulatory properties. hMSCs are commonly sourced from the bone marrow (BM), adipose (AD), and umbilical cord (UC) tissues. Studies have suggested that hMSCs isolated from different sources may have different immunomodulatory properties and gene expression profiles. In order to compare hMSCs from the three sources, we developed a transwell co-culture system to study the interactions between hMSCs and murine microglia cell line BV2 cells. Methods: BV2 cells were seeded and cultured in high-glucose DMEM supplemented with 10% FBS. After reaching 80%-90% confluency, BV2 were incubated with lipopolysaccharide (LPS) at 100ng/ml and 1000ng/ml separately for durations ranging from 6-24 hours. Real-time PCR was performed on total RNA extracted from the activated BV2 to measure the transcriptional expression levels of TNF-α, IL-1β, and IL-6. Then, BV2 cells were treated with LPS (1000ng/ml) for 6 hours, washed out, and co-cultured with the 3 types of hMSCs separately in a transwell plate for 24 hours. Real-time PCR was then performed on total RNA extracted from both BV2 and hMSCs to measure the transcriptional expression levels of TNF-α, IL-1β, and IL-6 in BV2, and TGF-β1, TGF-β2, and CX3CL1 in the 3 sources of hMSCs. Results: 1) LPS exposure increased robust BV2 cell transcriptional expression levels of TNF-α, IL-1β, and IL-6, dose-dependently and time-dependently, by as much as 80- (TNF-α), 7000- (IL-1β) and 18,000-fold (IL-6). 2) Co-culture with 3 sources of hMSCs dramatically reduced transcriptional expression levels of TNF-α and IL-6, but not IL-1β in BV2 cells. 3) Incubating 3 sources of hMSCs with activated microglia did not affect the hMSCs' transcriptional expression level of TGF-β. 4) Incubating BM and AD hMSCs with activated microglia resulted in a dramatic increase of the hMSCs' transcriptional expression level of CX3CL1. This increase in CX3CL1 expression was not seen in UC hMSCs. Conclusion: These results suggest that the therapeutic effects that hMSCs confer *in vivo* are likely mediated by immune cells, such as microglia within the nervous system, and that hMSCs from difference sources may have different immunomodulatory properties and therapeutic potentials.

Title: Pain modulating ethnobotanicals in Peruvian traditional medicine: a potential source of non-opioid therapeutics

Authors: *C. GALLO[1], G. POLETTI[1], R. ROJAS[1], J. ALBÁN[2], A. VAISBERG[1];
[1]Univ. Peruana Cayetano Heredia, Lima, Peru; [2]Univ. Nacional Mayor de San Marcos, Lima, Peru

Abstract: Chronic pain affects several million of individuals around the world being a leading cause of burden of disease and years lived with disability. This because of the lack of adequate relief provided by current therapies, which show low efficacy, development of tolerance, and dose-limiting toxicities. Opioids, particularly, are highly addictive and its dependence causes a large societal burden. Despite this, few novel non-opioid molecules targeting chronic pain have been identified in the past decade.Rescuing traditional medicine practices is one of the possible avenues to discover novel pharmacological approaches for clinical conditions like chronic pain. We have a repository of 1315 extracts from an equal number of plant collections corresponding to 350 species from 117 different plant families used in Peruvian traditional medicine. The collections were done in several localities and geographic regions of Peru.A total of 105 collections from this repository are used for the modulation of pain. Eighty-three of them were analyzed for cytotoxic effects; most (78%) showed very low or no cytotoxicity. Thirty-nine of these extracts were screened in binding and/or functional tests for 64 G-protein coupled receptors (GPCRs) and neurotransmitter transporters in the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill (UNC). From these 39 extracts, 11 showed non-significant binding to the mu, kappa or delta opioid receptors, and another 11 of them showed binding to the kappa or delta, but not to the mu opioid receptor.These preliminary data confirm the potential of Peruvian ethnobotanicals in the efforts directed to the discovery of novel non-opioid or less toxic and better tolerated therapeutics for pain disorders.

Title: Evaluation of adverse side effects of a novel glycinergic analgesic for treatment of chronic pain

Authors: *J. CAPOROSO, L. JIANG, T. S. TILLMAN, P. TANG, Y. XU;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Glycine receptors (GlyRs) are ligand-gated ion channels that mediate nociceptive signals in the central nervous system. Previously, we presented a novel analgesic (MJPY1) that alleviates thermal hyperalgesia and mechanical allodynia in rodent models of neuropathic and inflammatory pain. MJPY1 is a selective positive allosteric modulator of α3-containing GlyRs

and binds specifically to a transmembrane domain site for Δ9-tetrahydrocannabinol (THC), one of the major psychoactive components in cannabis.1,2 Here, we show that the glycinergic mechanisms of analgesia are independent of the psychoactive effects and modulation of opioid receptors. A battery of *in vivo* tests was performed with MJPY1 to assess its selectivity for α3-containing GlyRs, potential for psychomotor side effects, and potential for substance use disorder. To determine if MJPY1's analgesic action is mediated by other analgesic receptors, such as opioid receptors, Sprague-Dawley rats with chronic constriction injury induced-neuropathic pain were treated with MJPY1 in the absence and presence of the opioid receptor inhibitor naloxone. The thermal and mechanical hypersensitivities were assessed by Hargreaves and von Frey tests. Psychomotor side effects were examined using the open field and horizontal ladder rung walking tests in rats without pain conditions. Substance use disorder potential, such as drug seeking and reward behaviors, were investigated using the conditioned place preference test in naïve rats with repeated exposures to MJPY1. The results of these tests suggest that MJPY1 produces analgesia independent of opioid receptors, does not cause detrimental locomotor side effects, and does not establish substance use conditioning, making MJPY1 an attractive alternative to current chronic pain treatments. In conclusion, MJPY1 represents a novel class of analgesics that may transform chronic pain managements in the future.

Title: Dt095597 a new NPFFR1 antagonist devoid of addictive properties to fight opioid crisis

Authors: *S. AYACHI[1], C. DOEBELIN[1], M. FER[1], M. GIAMBELLUCO[1], A. DUMONT[1], L. DESHONS[1], E. STEINBERG[1], S. TARLET[1], S. MAYER[1], C. FRANCHET[1], N. LENNE[1], M. GERUM[2], A. MEDINA[2], F. PETIT[3], E. DARCQ[3], B. KIEFFER[3], F. SIMONIN[2], S. SCHANN[1]; [1]DOMAIN THERAPEUTICS, ILLKIRCH GRAFFENSTADEN, France; [2]CNRS, Univ. of Strasbourg, ILLKIRCH GRAFFENSTADEN, France; [3]McGill\Douglas Res. center, Montreal, QC, Canada

Abstract: Opioid analgesics are the cornerstones for treating moderate to severe pain despite numerous side effects including respiratory depression, constipation and itching. Upon chronic administration, they also induce analgesic tolerance, Opioid Induced Hyperalgesia (OIH) and addiction. Because of tolerance, opioids dose escalation is needed to achieve analgesia, unfortunately, this also increases the risk of respiratory depression involved in death by overdoses. In the United States, fatalities involving opioids now account for more deaths than motor-vehicle accident incidents. In the context of this opioid epidemic, there is an urgent need to discover novel strategies to prevent individuals from becoming opioid-dependent and ease

opioid detoxification. NPFF receptors (NPFFR) are GPCRs with an established anti-opioid activity, known to reduce OIH and analgesic tolerance. Based on NPFFR involvement in the pain homeostasis, identification of a selective NPFFR1 antagonist is a promising therapeutic strategy to fight the current opioid crisis. We present here the preclinical results of DT095597, a new orally bioavailable NPFFR1 antagonist candidate. These results include efficacy, selectivity profile and PK data in several species. We also present DT095597 in vivo results on several mice models. Used in combination with opioids, DT095597 reduces Morphine Induced Hyperalgesia which help prevent opioid dose escalation. In addition, DT095597 used in monotherapy is able to prevent and erase Induced Latent pain Sensitization induced by chronic morphine injection or by inflammatory pain (CFA). DT095597 effect on opioid detoxification has also been tested. DT095597 is able to prevent Oxycodone physical withdrawal when given in preventive or curative treatment. Finally, non-addictive properties of DT095597 has also been tested to assess its safety. Using intracranial self-stimulation on rats, we demonstrate that DT095597 induces no change on frequency rate curve indicating that it has no addictive properties and does not induce anhedonia nor dysphoria. In conclusion we have identified a potent and selective NPFFR1 antagonist orally available: DT095597. DT095597 is able to block OIH, and LS induced by chronic morphine or CFA injection, and also to reduce oxycodone physical withdrawal, while having no addictive properties. DT095597 effect on Latent pain Sensitization could prevent the acute to chronic pain transition. Results on opioid withdrawal are also promising concerning DT095597 involvement on opioid detoxification. Overall these data highlight DT095597 potential to reduce and prevent the progression and the severity of opioid epidemic crisis

Title: Inhibition of Heath Shock Protein 90 in the spinal cord enhances opioid anti-nociception by disabling an inhibitory GABA circuit

Authors: *C. S. CAMPBELL[1], P. R. LANGLAIS[2], J. M. STREICHER[3];
[1]Neurosci., [2]Med., The Univ. of Arizona, Tucson, AZ; [3]Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Opioid drugs used in the treatment of pain are in desperate need of replacement due to their deleterious side effects. One strategy on offer is developing dose-reductive compounds that, when co-administered with palliatives, can reduce the dose of opioid required for treatment, retaining analgesic efficacy while reducing unwanted side-effects such as addiction, respiratory depression, and death. We previously showed that intrathecal (IT) administration of the heat shock protein 90 (Hsp90) inhibitor 17-AAG potentiated the efficacy of morphine induced antinociception, while reducing or not changing opioid side effects, enabling a dose-reduction strategy. Proteomic analysis of the translational alterations induced by IT 17-AAG administration revealed an upregulation of GABA transporter 2 (GAT-2). To elucidate the role of GAT-2 in mediating the enhancement of morphine antinociception, 17-AAG treated mice were administered a GAT inhibitor, Nipecotic Acid (NA), in the tail flick assay. NA effectively blocked the 17-AAG enhancement of antinociception compared to controls, while not changing responses in Vehicle-treated mice, suggesting that GAT-2 mediates 17-AAG's antinociceptive enhancement. Since GAT-2 takes up GABA into the cell and reduces GABA activity, we hypothesized that an inhibitory GABA circuit is present in the spinal cord which reduces opioid antinociception and is disabled by Hsp90 inhibition and GAT-2 upregulation. To test this GABA hypothesis, mice were treated with IT GABA-A or GABA-B agonists (muscimol, baclofen) prior to systemic morphine administration. The GABA-A agonist reversed 17-AAG enhanced antinociception much like NA, supporting our hypothesis. Intriguingly, the GABA-B agonist

reversed 17-AAG antinociception in males but not females, suggesting a GABAergic sex-specific difference. To further test the inhibitory GABA circuit hypothesis, naïve mice (no 17-AAG) were injected with IT GABA-A or GABA-B antagonists (bicuculline, CGP54626) prior to morphine and tail flick. Males showed enhanced morphine antinociception with either antagonist, supporting the GABA inhibitory circuit hypothesis; however, neither drug had an impact on female mice, again suggesting mechanistic sex differences. These results taken together suggest that IT 17-AAG potentiates morphine-induced antinociception via upregulation of GAT-2, relieving an inhibitory GABAergic brake on opioid antinociception. This study provides mechanistic insight into how Hsp90 inhibitors can be used to boost opioid antinociception and may have identified a novel inhibitory circuit of opioid antinociception.

Title: Mindfulness-based stress reduction for chronic neuropathic pain relief in breast cancer survivors? The brain says yes!

Authors: *O. BROWN[1], T. HATCHARD[1,2], O. MIODUSZEWSKI[1], Y. SHERGILL[3], Z. FANG[1], P. POULIN[1,3,4], A. SMITH[1];
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Youth Wellness Centre, St. Joseph's Healthcare Hamilton, Hamilton, ON, Canada; [3]The Ottawa Res. Hosp. Res. Inst., Ottawa, ON, Canada; [4]Psychology, The Ottawa Hosp., Ottawa, ON, Canada

Abstract: Rationale and Objective: Chronic neuropathic pain (CNP), often caused by injury to peripheral nerves, affects 25-60% of women following breast cancer treatment. Current pharmacological treatment does not often help with CNP relief. Mindfulness-based stress reduction (MBSR), a psychological intervention, may be able to help. This work summarizes neuroimaging results from a group of women in a randomized control trial that investigated the effects of MBSR on CNP following breast cancer treatment. Methods: Twenty-three women were scanned with a 3T Siemens MRI scanner, including an Emotional Stroop fMRI task, resting state fMRI and diffusion tensor imaging (DTI). All participants were scanned two times, one at baseline after medical optimization and again after an 8 week MBSR course (n=13) or care as usual (n=10). They were also given the Brief Pain Inventory (BPI) at both scanning times. Results: The MBSR group had a significant reduction in pain severity following the intervention, while the control group did not. The Emotional Stroop results found that MBSR was associated with less blood flow in regions involved in pain processing and visual activity. The DTI results

showed that MBSR was related with greater fractional anisotropy (FA) post-intervention in left subcortical regions, which was correlated with lowered pain severity. The final imaging sequence reported greater functional connectivity within the default-mode network (DMN), specifically between the posterior cingulate cortex and medial prefrontal regions, following the MBSR intervention. This increase in functional connectivity within the DMN was associated with decreased pain severity. Conclusions: These studies provide compelling evidence of MBSR as a promising alternative to pharmacological treatment for pain-related problems in women suffering from CNP as a result of breast cancer treatment.

Title: Activation of TRPM3 induces mitochondrial activity and enhances neurite outgrowth in adult sensory neurons

Authors: *S. CHAUHAN, P. FERNYHOUGH;
Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Peripheral neuropathy affects approximately 50% of the population with diabetes mellitus depending on age and disease severity. It is associated with substantial morbidity and is characterized by induction of pain and loss of sensory function beginning distally in the lower extremities. Recent studies suggest that molecular cascades maintaining mitochondrial function and calcium homeostasis are effective therapeutic targets for diabetic peripheral neuropathy. Interestingly, our lab has recently reported that muscarinic acetylcholine type 1 receptor (M1R) antagonists stimulated neurite outgrowth, in part, by activating Ca^{2+}/calmodulin-dependent protein kinase kinase II (CaMKKII) and mobilization of AMP-activated protein kinase (AMPK). This further augmented mitochondrial function in sensory neurons imparting protection against small and large fiber neuropathy in various rodent models of peripheral neuropathy (including diabetes). Transient receptor potential melastatin receptor 3 (TRPM3) is a TRP type cation channel that triggers Ca^{2+} influx. TRPM3 is quite unique in that it binds calmodulin and is open under high phosphoinositide levels (the latter would be predicted during blockade of the M1R). We hypothesized that opening of TRPM3 could activate CaMKKII and induce neurite outgrowth and may mimic antimuscarinic drug effects. Dorsal root ganglion (DRG) neurons were isolated from adult control and streptozotocin-induced type 1 diabetic male Sprague–Dawley rats. Assessment of neurite outgrowth was performed in response to pregnenolone sulphate (PS) or CIM0216 (selective and specific TRPM3 agonists, respectively). A significant dose-dependent

elevation of neurite outgrowth was observed. These TRPM3 agonists also increased AMPK activation and extracellular signal-regulated kinases (ERK) signaling in control and diabetic DRG neuron cultures. There was also a significant augmentation of mitochondrial activity. Specifically, TRPM3 agonists elevated maximal respiration in diabetic DRG neuronal cultures. Our investigations towards understanding of TRPM3 activation and its downstream molecular cascade will hopefully lead to potential therapeutic targets for impeding detrimental effects of peripheral neuropathy.

Title: Piezo2 channel has critical roles in light-touch mechanosensitive sensory neurons in mouse hairy skin

Authors: *Y. BABA[1], C.-K. TONG[2], *E. A. LUMPKIN[1];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Columbia Univ., New York, NY

Abstract: PIEZO2 is a mechanically gated ion channel expressed in somatosensory neurons and mechanosensory epithelial cells. Because global *Piezo2* knockout causes perinatal lethality, Previous studies of PIEZO2 function in neurons have used the tamoxifen-inducible Cre/lox system or caudally restricted Hoxb8-driven Cre, as global knockouts of Piezo2 in the nervous system are perinatal lethal (Ranade et al. 2014; Murthy et al. 2018). These studies have shown that Piezo2 is critical for the function of proprioceptors, low-threshold mechanoreceptors and tactile allodynia. To perform constitutive knockdown of *Piezo2* over a broader anatomical area, we utilized a Cdx2-cre transgenic line. Using a tdTomato reporter line, we confirmed that Cre is expressed broadly in somatosensory neurons from the brachial plexus through thoracic ganglia. $Cdx2^{Cre}$; $Piezo2^{fl/fl}$ (Piezo2CKO) suppressed Piezo2 expression completely in the $Cdx2^{Cre}$ expression domain. Piezo2CKO mice survived until adulthood but were smaller than control mice and displayed abnormal limb movements, consistent with the loss of functional proprioceptors as previously reported. Using this mouse model, genotype-blinded recordings from cutaneous sensory neurons in response to mechanical stimulation were surveyed in ex-vivo skin nerve preparations (n=44 units from 18 mice). Many types of sensory neurons displayed mechanosensory defects in Piezo2CKO mice. Rapidly adapting mechanosensory neurons were not observed in Piezo2CKO mice (n=0/44 units) compared with control (CTRL) genotypes (n=17/36 units). Additionally, low-threshold slowly adapting responses associated elicited by stimulation of guard hair and touch domes were never observed (Piezo2CKO: n=0/20 units,

CTRL: n=28/30). By contrast, A mechanonociceptors (AMs) showed lower firing rates for initial phase of stimulation than control mice (Piezo2CKO: n=11/44 units, CTRL: n=2/19); however, their mechanical sensitivity was not lost completely. The von Frey thresholds of AMs were comparable between genotypes (median & interquartile ranges: Piezo2CKO:5.9, 2.2-19.6; CTRL:3.9, 0.7-19.6 mN). Together, these data confirm that Piezo2 channels are essential for encoding tactile stimuli with high sensitivity, and demonstrate that other mechanosensory transduction mechanisms suffice in A mechanonociceptors.

Title: Where does touch take place? Protein micropatterning to study how mechanoelectrical channels find their station

Authors: *J. A. FRANCO[1], A. DAS[2], B. PRUITT[3], M. B. GOODMAN[1,2];
[1]Dept. of Mechanical Engin., [2]Dept. of Mol. and Cell. Physiol., Stanford Univ., Stanford, CA;
[3]Departments of Mechanical Engin. and Molecular, Cellular, & Developmental Biol., Univ. of California Santa Barbara, Santa Barbara, Santa Barbara, CA

Abstract: Mechanoelectrical transduction (MeT) ion channels allow for the rapid conversion of physical stimuli into neural impulses. The positioning of these MeT channels along the neurite is hypothesized to play a critical role in setting mechanoreceptor sensitivity. In the roundworm Caenorhabditis elegans, mechanoreceptors called the Touch Receptor Neurons (TRNs) are responsible for detecting gentle touch. TRN function requires the expression of the DEG/ENaC ion channel subunit MEC-4. In wild-type TRNs, MEC-4 clusters into discrete puncta that are distributed along the neurite with inter-punctum spacing that increases distally from the cell body. Previous work established that the positioning of these puncta depends on genes encoding extracellular matrix (ECM) proteins, but did not identify which aspects of MEC-4 trafficking, localization, or anchoring had been disrupted. Aiming to dissect the biological processes underlying MEC-4 positioning, we conducted the first ever exploratory analysis of MEC-4 expression along neurites of isolated TRNs from dissociated C. elegans embryos. To control for

the potentially confounding effects of neurite morphology, and to simplify image acquisition and analysis, we cultured TRNs expressing an mNG::MEC-4 fusion protein on custom micropatterns of peanut agglutinin (PNA). In most cases, as was expected, TRN neurite morphology closely mirrored micropattern geometry. Using custom image analysis code, we quantified the fusion protein distribution along the full length of the neurite and used time lapse imaging to characterize protein mobility. We found that MEC-4 puncta were more sparse and more mobile than their in vivo counterparts. Upon repeating these experiments with TRNs from animals also expressing the mCherry::RAB-3 vesicle marker, we found that most of the MEC-4 puncta were likely sequestered within vesicles and had not reached the plasma membrane. Since laminins are a conserved and ubiquitous element in ECMs, we also asked whether or not the addition of laminin to the micropattern would be sufficient to create denser, more stable MEC-4 puncta. We developed a procedure for patterning PNA stripes alongside randomly distributed laminin microdots, and found this did not appreciably alter MEC-4 puncta. Our results confirm that the punctate distribution of MEC-4 seen in vivo is a primarily non-cell autonomous process, but suggest a potentially cell intrinsic mechanism regulating MEC-4 trafficking. The experimental technique developed here shows promise as a tool for direct, live imaging of protein mobility and may serve as a testbed for further exploring the interplay of neurite shape and channel trafficking.

Title: Recent trial history cues attentional selection of whisker stimuli in mice

Authors: *D. L. RAMAMURTHY, A. CHEN, G. KRISHNA, P. BHARGHAVAN, K. CASALE, D. E. FELDMAN;
Helen Wills Neurosci. Inst. and MCB Dept., UC Berkeley, Berkeley, CA

Abstract: The ability to selectively direct attention to behaviorally relevant stimuli is critical for animals in complex environments. To examine how stimulus statistics and performance history guide attentional selection for tactile processing, we trained head-fixed mice to perform a Go/NoGo whisker detection task. Mice had nine whiskers inserted in a piezo array. On each trial, one randomly chosen whisker was deflected (Go trials) or no whisker was deflected (NoGo trials). Mice were rewarded for licking on Go trials (hits), but were neither rewarded nor punished for licking on NoGo trials (false alarms). The identity of the deflected whisker on Go trials was randomly selected, with varying probabilities. Thus, sequential trials included random

sequences of whiskers and repetitions of specific whiskers, with NoGo trials interspersed throughout. Behavioral performance was strongly influenced by the history of successful detections on recent trials. Multiple, consecutive hits led to an increase in lick probability on subsequent trials of the same whisker, causing behavioral shifts in both detection sensitivity (d') and decision criterion (c). The increase in d' reflected increased hit rate after consecutive prior hits, which was greater than a more modest elevation in false alarm rate. Improvement in d' was maximal following consecutive hits on the same whisker, and was much weaker following multiple hits on random whiskers or repetitions of a different whisker. Thus, recent hit trials engage a whisker-specific attentional effect. This effect lasted ~10 s before subsiding, and was flexibly shifted among whiskers based on their recent history. It did not occur when whisker repetitions were not successfully detected (misses), indicating that sensory repetition alone did not drive this effect, rather, the conjunction of whisker stimulation and reward was essential. Thus, mice used the recent history of whisker deflections and rewards to modulate sensory processing of spatially specific whisker stimuli on a rapid timescale, consistent with attentional selection. We are now investigating the role of cortical interneurons in gating enhanced sensory detection during this attentional selection process.

Title: Fine structure and stability of the whisker map in layer 2/3 of somatosensory cortex in awake, behaving mice

Authors: *H. WANG, D. E. FELDMAN;
Univ. of California, Berkeley, BERKELEY, CA

Abstract: The whisker map in rodent somatosensory cortex is well characterized under anesthesia, but its organization during awake sensation is unknown. Using a novel behavioral task, we measured whisker receptive fields, map structure, and map stability in awake mice with 2-photon calcium imaging. During a whisker-attentive task, layer 2/3 pyramidal neurons were sharply tuned for one or a few whiskers, and cells tuned to different whiskers were intermixed in each column. This salt-and-pepper organization was superimposed on a sub-columnar tuning gradient and mean barrel-related map. In mice performing a sound-attentive task whisker tuning was more homogeneous in each column, and pairwise firing correlations were increased, indicating that the whisker map becomes decorrelated during whisker-attentive behavior. To assess map stability, we performed the same behavioral task in Drd3-Cre/TIGRE2.0-GCaMP6s

mice, which stably expressed Ca^{2+} sensor in layer 2/3 pyramidal cells, and imaged longitudinally from the same neurons every ~4 days for 2 weeks. Whisker tuning was highly dynamic, with 30% of neurons significantly changing their whisker tuning over a 4-7 day period, and many neurons losing or gaining whisker responsiveness across days. Only 60 % of consistently responsive units maintained constant tuning across sessions. Tuning was more stable for neurons tuned for the columnar whisker than for those tuned to non-columnar whiskers. Tuning dynamics persisted when whisking was abolished with Botox, suggesting that active whisker use does not drive the dynamic instability of the map. The ever-changing nature of the sensory map may provide a substrate for selecting optimal representations to perceive the complex environment.

Title: C-fos reports experience-dependent but not learning-related activity in mouse somatosensory cortex

Authors: *J. LEE[1], M. ZHU[1], D. J. MARGOLIS[2], A. L. BARTH[1];
[1]Dept. of Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA; [2]Cell Biol. & Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: Immediate-early gene expression induced by neural activity has been used to map discrete neural ensembles involved in sensation, cognition, and behavior. C-fos has commonly been assumed to identify neural engrams associated with learning or experience. Here we investigate how expression of the immediate-early gene c-fos is controlled by sensory experience and learning in mouse barrel cortex, a brain area strongly implicated in learning. Using longitudinal 2-photon imaging in superficial layers of mouse somatosensory cortex in a fosGFP transgenic mouse, we find that sensory association learning using a multiwhisker stimulus paired with a water reward did not enhance or stabilize fosGFP expression compared to baseline conditions. Acute whisker stimulation in awake mice also did not drive elevated fosGFP expression. However, exposure to an enriched tactile environment rapidly increased fosGFP expression across the previously labeled population. Sensory deprivation profoundly shifted fosGFP ensembles, increasing expression in weakly labeled cells while reducing expression in brightly labeled cells. These data indicate that monitoring immediately-early gene expression does not reveal a learning-specific engram in primary sensory cortex. We propose that fosGFP expression in primary sensory cortex is regulated by feedforward sensory drive as well as internal brain dynamics.

Title: Context dependent sensorimotor processing during active sensation: elucidating motor cortex's role during whisker movement

Authors: ***G. I. TELIAN**, J. BROWN, H. ADESNIK;
UC Berkeley, Berkeley, CA

Abstract: Mice actively adapt their whisking strategy to explore their environment. Vibrissae somatosensory cortex (vS1) is thought to convey sensory information to vibrissae motor cortex (vM1) in order to rapidly update the whisker motor program. However, this hypothesis has not been explicitly tested. Here we compare vM1's role in sensory-motor processing between untrained mice, and trained mice performing a whisker-dependent discrimination task. In both contexts, animals were head-fixed and free to palpate a tactile stimulus while freely running on a circular treadmill. Using high-density extracellular recordings, optogenetic silencing, and high speed videography we probe the sensory representation of tactile stimuli in vM1 and ask whether vM1 activity is necessary for adaptive whisking strategies and selecting appropriate behavioral choices. We find that vM1 represents tactile stimuli independent of vS1, putatively relying on its direct thalamocortical input. In untrained mice, vM1 silencing had no detectable impact on whisking kinematics, but had a dramatic impact when mice were engaged in the tactile discrimination task. During behavior silencing caused a retraction of whisker set-point as well as an early onset of licking. vM1 silencing also dramatically impaired performance on the task which is a potential consequence of both impaired adaptive whisking, the elimination of refined sensory representations in vS1, or an impairment in choosing the appropriate behavioral response. The effects of vM1 silencing on whisking kinematics were only apparent when mice were actively engaged in the discrimination task. Disengaged mice exhibited behavior similar to untrained mice with no changes to their whisker movements. We conclude that vM1 can encode the tactile environment independent of S1, its control over whisker movements is context dependent, being specifically engaged during demanding sensory tasks, and that it may play a role in selecting behavioral choices as changes in whisking did not always coincide with changes in choice.

Title: Reciprocal inhibition in PV and SST neurons inhibitory networks in mouse barrel cortex during sensory association training

Authors: *E. PARK, D. KULJIS, A. BARTH;
Carnegie Mellon Univ., PITTSBURGH, PA

Abstract: Inhibitory neurons form a highly interconnected network in the neocortex. Althoughreduction of inhibition, or disinhibition, has been proposed as one of the critical mechanismsof learning, it is unknown whether connections between inhibitory neurons are strengthenedto mediate disinhibition. Previous studies have shown that two types of inhibitory neurons,somatostatin (SST)-expressing neurons and parvalbumin (PV) neurons, are the primarysource of inhibition to excitatory pyramidal neurons and that both sources of inhibition maybe reduced during sensory or motor learning. Experimental evidence indicates that SSTneurons and PV neurons are reciprocally connected, but it is unknown whether thesesynaptic connections are altered during learning. We used ChR2 expressed in either PV orSST neurons and targeted postsynaptic inhibitory neurons in layer 2/3 of mousesomatosensory (barrel) cortex for whole cell patch-clamp recording in vitro to compare therelative strength and plasticity of this inhibitory subnetwork. Under baseline conditions, SST-inhibitory postsynaptic currents (IPSCs) in PV neurons were greater than PV-IPSCs in SSTneurons. Next, we investigated whether the strength of reciprocal connectivity between PVneurons and SST neurons change after learning in a whisker-dependent sensoryassociation training paradigm. We hypothesized that increased inhibitory input betweenSST neurons and PV neurons might facilitate disinhibition and network rewiring duringlearning. We found that SST-IPSCs in PV neurons were unaltered after sensory associationtraining. Our results suggest that potentiation of SST synapses onto PV neurons may not beengaged to trigger PV-mediated disinhibition during learning.

Title: Long-term sensory association training decreases stimulus-evoked activity inL2/3 pyramidal neurons in mouse barrel cortex

Authors: *M. ZHU[1], A. L. BARTH[2], S. J. KUHLMAN[1];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Carnegie Mellon U., Pittsburgh, PA

Abstract: Sensory learning alters cortical response properties and is linked to site-specific synaptic changes. We used longitudinal in vivo Ca imaging to determine how the stimulus-evoked activity of L2/3 pyramidal neurons in mouse barrel cortex changed throughout the course of training in a sensory association task, where a multi-whisker stimulus is coupled to a delayed water reward in freely-moving animals. Ca imaging was performed each day during a 6-day baseline and 10-day training period in head-fixed mice, where the stimulus alone was used to monitor the evolution of sensory responses in barrel cortex. Stimulus-evoked responses across the entire imaged population for naïve mice (during the pretraining period) were characterized by a brief increase in activity followed by a prolonged inhibition that lasted for several seconds. During the sensory association training process, the stimulus-evoked responses progressively reduced. After a week of sensory association training where all animals displayed behavioral changes indicating that they had learned the association, short-latency stimulus-evoked activity was significantly suppressed in all cells across the population compared to the pretraining period. Notably, the changes in cell activity after training is dependent upon the baseline activity of the cell during the pretraining period. The stimulus-evoked responses of the top 20% of cells that showed strongest baseline activity decreased quickly after training; the stimulus-evoked responses of the middle 60% of cells gradually reduced across training; the bottom 20% of cells showed increased stimulus-evoked activity and reduced post-stimulus inhibition during the early training period, which renormalized back to baseline after a week of training. Our experiments help address the question of how changes in sensory-evoked cell activity are related to both network rewiring and also behavioral improvement during long-term training.

Title: In vivo calcium imaging identifies functionally and molecularly distinct subsets of tongue-innervating mechanosensory neurons

Authors: *Y. MOAYEDI[1], S. XU[2], B. U. HOFFMAN[1], G. J. GERLING[2], E. A. LUMPKIN[3]; [1]Columbia Univ., New York, NY; [2]Univ. of Virginia, Charlottesville, VA; [3]Univ. of California, Berkeley, CA

Abstract: Mechanosensory neurons in the mouth provide essential information for guiding food choice, feeding ability, and speech. Yet, little is known about the functional diversity of mechanosensory neurons that innervate mammalian oral cavity. To address this gap, we previously mapped the distribution of neuronal endings in mouse and human oral cavity. We found that tongue is equipped with putative mechanosensory afferents including Krause end bulbs and perigemmal collars, whose functions in sensation are not known. To interrogate the functional diversity of mouse lingual mechanosensory neurons, we used in vivo calcium imaging of trigeminal ganglia. Experiments were performed in male and female animals with at least 3 animals/experiment. We investigated calcium responses of tongue-innervating trigeminal neurons that respond to thermal and mechanical stimulation (e.g. pressure, fluid flow, temperature changes). Nearly half of all responding neurons responded to mechanical stimulation (pressure or fluid flow). Delivery of somatosensory stimuli revealed stimulus tuning of neurons correlates with cell body size, as in cutaneous sensory neurons. Large-diameter tongue-innervating neurons responded to mechanical stimuli whereas small-diameter neurons responded best to temperature and flow. Based on stimulus-response times, we found distinct subgroups that responded well to brushing, pressure, or pressure & brushing. We next developed an unbiased clustering approach to classify calcium response characteristics to pressure stimulation. This approach revealed that pressure responding neurons displayed three distinct stimulus-response profiles to pressure: on only, on & off, or sustained responses throughout the duration of stimulation. Next, based on known genetic markers for skin mechanoreceptors, we screened for markers that selectively labeled subsets of physiologically distinct tongue-innervating neurons. Based on this screen, we mapped peripheral anatomy of specific types of end organs to response profiles and found that distinct end organs have unique response profiles to stimulation. These studies lay the foundation to define functional differences between somatosensory neurons in the mouth and how they encode tactile features of foods and contribute to oral functions.

Title: Tactile and multisensory responses to tooth sensation in the neocortex of the naked mole-rat (Heterocephalus glaber)

Authors: *N. J. HITE[1], J. NIE[2], D. K. SARKO[3];
[1]Dept. of Physiol., [3]Dept. of Anat., [2]Southern Illinois University, Sch. of Med., Carbondale, IL

Abstract: Dentition is highly critical to overall health and well-being. Behaviors such as eating and speaking require simultaneous processing of multiple sensory modalities, yet little is understood about the neural substrates related to dentition. In this study, we investigated how individual neurons in the naked mole-rat cortex adjusted their response properties to combinations of auditory, visual, and tactile stimuli, with a focus on neurons responsive to dental and orofacial regions. In addition, we assessed tactile response preferences including response threshold and directionality preferences for the naked mole-rat's highly sensitive and behaviorally critical incisors. Using in vivo electrophysiology in anesthetized naked mole-rats, the integrative properties of neurons were compared between central somatosensory regions and those bordering auditory and visual cortices. We hypothesized that additional sensory stimuli would modulate the dominant tactile responses of the somatosensory cortex, resulting in increased firing rates and reduced response latencies compared to unimodal stimulus presentations. We further hypothesized that cortically expanded somatosensory regions such as the incisors would have greater incidences of multisensory integration compared to other areas. These studies help to elucidate the neural substrates of dental perception and the modulatory role that additional sensory stimuli play regarding dental sensation.

Title: Tactile-thermal interactions influence cutaneous communication systems

Authors: *L. A. JONES, A. SINGHAL;
MIT, Cambridge, MA

Abstract: Much of the fundamental research on tactile-thermal interactions has examined the effect of changing either the temperature of a display in contact with the skin or of the skin itself on threshold-level responses. There have been few studies that have systematically explored the effects of concurrently varying thermal and tactile inputs on the perception of supra-threshold stimuli. It is unclear whether one signal masks the perception of another, facilitates its identification, or even if tactile and thermal cues can be perceived independently when presented concurrently. The objective of the present series of experiments was to determine whether tactile pattern identification is affected by concurrent thermal stimulation and conversely, if the identification of thermal patterns is influenced by concurrent tactile stimulation. A multisensory display was built to provide tactile and thermal cues to the skin. An annular Peltier device with

an outer diameter of 24 mm and contact area of 377 mm2 was used to deliver warm and cool stimuli to the skin on the thenar eminence. A motor was mounted in the center of the Peltier device that could either indent the skin to deliver a low frequency pressure stimulus or vibrate the skin at 100 Hz. The pressure stimuli ranged from 1.7 kPa to 10.9 kPa and the vibrotactile stimuli varied in intensity or duration (0.5-1.5 s). In the first set of experiments, the thermal stimuli were defined relative to baseline skin temperature and either warmed (+5 ºC) or cooled (-7 ºC) the skin. Each tactile stimulus was presented three times to 10 participants who had to identify the tactile pattern using a visual template. The same display was used in the second series of experiments to present six thermal patterns that had to be identified during concurrent tactile stimulation. The thermal patterns varied with respect to waveform (square wave, step and ramp) and the rate of change in temperature (0.7-3 ºC/s). In all experiments performance was compared to that achieved at neutral skin temperature. The results indicate that concurrent thermal stimulation influences the ability to identify tactile stimuli, and that this effect is temperature specific. Warming the skin facilitated identifying the intensity of tactile stimuli (90% correct) but impeded the processing of temporal cues (62% correct). In contrast cooling the skin did not affect perceptual performance. This finding may reflect the enhanced activity of cutaneous thermoreceptors during warming and possibly also the change in the mechanical properties of the skin with warming. Concurrent tactile stimuli influenced thermal pattern identification, with the effect being greater for warm stimuli.

Title: Early Sensory Processing of Tactile Texture in the Brain

Authors: *A. R. LOOMES[1], H. A. ALLEN[2], R. D. ROBERTS[1], H. KWOK[1], A. M. WING[3]; [1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. of Nottingham, Nottingham, United Kingdom; [3]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Psychophysical studies support a duplex theory of tactile texture (Hollins et al 2001) processing with fine textures mediated by vibration signals and coarse textures by signals conveying spatial detail. Here we asked whether auditory and visually selective brain areas contribute to the processing of tactile stimuli. In two fMRI experiments we examined activity in somatosensory, auditory and visual cortices during static (1.5s) and dynamic (20mm/s) application of coarse (spatial period of 1600 μm, ridge width of 400 μm) and fine (spatial period 400 μm, ridge width of 100 μm) textures to the fingertip. A region of interest analysis, using

localisers identified with 10Hz and 200Hz vibrotactile stimuli, and anatomically localised auditory and visual areas revealed contralateral activation in somatosensory and auditory cortex during contact between the textures and skin. Moreover, these areas were significantly more activated with dynamic than static stimulation. In contrast, movement dependent activation was not observed in the visual cortex. These findings were replicated in a control experiment where the static stimulus was applied twice in quick succession. Activation of auditory areas was significantly greater during dynamic compared to static stimulation. Together these findings provide neuroimaging evidence of contrasting cortical processing of dynamic compared to static tactile input consistent with duplex theory. However, in contrast to duplex theory, the effect is seen with both coarse and fine textures.References:Hollins, Sliman J. Bensmaïa, Sean Washburn, M. (2001). Vibrotactile adaptation impairs discrimination of fine, but not coarse, textures. *Somatosensory & motor research*, *18*(4), 253-262.

Title: Comparison between psychophysical performance of rats and incremental Bayesian models based on average firing rates of SI cortical neurons

Authors: *S. ÖZTÜRK[1], I. DEVECIOğLU[2], B. GÜÇLÜ[1];
[1]Inst. of Biomed. Engin., Boğaziçi Univ., İstanbul, Turkey; [2]Biomed. Engin. Dept., Tekirdağ Namık Kemal Univ., Tekirdağ, Turkey

Abstract: Cortical motor neuroprostheses depend on the simultaneous activity of many neurons for predicting movement parameters. We used a similar approach to predict the detection of a vibrotactile sensory stimulus in a psychophysical yes/no task performed by trained rats. The algorithms presented in this study may be useful for future brain-computer interfaces aimed to provide somatosensory function. 10 awake behaving rats were tested with vibrotactile stimulus applied on the hindpaw glabrous skin (frequency: 40 Hz, duration: 0.5 s, amplitude: 200 μm) while they performed the detection task. Multiunit spike activity was recorded with 16-channel microwire array electrodes implanted in the hindpaw representation of SI cortex. Band-pass filtered (500 Hz - 8 kHz) spike data were sorted into units by using the Wave_Clus spike sorting algorithm. Combinations of average spike rates from all (approximately 35 units in each rat) units (FR, within the stimulus duration) and task-related features (stimulus presence (S) in the current trial; one (P1), two (P2), and three (P3) most recent responses in successive trials) were

input to 12 incremental Bayesian models to predict the vibrotactile stimulus in each rat experiment. The models were implemented in a probabilistic programming framework (PyMC3). Nonparametric sensitivity index (A') and bias index (B'') were used to compare model performances with psychophysical data. Although the primitive models without FR (i.e. with only S, with S+P1, with S+P2) had significantly higher A' values than those obtained from psychophysical data, they had substantially higher bias. Inclusion of FR into the models decreased the bias, but also decreased detectability to values close to experimental data (paired t-tests: p's > 0.1 and p's > 0.2, for A' and B'' respectively). As a matter of fact, a Bayesian model based on average firing rates from a population of cortical neurons seems to be adequate to yield the psychophysical performance in a yes/no detection task. We are currently testing time-dependent neural features to further improve this *in silico* brain based on Bayesian inference.

Title: Cortical Localization of Sensory-Motor Transformation in a Whisker Detection Task in Mice

Authors: *B. ZAREIAN[1], Z. ZHANG[2], E. ZAGHA[1,2];
[1]Dept. of Psychology, [2]Neurosci. Grad. Program, Univ. of California, Riverside, CA

Abstract: Responding to a stimulus requires transforming an internal sensory representation into an internal motor representation. Where and how this sensory-motor transformation occurs is a matter of vigorous debate. Here, we trained male and female mice in a whisker detection go/no-go task in which they learned to respond (lick) following a transient whisker deflection. Using single unit recordings, we quantified sensory-, motor- and choice-related activities in whisker primary somatosensory cortex (S1), whisker primary motor cortex (wMC) and anterior lateral motor cortex (ALM). Based on the criteria of having both strong sensory and motor representations and early choice probability, we identify whisker motor cortex as the cortical region most directly related to the sensory-motor transformation. Suppression of both S1 and wMC altered task performance, yet in notably different ways. Our data support a model of sensory encoding originating in S1, sensory amplification and sensory-motor transformation occurring within wMC, and motor signals emerging in ALM after the sensory-motor transformation.

Title: Sensitrak- automated assessment of forelimb sensation in rodents

Authors: D. YOO[1], *A. RAMAMURTHY[1], A. SLOAN[2], J. CARMEL[1];
[1]Columbia Univ., New York, NY; [2]Vulintus, Inc., Louisville, CO

Abstract: Somatosensory function is routinely measured in humans by determining the threshold for detection of a vibrotactile stimulus applied to the hand, and this measure correlates with dexterity. Assessment of vibration sensation in animals has been largely missing because of the need to train behaviors that signal detection of the stimulus. Two commonly used somatosensory assessments in rats, the Hargreaves test for heat and the von Frey test for pain, rely on reflexes and do not require training, but they test a separate sensory pathway, and response may be compromised by motor deficits that may hinder withdrawal of the limb. There are currently no turnkey systems for behavioral testing of forelimb touch. We thus created SensiTrak, a behavior system to determine the sensitivity of rodents to vibration applied to the forepaw. Rats are trained to hold to a lever and to release when they feel a vibration. The lever is fitted with a linear resonant actuator for delivering vibration and a force sensor to signal when to start the trial and when the rat releases the lever. Control software is used to deliver stimuli of varying duration and to reward the rats if they release the handle within 0.5 seconds of vibration or do not release during no stimulation (catch) trials. To determine sensitivity, response rate was plotted against duration of the vibration. We hypothesized that this task could be implemented in a semi-automated fashion, and that the resulting psychophysical profiles would allow reproducible sensory thresholds. After associating the handle with a reward (~2 weeks), rats can be trained by the automated reward system to hold and to release when they feel a vibration (~5 weeks). Upon testing, our first three rats produced clear sigmoid-shaped psychometric curves, similar to those observed for somatosensation testing in humans and other sensory functions in rats. We set the threshold as 50% as the difference between the true positive rate and the false positive rate, which we call the corrected positive rate. Rats achieved the 50% rate at a stimulus duration of between 40 and 60 ms (vibration frequency of 166Hz). In addition to this relatively narrow range between rats, each rat showed stability within their respective thresholds as far out as 13 weeks after psychometric testing began. Backed by these results, SensiTrak seems to be a reliable measure of somatosensation in rats. Future studies will test the utility of this system for mice and will measure function after the touch sensory system injury and recovery.

Title: Behavioral and Neural Bases of Tactile Shape Discrimination Learning in Head-Fixed Mice

Authors: *J. KIM, A. ERSKINE, J. A. CHEUNG, S. A. HIRES;
USC, Los Angeles, CA

Abstract: Tactile three-dimensional shape recognition requires perception of object surface angles. We investigated how object surface angles are represented in the brain, how this representation is constructed from sensory inputs, and how it reorganizes across learning. Head-fixed mice learned to discriminate object angles by active exploration with one whisker. Calcium imaging of excitatory neurons in layers 2-4 of barrel cortex revealed maps of object-angle tuning before and after learning. Three-dimensional whisker tracking demonstrated that the sensory input components that best discriminate angle (vertical bending and slide distance) also have the greatest influence on object-angle tuning. Despite high turnover in active ensemble membership across learning, both the population distribution of object-angle tuning preferences and individual preferences remained stable. Motor strategy and sensory inputs were not changed across learning, but population response from touch-response neurons better discriminated object angle after learning. These results show how discrimination training enhances stimulus selectivity in primary somatosensory cortex while maintaining perceptual stability.

Title: Potential correlates of neuronal survival in the dLGN of macaques with longstanding V1 damage

Authors: A. M.-H. AUERBACH[1], ***H. R. RODMAN**[2];
[1]Program in Neurosci. & Behavioral Biol., [2]Psychology, Emory Univ., Atlanta, GA

Abstract: Surviving visual function after damage to primary visual cortex (V1) in primates ("blindsight") was originally believed to depend on alternative pathways through the tecto-pulvinar system. However, more recent studies established a crucial contribution of surviving neurons in the dorsal lateral geniculate nucleus (dLGN) (Schmid et al., *Nature, 466,* 2010). After V1 damage, most retinotopically corresponding dLGN cells degenerate, but a subset of extrastriate-projecting neurons survive, primarily in interlaminar zones, and have roughly normal response properties (Yu et al., *J. Neurosci, 38,* 2018). We investigated whether vascularization patterns and surviving retinal inputs might play a role in the survival of this small population. Subjects were 6 *M. mulatta* (both sexes) with lesions of left V1 made either at 5-6 weeks or in adulthood and survival of 4-7 yr. Cell and blood vessel measurements were made in coronal sections immunoreacted to reveal calbindin-D28K (Cal, a marker of the cell population of interest) or cholera toxin B-subunit label (from retinal injections) and counterstained with Giemsa. Using each animal as its own control, and quantifying blind as to age at lesion, we found that the proportion of the dLGN occupied by blood vessels was significantly greater on the lesioned side, with comparatively greater effects in adult-lesioned cases ($p < 0.05$, Mann-Whitney *U*). Contrary to predictions, we did not find, overall, that surviving dLGN cells within degenerated zones were closer to blood vessels than expected by a random distribution; however, surviving cells in adult-lesion cases were significantly closer to vessels than were comparable neurons in the infant-lesion cases. We also predicted that surviving dLGN cells would be more preferentially clustered in areas of high residual retinal input, relative to the distribution of Cal cells and retinal label on the intact side, but found this to be the case only in one of the infant-lesioned subjects. Finally, with respect to the phenotype of surviving neurons *per se*, we observed a significant proportion of surviving Cal-negative neurons in the adult-lesion cases (approximately 20%), whereas virtually all the surviving cells after lesions in infancy contained Cal. The results are thus not consistent with an important role for access to either vasculature or clumps of retinal label for the precise subset of dLGN neurons that survive V1 damage. However, the analyses revealed several differences in dLGN architecture and surviving cell populations after damage in infancy compared with similar damage in adulthood, suggesting subtle differences in mechanisms of reorganization at the dLGN level.

Title: Somatosensory and Auditory Loops Support Tactile Frequency Discrimination

Authors: *A. GRENIER, P. ALBOUY, A. SHARP;
Ctr. De Recherche CERVO, Québec, QC, Canada

Abstract: Somatosensory and auditory loops support tactile frequency discrimination Auditory scene analysis is essential to many daily activities: understanding speech in noise, localization of sounds, musical perception, etc. Most of the time, several senses are involved in these activities. For example, a violinist plays a note, sounds and vibrations are produced by the instrument. Hearing and tactile systems are activated. Understanding how the brain recruits each of these senses and how they interact with each other remains a matter of study. In order to better understand tactile perception, the study of neuroanatomical correlates is necessary via low-level tasks. This is why the main goal of this study was to investigate neural correlates of tactile perception during a simple frequency discrimination task via the tactile modality only (no auditory perception). We hypothesized that both somatosensory and auditory systems will be recruited during the frequency (pitch) discrimination task even if no sounds were presented to the auditory system. During and EEG recording, participants were presented with a vibrotactile oddball paradigm (left hand vibrotactile stimulation glove) in which deviant stimuli (225Hz, 250 Hz, 500Hz, 800Hz, 1000Hz) differing in frequencies from the standard stimuli (200Hz). To control for auditory perception, participants were asked to listen to a continuous noise during the entire experiment. Source reconstruction of vibro-tactile event related potentials showed right lateralized Mismatch Negativity response in both somatosensory and auditory regions for each deviant stimulus in comparison to the standard stimulus. The somatosensory response was earlier than the auditory response. Also, the MMN amplitude increased with increasing frequency changes except for the 1000Hz condition which is at the limit of the frequency range perceivable by the tactile system. These findings suggest that pitch discrimination without auditory perception is performed by an interplay between tactile and auditory systems. Time-frequency analyses and directed functional connectivity will inform us about the oscillatory patterns supporting this interplay as well as the direction of the connections. These results will allow a better understanding of multisensory interaction during tactile unisensory perception. Also, these new findings can help find ways to improve auditory scene analysis in individuals who have difficulty with activities involving the treatment of several sound sources.

Title: Perforated patch clamp survey of cyclic nucleotide-dependent ionic currents in olfactory receptor neurons of the hawkmoth Manduca sexta

Authors: J. DOLZER[1], K. SCHROEDER[2], ***M. STENGL**[2,1];
[1]Biol., Univ. of Regensburg, Regensburg, Germany; [2]Biol., Univ. of Kassel, Kassel, Germany

Abstract: Olfactory receptor neurons (ORNs) of the hawkmoth *Manduca sexta* sensitize via cAMP- and adapt via cGMP-dependent mechanisms on fast time scales, dependent on previous acute odor exposure. Furthermore, circadian rhythms in the concentration of the stress hormone octopamine in hawkmoth antennae generate peaks of cAMP during the moth´s activity phase, modulating olfactory sensitivity and kinetics daytime-dependently on a 24 h time scale. With perforated patch clamp recordings of cultured hawkmoth ORNs employing voltage-step protocols (n=223) we searched for voltage-gated cyclic nucleotide-dependent potassium- and non-specific cation currents that could be targets during fast or slow modulation of odor transduction. First, eleven types of currents were distinguished and named according to reversal potential, current-voltage relation, time course, and pharmacology. Then, the membrane-permeable cyclic nucleotide-derivatives 8bcAMP (n=13) and 8bcGMP (n=13) were applied and currents were evaluated in three different time windows after application in search for statistically significant cyclic nucleotide-dependent changes (Student's t-test vs. no application). Either cAMP- and/or cGMP-derivatives antagonistically affected three of five K^+ currents and two non-specific cation currents. The Ca^{2+}-dependent K^+ current $I_{K(Ca^{2+})}$ and the sensitive pheromone-dependent K^+ current $I_{K(cGMP-)}$ that both express fast kinetics were significantly inhibited by 8brcGMP, while a slow K^+ current $I_{K(cGMP+)}$ was significantly activated by 8bcGMP. Furthermore, application of 8bcAMP significantly blocked the slowly activating, zero mV reversing non-specific cation currents I_{LL} and $I_{cat(PKC?)}$ that remain activated in presence of 8brcGMP. Their activations pull the membrane potential towards their 0 mV reversing potentials, in addition to increasing intracellular Ca^{2+} levels voltage- and I_{LL}-dependently. Twenty minutes after application 8brcGMP significantly blocked a TEA-independent K^+ current $I_{K(noTEA)}$ and the fast cation current $I_{cat(nRP)}$ that both shift the membrane potential to negative values. We conclude that at high levels of cAMP conditions of sensitization are maintained via specific opening/closure of ion channels that allow for fast kinetics, hyperpolarized membrane potentials, and low intracellular Ca^{2+} levels. Adaptation is supported via cGMP that antagonizes cAMP, opening Ca^{2+} permeable channels with slow kinetics that stabilize depolarized resting potentials. Title: Olfactory neuroepithelium ACE2 downregulation in eosinophilic inflammation: a potential protective factor for COVID-19?

Authors: *C. MARIN, V. TUBITA, C. LANGDON, M. FUENTES, M. LÓPEZ-CHACÓN, A. VALERO, I. ALOBID, J. MULLOL;
IDIBAPS, Barcelona, Spain

Abstract: Sudden and severe loss of smell is one of the initial symptoms of COVID-19. Via entry proteins (angiotensin-converting enzyme 2 (ACE2)/transmembrane protease serine-2 (TMPRSS2) in sustentacular cells), SARS-CoV-2 may induce inflammation in the olfactory epithelium or enter to the central nervous system damaging olfactory bulbs, causing loss of smell. The impact of COVID-19 in airway chronic diseases, such as chronic rhinosinusitis (CRS), has been found reduced and potentially linked to respiratory tissue eosinophilia and reduced ACE2 expression, suggesting that this downregulation might be a protective factor for COVID-19. However, the ACE2/TMPRSS2 expression in the olfactory epithelium in patients with eosinophilic inflammation has not been investigated yet.Our objective was to investigate whether the olfactory epithelium entry protein levels in eosinophilic CRS are downregulated compared to healthy control cases, potentially suggesting a reduced risk of SARS-CoV-2 infection of the olfactory system.We investigated ACE2 and TMPRSS2 expression in the olfactory epithelium from eosinophilic CRS with nasal polyps (CRSwNP, n=13) patients and healthy controls (n=11). Immunohistological studies were performed to identify olfactory neurons (OMP+), sustentacular cells (Hsp25+), eosinophil infiltration (BMK13+), and ACE2 protein expression. Real-time PCR studies were performed to quantify ACE2 and TMPRSS2 mRNA.Olfactory epithelium from CRSwNP patients showed an increased number of eosinophils (BMK13+) ($p<0.05$) in association with a decrease in olfactory neurons (OMP+) ($p<0.01$) and sustentacular cells (Hsp25+) ($p<0.05$). The expression of ACE2 protein ($p<0.01$) and mRNA ($p<0.05$), and TMPRSS2 mRNA ($p<0.05$) was significantly decreased in the olfactory epithelium.These findings suggest that ACE2/TMPRSS2 downregulation in the olfactory epithelium of CRSwNP patients might be related to tissue eosinophilic inflammation, potentially leading to a decreased risk of olfactory epithelium damage and entry to the olfactory bulbs by SARS-CoV-2.

Title: Wiring logic of the rodent olfactory system revealed by sequencing of single cell projections

Authors: ***Y. CHEN**[1], X. CHEN[1], ***B. BASERDEM**[2], J. M. KEBSCHULL[3], H. ZHAN[1], Y. LI[1], M. DAVIS[1], A. M. ZADOR[1], A. KOULAKOV[1], D. F. ALBEANU[1];

Abstract: The olfactory system relies on hundreds of odorant receptors to recognize numerous volatile compounds. However, the neuronal substrates of odor perception remain elusive, partially due to lack of insight into how the brain sorts the inputs from the sensory periphery. In contrast to the structured long-range connectivity and spatial representations in other sensory modalities, previous axonal tracing studies found that olfactory bulb (OB) outputs, the mitral and tufted cells, project in a highly distributed and seemingly random fashion to their largest cortical target, the piriform cortex (PC). However, previous studies were limited by the small number of neurons whose projections were traced, which may obscure any potential spatial structure in OB output. To investigate the wiring logic of the olfactory system, here we analyze the projections of 5,309 OB output neurons and 30,433 PC output neurons at single-cell resolution. We employ highly multiplexed barcode sequencing-based mapping techniques (MAPseq and BARseq), which enable discriminating different types of OB output neurons by their soma locations and brain-wide projections. We identify structured OB (mitral cell) projection modules, reproducible across mice, which tile the anterior-posterior (A-P) axis of the piriform cortex and co-innervate distinct brain regions. In addition, we find characteristic sets of PC output neurons which project to different brain targets, and are enriched at specific A-P locations in the piriform cortex. Drawing from these results, an organizing principle emerges: matched input-output, parallel circuit motifs span the A-P axis of the piriform cortex and co-innervate specific sets of OB target areas. These results challenge the canonical framework of piriform cortex as a random network, at the core of current understanding of olfactory processing. They encourage further investigation into the function of these neural circuits, and the formulation of novel computational models to account for the logic of information flow in the olfactory system.

Abstract: The human olfactory system has been historically considered as a system mainly involved in odor recognition. Nevertheless, during the last decade, olfactory dysfunction has been studied as a preclinical symptom related to Parkinson's and Alzheimer's diseases. The olfactory system appears to be a direct pathway to other cortical olfactory regions of the brain for some pathogens or prion-like diseases, and the anatomy of sensory neurons, directly exposed to the environment in the nasal cavity allows it. In parallel, most mammals generate new neurons during adulthood which incorporate into a preexisting olfactory circuitry, presumably to preserve its functionality intact. However, in adult humans this process has not been demonstrated, and the information concerning cellular composition of different olfactory structures as the olfactory peduncle is still scarce. In this work, we studied 28 humam olfactory nerves ranging from 19 to 93 years old and 5 cases of young adult primates (*Macaca fascicularis*). The olfactory nerves of both species were divided into main olfactory bulb, and anterior, medial and posterior regions of the olfactory peduncle. One sample of each region was embedded in Durcupan resin and transversely sectioned in semithin sections (1.5µm). Other samples were transversely sectioned at 30µm in a freezing microtome. We then studied morphology and the cytoarchitecture of all different portions of the olfactory peduncle along adulthood. Furthermore, by using stereological and statistical analysis, we assessed the presence and distribution of blood vessels and corpora amylacea (spherical bodies that accumulate in some areas). Immunohistochemical techniques and electronic and confocal microscopy were performed with the aim of identifying the distribution of different cell populations such as glia, mature and putative young neurons and undifferentiated cells in the olfactory peduncle. Regarding Macaca, we observed a very homogeneous peduncle, with few corpora amylacea and blood vessels, mainly present in the core. In humans, we observed different morphologies following patterns. All the cases showed a vertex in the dorsal portion, corresponding to the region below the olfactory sulcus and higher density of cells and fibers in the medial region. In addition to the anterior olfactory nucleus (sometimes present), we also distinguished different layers. Our findings advance our knowledge of the structure of the olfactory peduncle and may be of use in understanding adult neurogenesis and the processes underlying normal and pathological aging.

Title: Odor coding by attractor switching in the locust antennal lobe

Authors: *R. MOHANTA, C. ASSISI;
Biol. Dept., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: The antennal lobe, the insect equivalent of the olfactory bulb in mammals, is a dense network of excitatory projection neurons (PNs) and inhibitory local interneurons (LNs). In the locust, this network is known to generate elaborate spatiotemporal patterns of activity in response to an odor. Computational models of the antennal lobe have typically assumed that the input to the inhibitory interneurons is narrowly tuned. That is, each interneuron receives input from a small fraction of olfactory receptor neurons (ORNs) and responds reliably to only a small subset of odor inputs. However, we know from a number of experiments, this is not the case. Interneurons arborise extensively across the antennal lobe and receive input from nearly 70% of all ORNs in the antennae. Therefore, odor input to different LNs is not as distinguishable as one would expect if the neurons were narrowly tuned. Using a realistic computational model of the locust antennal lobe, we sought to understand the effect that broad odor tuning has on the repertoire of spatiotemporal patterns the network can reliably generate. We modeled PNs and LNs as conductance-based neurons with properties matching in vivo observations. Spiking ORN input drove PNs and LNs in a manner that replicated experimentally observed statistics of PN responses. Earlier studies have shown that competitive interactions between interneurons can result in distinct patterns of activity; spatiotemporal attractors that are defined by the topology of the inhibitory sub-network. The inhibitory network can, in turn, entrain projection neurons. Here, we explore the hypothesis that excitatory input from projection neurons act as perturbations that drive the inhibitory network through a sequence of attractors. We examined the dynamics of switching as a function of the balance between excitatory (PN and ORN drive to the interneurons) and inhibitory (reciprocal interactions between interneurons) drive in the LN network.

Title: Flexible Categorization in the Mouse Olfactory Bulb

Authors: *E. KUDRYAVITSKAYA, E. MAROM, H. SHANI-NARKISS, D. PASH, A. MIZRAHI;
Dept. of Neurobio., The Edmond and Lily Safra Ctr. For Brain Sci. (ELSC), The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The ability to group sensory stimuli into categories is crucial for efficient interaction with a rich and ever-changing environment. In olfaction, basic features of categorical representation of odours were observed as early as in the olfactory bulb (OB). Categorical representation was described in mitral cells (MCs) as sudden transitions in responses to odours that were morphed along a continuum. However, it remains unclear to what extent such response dynamics actually reflect perceptual categories and decisions therein. Here, we tested the role of learning on category formation in the mouse OB, using *in vivo* two-photon calcium imaging and behaviour. We imaged MC responses in naïve mice and in awake behaving mice as they learned two tasks with different classification logic. In one task, a 1-decision boundary task, animals learned to classify odour mixtures based on the dominant compound in the mixtures. As expected, categorical representation of odours, which was evident already in naïve animals, further increased following learning. In a second task, a multi-decision boundary task, animals learned to classify odours independent of their chemical similarity. Here, odour discrimination was based on the meaning ascribed to them (either rewarding or not). Following the multi-decision boundary task, odour representations by MCs reorganized according to the odour value in the new category. This functional reorganization was also reflected as a shift from predominantly excitatory odour responses to predominantly inhibitory odour responses. Our data shows that odour representations by MCs is flexible, shaped by task demands, and carry category-related information.

Title: Chemoanemotaxic responses to selected odorants by house crickets

Authors: C. E. WEAVER, *V. D. SHIELDS;
Biol. Sci. Dept., Towson Univ., Towson, MD

Abstract: The olfactory system of insects is a prominent model in neuroscience that allows us to address how insects detect, encode, and process olfactory stimuli. Stimulation of olfactory receptors may allow insects to detect and identify food, mating partners, and avoidance of predators. These receptors are located in cuticular sensory organs (sensilla) found on their long, paired, multi-segmented antennae. The cuticle of these sensilla is pierced by numerous small pores with underlying olfactory receptor cells, responsible for detecting odorants. Here, we studied the olfactory capability of the house cricket, *Acheta domesticus*, an omnivorous scavenger from the Gryllidae family. These insects use their antennae to detect chemosensory (smell and taste), mechanosensory (touch), and possibly thermo-hygrosensory (temperature and humidity) information. The overall aim of this study was to determine if food samples, deemed biologically-relevant from the habitat of the crickets (e.g., fruits, vegetables, proteins), elicited positive anemotaxis (oriented movement in response to odor from the food source) and acted as food baits. We tested fruit samples including, blueberries, strawberries, oranges, apples, red grapes, and bananas. Vegetable samples included, tomatoes, carrots, cauliflower, broccoli, onion, green beans, and green peppers. Sources of protein included, various flavors of cat food (e.g., poultry and fish). Female and male juveniles and adults were tested. We hypothesized that some of the food samples tested would elicit significant positive anemotaxis, while others would not. The fruits and vegetables tested proved to be ineffective food baits, while initial testing of protein samples showed promising results. If attractive, these samples could serve as possible baits, as house crickets are pests and can contaminate foods with their feces. This raises concerns about foodborne illnesses associated with microbial pathogens and creates health concerns, especially in developing countries.

Title: Mechanisms of lactic acid taste in Drosophila melanogaster

Authors: *M. STANLEY, B. GHOSH, Z. F. WEISS, J. CHRISTIAANSE, M. D. GORDON;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Sour has been studied almost exclusively as an aversive taste modality. Yet, recent work in the fruit fly, *Drosophila melanogaster,* shows that carboxylic acids differ in their behavioural valence and molecular mechanisms of detection. Here, we investigate the less explored pathway of gustatory acid attraction focusing on lactic acid. Lactic acid is produced by

fermentative bacteria and the smell is attractive to mammals and insects, but attractive taste qualities have not been described. We found that lactic acid is appetitive to *Drosophila*, even without olfaction, and sought to uncover the cellular and molecular mechanisms of this gustatory attraction by using multiple behavioural assays and *in vivo* calcium imaging of fly gustatory receptor neurons (GRNs). Silencing of sweet GRNs completely abolishes these attractive behaviours, and flips the valence to aversion, suggesting that lactic acid activates both attractive and aversive sensory neurons. Calcium imaging of GRNs with labellar lactic acid stimulation revealed strong activation of sweet GRNs and weaker responses in bitter GRNs. The calcium responses in sweet GRNs have unique kinetics with distinct peaks accompanying both stimulus onset and removal. Mutants for the broadly expressed ionotropic receptor 25a (IR25a) or the GR64 cluster of sweet gustatory receptors each display partially reduced attraction to lactic acid, while combined mutants avoid it. Strikingly, each receptor class is required for distinct aspects of the sweet GRN calcium response: IR25a mutants show a dramatic reduction in the onset response to lactic acid stimulation, while the GR64 cluster mutants show a significant reduction in the response due to lactic acid removal. Thus, lactic acid drives robust behavioural attraction by acting through multiple classes of receptors to activate a single sensory neuron class in physiologically distinct ways.

Title: In vivo calcium imaging of taste responses in the vagal ganglion

Authors: *B. E. FOWLER, S. HUMAYUN, L. J. MACPHERSON;
Biol., UT San Antonio, San Antonio, TX

Abstract: The majority of taste research has focused on the pathway from the frontal papillae (FP) through the chorda tympani nerve to the geniculate ganglion. This has left the pathway from the circumvallate (CV) through the glossopharyngeal nerve to the petrosal of the vagal ganglion largely unexplored. Relative to the FP, the CV boasts an enriched population of bitter responding TRCs, and whole nerve studies have shown that taste signals carried through the glossopharyngeal nerve favor bitter and sour tastants.Calcium imaging of the geniculate ganglion has profiled the responses of individual gustatory neurons to taste stimuli. These studies have shown highly specific responses by individual neurons to behaviorally relevant concentrations of tastants representing all five tastants. What are the response patterns of individual petrosal

neurons to taste stimuli? To image the activity of vagal neurons to taste stimuli applied to the posterior tongue, we surgically exposed vagal ganglia in transgenic animals of both sexes expressing GCaMP under the Snap25 promoter. We then imaged the exposed ganglia while perfusing the CV with a panel of taste stimuli. The imaging protocol was repeated three times per ganglion. We then analyzed the videos by taking the dF/F of the video and measuring changes in brightness for individual cells. Once responses had been verified, response profiles were compared to determine the proportion of cells responding to each taste. These results were compared to results obtained using this protocol to image geniculate neurons while stimulating the FP with the same tastant panel.

Title: Sex differences in sodium butyrate enhancement of conditioned taste aversion

Authors: *D. MUKHERJEE, T. HOUPT;
Biol. Sci., Florida State Univ., Tallahassee, FL

Abstract: Animals can easily develop new food preferences and aversions through associative learning processes. If they consume a novel flavor and experience malaise, they develop an aversion towards that particular flavor, food or fluid. They also learn to prefer a particular flavor that provides positive consequences. Conditioned taste aversion (CTA) requires gene expression and histone acetylation, which can be enhanced by HDAC inhibitors such as sodium butyrate (NaB). Previously, it was shown that CTA is enhanced in male rats by NaB (Kwon and Houpt 2010). Here, we sought to determine whether enhancement of CTA using NaB is subject to sex-specific difference through changes in histone modification. Adult male (n=8) and female (n=8) Sprague-Dawley rats were placed on water restriction for 7 days with ad lib food to ensure intake on conditioning day. On the conditioning day they were given 30 min access to saccharin (0.125%) and then injected with lithium chloride (LiCl) (0.15M, 3ml/kg). Ten minutes later, half the rats were injected with NaB (0.3M, 12ml/kg) or NaCl (0.3M, 12ml/kg). Beginning the next day, 2-bottle 24-h preference tests of water vs. saccharin was carried out for 10 days. In preliminary results, the saline-injected rats showed moderate CTA which extinguished over the 10 days of preference testing. Male rats injected with NaB appeared to have a greater CTA then saline-injected rats. However, NaB did not appear to enhance CTA in the NaB-injected females. Thus, female rats appear to be less sensitive to the CTA-potentiated effects of NaB. This could be due to (a) differences in pharmacokinetics or (b) differences in gene-regulation during CTA learning and its modulation by histone acetylation. Future studies could explore the role of

estrogen on NaB effects, e.g., by testing the enhancement of CTA by NaB in ovariectomized female rats.

Title: Gustatory cortex responses evolve through incidental taste exposures

Authors: ***V. L. FLORES**[1], J.-Y. LIN[2], D. B. KATZ[3];
[1]Furman Univ., Greenville, SC; [3]Dept Psychol, [2]Brandeis Univ., Waltham, MA

Abstract: Experience has been widely shown to impact learning and sensory perception. In the field of taste, familiarity with taste stimuli that later become the conditioned stimulus (CS) has long been known to reduce the strength of aversion learning when subsequently pairing with gastrointestinal illness (unconditioned stimulus [US]; Lubow 1973; De La Casa and Lubow 1995). Recently, we have demonstrated that even experience with "incidental" (i.e., non-CS and non-US) stimuli can also influence later learning: specifically, female Long Evans rats pre-exposed to salty and sour tastes developed a stronger learned aversion to novel sucrose. This work suggests that incidental taste experience changes the neural dynamics underlying the processing of familiar and new tastes in gustatory cortex (GC). Here, we begin to explore this possibility by evaluating how GC cortical responses to tastes themselves change over three days of exposure. Our results demonstrate that familiarity with tastes increases the discriminability of water and sodium chloride-evoked GC responses. Furthermore, as animals are familiarized to tastes, the overall percentage of cortical neurons showing identity- and/or palatability-related activity increases. In the held-unit analysis, we found that single-neuron responses to tastes show a greater absolute change in firing rate following taste exposure when compared to water exposure. These findings begin to characterize the impact of familiarity on neural dynamics of taste processing and give insight into how incidental taste experience impacts future learning.

Title: Taste neuronsvary in degree of converging input from taste receptor cells.

Authors: *L. OHMAN, T. HUANG, Z. WHIDDON, R. F. KRIMM;
ASNB, Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Individual taste neurons show tremendous variation in peripheral morphology. The next step is to determine whether these morphological variations dictate variation peripheral connectivity to taste receptor cells (TRCs). Using a whole mount immunohistochemistry to stain taste buds combined with sparse cell genetic labeling of individual chorda tympani neurons, we analyzed the proximity of individual chorda tympani nerve fibers to TRCs using the Imaris software. We examined 77 separate fiber branches entering the taste bud, of these 52% contact (come within a distance below the resolution of the light microscope) one taste receptor cell (mean = 1.4, range= 0-4) whereas 36% contact more than one and 12% form no contacts. Of the fibers contacting TRCs, 87% of fibers contact TRCs of the same type and 13% contact TRCs of multiple types. Some fibers follow along a taste receptor cell for a considerable distance (13µm, long contacts), while others do not (short contacts, 3µm). Contacts are formed by all branch order types (1st-7th order) but most frequently with 3rd order branches. Next, we traced whole neurons from the base of the tongue. Some neurons (37.5%) innervate only one taste bud, branch sparsely (3-5 branch ends), and making 1-5 contacts with 1-2 taste receptor cells of the same type. Other neurons (62.5%) branch more robustly to innervate 3-5 taste buds, with 13-27 branch ends, making 7-14 contacts with 4-13 taste receptor cells of both types. The total length of the neuron in the taste bud predicts the range of contacts made with taste receptor cells innervated (r = 0.92). We suggest that sparsely branched neurons contacting only a few TRCs of the same type may be narrowly tuned, whereas neurons that branch robustly to innervate many taste receptor cells of different kinds may be broadly-tuned.

Title: Lingual nerve transection induces diffuse microglia response in nucleus of the solitary tract in Sprague-Dawley rats

Authors: *B. D. ANDERSEN, A. J. RIQUIER, S. I. SOLLARS;
Univ. of Nebraska at Omaha, Omaha, NE

Abstract: The anterior tongue contains fungiform papillae which are innervated by the somatosensory lingual nerve (LN). In rats, each papilla contains a single taste bud that is

innervated by the gustatory chorda tympani nerve (CT). Despite the CT and LN relaying different types of sensation, damage to either nerve can result in loss in both sensory systems, with both the taste bud and papillae degenerating during developmental injury (Sollars, 2005; Omelian et al., 2016). This sensory interaction, while common in the brain, is highly unusual in the peripheral nervous system. Both the CT and LN project to adjacent, but distinct, subnuclei within the nucleus of the solitary tract (NTS) of the brainstem. Since the two nerves are interrelated in the periphery, and project to closely related subnuclei within the brain, we examined whether the CT and LN may share an immune response following damage to a single nerve. To that end, microglia, the primary indicators of a central immune response, were examined in both the lateral LN subnuclei and the medial CT subnuclei. Twelve male and 12 female Sprague-Dawley rats received unilateral LN transection at 65 days of age, with the CT kept intact. Brains were extracted 1, 2, 3, 5, 8, or 16 days post-surgery and the NTS sectioned (40 μm). Every other section was stained with Luxol Fast Blue and cresyl violet to visualize nerve-specific subnuclei. Alternating sections were used to analyze microglia in respective NTS subnuclei using an Iba1 antibody. Medial (CT) and lateral (LN) microglia response densities were quantified using Neurolucida (MBF Bioscience). The ventral subnuclei, innervated by neither nerve served as a control for the specificity of the response. Preliminary data indicate that although microglia increased in all transected-side NTS subnuclei by 5 days post-surgery, this increase in microglia density was significantly weaker in the medial subnuclei of the intact CT relative to the lateral subnuclei of the transected LN. Additionally, an increase in microglia density observed in the control ventral subnuclei indicates there may be a diffuse microglia response occurring more broadly in the NTS following transection of the LN.

Title: Using GRASP to Map the Connectivity of Peripheral Taste Circuits

Authors: *S. M. LANDON, L. MACPHERSON;
Biol., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Precise re-wiring of gustatory neurons to distinct taste receptor cells (TRCs) within the taste bud happens continuously as TRCs undergo renewal. This rewiring of peripheral taste circuits is crucial for the preservation of taste perception over time; however, we do not currently have a way to monitor the formation and turnover of taste synapses during this dynamic process. Therefore, I have redesigned and employed GRASP (GFP Reconstitution Across Synaptic

Partners) in the peripheral taste system to visualize the synaptic connections between gustatory neurons and TRCs, and to probe the connectivity of candidate synaptic partners. GRASP is a novel technique that utilizes the reconstitution of genetically encoded split GFP proteins, called pre- and post-GRASP, in potential synaptic partners to visualize sites of synapse. First, I have created transgenic mice that express the cyan variant of the pre-GRASP (CRASP) protein under the PKD2L1 promoter, a marker for sour TRCs. Using immunohistochemistry, I have confirmed the expression of pre-CRASP proteins in sour TRCs. To complete CRASP reconstitution at taste synapses, I used a post-GRASP AAV which traffics the post-GRASP protein to the synaptic cleft and marks neurons with td-Tomato. After injecting the post-GRASP AAV into the NST of a PKD2L1 pre-CRASP mouse, I observed td-Tomato positive neurons contacting sour TRCs which elicited CFP puncta, marking the synaptic connections between sour TRCs and gustatory neurons. Recently, a population of geniculate ganglion neurons, marked by the expression of Penk, have been shown to be involved in relaying sour taste signals. To determine if Penk neurons make synaptic contacts with sour TRCs, I injected a PKD2L1 pre-CRASP; Penk-cre double transgenic mouse with cre-dependent post-GRASP AAV and found that these Penk neurons indeed make synaptic contacts with sour TRCs. Because I have validated that GRASP works in the peripheral taste system, I am expanding these studies by engineering more pre-GRASP transgenic mice for other taste modalities (bitter-GFP variant and sweet/umami-YFP variant) to map peripheral taste circuits and observe the dynamics of taste synapse turnover.

Title: The impact of persistent and resurgent voltage-gated sodium currents on excitability in vestibular ganglion neurons

Authors: *S. BAEZA LOYA, R. EATOCK;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: The vestibular inner ear transmits head-motion information to the brain via two populations of primary vestibular ganglion neurons (VGNs) which differ in the regularity of action potential (AP) timing (regular and irregular) and represent rate and temporal encoding, respectively (Jamali et al., Nat Comm 7:13229, 2016). Understanding the impact of diverse ionic currents on spike timing regularity is crucial to understanding how different sensory coding strategies arise. Although voltage-gated sodium (Nav) currents drive the rising phase of APs, their contributions to AP regularity differences are not fully understood. Nav currents through a

given α subunit can be transient (inactivating current), persistent (non-inactivating current), and/or resurgent (current flow after relief from inactivation block). We are interested in how these Nav current modes influence AP firing in VGNs. Whole-cell recordings were taken from mouse VGNs (postnatal days, P, 3-25) that were isolated and cultured overnight. However, it is difficult to experimentally distinguish the effects of these currents on spiking because we lack methods to isolate components. We therefore modified a computational conductance-based VGN model (Hight and Kalluri, J Neurophysiol 116:503, 2016; Ventura and Kalluri, J Neurosci 39:2860, 2019), which included generic transient Nav current, by adjusting and adding expressions for transient, persistent, and resurgent Nav components with properties based on our data. In a sample of 68 VGNs, all had large transient Nav currents that were blocked by 1 μM TTX; 37 had persistent Nav current (P3-25), 5 had resurgent Nav current (P17-20), and 3 (P17-20) had both persistent and resurgent currents. Application Nav1.6 blocker 4,9-anhydro-tetrodotoxin (4,9-ah-TTX) partially blocked both transient and persistent currents, indicating substantial portion of each is carried through Nav1.6 channels. In current clamp, 4,9-ah-TTX decreased neuronal excitability: increasing current threshold for spiking in all VGNs, and decreasing AP rate in sustained (regular) VGNs. In the computational model, adding persistent and resurgent current components had a negligible effect on firing by the model transient (irregular) VGN. For the model sustained (regular) VGN, adding persistent and resurgent currents decreased spike latency (delay relative to current step onset) and increased spike rate. Increasing Nav channel availability in the after-spike interval with persistent and resurgent currents may enhance the excitability of regular VGNs and so help to shape sensory encoding by the vestibular inner ear.

Title: Computational Model of Non-Quantal Synaptic Transmission at the Vestibular Hair Cell-Calyx

Authors: *A. GOVINDARAJU[1], A. LYSAKOWSKI[2], R. EATOCK[3], R. RAPHAEL[1]; [1]Rice Univ., Houston, TX; [2]Dept. of Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [3]Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Vestibular Type I hair cells detect and relay information on head motion to afferent neurons, which in turn guide motor reflexes that maintain gaze, balance, and our sense of orientation. Type-I hair cells transmit to a unique enveloping structure (Calyx) of the afferent neuron by both **quantal** release of glutamate from vesicles and **non-quantal (NQ)** flow of ions

through the pre-synaptic membrane of the hair cell into the synaptic cleft and through the post-synaptic calyx membrane. Recording electrodes cannot access the synaptic cleft between the vestibular hair cell-calyx (VHCC) synapse without disrupting its structure and function. As a result, ion concentrations [Ion] and electric potential (ϕ) within the synaptic cleft (SC) cannot be measured and the voltage of the post-synaptic membrane cannot be directly obtained. This has posed a barrier to understanding NQ transmission. We have developed a computational biophysical model of the synapse to overcome this limitation. The input to the model is a step or sinusoidal deflection of the hair bundle, and the outputs include the spatio-temporal profile of $[K^+]_{SC}$, $[Na^+]_{SC}$, ϕ_{SC} and ϕ_{Calyx}. To simulate the behavior of the system, the VHCC model uses expressions for K^+ and Na^+ electrodiffusion in the cleft, simplified Hodgkin-Huxley-style ion currents based on whole-cell recordings, and the cable equation. Electrical potentials within the hair cell and the afferent neuron are calculated as a function of $[K^+]_{SC}$ (K^+ modulation), and ϕ_{SC} (Ephaptic coupling) which alter driving forces of currents across the presynaptic and postsynaptic membranes. By allowing $[K^+]_{SC}$ or ϕ_{SC} to be held constant as required, the model allows the separation of these two processes which cannot be achieved experimentally. Currents through the low-voltage-activated K^+ conductance ($g_{K,L}$) on the hair cell and Kv7.4 and HCN channels on the post-synaptic membrane were compared. At rest and during stimulation of the hair bundle, the currents through $g_{K,L}$ and Kv7.4 were an order of magnitude greater than current through HCN. $g_{K,L}$ and Kv7.4 appear to be the foremost mediators of transmission during physiological operation. Model simulations suggest that both fast, frequency independent ephaptic coupling and low-pass K+ modulation can account for, and make non-quantal transmission between the hair cell and afferent neuron faster than chemical transmission.

Title: Topographic map for a developing vestibular peripheral circuit

Authors: *Z. LIU[1], D. G. HILDEBRAND[2], M. W. BAGNALL[1];
[1]Washington Univ. in St. Louis, St. Louis, MO; [2]Harvard Med. Sch., Boston, MA

Abstract: In most sensory systems, a topographic map is formed by orderly projections from the periphery to the central nervous system. Although hair cells in the vestibular end organ are oriented topographically, the organization of their postsynaptic afferents is as yet unknown. Here

we report that the topographic map of vestibular afferents, at the level of the ganglion, is organized by both sensory tuning and developmental age. Using serial-section electron microscopy, we reconstructed all synaptic connections between 91 hair cells and 105 afferents of one utricle in the larval zebrafish. The relative position of the kinocilium and stereocilia of each hair cell reflected its orientation tuning. Near the line of the polarity reversal, a band of hair cells had the longest kinocilium and stereocilium with their (k/s) length ratio close to 1. These hair cells were presumed most mature and identified as striolar on the lateral edge of the macula. Outside this band, we categorized hair cells as extrastriolar (k/s ratio larger than 1.7) or developing / newborn (small kinocilium absolute length). We found that 16/105 utricular afferents were fully myelinated, presumably the earliest born, while other afferents were only partially myelinated or not myelinated at all. Myelinated utricular afferents preferentially innervated early-born striolar hair cells, with more synaptic ribbons, than unmyelinated afferents. The somata of these older myelinated afferents were also positioned more laterally in the utricular ganglion, with younger unmyelinated afferents located more medially. In adult animals, afferents derived from striolar and extrastriolar zones are known to encode phasic and tonic vestibular signals, respectively. Thus, our data suggest that the phasic pathway matures earlier to compensate for fast self-movements, and the tonic pathway develops later for slow self-movements. Moreover, we find the vestibular ganglion also organized by sensory tuning: most afferents in the rostral region of the ganglion innervated hair cells tuned to rostral tilt, whereas those in the caudal region innervated hair cells tuned to ipsilateral tilt. In all, we show that vestibular afferents contact hair cells with selective orientation and striolar identity, and they are topographically organized by both sensory tuning and age.

Title: Bouton afferent terminal activity in the mouse utricle

Authors: *A. GONZALEZ GARRIDO, O. LOPEZ RAMIREZ, R. EATOCK;
Neurobio., Univ. of Chicago, Chicago, IL

Abstract: Vestibular afferent neurons drive reflexes that stabilize gaze and head position. In mammals, vestibular afferent neurons terminate on hair cells with either bouton endings on type II hair cells or calyceal endings on type I hair cells. These terminals distribute differently in the functional zones of the sensory epithelium. The utricular epithelium, has striolar (central) and extrastriolar (peripheral) zones with anatomical and functional differences, including a difference in spike timing regularity. While whole-cell recordings from vestibular afferent calyces are

available in some rodent species, there have been no reported recordings from vestibular bouton terminals. Here, we report preliminary observations on the membrane conductances and action potential properties of mammalian vestibular bouton terminals. We used whole-cell patch clamp to record from boutons in the in vitro semi-intact preparation of CD1 mouse utricle (P10-21). This preparation conserves the hair cells, primary afferent innervation and mechanosensory pathway, allowing the study of primary afferent synapse mechanisms. Bouton morphology was revealed by fluorescent dye from the recording pipette. Bouton endings were tested for voltage-dependent conductances, voltage responses to current injection, and synaptic transmission evoked by deflecting the bundles of type I and type II hair cells. Boutons had HCN and voltage-gated K (KV) channels (IKDR, KLV and A-type). Striolar boutons were larger (3.4 ± 0.7 pF) than extrastriolar (2.1 ± 0.1 pF; $p = 0.03$) and, similar to calyces, had more negative resting potentials (-74.3 ± 1.4 mV vs. -67.7 ± 1.7 mV; $p = 0.04$), input resistances did not differ significantly. As with calyces, positive current steps evoked sustained and transient firing patterns. In dimorphic afferents, we demonstrated electrotonic propagation of non-quantal calyceal responses to bouton terminals in the same afferent. We recorded both regular and irregular spontaneous activity of bouton endings, without clear correlation with zone. In one case, we recorded a bouton on a bouton-only extrastriolar afferent; it had relatively small capacitance (1.8 pF), high input resistance (691.2 MΩ vs 255.7 ± 51.7 MΩ for 8 dimorphic ES boutons), small voltage-gated currents, and a transient spiking response to injected currents with a low current threshold (40 pA). These preliminary bouton data show a range of voltage-gated conductances and firing properties that have also been described in calyceal recordings. These data will help to build a model of how information from boutons and calyces is electrically integrated in vestibular afferent firing. Supported by NIDCD (R01 DC012347).

Title: Characterizing inner ear mitochondria

Authors: V. BABU[1], N. LABAN[2], R. BAHARI[1], Z. S. ABDUL[1], D. RUYYASHI[1], D. N. MARBINA[1], S. IRUKULLA[1], A.-A.-R. S. AL-RIFAI[1], P. B. SATANI[1], I. BHUPTANI[1], B. O. ZAKKAR[1], A. W. AL-NAJJAR[1], A. A. PATEL[1], M. LOPEZ[1], S. D. PRICE[2], G. PERKINS[3], *A. LYSAKOWSKI[2];
[1]Dept. of BIological Sci., [2]Dept. of Anat. and Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [3]NCMIR, Univ. of California at San Diego, San Diego, CA

Abstract: The main hypothesis of this study is that mitochondria in hair cells and inner ear sensory epithelia are non-homogeneous and that the structural and molecular differences they exhibit are related to their differential responses to ototoxic insults, such as aminoglycoside antibiotic toxicity, chemotherapeutics and noise, which can lead to deafness and dizziness. We utilized EM tomography and computer reconstruction methods in our structural analysis. Our results indicate that there are three populations of mitochondria of different sizes within the vestibular sensory epithelium (identified using surface area and volume measurements): large (found in the subcuticular plate region of central zone type I vestibular hair cells); medium (in all hair cells and afferents); and small (in efferent boutons). By constructing examples of each type, we can determine average volume and surface area for each type, as well as the number and type of cristae within each (lamellar, tubular or tubulo-lamellar). In addition, we are also studying the number, size, and locations of crista junctions (small intersections of cristae with the inner mitochondrial membrane) with respect to other important structures within the cell. For example, our structural findings have shown that in many hair cells, the cristae of mitochondria adjacent to the cuticular plate or to a striated organelle (SO) are perpendicular to, and polarized toward, the organelle. This indicates that these cristae, which are lamellar, align end-on with the cuticular plate and that the crista junctions (CJs) open towards the SO on that side of the mitochondrion. Crista junctions, which function as barriers to the diffusion of molecules inside mitochondria, thus concentrating the oxidative phosphorylation complexes that generate ATP, are thought to be key regulators for the release of apoptotic effectors. Our structural studies are also investigating the role of cytoskeletal filaments, known as tethers, that connect mitochondria to key structures in hair cells, such as striated organelles, cuticular plates or each other. We are exploring the many potential roles these tethers may serve, including positioning mitochondria near structures with high demands for energy or Ca^{2+} and facilitating crosstalk between organelles. We conclude that there are significant differences in morphology among these three mitochondrial sub-populations.

Title: Spatial learning in a complex environment

Authors: *A. POLTEROVICH, M. M. JANKOWSKI, A. KAZAKOV, J. NIEDIEK, I. NELKEN;
Edmond and Lily Safra Ctr. for Brain Sci., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: We explore rat behavior and electrophysiology in a complex setting (the Rat Interactive Fantasy Facility, RIFF). The RIFF consists of a large circular arena (160 cm diameter) with 6 interaction areas (IAs) that each have a water port, a food port, and two loudspeakers. Rat behavior is monitored online using video tracking and nose-poke identification. Neural responses are recorded using telemetry (a 64-channel TBSI transmitter integrated in an Alpha-Omega SNR data acquisition system) or a logger on the head of the animal (RatLog-64, Deuteron Technologies). We trained rats to perform a sound localization task in the RIFF. Auditory cues consisted of 6 different modified human words that were played from each IA separately. When a rat reached the center of the arena, one of the sounds started playing (once every 2 seconds) and the rat had to identify the correct location and collect a reward (food or water) within 20 seconds. Trials were otherwise terminated by access to a wrong port or by time out. The rats were able to learn the task rapidly without guidance. Different rats showed different strategies of exploration and reward collection. Recording neural activity in primary auditory cortex during behavior, we found significant correlations between neuronal activity and a range of non-auditory behaviorally-related variables. Interestingly, behavioral outcomes were correlated with the neural responses before sound presentation, but not with the neural responses to sounds.

Title: The effect of MAP2 gene deficiency on hearing

Authors: *K. TANAKA[1], T. MIYASAKA[1], A. HARADA[2], K. I. KOBAYASI[1];
[1]Doshisha Univ., Kyotanabe, Japan; [2]Osaka Univ., Suita, Japan

Abstract: Microtubule-Associated Protein 2 (MAP2) is thought to critically contribute to the polymerization and stabilization of microtubules in neurons. MAP2 gene knockout C57BL/6 (MKO) mice, however, were fertile, developed normally and had no apparent abnormality. Thus, detailed physiological functions of MAP2 in living organisms have not been fully clarified. We recently found that the strain shows poor auditory responsiveness including weak auditory startle reflex. Here focused on the functions of the MAP2 gene in hearing by examining the auditory brainstem response (ABR) in MKO and wild-type (WT) mice. A measurement electrode was placed in the inferior colliculus, and sound stimuli were presented using 10 frequencies of 2, 4, 8,

16, 32, 50, 60, 64, 68, and 72 kHz. The sound pressure level was varied from 0 to 90 dB SPL in 5 dB steps. The recording was performed under anesthesia. The minimum audible sound pressure levels (auditory thresholds) were estimated from the presence of wave V of ABR, the inferior colliculus response. The auditory thresholds of WT mice were comparable to those of previous reports over all frequencies. The auditory thresholds of MKO mice were significantly higher than those of WT in the 2-32 kHz range with 16 kHz stimulus showing the maximum increase in the auditory threshold by 40 dB (2&4 kHz : $p<0.05$, 8&32 kHz : $p<0.01$, 16 kHz : $p<0.001$). In the frequency above 50 kHz, the ABR was not confirmed in MKO mice. In addition, decrees of ABR amplitude from wave I to V were relatively equivalent, suggesting that the increment of the threshold was primarily caused by unresponsiveness related to wave I (i.e., cranial auditory nerve), or earlier auditory process. We further assessed the morphology of MKO mice's auditory periphery and found no physical defects in the tympanic membrane, ossicles, or the organ of Corti. Together with a previous study showing the MAP2 expression in cochlea hair cells, our data suggest that MAP2 gene deficiency might cause an increase in the auditory threshold by disrupting the function of hair cells.

Title: Effects of NMDA Receptor Antagonism on Mismatch Negativity in Rodents

Authors: S. KABU[1], D. J. GRAZIANO[1], *M. M. SIDOR[2];
[1]Novartis Inst. for Biomed. Res., Cambridge, MA; [2]DeepCure Inc., Boston, MA

Abstract: Various neuropsychiatric conditions are associated with impairments in cortical information processing that can be measured via electroencephalography (EEG) using sensory evoked responses. Furthermore, these deficits can be modeled in rodents and are widely considered a robust translatable biomarker between humans and rodents. Mismatch negativity (MMN) is a type of sensory-evoked response that probes the ability of the cortex to store a mnemonic memory of repeating tones (standard tones) in order to respond differentially to a qualitatively different tone (e.g. pitch deviant tone). Deficits in MMN generation are one of the most widely replicated neurophysiological findings in schizophrenia and can be re-produced by N-methyl d-aspartate (NMDA) receptor antagonism, suggesting a role for NMDA signaling in both the generation of MMN responses and schizophrenia pathology. The current study sought to determine whether and to what extent NMDA modulation can impact rodent MMN. Two approaches were explored: 1) acute NMDA antagonism with (+)-MK-801 hydrogen maleate (MK-801) and 2) a sub-chronic phencyclidine hydrochloride (PCP) paradigm to explore possible sustained effects. Male Sprague Dawley rats were implanted with subcutaneous telemeters that wirelessly transmit EEG signal recorded over the frontal cortex. After recovery, separate cohorts

were administered either an acute dose of MK-801 (0.1 or 0.3mg/kg, i.p.) or were enrolled in a sub-chronic PCP (scPCP) paradigm (7 days of 5mg/kg PCP, BID). Auditory stimuli were delivered in a sound-attenuating chamber at 6kHz and 8kHz in a flip-flop sequence. Average evoked responses to 8kHz standard tones were subtracted from 8kHz deviant evoked responses to calculate a difference wave (i.e. the mismatch response). Rats displayed a similar neuro-oscillatory signature to human MMN with deviant tones producing significantly larger evoked responses in the negative (N1: 35-50ms post-tone) and positive (P2: 50-120ms) components of the MMN-complex compared to standard tones. NMDA antagonism with MK-801 and scPCP differentially impacted these components. Overall, MK-801 was able to produce acute and reversible dose-dependent MMN deficits in both the peak amplitude and area under the curve of the N1 (0.3mg/kg) and P2 (0.1 & 0.3mg/kg) components. Conversely, scPCP administration only impacted the P2 component but this effect was sustained for 7 weeks post-washout. The current results demonstrate that NMDA antagonism impacts deviance detection in rodents and highlights two putative models of pharmacologically-induced MMN deficits. The differential impact of these models on the MMN-complex should be considered.

Title: Clozapine dose-dependently improves 40 Hz auditory steady-state response but partially protects against MK-801-induced disruption.

Authors: *M. U. RAZA, S. V. DIGAVALLI;
East Tennessee State Univ., Johnson City, TN

Abstract: Auditory steady-state response (ASSR) refers to the entrained activity of cortical neurons to a repetitive auditory stimulus, as measured by electroencephalography. Entrainment is quantified by time-frequency measures such as evoked power, intertrial coherence (ITC), and induced power. ASSR at 40 Hz is especially reduced in schizophrenia patients, likely due to reduced NMDA-mediated sensory transmission, a proposed pathophysiological mechanism. In the current study, we confirmed this hypothesis using a high affinity, non-competitive NMDA receptor inhibitor, MK-801, in chronically implanted female rats (n=12). Auditory stimuli were presented (20 clicks for 0.5 seconds (40 Hz), 65 dB, 2 sec inter-stimulus interval) at 30, 60, 90- and 120-minutes post-MK-801 administration (IP). Recordings were made from the vertex electrode using a cerebellar reference. Evoked power and PLF were reduced in a dose-dependent manner by MK-801 (0.05-0.15 mg/kg), while induced power was increased. These effects mimic changes seen in schizophrenia patients. Next, we tested the effect of clozapine (an atypical antipsychotic; 2.5, 5 & 10 mg/kg, sc), which has been shown, among other effects, to augment NMDA transmission. Clozapine doses were chosen to reflect clinically relevant D2 occupancy.

Clozapine by itself improved the 40 Hz ASSR (evoked power, ITC, and induced power) in a dose and time-dependent manner. Next, we tested if clozapine can protect against MK-801-induced 40 Hz ASSR deficits. For this, clozapine (5 or 10 mg/kg, sc) or vehicle were given 20 minutes before MK-801 (0.1 mg/kg, IP) administration. A vehicle/vehicle group was a negative control. ASSR was recorded at 30, 60, 90- and 120-minutes post-MK-801 injection. Compared to veh+veh, veh+MK801 produced robust deficits in 40 Hz ASSR measures at all time points. Clozapine (10 mg/kg only) provided significant but partial and temporally short-lived (~ 60 min) protection. These studies highlight the following: 1. Clozapine improves sensory transmission by itself; 2. The partial efficacy of clozapine in protecting against NMDA disruption points to its therapeutic limitation in normalizing NMDA neurotransmission; 3. Our work illustrates the utility of the 40 Hz ASSR as a circuit-based pharmacodynamic biomarker for drug development.

Title: Discrete Functional Subnetworks within Secondary Auditory Cortex Integrate Multi-Frequency Sounds with Synchronous Onsets

Authors: *A. M. KLINE, D. A. APONTE, H. TSUKANO, A. GIOVANNUCCI, H. K. KATO; Psychiatry and Neurosci. Ctr., Univ. of North Carolina, Chapel Hill, NC

Abstract: Integration of multi-frequency sounds into a unified perceptual object is critical for recognizing syllables in speech. This “feature binding” relies on the precise synchrony of each component’s onset timing, but little is known regarding its neural correlates. We find that multi-frequency sounds prevalent in vocalizations, specifically harmonics, preferentially activate the mouse secondary auditory cortex (A2), whose response deteriorates with shifts in component onset timings. The temporal window for harmonics integration in A2 was broadened by inactivation of somatostatin-expressing interneurons (SOM cells), but not parvalbumin-expressing interneurons (PV cells). Importantly, A2 has functionally connected subnetworks of neurons encoding harmonic, but not inharmonic sounds. These subnetworks are stable across days and exist prior to experimental harmonics exposure, suggesting their formation during

development. Furthermore, A2 inactivation impairs performance in a discrimination task for coincident harmonics. Together, we propose A2 as a locus for harmonic integration, which may form the circuit basis for vocal processing.

Title: Gap responses in awake rats: on-off response adaptation and omission responses reveal a representation of prediction errors

Authors: *B. AWWAD[1], M. JANKOWSKI[2], A. POLTOROVICH[2], S. BASHARI[2], I. NELKEN[3];

Abstract: The detection of sensory deviance is an important computational task that may provide an evolutionary advantage to organisms. Deviance can be detected by using a memory trace of past stimuli to predict what may occur next. Large prediction errors mark sensory deviance. In human studies, mismatch negativity (MMN) has been suggested to indicate automatic deviance detection. In animal models, stimulus-specific adaptation (SSA) shows some corresponding features. However, while MMN has been shown in response to omitted stimuli, omission responses are rare in animal studies. Using temporal gaps, we show that offset responses, which were absent in anesthetized rats, were widely present in awake rats. These offset responses showed SSA, similar to the onset responses. Most importantly, continuous noise bursts were embedded as deviants in a sequence of gap stimuli, robust omission responses to the expected gaps that did not occur were evoked, reflecting prediction error under adaptation. These omission responses, together with the on-off response SSA, reveal a representation of prediction error in auditory cortex neurons.

Title: Effect of clutter on the neural representation of acoustic objects in the bat midbrain

Authors: *K. M. ALLEN[1], A. SALLES[1], S. PARK[2], M. ELHILALI[2], C. F. MOSS[1];
[1]Dept. of Psychological and Brain Sci., [2]Electrical and Computer Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Auditory processing in complex environments is a challenge for humans and animals alike. Auditory objects are the individual sound sources that comprise auditory scenes. Deciphering the neural encoding of auditory objects is a first step to understanding how rich soundscapes are perceived. Echolocating bats are a powerful animal model to explore this problem. Aerial hawking bats hunt on the wing, and actively probe auditory objects in their surroundings via echolocation. Bats produce brief ultrasound signals, interrupted by periods of silence, rendering echo snapshots of auditory objects which change with viewing angle, distance, and the presence of clutter and acoustic distractors. Relying on dynamic and discontinuous echo information, bats simultaneously track prey and avoid collisions with obstacles in highly cluttered environments. This natural task requires that bats process spatially and temporally overlapping echoes to make split-second decisions, exemplifying the need for rapid object discrimination and classification. The effects of both physical clutter and masking noise on bat sonar discrimination have been explored. However, it is unknown if there are conditions in which acoustic clutter may enhance the representation of auditory targets. In this work we studied the responses of neurons in the auditory midbrain of the big brown bat, *Eptesicus fuscus*, to echoes from 3-dimensional objects in the vicinity of physical clutter. Our analysis reveals population coding of echo features that can be used to discriminate between auditory objects. We further investigated the effects of environmental clutter on the discrimination of auditory objects. We discovered that effect of clutter on object discrimination is highly variable, depending on object properties and object distance from clutter. In many conditions clutter predictably impaired discrimination of auditory objects. However, in some instances clutter enhanced object features, leading to higher levels of discrimination. These findings suggest that in natural settings, environmental clutter may actually provide beneficial information to bats engaged in target tracking and provides further evidence in a growing body of literature that noise is not universally detrimental to sensory encoding.

Title: Auditory and visual system function and white matter condition is differentially impacted by normative aging in macaques

Authors: ***D. T. GRAY**[1,2], N. M. DE LA PEÑA[1], L. UMAPATHY[3], S. N. BURKE[6], J. R. ENGLE[1], T. P. TROUARD[1,4], C. A. BARNES[1,2,5];

Abstract: Normative brain aging results in decreased function across multiple sensory systems that compromises an older individual's ability to detect and process behaviorally relevant information and can substantially reduce quality of life. Deficits in auditory and visual processing, in particular, are commonly encountered by older individuals due to age-associated pathologies at the level of the cochlea and eye, and from multiple changes that occur along the ascending auditory and visual pathways that further reduce sensory function in each domain. One fundamental question that remains to be directly addressed is whether the structure and function of the central auditory and visual systems follow similar trajectories across the lifespan, or sustain the impacts of brain aging independently. Advances in the quality and precision of sensory prosthetics have made it clear that distinct sensory deficits require unique approaches, and precisely understanding how particular age-associated neurobiological changes impact different facets of sensory processing is critical for optimizing intervention strategies that maintain sensory function in older individuals. The present study used diffusion magnetic resonance imaging and electrophysiological assessments of auditory and visual system function in adult and aged macaques to better understand how age-related changes in white matter connectivity at multiple levels of each sensory system might impact auditory and visual function. Sensory processing and sensory system fractional anisotropy (FA) were both reduced in older animals compared to younger adults. Corticocortical FA was significantly reduced only in white matter of the auditory system of aged monkeys, while thalamocortical FA was lower only in visual system white matter of the same animals. Importantly, these structural alterations were significantly associated with sensory function within each domain. Together these results indicate that age-associated deficits in auditory and visual processing emerge in part from microstructural alterations to specific sensory white matter tracts, and not from general differences in white matter condition across the aging brain. Accounting for this sort of

specificity will aid in designing individualized intervention strategies that optimally correct and maintain brain function across the lifespan.

Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Title: Methyl CpG Binding Protein 2 in Parvalbumin Cortical Interneurons is Critical for Processing Ultrasonic Vocalizations
Authors: Deborah Rupert.[1, 2], Alexa Pagliaro[1], and Stephen Shea,[1]
Affiliations:(1) Neuroscience, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.(2) Medical Scientist Training Program, Stony Brook University, Stony Brook, NY.
Background: Rett Syndrome (RTT) is a pervasive, neurodevelopmental disorder previously classified as an Autism Spectrum Disorder and caused by loss of function mutations in the X-linked gene methyl CpG binding protein 2 (*MeCP2*). *MeCP2* codes for the protein by the same name, a ubiquitously expressed transcription factor that maintains mature neuronal synapses.
Objectives: Our goal is to determine the contribution of cell-type specific *Mecp2* mutation to disruptions of auditory cortical circuitry and plasticity that degrade social vocal perception in a mouse model of Rett syndrome.
Methods: To achieve this goal, we use a cell-type restricted *Mecp2* mutant mouse model in combination with a behavioral paradigm that relies on vocal communication. We employ pup retrieval a natural, auditory-dependent, learned maternal behavior that we report to be impaired by *Mecp2* mutation. Maternal retrieval is cued by ultrasonic vocalizations (USVs)- high-pitched distress calls emitted by isolated infant pups. Our previous work suggests lack of plasticity in auditory cortex (ACtx), a brain region required to detect and interpret vocalizations, underlies impaired retrieval performance. Here we build on these findings by parsing out the contributions of specific subclasses of inhibitory interneurons (i.e. parvalbumin-, somatostatin-, and vasoactive intestinal peptide- positive populations) to auditory processing. We examine the effects of restricted *Mecp2* mutation in these inhibitory interneuron subclasses on pup retrieval behavior, *in vivo* neural circuit activity, and calcium imaging in the ACtx in response USVs.
Results: We find *Mecp2* mutation restricted to the parvalbumin positive (PV+) cell type is

impairs pup retrieval behavior, and degrades ACtx neuronal activity in response to pup vocalizations.
Conclusions: This work focuses on functional consequences of *Mecp2* mutation to auditory processing circuitry that expands our understanding of the underlying etiology of RTT and informs pathophysiological mechanisms underlying neurodevelopmental disorders more broadly.

Title: Vocal perceptual category boundaries are modified by maternal experience in female mice

Authors: *L. SHEN, S. D. SHEA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Only a fraction of sounds an organism encounters are behaviorally significant. One example is vocalizations, which occur against a backdrop of sounds with overlapping features, and also exhibit substantial variability. This presents two competing challenges: detection must be selective enough to minimize false alarms while also being tolerant to natural variation. The equilibrium of these demands can result in 'categorical perception', in which steep perceptual boundaries exist along a continuous stimulus dimension. Here we use a vocally-motivated pup retrieval behavior to reveal how the brain adjusts and enforces perceptual boundaries between vocal signals and other sounds. When pups are separated from their nest, they emit an ultrasonic vocalization (USV) that maternally-experienced mice can use to locate and retrieve the pups back to the nest. We have developed a high-throughput, quantitative behavioral paradigm where nulliparous female mice are water-deprived and trained in a probabilistic go/no-go task. They are conditioned to lick a water spout in response to playback of a USV, and to withhold licking in response to a synthetic tone. Once stable criterion performance (>80%) is achieved, the mice are separated into two groups: mice that are housed with pups and gain maternal experience ('surrogates'), and mice that have never been exposed to pups ('naïves')., We next present a set of novel sounds to the mouse as infrequent and unrewarded catch trials (including bandwidth-limited noise and pitch-shifted USVs), and we use licks to the novel stimuli as a measure of perceived similarity to natural USVs. These infrequent stimuli are never rewarded, and USVs are only rewarded on 80% of trials, thus the mouse receives no instruction with regard to catch trials. Nevertheless, we find that responses to the synthetic sounds show evidence of learning between initial and late trials that differs in naives and surrogates. Initial responses of surrogates towards broadband sounds in the range of USVs are similar to those of the Go-Cue, while naïve mice tend to initially have lower response rates to those same sounds. Late responses of surrogate

mice toward those same sounds were generally lower than those of the naïve mice. These results align with electrophysiological data in the primary auditory cortex done before and after behavioral training, suggesting that auditory cortex neurons adjust their firing rate following both pup exposure and task learning. Taken together, our results shed light on how vocal perceptual filters are optimized during maternal experience, and will provide insight into how categorical perception contributes to speech processing and learning.

Title: Partial reconstruction of the canonical microcircuit of owl ICX

Authors: P. HARRAST[1], E. BUSHONG[2], D. SANCULI[1], M. MADANY[2], W. WONG[2], P. JAIN[1], V. PIERCE[1], C. RESNGIT[1], C. STERNER[1], M. ELLISMAN[2], *W. M. DEBELLO[1]; [1]UC Davis, Davis, CA; [2]UCSD, La Jolla, CA

Abstract: We report new findings towards the long-term effort to reconstruct the canonical microcircuit of the owl auditory space map. Previous work applied the volume electron microscopy (EM) method of serial block face EM (SBEM) to analyze a 0.25 x 10^6 μm^3 volume of tissue containing a peroxidase-labeled space-specific neuron (SSN) from the owl inferior colliculus. We discovered that SSNs are studded with a novel type of dendritic spine, toric spines, named for their topological holes. Here we report SBEM imaging and preliminary analysis of an unlabeled SSN in a larger volume (2.4 x 10^6 μm^3), revealing the cytoplasmic features of the toric spines with significantly more detail throughout. Axons projecting horizontally and onto SSNs within the external nucleus of the inferior colliculus (ICX) were labeled *in vivo*, prospectively imaged by 2-photon microscopy, and the axon-laden region was isolated for SBEM. This volume contains >50 SSNs and an estimated >5,000,000 synapses. In comparison to the previous volume: 1. Asymmetric synapses with spherical vesicles are clearly distinguishable from symmetric synapses with pleiomorphic vesicles. 2. The internal structure of putative toric spines is apparent. They contain mitochondria, not found in typical mushroom spines, and smooth endoplasmic reticulum (SER). 3. Most postsynaptic structures are rife with SER, likely involved in Ca sequestration and lipid metabolism. 4. Astrocytic processes identified by the presence of glycogen particles and intermediate filaments (presumably GFAP) are intimately associated with SSNs. 5. The spatial density of myelinated axons is higher than in the previous volume, likely reflecting a more lateral position within ICX. 6. Preliminary, incidental observations also indicate that Nodes of Ranvier on different myelinated axons appear spatially

clustered, speculatively suggesting a possible potential role in coordinating action potential firing properties among nearby axons. 7. Nuclear pores, sub-surface cisternae, heminodal organization and many other classical features of neuronal ultrastructure are clearly apparent. To extract the microscale connectome, we are currently using a team of annotators to produce dense reconstructions of small sub-volumes. These will be used to train newly developed machine learning algorithms for automated segmentation. Finally, segmented axons will be registered to the 2-photon volume to identify functional connections within ICX. In summary, the results to be shared are expanding our knowledge of the ultrastructure of toric spines and SSNs, and establish a clear path towards mapping the local synaptic network in which they are embedded.

Title: The role of PnC glycinergic interneurons in prepulse inhibition in the context of aging

Authors: *W. HUANG, K. FENELON;
UMass Amherst, Amherst, MA

Abstract: BACKGROUND: Prepulse inhibition (PPI) of the auditory startle reflex is the suppression of an acoustic startle response to an intense stimulus when a weak stimulus (prepulse) precedes the startle stimulus (pulse). PPI is the classic operational measure of sensorimotor gating, and is used both in humans and animal models. As a hallmark of schizophrenia, PPI deficits are also found in other neuropsychiatric disorders and are associated with deficits in attention. In addition, both human and rodent studies show age-dependent alterations of PPI, but the underlying mechanisms remain unclear. The brainstem caudal pontine reticular nucleus (PnC) is at the core of the PPI pathway, relaying sensory inputs from several brain regions to motor neurons. The PnC contains neurons expressing the glycine transporter type 2 (GlyT2), which are widely distributed and closely intermingle with startle-mediating giant neurons. $GlyT2^+$ PnC inhibitory neurons are found in both humans and mice and were shown to play a major role in behavioral arrest (Giber et al, 2015). Although glycine inhibits PnC giant neurons and reduces the startle response in rats (Koch and Friauf, 1995; Geis and Schmid, 2011), the contribution of $GlyT2^+$ PnC inhibitory neurons to PPI remains unknown. Therefore, here, we investigated the role of $GlyT2^+$ PnC inhibitory neurons in PPI and in the context of aging. METHODS: To drive Archaerhodopsin expression (Arch3.0; optogenetic inhibitory tool

sensitive to green light) in GlyT2$^+$ PnC neurons, adult GlyT2-Cre mice (3-6 months old) were injected with AAV-Dj-EF1a-DIO-Arch3.0-eYFP in the PnC. The acoustic startle response (ASR) and PPI were performed 4 weeks post injection, both in the presence and in the absence of the photo-inhibition in GlyT2-Cre mice, which were compared to control adult C57BL/6J mice. In addition, the effect of age on PPI was assessed in another cohort of older GlyT2-Cre mice, aged between 9-12 months. Using these mice, GlyT2$^+$ PnC neurons were also photo-inhibited to determine their contribution to the age-related reduction in PPI.
RESULTS: Photo-inhibiting GlyT2$^+$ PnC neurons had no effect on ASR in adult GlyT2-Cre mice, their control C57BL/6J littermates and older GlyT2-Cre mice. Interestingly, photo-inhibition significantly decreased PPI ($p=.028$) but only in adult GlyT2-Cre mice, particularly at the 30 ms ($p=0.048$) and 50 ms ($p=0.023$) inter-stimulus intervals between the prepulse and the pulse.
DISCUSSION: The findings suggest that: 1) GlyT2$^+$ PnC inhibitory neurons contribute to PPI in adult mice and 2) the contribution of GlyT2$^+$ PnC inhibitory neurons to PPI declines with age, providing a possible explanation for age-related PPI impairments.

Title: A convolutional neural-network model of the inner-hair-cell and auditory-nerve-fiber complex

Authors: F. DRAKOPOULOS, D. BABY, ***S. VERHULST**;
Dept. Information Technol., Ghent Univ., Zwijnaarde, Belgium

Abstract: Analytical descriptions of inner-hair-cell (IHC) and auditory-nerve-fiber (ANF) processing have evolved over the years, with IHC transduction models shifting from simplified low-pass filters to detailed conductance models which include basolateral outward K^+ currents. State-of-the-art models of the IHC-ANF synapse complex describe the vibrations of the IHC stereocilia based on the mechanical drive to the IHC and model ANF spikes or instantaneous firing rates as resulting from the depletion and replenishment of different neurotransmitter stores. While such sensory models have progressed to accurately capture the nonlinear and dynamic properties of the neuronal processes associated with hearing, they typically comprise mechanistic descriptions and coupled sets of ordinary differential equations, rendering these models slow to compute.Here, we present a hybrid computational neuroscience - deep neural network (DNN) framework which simulates auditory IHC-ANF processing, to offer a fast and differentiable model which can be used in large-scale neuronal network models. Based on a state-of-the-art

biophysical model of the auditory periphery (including human cochlear mechanics, IHC and ANF processing), we trained several convolutional neural network (CNN) architectures to learn the computations performed by the IHC-ANF complex (CoNNear$_{IHC-ANF}$). We determined the hyperparameters in these architectures (different layers, filter lengths, input and context windows, activation functions) on the basis of well-known single-unit IHC and ANF properties derived from experimental neuroscience studies. The model was trained using an acoustic speech corpus, and its performance evaluated using basic acoustic stimuli which were not included in the training set. The final CoNNear$_{IHC-ANF}$ model offers a 70-fold speed-up factor on a CPU and a 280-fold factor on a GPU when compared to the analytical IHC-ANF model processing computations. When connected to a DNN-based cochlear model, preferably CoNNear$_{cochlea}$, population responses (e.g. CAP, ABR wave-I) can be simulated across a large number of cochlear tonotopic locations, and be used for backpropagation purposes. Our auditory periphery framework can be applied for the development of large-scale neural-network circuits aimed to advance our knowledge of unknown neuronal systems such as the brainstem and subcortical pathways, or the human auditory cortex. Title: The geometry of sound representation along the auditory pathway

Authors: *A. BERROU[1], H. ZHANG[2], M. JANKOWSKI[1], M. HARPAZ[1], T. SHARPEE[2], D. HANSEL[3], I. NELKEN[1];
[1]Edmond and Lily Safra Ctr. for Brain Sciences, Hebrew Univ. of Jerusalem, Jerusalem, Israel; [2]Computat. Neurobio. Laboratory, Salk Inst. for Biol. Studies, La Jolla, CA; [3]Integrative Neurosci. & Cognition Center, CNRS-UMR8002, Paris, France

Abstract: Ongoing activity in the absence of stimulation is known to reflect aspects of the evoked activity but much remains to be understood about how sounds are represented. Here, we study features of the spontaneous activity of the sound-responsive (R) and sound-unresponsive

(U) neurons at three stages of the ascending auditory pathway. Units were recorded extracellularly in the Inferior colliculus (IC, n=4), Medial Geniculate Body (MGB, n=4) and primary Auditory Cortex (A1, n=5) of anesthetized rats using Neuropixel probes. Sound stimulation included pure tones - 37 frequencies (6 tones/octave) at 8 possible attenuations (30-100 dB SPL). The ongoing activity was recorded before each session for about 10 seconds. Units were extracted using Kilosort followed by manual curation. For each stimulus, the total number of spikes, k, was counted and the spontaneous rate, λ, estimated. These were used to compute the probability, ps, of emitting k spikes or more in response to stimulus s assuming a homogeneous Poisson process with rate λ. A cluster was classified R if ps<0.05/nstim for one stimulus at least. We observed that i) the spontaneous firing rates of R and U were distinct and their difference increased from IC to A1; ii) the average pairwise spike correlations between nearby R clusters in MGB and A1 were higher than the correlations between R and U clusters or between U clusters; and iii) the spatial mixing between R and U increased on average from IC to A1. Overall, R and U populations exhibited distinct activities despite their anatomical mixing. We also analyzed the topological structure of the activity in the three stations. This activity does not allow for low-dimensional Euclidean representations, and instead requires mappings with hyperbolic geometry. This was true for all three stages of auditory processing. However, responses only within the IC, and not in the MGB and A1, were consistent with a uniform distribution of points in a three dimensional hyperbolic space. Because hyperbolic geometry is congruent with hierarchical tree-like organization, the hyperbolic coordinates make it possible to arrange neurons in a hierarchical way. We find that hyperbolic coordinates in IC aligned with the latency of neural responses in a way that allows for gradual refinement of auditory responses following their representation. This code is well suited for fast and organized communication of dynamic acoustic features. Together, these studies unravel the effects of the recurrent connectivity, both within and across stations, on sound representation in the ascending auditory system. We develop theoretical models to reproduce these results.

Abstract: We used Neuropixels probes to study processing of sounds in the auditory field located in the Insular cortex (InsC) in anesthetized rats. InsC is a multi-modal cortical area composed of functionally distinct subregions that differ in their connectivity with other brain areas. Detailed histological analysis of electrode tracks revealed auditory responsive neurons in Insular cortex (InsC, n=508), as well as more dorsally, in the adjacent secondary somatosensory cortex (S2, n=372). The band of auditory responsive neurons extended continuously from ventral S2 and into granular insular cortex (GI). Units recorded throughout this band had short minimal onset latencies that were sometimes shorter than for A1 units. These short-latency responses were dominant in S2 while InsC contained in addition a subpopulation of units with longer latencies. Auditory units in S2 and InsC showed pronounced adaptation to repeated pure tones and moderate stimulus-specific adaptation (SSA) to pure tones, smaller than in A1. They had minor (InsC) or no (S2) SSA to complex spectrally balanced tone clouds. Units in InsC and S2 auditory field had different profiles of sensitivity to the structure of tone sequences compared to A1. In conclusion, under anaesthesia, despite the similarity in their responses to simple sounds, neurons in rat InsC and S2 perform computations that differ significantly from those performed by neurons in A1.

Title: Phase Reset in Ongoing Oscillations -Response to, or Prediction of External Sensory Stimuli?

Authors: *H. CHO[1,2], R. T. KNIGHT[3], P. BRUNNER[1,4];
[1]Neurosurg., Washington Univ. Sch. of Med. in St. Louis, St. Louis, MO; [2]Nactional Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Psychology and the Helen Wills Neurosci. Inst., Univ. of California at Berkeley, Berkeley, CA; [4]Neurol., Albany Med. Col., Albany, NY

Abstract: Ongoing cortical oscillations are known to exhibit phase resets related to external sensory stimuli. It is thought that phase reset lowers the membrane potential and increases the excitability of neuronal ensembles. However, whether phase reset is a response to or prediction of an external sensory stimulus remains unclear. To answer this question, we investigated phase resets in the ongoing cortical oscillations of five human subjects that attended to repetitions of the 'La-La-Ba La-La-Ga' syllable pattern. This pattern created a temporal expectation of the 'Ba' or 'Ga' syllables. To ensure the subjects' attention, we asked them to respond with a button press to a 'Ta' syllable that occurred randomly in place of 12% of the 'Ga' syllables. Similarly, to determine whether phase reset occurs in prediction of a stimulus, we randomly omitted 30% of the 'Ga' syllables. The syllables were 410ms in duration and separated by each other by a 200ms ISI. Over the 40 minutes of this experiment, we recorded 1280 sequences that contained 160 omitted and 64 'Ta' syllables. In our analysis, we were interested in detecting phase resets in the ongoing cortical oscillations. For this purpose, we first identified those cortical locations that exhibited a statistically significant high frequency activity (HFA;70-170 Hz) response to the syllables. For each location and each syllable, we then calculated the likelihood of phase reset over time using phase-amplitude coupling (PAC) between the phase of ongoing low-frequency oscillations (<40Hz) and the amplitudes of high gamma activity. Finally, we determined whether phase reset occurred before or after the syllable onset by grouping the PAC results into 'Ba,' 'Ga' and omitted syllables, and calculating the cumulative likelihood of phase reset. In this analysis, we first determined the Gaussian distribution of PAC onsets. Since PAC is known to immediately follow phase reset, we defined the phase reset onset as the Gaussian distribution onset. This analysis shows that, on average, PAC occurs within the superior temporal gyrus approximately 200ms after syllable onset and that it is preceded by phase reset by 100ms. Further, we found a peak in the high gamma activity during the trough period that immediately followed the phase reset. In summary, these results show that the onset of PAC follows the onset of the 'Ba', 'Ga' and omitted syllables. Thus, our study supports the notion that phase reset is a response to an external sensory stimulus and not a prediction.

Title: Distinct synaptic plasticity mechanisms determine the diversity of cortical responses during behavior

Authors: *M. INSANALLY[1], B. ALBANNA[1], J. TOTH[1], B. DEPASQUALE[2], S. FADAEI[3], K. RAJAN[4], R. FROEMKE[3];

Abstract: Spike trains recorded from the cortex of behaving animals can be complex, highly variable from trial to trial, and therefore challenging to interpret. A fraction of cells exhibit trial-averaged responses with obvious task-related features such as pure tone frequency tuning in auditory cortex. However, a substantial number of cells (including cells in primary sensory cortex) do not appear to fire in a task-related manner (Jaramillo et al, 2010; Rodgers & DeWeese 2014) and are often neglected from analysis. Even classically responsive cells lose their stimulus representation during task-engagement without impairing behavior (Otazu et al, 2009; Bagur et al, 2018). These results suggest that non-classically responsive cells may play an underappreciated role in sensory processing and cognition. We recently used a novel single-trial, spike-timing-based analysis to show that both classically responsive and non-classically responsive cortical neurons recorded from auditory and frontal cortex contain significant information about sensory stimuli and behavioral decisions (Insanally et al, 2019). In addition, we showed that non-classically responsive neurons can predict behavioral errors and encode abstract cognitive variables better than classically responsive cells. Here we expand this investigation to explore the synaptic origins and potential contribution of these cells to network function. To do so, we trained a novel spiking recurrent neural network (RNN) model that incorporates spike-timing-dependent plasticity (STDP) mechanisms to perform the same task as behaving animals. By leveraging excitatory and inhibitory plasticity rules this model reproduces neurons with response profiles that are consistent with our previously published experimental data, including classically responsive and non-classically responsive neurons. We found that both classically responsive and non-classically responsive neurons encode behavioral variables in their spike times as seen in vivo. Interestingly, heterosynaptic plasticity in excitatory-to-excitatory synapses increased the proportion of non-classically responsive neurons and may play a significant role in determining response profiles. Finally, our model also makes predictions about the synaptic origins of classically and non-classically responsive neurons which we compare to *in vivo* whole-cell recordings taken from the auditory cortex of behaving animals. This approach successfully recapitulates heterogeneous response profiles measured from behaving animals and provides a powerful lens for exploring large-scale neuronal dynamics and the plasticity rules that shape them.

Title: Correlates of auditory decision making in prefrontal, auditory and basal lateral amygdala cortical areas

Authors: *J. L. NAPOLI, C. R. CAMALIER, A. L. BROWN, J. JACOBS, M. M. MISHKIN, B. B. AVERBECK;
NIH, Bethesda, MD

Abstract: Spatial selective listening and auditory choice underlie important processes including attending to a speaker at a cocktail party and knowing how (or if) to respond. To examine task encoding and relative timing of potential neural substrates underlying these behaviors, we developed a spatial selective detection paradigm for monkeys, and recorded activity in primary auditory cortex (AC), dorsolateral prefrontal cortex (dlPFC) and the basolateral amygdala (BLA). A comparison of neural responses among these three areas showed that, as expected, AC encoded the side of the cue and target characteristics before dlPFC and BLA. Interestingly, AC also encoded the monkey's choice before dlPFC and around the time of BLA. Generally, BLA showed weak responses to all task features except the choice. Decoding analyses suggested that errors followed from a failure to encode the target stimulus in both AC and dlPFC, but again, these differences arose earlier in AC. The similarities between AC and dlPFC responses were abolished during passive sensory stimulation with identical trial conditions, suggesting that the robust sensory encoding in dlPFC is contextually gated. Thus, counter to a strictly PFC-driven decision process, in this spatial selective listening task, AC neural activity represents the sensory and decision information before dlPFC. Unlike in the visual domain, in this auditory task, the BLA does not appear to be robustly involved in selective spatial processing.

Title: Activity-dependent Kv1.1 membrane expression drives intrinsic plasticity in the zebra finch auditory cortex

Authors: *Y. LU, C. D. MELIZA;
Univ. of Virginia, Charlottesville, VA

Abstract: In zebra finches and other songbirds, the auditory system undergoes a sensitive period where the general acoustic environment shapes auditory processing that support auditory perception of vocalizations. In the caudal mesopallium (CM), a cortical-level auditory area implicated in discriminating and learning species-specific vocalizations, there is subset of neurons that only fire transiently at the onset of current injections (i.e., phasic firing), and phasic firing can enhance the reliability and selectivity of neural responses to complex acoustic stimuli. Previous work shows phasic excitability peaks during the sensitive period for song memorization. Changing side by side with phasic excitability is the proportion of CM neurons that express Kv1.1, a low-threshold potassium channel that facilitates phasic firing. These correlated changes in intrinsic plasticity and Kv1.1 expression only occur in a noisy acoustic environment, suggesting that an experience-dependent mechanism regulates expression of Kv1.1 and its localization to the plasma membrane. Here, we investigated the cellular mechanisms underlying this intrinsic plasticity. We stimulated CM neurons in brain slices under current clamp to determine the intrinsic dynamics, followed by post-hoc Kv1.1 expression analysis. We found that Kv1.1-positive neurons were significantly more phasic than Kv1.1-negative neurons. Furthermore, stimulating CM neurons with a complex, broadband current caused neurons to become more phasic over the course of several minutes. These data suggest Kv1.1 may be rapidly relocalized to the cell membrane in an activity-dependent manner, thus driving a change towards phasic excitability.

Title: Categorical representation by suppression or enhancement of stimuli during auditory perceptual learning

Authors: *K. A. MARTIN, C. BREDENBERG, A. M. LEMESSURIER, E. P. SIMONCELLI, C. SAVIN, R. C. FROEMKE;
New York Univ., New York, NY

Abstract: Auditory perceptual learning reliably enhances cortical representations of task-relevant stimuli in trainedanimals relative to naive ones. Despite being associated with perceptual improvement, such changesin neural tuning are typically not measured throughout learning and do not investigate differences inactivity between neuronal subtypes. To address these limitations, we developed an experimental andcomputational framework for describing how sensory representations in both excitatory and inhibitoryneurons change during auditory

perceptual learning.We performed longitudinal two-photon imaging in auditory cortex throughout two-alternative forced-choice auditory conditioning in head-fixed mice. We recorded from excitatory and inhibitory neurons inlayer 2/3 and inhibitory neurons in layer 1. To obtain water reward, animals learned to classifyfrequencies as a single, center frequency (11-16 kHz) or non-center by licking left and right,respectively. Discrimination between center and non-center frequencies improved over 9-21 days. Intrained animals, despite similar behavioral performance, we observed two distinct tuning profiles ofexcitatory neurons in across different animals. Specifically, animals exhibited either a relativeenhancement or suppression of the center frequencies reported as center. This was seen at both thesingle cell and population level as well. We examined when these response profiles emerged duringlearning. We could detect whether an animal would likely exhibit enhancement or suppression as earlyas day 6 in behavioral learning.To make sense of these findings, we developed a network model of excitatory and inhibitory neuronsto explore what may account for these individual differences and how they arise over learning. Wetrained a network model of excitatory and inhibitory neurons by reward-modulated Hebbian synapticlearning (Williams, 1992) to solve the same task. We found that the simulated network learns at similarrates as real animals and captures the across-animal variability in tuning. Overall, both data and modelreveal nontrivial learning dynamics associated with perceptual learning in auditory cortex, with initialtuning driving across-animal variability in the emerging representations.

Title: Neuromodulation enhances plasticity in a rat model of cochlear implant use

Authors: *E. G. GLENNON[1], A. ZHU[1], M. SVIRSKY[1], R. C. FROEMKE[2];
[1]NYU Sch. of Med., New York, NY; [2]Otolaryngology, NYU Med., New York, NY

Abstract: Rates of auditory perceptual learning with cochlear implants are highly variable across patients. Adaptation to cochlear implants is believed to require neuroplasticity within the central auditory system. However, mechanisms by which behavioral training enables plasticity and improves outcomes are poorly understood. Here we hypothesize that neural mechanisms promoting plasticity in the rat auditory system are key to optimizing cochlear implant usage. Specifically, we examined the effect of pairing locus coeruleus stimulation with an auditory

stimulus on auditory learning when the animal has to relearn a tone identification task (self-initiated, go/no-go) using a cochlear implant. Initial training was done using acoustic stimuli in normal hearing animals. Animals were then bilaterally deafened, unilaterally cochlear-implanted, and retrained with the new target delivered by intracochlear electrical stimulation. Prior to daily behavioral training sessions, rats underwent 5-10 min pairing sessions either with optogenetic locus coeruleus or sham stimulation. Pairing accelerated learning with cochlear implants. We then conducted multi-unit recordings in the auditory cortex to assess responses to the cochlear implant. Animals that had been trained with the cochlear implant had increased activation of the cortex, and those that underwent pairing had a sharper representation of the target cochlear implant channel. We used fiber photometry to monitor activity of noradrenergic locus coeruleus neurons. During auditory learning, cochlear implanted animals display dynamic locus coeruleus activity, specifically during the acquisition of the meaning of reward relevant tones. These studies indicate that neuromodulation can play a powerful role in shaping outcomes with cochlear implant use and training.

Title: Impact of presbycusis on static postural control

Authors: *L. BEHTANI[1,2], M. MAHEU[1], F. CHAMPOUX[1,2];
[1]Univ. of Montreal, Montréal, QC, Canada; [2]Ctr. de recherche de l'Institut Universitaire de Gériatrie de Montréal, Montréal, QC, Canada

Abstract: Falls represent the second leading cause of injuries and deaths among older adults. One common factor associated with increased risks of falls is age-related decline in postural control. Recent neuro-otology studies suggest that hearing plays a role in postural control. However, the effect of age-related hearing loss on postural control is still unknown. Age-related hearing loss, also known as presbycusis, affects nearly two-thirds of the US population over 70 years and represents an important risk factor for increasing falls among older adults. The aim of this study was to to determine the influence of presbycusis on static postural control in normal-hearing and hearing-impaired older adults. Thirty participants underwent a comprehensive audiological evaluation by a certified audiologist with the aim to determine their hearing

thresholds . The modified Clinical Test of Sensory Integration and Balance was used to measure body sway control using a force platform. Participants were required to stand still on a force platform or on a foam surface with eyes open or with eyes closed. A significant group difference was found for both sway velocity and path length measures. Postural sway was increased among hearing-impaired older adults, suggesting poorer postural control as compared to normal-hearing older adults. Our findings suggest that a reduction in auditory inputs due to hearing loss (i.e. presbycusis) significantly affects postural control. Thus, presbycusis could contribute to the decline in postural control among older adults.

Title: Opposing Intensity Adaptation Effects in Auditory Event-Related Potentials from Young Children

Authors: *P. DWYER[1], C. D. SARON[2], S. M. RIVERA[1];
[1]Dept. of Psychology, [2]Ctr. for Mind and Brain, Univ. of California Davis, Davis, CA

Abstract: Introduction Although the intensity of a stimulus preceding a sound is known to affect the subjective loudness of that sound, a prior study has found no effect of prior stimulus intensity on the neural response to a second stimulus (Ninomiya et al., 2000). However, that study had a relatively small sample. The present study examined intensity adaptation in ERPs from a larger sample of young children.
Methods Participants with usable ERPs were 81 typically-developing children (52 male, M_{age} = 37.09 mos, range 25-57 mos, M_{DQ} = 107.37, range 79-129). While watching a quiet video, participants heard, via headphones, brief complex tones pseudo-randomly varying in intensity between 50, 60, 70 and 80 dB SPL (~200-300 trials/intensity) with the restriction that tones of the same intensity were never presented in succession. ISI randomly varied between 1-2 s. 61-channel EEG was sampled at 1000 Hz. P1 amplitudes were quantified as mean amplitudes over fronto-central channels ±50 ms around the grand-average peak for each intensity: 73-173 ms (50 dB), 60-160 ms (60 dB), 45-145 ms (70 dB), and 42-142 ms (80 dB). We computed differences

between averaged responses to the 2nd stimulus presented in each of the 12 intensity pairs and an overall average of responses to the 2nd stimulus across all prior intensities. More positive difference values indicate a more positive (i.e., larger) P1 response for a given prior intensity. ANOVA was used to examine effects of prior stimulus and hemisphere on difference values from each 2nd stimulus intensity condition.
Results There was a main effect of prior intensity on responses to 50 dB tones, $F(2,160) = 4.23$, $p = .02$. P1 responses to 50 dB tones were significantly larger after 60 dB than after 70 dB or 80 dB sounds, both corrected $p < .05$.
For 60 dB tones, there was an interaction between prior stimulus intensity and hemisphere, $F(2,160) = 4.17$, $p = .02$. Responses were modulated by preceding stimulus intensity over the left hemisphere, corrected $p < .05$. Left hemisphere responses to 60 dB sounds trended towards being smaller after 50 dB tones than after either 70 dB, corrected $p = .08$, or 80 dB, corrected $p = .10$. There were no effects of prior intensity on responses to 70 dB or 80 dB sounds.
Discussion Refractoriness or adaptation may suppress responses to 50 dB sounds after 70 and 80 dB sounds, but responses to 60 dB sounds after 50 dB sounds may be attenuated due to diminished attention capture by the latter. Responses to louder 70 dB and 80 dB sounds were not modulated by prior intensities, suggesting these stand on their own more than soft sounds. Overall, these data suggest effects of prior stimulus intensity on neural responses are shaped by immediate context.

Title: Illuminating the abnormalities of brain dynamics during pre-attentive change detection in Autism Spectrum Disorder (ASD)

Authors: *Y. WANG[1], X.-Z. XIAO[2], Y.-H. SHUM[3], C.-Y. TSE[1];
[1]The City Univ. of Hong Kong, Hong Kong, China; [2]The Chinese Univ. of Hong Kong, Shenzhen, Shenzhen, China; [3]The Chinese Univ. of Hong Kong, Hong Kong, China

Abstract: Autism Spectrum Disorder (ASD) is known for deficits in processing emotional information. However it is still largely unknown regarding the brain dynamics involved in cognitive processing of ASD. We examined the difference in frontotemporal brain dynamics involved in the pre-attentive detection of emotional (angry and happy speech) versus non-emotional changes (neutral speech and pure tone) between children with ASD and normal control. Pre-attentive change detection is the ability of human brain to automatically extract

regularities from environment for predicting future event. When a prediction violation occurs, mismatch responses in the frontotemporal network are elicited. Different activation patterns of the frontotemporal network have been revealed for detecting salient (a temporal-followed-by-frontal pattern) versus ambigious change (an early frontal-temporal-late frontal pattern) using Event-related optical signal (EROS) technique. EROS measures changes in optical properties associated with neural responses with superior spatial and temporal resolution, thus was adopted in the current study to capture the dynamics of the frontotemporal network during pre-attentive change detection. Compared to the normal control, children with ASD was hypothesized to be more sensitive to non-emotional change and less sensitive to emotional change indicated by the different activation patterns in the frontotemporal networks. Children diagnosed with ASD (6-12 years old; N=19) and their age and gender matched normal controls (N=19) watched a self-selected silent movie with subtitles and were told to ignore the auditory events presented at the background. Four types of changes, including angry, happy, and neutral speeches as well as pure tone, were presented, while EROS mismatch responses were recorded from the frontal and temporal cortices. The control group showed the (salient) temporal-frontal mismatch response pattern to the angry speech and pure tone changes, while the (ambigious) frontal-temporal-frontal pattern to the happy and neutral speech changes in both hemispheres. Children with ASD only demonstrated the (ambigious) frontal-temporal-frontal pattern for happy speech, neutral speech, and pure tone changes in the right hemisphere, while no mismatch response was observed for the angry speech change. Children with ASD were able to detect non-emotional and emotional (happy) change by adopting a frontotemporal brain network for ambigious change and showed deficits in detecting angry speech change.

Title: Evaluation of operational feeling of rotating seat by the vestibulo-ocular reflex

Authors: ***Y. SATO**, T. WADA, Y. KASHIWAGI, Y. TAKEBAYASHI;
Ritsumeikan Univ., Kusatsu City, Japan

Abstract: The vestibulo-ocular reflex (VOR) is a reflex eye movement generated in the direction opposite to the head movement to suppress blurring of the image reflected on the retina. Some studies have indicated that a gain in VOR (ratio of eye to head rotation velocity) is greater during active than during passive head movement (Derner, 1993), although some studies revealed no significant difference (Hanson, 1998). Furthermore, a parameter in a mathematical model for

estimating VOR is known to be different during active and passive operations of a rotating seat (Uefune, 2018). However, it is unclear whether or not VOR can be used to evaluate the operational feeling of a rotating seat. Therefore, in this study, we investigated the relationship between the operational feeling of the rotating seat and VOR. The subjects (n = 12) sat on a seat that rotated in the yaw direction by operating a joystick. While gazing at a fixation point, the subjects performed a task of rotating the seat to the target angle (± 30°) for 60 s following the metronome sound with a frequency of 0.5 Hz. The experimental parameters were set as the operating parameters of the rotating seat, particularly, the gain and time constant in the first-order lag transfer function from the joystick angle to the motor torque attached to the rotating seat, which determines the time response of the rotation by the joystick operation. There were two types: operating parameters A and B. Because operating parameter B has a larger gain and time constant than operating parameter A, the rotation torque is large, and the time response for the joystick operation is slow. Dependent variables were set as the operational feeling of the rotating seat and VOR. The operational feeling was evaluated using a questionnaire (visual analog scale). The VOR was evaluated by a parameter in a mathematical model for estimating the VOR. Under the condition of operation parameter A, the subjects practiced the operation of the rotating seat for 5 min and then performed the task once. Subsequently, the task was performed four times under the condition of operation parameter B. The subjects did not know which operational parameters were applied to each task. As a result, when the operation parameter changed from A to B, the operational feeling deteriorated, and the VOR model parameter decreased. Furthermore, there was a significant positive correlation between the operational feeling and the VOR model parameter ($r = 0.41$, $p < 0.01$, Spearman's). These results suggest that the operational feeling of the rotating seat can be objectively evaluated by VOR.

Title: Detection performance improves based on the three principles of audiovisual integration in head-fixed Mongolian gerbil

Authors: ***Y. ITO**[1], T. OSUKA[1,2], K. I. KOBAYASI[1];
[1]Doshisha Univ., Kyoto, Japan; [2]Osaka Univ., Osaka, Japan

Abstract: We can gain behavioral benefits such as increased accuracy and rapid response by integrating auditory and visual information. The sensory integration is governed by three principles: temporal rule, spatial rule and principle of inverse effectiveness. Few researches, however, examine these principles at the same species. we focused on Mongolian gerbil

(*Meriones unguiculatus*). They have relatively sensitive low-frequency hearing comparable to humans and show more diurnal behavioral pattern than mice or rats. we consider gerbils as appropriate animal model for audiovisual integration research. the purpose of this study was to investigate whether gerbil's behavior improved by audiovisual integration.Total of 7 Mongolian gerbils (4 males and 3 females) were used. the age of the gerbils was about 10 weeks at the first day of behavioral training. We anesthetized gerbils with isoflurane and attached custom-made head plate to the skull before behavioral training. The head-fixed gerbils were trained to lick in response to the auditory or visual stimulus. The duration of stimulus was 500 ms at beginning of training and was then shortened to 10 ms. We presented 11 different intensity of auditory stimuli and 9 different intensity of visual stimuli to measure auditory and visual detection threshold, respectively. First, we examined whether gerbil's behavior follows principles of inverse effectiveness. Subjective stimulus intensity was classified into 4 levels based on the detection rate: Sub threshold (under 35 % detection rate), Around threshold (35 ~ 65 %), Supra threshold (65 ~ 85 %) and max intensity (above 85 %). Auditory, visual and audiovisual stimuli of 4 levels intensity was presented. Gerbil showed higher detection rate to audiovisual stimuli compared to unisensory stimuli. Particularly, behavioral enhancement was prominent when their intensities were around perceptual threshold. Next, we examined the temporal rule in the same experimental setup. Audiovisual stimuli that had different temporal lag between the sound and light (± 200, ± 160, ± 120, ± 80, ± 40, 0 ms) were presented. As a result, Reaction time to audiovisual stimuli was faster than that to unisensory stimuli, and the reaction time to simultaneous audiovisual stimuli was faster than that to asynchronous audiovisual stimuli. These data showed that gerbil's behavior was improved when combination stimuli of auditory and visual stimulus was presented, and suggest that their behavior follows the principle of inverse effectiveness and temporal rule, similar to other animals. In the future study, we will investigate how three principles of integration are neuronally implemented.

Title: Auditory detection is modulated by theta phase of silent lip movements

Authors: *E. BIAU[1], D. WANG[4], H. PARK[2], O. JENSEN[3], S. HANSLMAYR[4];

Abstract: Audiovisual speech perception relies, among other things, on our expertise to map a speaker’s lip movements with speech sounds. This multimodal matching is facilitated by salient

syllable features that align lip movements and acoustic envelope signals in the 4 - 8 Hz theta band. Although non-exclusive, the predominance of theta rhythms in speech processing has been firmly established by studies showing that neural oscillations track the acoustic envelope in the primary auditory cortex. Equivalently, theta oscillations in the visual cortex entrain to lip movements, and the auditory cortex is recruited during silent speech perception. These findings suggest that neuronal theta oscillations may play a functional role in organising information flow across visual and auditory sensory areas. We presented silent speech movies while participants performed a pure tone detection task to test whether entrainment to lip movements directs the auditory system and drives behavioural outcomes. We show that auditory detection varies depending on the ongoing theta phase conveyed by lip movements in the movies. In a complementary experiment, presenting the same movies while recording participants' electro-encephalogram (EEG), we find that silent lip movements entrain neural oscillations in the visual and auditory cortices with the visual phase leading the auditory phase. Together, these results suggest that the brain's natural reaction to visual speech stimuli might be to align the excitability of the auditory cortex with sharp mouth-openings because that is when one expects to hear corresponding acoustic syllable edges. Such a neural process could be a very effective filtering method to increase the sensitivity of the auditory cortex in these relevant time windows for speech comprehension.

Title: Effects of eccentric viewing in orientation discrimination

Authors: *A. VELISAR, N. M. SHANIDZE;
The Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Vestibular deficits are particularly evident in individuals with central visual field loss (CFL): two thirds of those with CFL complain of dizziness and instability, and have an increased rate of falls, injury, oscillopsia, and a fear of falling. Correct assessment of spatial orientation and movement is essential for fall-free walking and standing. Orientation information is normally provided through a weighted combination of visual, vestibular, proprioceptive and somatosensory signals. In CFL the problem is compounded by a largely deteriorated visual signal and a potentially mis-calibrated vestibular system. To assess these changes, we first set out to study the effects of eccentric viewing alone on orientation judgements in 8 healthy controls (6F) across the lifespan (22-74yo). Participants were seated in complete darkness with the head

upright. A bar (length=10.5º vis. ang.) was flashed on a monitor either in the center or 7.5º to the right or left of fixation for 41 ms. The width of the bar was scaled with eccentricity (M-scale= 0.333), but the length of the bar was kept the same. Observers indicated if it was rotated clockwise or counterclockwise of vertical in a 2AFC design. Participants performed 504 trials (7 orientations, 2 directions, 3 positions, 12 repetitions), after a short set of practice trials. The bias (Fig1A) and the discrimination sensitivity (Fig1B) were estimated (probit fit) at each eccentricity, for each participant. There was no significant difference in bias or sensitivity for bars presented at the three eccentricities across our observers ($p > 0.2$, 1-way rm ANOVA, Tukey correction). Our pilot data suggest orientation discrimination is preserved when viewing peripherally, up to 7.5º visual angle. For large, high visibility stimuli any changes in subjective visual vertical observed in individuals with CFL are unlikely to be due to differences in viewing eccentricity due to the loss of the fovea. Changes in judgement bias are likely to be representative of a less reliable reference frame re gravity due to degradation of available vestibular information.

Title: Can the short interval of several minutes reduce motion sickness in repetitive experience of the motorcycle simulator?

Authors: ***M. HAYASHI**[1], Y. ITAGUCHI[2,1], K. AIGOU[1], M. MIKI[3], T. KIMURA[3], M. MIYAZAKI[2,1];
[1]Grad. Sch. of Integrated Sci. and Technol., [2]Dept. of Computer Science, Fac. of Informatics, Shizuoka Univ., Hamamatsu, Japan; [3]YAMAHA MOTOR Co.,Ltd, Iwata, Japan

Abstract: Using simulators can safely evaluate the behavior of motorcycle drivers. However, the simulators often induce motion sickness (simulator sickness). Previous studies have reported that the degree of the motion sickness is reduced by repetitive experience of the simulators with intervals of one day or more. If utilizing such an adaptation effect, we can develop a method of reducing motion sickness. However, there are many unclear points in the mechanisms or properties for the adaptation to stimuli inducing motion sickness. In this study, we examined whether the adaptation to a motorcycling simulator occurs even by a short interval of several minutes. Moreover, we measured the degree of motion sickness not only during the simulator experience but also during the non-simulator period to clarify the recovery processes of the sickness. Twenty male volunteers participated in the experiment. The participants wore a head-mounted display (HMD) and sat on a motorcycle chassis. The HMD presented a motorcycling scene along a winding road from a first-person viewpoint. Sounds or vibrations were not presented. The participants continuously experienced two sets of a 6-minute motorcycling scene (simulator period) and 6-minute non-scene period (non-simulator period) [i.e., simulator→non→simulator→non]. They verbally reported the degree of motion sickness by number from 0 (no sickness at all) to 20 (frank sickness) [fast motion sickness (FMS) scale] every 30 seconds. As a result, the FMS scores during the simulator and non-simulator periods were significantly greater for the second set than for the first set, although there was no difference in the peak FMS scores at the ends of the simulator periods between the first and second set. In addition, the decrease of the FMS score immediately after the end of the simulator period (i.e., the beginning of the non-simulator period) was significantly smaller in the second set than in the first set. These results suggest that the 6 minutes of the short interval does not induce adaptation to the stimulator. Rather, motion sickness increased in the second set. Notably, the results also showed that the FMS scores did not reduce to zero at the end of the non-simulator period in the first set. The remained motion sickness might cause the accumulation of the sickness in the subsequent second set.

Title: Vestibular function modulates the impact of nGVS on postural control in older adults

Authors: *M. NOORISTANI[1], C. BIGRAS[1], L. LAFONTAINE[1], B.-A. BACON[2], M. MAHEU[1], F. CHAMPOUX[1];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Carleton Univ., Ottawa, ON, Canada

Abstract: Previous studies have reported an important relationship between increasing age, vestibular impairment and increased risk of falls. Recently, noisy galvanic vestibular stimulation (nGVS) has been shown to improve postural control in older adults during and potentially following stimulation. However, this effect of nGVS in older adults has not been examined in interaction with the integrity of the vestibular function. We aimed at determining the effect of nGVS on postural control in older adults with and without vestibular impairment and ii) at examining the sustained effect of nGVS as compared to a sham stimulation. 36 older adults were randomly assigned to the nGVS group [n=24] or the sham group [n=12]. In the nGVS group, 12 participants had normal vestibular function and 12 had vestibular impairment. Static postural control was assessed prior to stimulation, during stimulation and immediately following 30 minutes of nGVS. Results showed that nGVS induced a significant improvement in sway velocity ($p<0.001$) and path length ($p<0.001$) compared to sham stimulation. Furthermore, nGVS induced a significantly greater improvement of sway velocity ($p<0.05$) and path length ($p<0.05$) in older adults with vestibular impairment, compared to older adults with normal vestibular function. Improvements in sway velocity ($p<0.001$) and path length ($p<0.001$) induced by nGVS were sustained immediately following stimulation. These findings suggest that nGVS improves postural control in older adults, and that the effect of nGVS varies depending on the integrity of the vestibular function. Results also show that nGVS effect on postural control, compared to a sham stimulation, can be sustained after the end of stimulation.

Title: Nonhuman primate responses to platform tilts resemble those of humans in health and vestibular loss

Authors: *O. M. E. LEAVITT, K. E. CULLEN;
Johns Hopkins Univ., Baltimore, MD

Abstract: An important development for restoration of profound vestibular loss is a vestibular implant which stimulates vestibular afferents in response to head rotations. Vestibular implants are in clinical trials but further research can improve their performance. Experimentation in animal models is essential to further prosthesis development by probing how vestibular circuits involved in balance respond to prosthetic stimulation. In response to sinusoidal tilt perturbations, human subjects transition from a strategy maintaining body position relative to the surface (platform-fixed) to maintaining the head position in space (head-fixed) at 0.5 Hz. Prediction is involved; during unpredictable pseudorandom tilts subjects are less stable with either strategy. Further, regardless of predictability, subjects with bilateral vestibular loss (BVL) demonstrate greater postural instability at low frequencies during platform tilts.
Here, to determine whether postural strategies persist in a monkey model, we used sinusoidal and pseudorandom stimuli. Two rhesus macaques, one normal and one with BVL, stood in an enclosure on a motion platform. The animal was tracked using markerless pose estimation (DeepLabCut), a head-mounted IMU, and a force plate. Sinusoid stimuli included 6 frequencies of sine wave roll tilts of constant peak velocity, and pseudorandom stimuli were constructed from a pseudorandom ternary sequence. Like humans, during sinusoidal roll tilts the normal monkey demonstrated a transition from a platform-fixed to a head-fixed strategy. At low frequencies the body moved little relative to the platform, and at high frequencies the head remained stationary in space. The monkey's transition frequency was 1 Hz, higher than humans' due to biomechanics. The transition frequency persisted during pseudorandom stimuli, but with greater instability than sinusoidal, as with normal humans. The BVL animal's postural responses mirrored those of human subjects with BVL: greater instability during low-frequency sinusoidal stimuli, and less stable response to pseudorandom than sinusoidal stimuli. These results indicate that rhesus provide a useful model of posture in normal and BVL conditions for probing how vestibular circuits involved in balance respond to prosthetic stimulation.

Title: Functional Correlates of Noise-Induced Damage to the Vestibular Periphery

Authors: *C. E. STEWART[1,2], D. S. BAUER[1], A. VELISAR[3], N. M. SHANIDZE[3];
[1]Kresge Hearing Res. Inst., Univ. of Michigan, Ann Arbor, MI; [2]Res. Service, VA Ann Arbor Healthcare Syst., Ann Arbor, MI; [3]Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Despite the accumulating evidence that noise exposure damages the vestibular periphery (for review, Stewart et al., 2020), it is often overlooked as a potential source of vestibular damage. Reduced vestibular function plays a significant role in elevated fall risk (Agrawal et al., 2012); however, diagnosis of vestibular disorders can be difficult. Symptoms are often nonspecific and can be attributed to disturbances of other senses, such as vision, hearing or proprioception (Agrawal et al. 2009). Simple measures of otolith organ dysfunction are of considerable value in detection and tracking of noise-induced vestibular loss in human subjects, while rodent studies provide direct measures of physiological and cellular damage with controlled noise exposure dosing. To understand the impact of degree of noise exposure on otolith organ dysfunction, rat and human vestibular data were correlated with degree of noise exposure. In rats, vestibular short-latency evoked potentials (VsEPs) were used to evaluate central and peripheral vestibular activity arising from the otolith organs. In humans, ability to judge static orientation using the subjective visual vertical task was used as a measure of otolith organ function (Alberts et al., 2019).
Rat VsEP loss was related to degree of noise exposure (110-120 dB, 2-6 hrs). While lesser noise exposures produced transient attenuation of VsEP responses, more intense noise exposures produced loss of responses to small head-jerk stimuli (0.32-1.1 g/ms) and significant, persistent attenuation of responses to larger head-jerk stimuli (2.2-5.5 g/ms).
In a preliminary human study, we recruited 4 individuals with a history of noise exposure (3F, age: 35-49) and 4 age-matched controls (1F, age: 36-71). We assessed degree of noise exposure using the Noise Exposure Structured Interview (NESI, Guest et al. 2018). All participants viewed a monitor with the head upright while seated in complete darkness. A bar (length=12º, width=0.22º visual angle) was flashed for 17 ms and observers indicated if it was rotated clockwise or counterclockwise of vertical in a 2AFC design. Participants performed 120 trials (6 orientations, 2 directions, 10 repetitions), after a set of suprathreshold practice trials. In our pilot data we observed decreased sensitivities and greater bias in orientation judgements of individuals with a history of noise exposure across age groups.
Taken together, our data suggest that noise-induced otolith organ dysfunction is dependent on degree of noise exposure, providing a potential link between physiological effects of noise exposure on the vestibular periphery and functional outcomes to be probed further.

Title: The reduction in the velocity storage time constant due to unilateral hypofunction is a response to changing peripheral signal-to-noise characteristics

Authors: *F. KARMALI, A. MADHANI, R. F. LEWIS;
Jenks Vestibular Physiol Lab, Harvard Med. Sch., Boston, MA

Abstract: The velocity storage mechanism in a central mechanism that processes peripheral vestibular cues. This includes the elongation of the semicircular time constant of approximately 5 s to the central velocity storage time constant, which is roughly 15-25 s in individuals with no known vestibular pathology. The velocity storage time constant is an important clinical parameter which varies with age, pathology and stimulus amplitude. In fact, the velocity storage time constant is a key diagnostic parameter for peripheral loss, with a time constant of 6-12 s suggesting unilateral hypofunction. Despite its clinical utility, there is little mechanistic understanding of why unilateral hypofunction should result in a lower velocity storage time constant. It has been hypothesized that Bayesian optimal processing determines velocity storage dynamics based on the statistics of vestibular noise and experienced motion. Specifically, while a longer time constant would be advantageous because this would make the vestibulo-ocular reflex accurate over a longer period of time, it has been argued that this would amplify neural noise and thus, make the VOR less precise. In particular, it has been hypothesized that the brain determines the optimal velocity storage time constant based on vestibular noise to determine the optimal tradeoff between being accurate and being precise. In this study we applied a Bayesian optimal Kalman filter model to determine the ideal velocity storage time constant for unilateral hypofunction. Since the exact effect of unilateral hypofunction on vestibular noise is unknown, we developed four scenarios based on findings in the literature. In all scenarios, the models predicted a velocity storage time constant that was substantially lower than for normal subjects. In particular, one plausible model predicted velocity storage time constants between 7 and 10 s, which is consistent with clinical findings. This suggests that this clinically-relevant change results from the brain optimizing velocity storage in response to a change in the peripheral signal-to-noise ratio. These results complement our existing work showing that age-related time constant variations are explained by an optimal adjustment in response to hair cell death.

Title: Restoring vestibular afferent dynamics improves accuracy of prosthesis-evoked vestibulo-ocular reflex (VOR) responses

Authors: *K. P. WIBOONSAKSAKUL, D. C. ROBERTS, C. C. DELLA SANTINA, K. E. CULLEN;
Johns Hopkins Univ., Baltimore, MD

Abstract: An exciting and emerging approach to treat patients with impaired vestibular function is a prosthesis that senses head rotation and transforms this movement into vestibular afferent stimulation, substituting for the damaged periphery. Early results from clinical trials, while encouraging, have shown only partial functional improvement. Bridging a gap between basic science knowledge and clinical applications, we implemented biomimetic dynamics in vestibular prostheses for the first time. We asked whether representing the natural dynamics of vestibular afferents in the mapping between head motion and afferent stimulation would result in better performance. To test this proposal, we compared vestibulo-ocular reflex (VOR) responses evoked by the static mapping used by all current devices (no dynamics) to those evoked by 4 newly implemented mappings representing and exceeding the characteristic high-pass dynamics of vestibular afferent processing. Testing was done in two monkeys with profound bilateral vestibular loss that had been implanted with a prosthesis. VOR eye movements were first quantified in response to sinusoidal stimulation that spanned the natural frequency range (0.2 - 20 Hz). We found that afferent-like high-pass mappings evoked more robust VORs with more precise timing. In contrast, the standard static mapping showed a gain decline and increasingly sluggish timing with increasing frequency. Furthermore, mappings with high-pass dynamics exceeding natural range, produced an undesirable phase advance. VOR eye movements were also quantified in response to transient stimulation and similar trends were observed. Overall, using a mapping that mimicked the afferent subclass known to provide primary contribution to the VOR yielded optimal performance. This suggests that endogenous afferent dynamics are well matched to produce accurate VOR response and advocates for a more biomimetic prosthesis design. Together, these results confirm that the implementation of biomimetic mappings in vestibular prostheses can optimize functional outcomes for patients.

Title: Predictive processing by Purkinje cells in the anterior vermis during active versus passive self-motion

Authors: *O. ZOBEIRI[1], K. E. CULLEN[2];
[2]Dept. of Biomed. Engin., [1]The Johns Hopkins Univ., Baltimore, MD

Abstract: The ability to distinguish between self-generated (reafference) vs. externally-applied (exafference) sensory signals is fundamental for ensuring accurate motor control as well as perceptual stability. This is particularly evident in the context of the vestibular system, in which the same central neurons that receive direct afferent input also project to motor neurons that control vestibulo-spinal reflexes (VSR). Notably, while VSRs are essential for providing a postural response to unexpected perturbation, they are impeding during self-generated head motion. Previous studies by our group have shown that central VSR neurons selectively code passive head movements. Accordingly, here we recorded from Purkinje cells in the vestibular cerebellum (anterior vermis) in rhesus monkeys during comparable active & passive rotational and translational head movements. We first recorded neuronal responses to vestibular-only and neck proprioceptive-only passive stimulation. We found that the Simple spike activity encoded both stimuli in a direction-dependent manner. Accordingly, for each Purkinje cell, we first developed a model of the dynamics of simple spike response based on passive head and body movements kinematics in each direction. We then passively applied both vestibular and proprioceptive stimuli simultaneously (i.e., passive head-on-body rotations) and found that Purkinje cells linearly integrated these two inputs. Then to compare each neuron's responses to active versus passive movements, we fit comparable models to neuronal responses during preferred and non-preferred active head movements. We found that neuronal sensitivities were markedly attenuated in the active condition (~60%, $p<0.01$). Finally, we tested whether the attenuated responses during the active movement is a result of neck motor inputs to the Purkinje cells. We found that while in the majority of the Purkinje cells, the neck motor signals affect the simple spike firing, a simple linear model that integrates motor signal with the sensory feedback cannot explain the suppressed simple spike response during active movements. Taken together, these results provide new insights into the computations performed by Purkinje cells in anterior vermis that underlie the suppression of vestibular reafference, suggesting that the cerebellar Purkinje cells implement nonlinear sensorimotor integration to differentially encode externally-applied vs. self-generated head movements and suppress vestibular reafference signal.

Title: Retinal degeneration in KCNV2 retinopathy

Authors: *S. M. INAMDAR[1], J. G. LAIRD[2], E. A. MELTON[2], M. PUFALL[2], S. A. BAKER[2]; [1]Univ. of Iowa, IOWA CITY, IA; [2]Univ. of Iowa, Iowa City, IA

Abstract: Retinal degeneration in KCNV2 retinopathyShivangi M. Inamdar, Joseph G. Laird, Elizabeth Melton, Miles A. Pufall, Sheila A. BakerKCNV2 retinopathy also known as cone dystrophy with supernormal rod response (CDSRR) is a progressive retinal disorder that affects visual acuity beginning in childhood. It is caused by mutations in *KCNV2* that encodes for Kv8.2, a regulatory subunit of a voltage-gated potassium channel that controls photoreceptor signaling. The molecular pathogenesis of this disease is unknown. To model this disease, we generated a Kv8.2 KO mouse. The abnormal electrical signaling diagnostic of CDSRR patients that is measured using electroretinogram (ERG) recordings was phenocopied in Kv8.2 KO. Both supernormal rod activity and reduced cone activity were observed. Optical coherence tomography (OCT) imaging revealed a slow progressive degeneration resulting in 32% photoreceptor loss at 10 months of age. However, histological analysis of cone density showed no significant change. Transmission electron microscopy (TEM) indicated normal rod and cone ultrastructure at 3 months of age with the exception of the presence of autophagic-like structures in the Kv8.2 KO. RNA seq was performed to gain insight into any differential signaling occurring in the retinas of these mice. One cluster of upregulated genes included GFAP and vimentin indicating Muller cell gliosis. Upregulation of GFAP protein in KV8.2 KO was validated by immunohistochemistry and western blotting. In conclusion these data lead to a model where loss of the critical ion channel subunit, Kv8.2, prevents normal photoreceptor signaling that triggers autophagy and Muller cell stress.

Title: In Vivo 13C-Tracing of Metabolism Reveals Physiological Reversal of Succinate Dehydrogenase in the Retina

Authors: *D. T. HASS[1], C. BISBACH[2], B. ROBBINGS[3], *J. B. HURLEY[2];
[1]Vision Sci., [2]Univ. of Wahsington, Seattle, WA; [3]Univ. of Washington, Seattle, WA

Abstract: Intro: Investigations of energy metabolism are frequently performed in cell culture or in ex vivo tissue preparations. While such studies have yielded valuable information, these systems are removed from the physiological context of the body. Succinate dehydrogenase (SDH) is a key mitochondrial enzyme that fuels energy metabolism by converting succinate to fumarate. Our investigations in the *ex vivo* retina show a substantial ‘reverse’ SDH activity where succinate is instead formed by fumarate. We sought to determine whether this reversal

occurred *in vivo*, and whether it was unique to the retina.
Methods: We infused a bolus of 100 mg/kg $^{13}C_4$-malate into the bloodstream of freely moving C57BL6J mice through external jugular catheters (n=3 mice/endpoint). 0 (un-infused), 1, 2, 3 and 5 minutes following the infusion, we dissected retina and eyecup (containing retinal pigment epithelium and choroid) tissue. Five minutes following the infusion, we dissected white (WAT) and brown adipose tissue (BAT), liver, lung, and cerebellum tissue. To compare metabolism of malate, tissues were quickly dissected and snap-frozen before metabolite extraction, derivitization, and analysis using gas-chromatography-mass spectrometry.
Results: Malate flux into tissues was approximated using % abundance of $^{13}C_4$-malate. Tissue malate labeling from highest (%) to lowest (%) was: WAT (64) > Lung (50) > BAT (21.7) > Eyecup (20.7) > Liver (15.5) > Cerebellum (5.1) > Retina (2.5). $^{13}C_4$-fumarate labeling followed the same pattern. To adjust for tissue malate import and conversion to fumarate, we determined the relative % abundance of $^{13}C_4$ -succinate assuming 100% $^{13}C_4$-fumarate labeling. This metric of SDH reversal was highest in the retina, and followed the order; retina (20.9) > Liver (12.3) > Eyecup (9.5) > BAT (4.9) > Cerebellum (4.8) > Lung (4.6) > WAT (2.9). Each tissue has succinate pools of different sizes, and after adjusting to pool size and tissue protein, retinas still appear to produce $^{13}C_4$-succinate from $^{13}C_4$-fumarate to a greater extent than other tissues (~71 pmol/mg protein/min, R^2=0.73).
Discussion: This study revealed a surprisingly low degree of penetration of labeled malate into any neural tissue in this panel, suggesting that malate transport across the blood-brain barrier is heavily regulated. The malate that was transported into tissues equilibrated with fumarate and become $^{13}C_4$-succinate in the less conventional SDH reverse reaction. Our data supports that this reverse reaction occurs in the retina, to roughly twice the extent that it occurs in any other tissue. This suggests that other aspects of retina metabolism are likely quite unique from other tissues as well.

Title: Hcn1 is required for proper rod but not cone function

Authors: ***C. LANKFORD**[1], Y. UMINO[2], E. SOLESSIO[2], S. BAKER[1];
[1]Biochem., Univ. of Iowa, Iowa City, IA; [2]Ophthalmology, SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Rod and cone recovery from light-triggered hyperpolarization is controlled at two levels. A fast reset is driven by the transient depolarizing current carried by HCN1 channels,

while a slower reset is driven by inactivation and resetting of the biochemical phototransduction cascade. Inactivation of the phototransduction cascade is rate-limited by a GTPase activating complex and mutations in components of this complex, RGS9 and R9AP, result in the visual disorder Bradyopsia. Bradyopsia is characterized by impaired visual perception for moving stimuli which is evident by reduced temporal contrast sensitivity, as well as photophobia which in mice presents as light aversion. Because HCN1 and RGS9/R9AP both function to accelerate the photoreceptor response to light, we predict that HCN1 loss will result in Bradyopsia-like phenotypes. Retinal signaling measured by electroretinography (ERG) is altered in both RGS9 and R9AP knockout models of Bradyopsia and in HCN1 knockout mice, with prolonged rod activation resulting in extended rod driven retinal signaling leading to dampened responses to subsequent stimulation, particular to higher frequency flickering light. We predict that loss of HCN1 would also result in impaired visual perception similar to that observed in Bradyopsia, namely reduced temporal contrast sensitivity and light aversion. Because HCN1 is expressed throughout the brain including in other neurons of the retina, we tested this prediction using conditional HCN1 KO bred to rod or cone specific Cre-drivers. Immunohistochemistry was used to verify loss of HCN1 from rods or cones, respectively in HCN1-Rod KO or HCN1-Cone KO. Next ERG was used to characterize retinal signaling in these lines. HCN1-Rod KO mice phenocopy the ERG phenotype of global HCN1 KO, exhibiting prolonged rod driven responses and dampened cone driven responses, including response to flickering light. Conversely, HCN1-Cone KO mice exhibit no detectable phenotype suggesting that cones do not require HCN1 to respond normally to single flashes of light or a high frequency flicker. In line with that observation, the HCN1-Cone KO mice do not have altered temporal contrast sensitivity or light aversion. Future studies will continue to test for Bradyopsia-like phenotypes in HCN1-Rod KO animals using behavioral assays and explore the functional role of HCN1 in cones which may be required for dynamic vision under high intensity light or may be dispensable due to compensatory activity of other channels such as the heteromeric $K_v2.1/K_v8.2$ channels that carry the complementary current I_{kx}.

Title: Analysis of Cav1.4 Dependent Cone Synaptic Development

Authors: ***J. G. LAIRD**, A. KOPEL, C. LANKFORD, E. THORNBURG, S. A. BAKER; Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: The voltage-gated calcium channel, Cav1.4, mediates synaptic transmission and maintenance at the ribbon synapses of rods and cones. Mutations in the pore forming subunit, a1F, or the trans-synaptic accessory subunit, a2d4, result in congenital synaptic disorders such as, congenital stationary night blindness 2 (*CSNB2)*, and cone-rod dystrophy. Previous studies of mouse models of these diseases demonstrated that rods and cones have differing requirements for the Cav1.4 subunits. Since cones only make up a small percentage of photoreceptors, we decided to study synaptic development in a double-mutant mouse strain where all photoreceptors are cones. We refer to this strain as 'Conefull'. We crossed conefull and Cav1.4 mutants to generate 'cone:a1F KO' and 'cone:a2d4 KO' to further investigate the role of Cav1.4 in the development and function specifically of cone synapses. As a measure of vision, a visually guided water maze was used. Cone:a1F KO could not pass the visually guided water maze whereas the cone:a2d4 KO could navigate the water maze as efficiently as the control group. Retinal function was measured by electroretinogram (ERG) to show that each animal had an intact a-wave indicative of phototransduction. However, the b-wave, indicative of synaptic transmission was absent in cone:a1F KO and reduced in cone:a2d4 KO. Optical coherence tomography (OCT) imaging of the retinas in living animals revealed progressive retinal degeneration. Retinal thinning over 2-6 months of age progressed from 32-49% loss for cone:a1F KO but only 12-19% loss for cone:a2d4 KO. Histological analysis of cone:a1F KO demonstrated that photoreceptor loss begins as early as post-natal day 11, before eye opening. In summary we have created a useful model for detailed analysis of Cav1.4 dependent cone synaptic development.

Title: Frequency-dependent light adaptation in rod-driven trans-retinal ERGs

Authors: *Y. GUO, *Y. UMINO, S. LAMAGNA, E. SOLESSIO;
SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Human vision adapts to ambient light levels spanning > 8 orders of magnitude, maintaining an exquisite sensitivity to small differences in light (*i.e*. contrast). One consequence of adaptation is that visual responses speed up as light levels increase, enhancing flicker sensitivity at high temporal frequencies. Previously, we have shown that flicker sensitivity is mainly set by rod photoreceptors, whose temporal response kinetics to dim flashes also adaptively speed up. However, it is not known whether rod flash responses alone can fully

account for adaptive rod temporal frequency responses. Thus, the purpose of this work is to determine the mechanisms that shape the rod-driven frequency response in light adaptation. *Methods*: Trans-retinal flicker ERGs were recorded from WT mice. Retinas were perfused with Ames medium supplemented with DL-AP4 (50 μM), CNQX (20 μM) and BaCl2 (100 μM) to isolate the photoreceptor response. Rod-driven photoresponses to sinusoidal flicker of 75% contrast at 0.75 - 28 Hz were recorded at backgrounds ranging from 10 - 3200 R*/rod/s. *Results*: 1. The rod-driven frequency response have a characteristic low-pass shape at low backgrounds (10-200 R*/rod/s) that switches to band-pass shape as background levels rise above 200 R*/rod/s. Superfusion with cesium, a blocker of HCN1 channels, selectively increases the magnitude of the responses to low frequencies at high backgrounds.2. Light adaptation extends the bandwidth of the frequency response functions from a minimum of 1.75±0.03 Hz (Mean±SEM) at 10 R*/rod/s to an asymptote of 5.68±1.47 Hz at 3200 R*/rod/s. R9AP95 mice, with accelerated Gtα*-E* inactivation (the slowest step in the phototransduction cascade), display wider bandwidths than WT mice (2.35±0.07 Hz at 10 R*/rod/s to 8.13±0.29 Hz at 3200 R*/rod/s). 3. For low frequencies (0.75-3 Hz), gain decreases monotonically and phase speeds up as background levels rise (>10 R*/rod/s). For high frequencies (6-28Hz), gain remains constant up to 800 R*/rod/s and decreases for backgrounds >800 R*/rod/s. In this regime, phase remains constant <800 R*/rod/s and speeds up >800 R*/rod/s. *Conclusion*: This study has uncovered that light adaptation in rod-driven frequency responses has two regimes. Rod-driven signals to low frequencies adapts to light similarly as flash responses, while rod-driven signals to high frequencies have constant gain and phase. These results are in line with studies on horizontal cells (Tranchina, D., Gordon, J., & Shapley, R. M., 1984) and psychophysical temporal contrast sensitivity functions of mice (our lab) and humans (Kelly's data).

Title: The functional role of TRPM1 channels in the synaptic transmission between retinal rod bipolar and AII amacrine cells

Authors: ***F. TAMALU**[1], K. SHIBASAKI[2], M. SHIIBASHI[1], S.-I. WATANABE[1], N. MIWA[1]; [1]Saitama Med. Univ., Moroyama, Japan; [2]Univ. of Nagasaki, Nagayo-cho, Japan

Abstract: Retinal rod bipolar cells (RBCs) express the TRPM1 channel, which is a non-selective cation channel that opens in response to light resulting in depolarization. We show that RBCs depolarized approximately 20 mV as the temperature was raised from 22 ºC to 34 ºC, which showed significant differences (86.4 mV at 22 ºC and 66.8 mV at 34 ºC). When using

extracellular ruthenium red, which is a TRP channel inhibitor (RR), there was no significant difference in the membrane potentials of RBCs between 22 ºC and 34 ºC. Similarly, insignificant depolarization by heat was observed in RBCs of TRPM1 KO mice. Moreover, we found that both the frequency and amplitude of EPSCs observed in the AII amacrine cells, that are post-synaptic to RBCs, dramatically increased at a higher temperature. The electric charge of the EPSCs at 34 ºC was 4.3-times greater than that at 22 ºC and 3.1-times greater than that at 34 ºC with RR, respectively. The EPSC frequency increased significantly as the temperature increased from 22 ºC to 34 ºC, but decreased by adding RR at 34 ºC. Similarly, the EPSC amplitude increased at a higher temperature, but is partially inhibited by ruthenium red. In TRPM1 KO mice, there was no significant difference between 22 ºC and 34 ºC observed in terms of frequency, but the amplitude increased significantly at a higher temperature. Our findings indicate that the TRPM1 plays a role in the glutamate release frequency from RBCs at physiological temperature. It is likely that the body temperature may expand the dynamic range of glutamate release from RBCs by increasing the open probability of TRPM1 channel contributing to scotopic vision. Thus, TRPM1 deficiency might relate to retinal diseases such as the nyctalopia, in particular.

Title: Depth perception perturbation in mice with an altered retinofugal pathway

Authors: ***N. SLAVI**[1], C. MASON[2];
[1]Zuckerman Inst., [2]Pathology & Cell Biology, Neuroscience, and Opthalmology, Columbia Univ., New York, NY

Abstract: In animals with frontally positioned eyes, partial decussation of retinal ganglion cell (RGC) axons at the optic chiasm in specific proportions allows binocular integration of visual information in the brain, forming the basis of disparity-based stereopsis. The albino visual system is characterized by a reduction of ipsilaterally projecting RGCs, and a concomitant increase of the contralateral projection. Here, we examined whether aberrations in the eye-to-brain circuitry in albinism lead to impaired visually guided behavior. We compared the performance of pigmented and albino mice in the binocularly driven visual cliff behavioral task to assess depth perception. Mice were positioned in the center of an open-top platform with a shallow and a deep side, both displaying the same sized checkerboard pattern. Pigmented mice almost always chose to step on the shallow side, whereas albino mice failed to distinguish

between the shallow and deep side of the platform. To confirm that this behavior resulted from ipsi-/contralateral RGC axon misrouting in albino mice, we performed an additional visual task that does not depend on binocular disparity, but instead relies on a monocular cue, relative size. For this task, both sides of the behavioral apparatus were at the same height, but its two sides displayed a low- versus a high-spatial frequency checkerboard pattern. Pigmented and albino mice behaved similarly in this monocularly driven task. Our results thus show that perturbations in the ratio of ipsi-/contralateral RGC projection lead to reduced depth perception in albino mice, indicated by their compromised performance in the visual cliff task. This study provides a framework for assaying the functional integrity of the visual circuit in experimental models interrogating neurogenesis and proper output of ipsi- and contralateral RGCs.

Title: Partial Information Decomposition of the response from a Retina

Authors: ***Q.-R. LIN**[1,2], K.-H. CHEN[1,3], P.-Y. CHOU[1,4], C. CHAN[1];
[1]Inst. of Physics, Academia Sinica, Taipei, Taiwan; [2]Dept. of Physics, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Mol. Med., Natl. Tsing Hua Univ., Hsinchu, Taiwan; [4]Dept. of physics, Natl. Central Univ., Taoyuan, Taiwan

Abstract: In order to survive, escape of predators or pursuit of prey, animals must make predictions to compensate delays from visual processing pathway. Previous studies revealed that predictive information of motion is encoded in spiking activities of retinal ganglion cells (RGCs). In order to study the predictive properties of a retina in a more systematic manner, stimuli in the form of a stochastic moving bar are used in experiments with retinas from bull frogs in a multi-electrode system. Trajectories of the bar are produced by Ornstein Uhlenbeck (OU) processes with different time correlations (memories) induced by a butter-worth low-pass filter with various cut-off frequencies.
We then investigated the predictive properties of single RGC by calculating the time shifted (δt) mutual information ($I(x,r;\delta t)$) between spiking output ($r(t)$) from RGCs and the bar trajectories ($x(t)$). Our measurements show that some RGCs (P-RGCs) are predictive while the others are non-predictive (NPRGCs). It is very reasonable that a P-RGC encodes both position (x) and velocity (v) of the input. So we perform partial information decomposition (PID)[1] on the mutual information between r and the combined state $\{x,v\}$ which can be written as $I(\{x,v\},r) = S + U_v + U_x + R$. U_v and U_x are the unique contribution from x and v to r, respectively. R, the redundancy, is the information that x and v can both provide. Finally, S represent synergy contribution from x and v. Then, we construct a model for P-RGC with the spiking response being a linear combination of x and v: $r=(1-\lambda)*x+\lambda*v$. By comparing the PID of our

experimental results and those of this simple model, we find that λ≈0.45 fits our data quite well (Fig.1). Implication of this simple coding strategy of the retina will also be discussed.

Title: Anticipation and Negative Group Delay in a Retina

Authors: *P.-Y. CHOU;
Academia Sinica.

Abstract: The mechanism of negative group delay (NGD) is used to understand the anticipative capability of a retina. Experiments with retinas from bull frogs are performed to compare with the predictions of the NGD model. In particulars, whole field stochastic stimulation with various time correlations are used to probe anticipative responses from the retina. We find that the NGD model can reproduce essential features of experimental observations characterized by the cross correlations between the simulation and the retinal responses. The main finding is that the

prediction horizon of a retina depends on the correlation time of the stimulation as predicted by the NGD model. Experiments with dark and bright Gaussian light pulses further support the NGD mechanism; but only for the dark pulses indicating that the NGD effect of a retina might originate from its OFF response. Our finding suggests that sensory systems capable of using negative feedback for adaptation can give rise to anticipation as a consequence of the delay in the system.

Title: The spatial and temporal aspects of retinal ganglion receptive fields are dependent on ambient light conditions

Authors: *N. T. INGRAM, F. RIEKE;
Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: Current studies in visual neuroscience look to understand how adaptive modulations and circuit routing affect stimulus encoding across layers of the retina. At the output of the retina, retinal ganglion cells (RGCs) are able to encode rapid stimulus fluctuations despite the relatively slow input they receive from upstream photoreceptors. They also have receptive fields that display center-surround antagonism, in which lateral inhibition driven by the surround inhibits responses generated from stimulating the center (Barlow, 1957). Previous studies in mouse show that the spatial dimensions of center versus surround depend on ambient light conditions (Hoggarth et al., 2015; Farrow et al., 2013). It is not known if all RGC subtypes undergo similar shifts, to what degree circuit mechanisms like changes in rod-cone signal routing are responsible, and if other receptive field features such as surround-dependent temporal filtering are similarly dependent on light level. To answer these questions in the primate retina, we make electrophysiological recordings from primate RGCs with stimuli that span 8 orders in magnitude in light intensity. We measure light-dependent shifts in spatial receptive fields through this entire range of stimuli and in multiple RGC subtypes. Both parasol and midget RGC receptive fields show a similar light dependence when measuring spatial features. In addition, we show for the first time, that the strength of surround-mediated temporal filtering also depends on the background light intensity. Interestingly, the effects of surround-mediated temporal filtering are greater in dim light, a condition in which the surround contributes little to the spatial receptive field. Light-dependent changes in these receptive field features are likely to have large

effects on an organism's ability to perform complex visual tasks which depend on correlations between space and time (e.g. motion detection).

Title: Designing stimuli that minimize cone adaptation to study neural coding

Authors: ***Q. CHEN**, F. RIEKE;
Physiol. and Biophysics, Univ. of Washington, Seattle, WA

Abstract: Classic work on how adaptation enhances the encoding of visual inputs focuses on the mechanisms accommodating day/night changes in luminance. But light levels encountered by visual neurons change dramatically as gaze shifts from one location to another within a single scene. Thus, efficient encoding of naturalistic environments requires rapid and strong adaptational mechanisms that match the statistics of visual inputs to the limited dynamic range of visual neurons. In steady-state, multiple mechanisms work in concert to maintain visual sensitivity across light levels, with adaptation in cone phototransduction playing a particularly prominent role. We lack, however, a similar understanding of the location and properties of the adaptational mechanisms that operate during dynamic natural viewing. Moreover, in primate models, whose visual system and eye movements closely recapitulates that of humans, we lack tools like genetic manipulations to reveal the operation of neural circuits. Here, we use a biophysical model that captures the responses of cone photoreceptors to a wide range of stimuli. This model constitutes a set of differential equations, describing the biochemical components of phototransduction. We verified the accuracy of this model via directly record primate cones. We then develop a reverse-engineering paradigm through optimization to design a transformed version of original stimuli to cause cones to respond as if they lacked adaptation. This novel tool allows us to determine the contribution of photoreceptor adaptation to the final output of primate retina in different visual pathways. In fact, we found that light adaption in parvocellular pathway is dominated by cone photoreceptor adaptation while magnocellular pathway engages strong post-receptoral adaption. The methodology, per se, could pave new way of physiologically and psychophysically studying both non-human primate and human visual systems.

Title: Retinal direction selectivity maps develop independently of visual input but require retinal waves

Authors: *A. TIRIAC[1], K. BISTRONG[2], M. B. FELLER[3,2];
[1]Mol. and Cell Biol., [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA;
[3]Univ. of California Berkeley, Berkeley, CA

Abstract: Detecting the directions in which objects move is critical for everyday behavior. In mice, directional motion detection begins in the retina where a subset of direction selective retinal ganglion cells (DSGCs) fire more action potentials in response to visual stimuli moving in one direction, called the preferred direction, than visual stimuli moving in the opposite direction, called the null direction. In adult mice, the preferred directions cluster along four directions that align along two optic flow axes—paths that visual stimuli trace across the retina as the animal moves through space (Sabbah et al., Nature 2017). Here, we used two-photon calcium imaging to confirm that in normal-reared mice, the preferred directions of DSGCs changed as a function of their location on the retina, with the axes of preferred directions of DSGCs skewed in the more ventral parts of the retina, consistent with their alignment along the axes of optic flow. Furthermore, we show that the direction selectivity map is present at eye opening and is not impacted by dark rearing. However, disruption of cholinergic retinal waves prevented the maturation of direction-selective responses along the horizontal optic flow axis but did not affect the vertical preferring responses. Hence direction selectivity maps are established prior to vision in a manner dependent on the presence of retinal waves.

Title: Visual responses in the tree shrew superior colliculus

Authors: *E. L. SAVIER[1], S. TANABE[1], H. CHEN[1], J. CANG[2];
[2]Biol. and Psychology, [1]Univ. of Virginia, Charlottesville, VA

Abstract: Visual signals produced by the retina are transmitted to two parallel pathways, often referred to as the primary (retina → thalamus→ primary visual cortex (V1)) and the secondary visual pathways (retina → superior colliculus (SC) → pulvinar → visual cortex). The two pathways are traditionally thought to mediate different aspects of vision, with the primary pathway for conscious vision and the secondary pathway for reflexive behaviors. However, there is increasing evidence that the secondary visual pathway is also involved in higher perceptive and cognitive functions, via their massive connections with many brain structures. Tree shrews have a well-developed SC, which makes them an ideal subject to study the role of the secondary visual pathway in visual behaviors. These animals are among the closest relatives to primates, are diurnal, have a cone-dominant retina and display exquisite visual behaviors. However, a systematic characterization of the SC visual receptive fields is lacking. We sought to characterize the visual response in tree shrew SC using multi-electrode array recordings. We performed recordings in both male and female tree shrews under awake conditions, using high density silicon probes. We tested the visual responses to drifting gratings, moving dots, sparse and dense noise. With this stimulus set, we found a surprisingly wide range of receptive fields sizes and shapes, variety of speed tuning and distribution of spatial frequency tuning. This study lays the foundation towards a better understanding of the distinct visual processing between the two visual pathways.

Title: Binocular integration in the superior colliculus

Authors: *R. BROERSEN, G. J. STUART;
Australian Natl. Univ., Canberra, Australia

Abstract: The superior colliculus (SC) is a layered, evolutionarily conserved midbrain structure involved in different behaviours, such as saccadic eye movements, orienting movements and innate defensive behaviours. It is a major visual centre in rodents, receiving input from 85-90% of retinal ganglion cells that terminate predominantly in the superficial layers. The SC is also innervated by the ipsilateral primary visual cortex and the SC in the opposite hemisphere. While integration of visual inputs from both eyes takes place at different stages within the visual

system, the effect of binocular summation on visually-evoked neuronal responses in SC remains largely unexplored. Here we determine the characteristics of binocular responses in SC to a range of visual stimuli relevant to natural situations and dissect the neuronal circuit involved. In vivo juxtasomal recordings in urethane-anaesthetized adult male Bl6 mice were used to study neuronal responses to brief, full-field (LED) flashes, flashing dark spots as well as looming stimuli. This was combined with AAV viral injections, optogenetics and histology to allow neuronal circuit mapping. We find that binocular neurons are located across multiple layers of SC. While the vast majority of neurons were solely driven by contralateral visual input and therefore were monocular, a subset of neurons was driven by both contralateral and ipsilateral visual input and were therefore characterised as binocular (~5-25% of neurons, depending on the visual stimulus). Binocular neurons responding to LED flashes were located mainly in superficial layers, while those responding to more complex stimuli (flashing or looming spot) were located in intermediate and deeper layers. Binocular stimulation consistently resulted in larger spike responses compared to monocular stimulation, but summation was predominantly sublinear. Optogenetic activation of the opposite SC using Channelrhodopsin-2 showed that the amplitude of optogenetically evoked responses correlated with the amplitude of ipsilateral visually-evoked responses, suggesting that ipsilateral eye responses in binocular neurons originate from interhemispheric connections. Our findings indicate that while visual responses in SC are primarily driven by the contralateral eye, a significant subset of SC neurons respond to binocular stimuli. Furthermore, the data are consistent with the idea that ipsilateral eye responses in these binocular SC neurons are largely driven by interhemispheric connections from the opposite SC.

Title: Visual receptive field properties of superior colliculus neurons in a diurnal precocial rodent (Octodon degus).

Authors: ***N. I. MÁRQUEZ**[1], I. PERALES[1], A. DEICHLER[1], P. FERNÁNDEZ-ABURTO[1], J.-C. LETELIER[1], G. MARÍN[1], J. MPODOZIS[1], S. L. PALLAS[2];
[1]Dept. of Biol., Univ. de Chile, Santiago, Chile; [2]Dept. of Biol., Univ. of Massachusetts, Amherst, MA

Abstract: The superior colliculus (SC) is a layered structure at the dorsal surface of the midbrain that receives a massive direct input from the retina, as well as from other sensory modalities. The SC controls visually driven behaviors such as gaze shifts, reorientation toward objects of interest, and escape or freezing responses to a looming object. Neurons from the superficial layers of the SC (sSC) are tuned to specific configurations of visual stimuli within their receptive fields (RFs). Recent studies comparing the RF properties of SC neurons in normal (NR) and dark reared (DR) rodents have challenged the general assumption, derived from studies in the visual cortex of cats and monkeys, that visual experience is necessary for RF refinement. It should be noted, however, that the rodent species studied so far (hamsters and mice) are nocturnal, altricial, and possess a poorly developed visual system. As a counterpoint to these studies, we have characterized the RF properties of SC neurons in Chilean degus, a diurnal, precocial rodent species with a well-developed visual system, as an initial step for comparing their RF properties with those of DR degus. We isolated single neurons from the sSC in anesthetized NR degus and characterized responses to four types of visual stimuli: (1) a moving white square on a dark background, (2) sinusoidal gratings with varying spatial frequencies and contrasts, (3) a black, looming circle, and (4) a stationary black circle. We sampled the anterior part of the sSC representing the frontal visual field. As we reported previously for multiunit recordings, RF sizes of single units were consistently smaller in the most superficial layers (3° - 9° in diameter in the first 500 μm) and increased in size with depth (8.3° - 40° from 500 - 1100 μm). Most units responded to moving sinusoidal gratings and displayed specific spatial frequency tuning that we classified as low-pass (with responses decaying below 50% near 0.08 cycles per degree (cpd)), band-pass (with peak frequencies between 0.04 - 0.24 cpd) or hi-pass (with peak responses above 0.08 cpd). Lastly, we found two kinds of neurons that responded to looming objects in a similar way to neurons previously described in pigeons and cats. These neurons differed in their peak firing rate with respect to the time the object reached maximum size, reducing their activity before or at this time point. When these units were stimulated with a stationary black circle they showed ON, OFF or ON-OFF responses. Our study is an important step in understanding the role of visual experience in a rodent species that has a different visual ecology and that represents a different phylogenetic group than more commonly studied species.

Title: Erasing motion: The scrambling of direction selectivity in visual cortex during saccades

Authors: *S. K. MIURA[1], M. SCANZIANI[2];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: Sensory stimuli are often generated by the animal's own movements. Many sensory systems suppress these self-induced inputs and selectively respond to externally generated stimuli, thereby maintaining the perceptual stability of the external world. Rapid eye movement, called saccades, induces motion of the visual scene on the retina. Several mechanisms have been proposed that prevent the perception of such motion. Yet, how they are implemented in the circuitry of visual cortex is poorly understood. Here, we focused on the mouse primary visual cortex (V1). In V1, neurons encode the motion direction of visual stimuli. We began by comparing the response of V1 neurons to spontaneous saccades and their response to external visual stimuli designed to mimic the motion of visual scene induced by saccades, which we termed "pseudo-saccades". Many neurons showed direction selectivity for saccades (i.e., responded more to saccades moving in one direction than to those in the other direction) as well as for pseudo-saccades. Interestingly, however, there was no correlation between the direction selectivity for the two conditions. Consequently, a downstream decoder that discriminates the direction of pseudo-saccades based on the population activity in V1 is unable to discriminate the direction of visual motion induced by actual saccades. Thus, in V1, direction selectivity is scrambled during saccades, and information about the direction of motion is suppressed. Where does this scrambling originate from? We discovered that V1 receives a non-visual input from the pulvinar nucleus of the thalamus around the time of saccades. To determine whether this pulvinar input mediates the scrambling of direction selectivity, we pharmacologically silenced the pulvinar. Upon silencing this thalamic nucleus, the direction selectivity for real saccades and pseudo-saccades became correlated. Thus, the pulvinar erases saccade-induced motion of the visual scene in V1 by scrambling direction selectivity.

Title: Neurons in tree shrew V1 are highly selective for binocular disparity

Authors: *S. TANABE, J. CANG;
Univ. of Virginia, Charlottesville, VA

Abstract: The visual system uses small differences between the two eye's images, i.e., binocular disparity, to construct depth information in a perceptual process called stereopsis. The neuronal responses to stereoscopic images have revealed certain general principles. For example, it is

known that the two eyes' inputs remain segregated until the primary visual cortex (V1), where neurons sensitive to binocular disparity are first seen. Despite these advances, the circuit mechanisms underlying stereopsis and their developmental processes remain largely unknown. The main reason for the lack of progress is limitations in the animal models that are currently used in binocular vision research, most notably monkeys and mice. Monkeys are not yet an ideal model for circuit and developmental studies because of the still limited technology available to primate research and long generation time. In comparison, mice provide opportunities for genetic, optogenetic, viral, and imaging techniques. Unfortunately, mice are not ideal subjects for studying stereopsis because of their low visual acuity and rudimentary binocular vision. We set out to establish a novel animal model, the tree shrew, for the neurophysiological investigation of binocular vision. Tree shrews are agile in an arboreal environment, which requires well-developed stereopsis. In our experiments, the animals were head fixed to be presented with monocular or dichoptic visual stimuli through a mirror stereoscope. We inserted multi-electrode silicon probes (64 channels spanning all cortical layers) into the binocular region of the primary visual cortex (V1). We tested the orientation tuning with monocularly presented gratings, disparity tuning with dynamic random-dot stereograms, and linear and nonlinear receptive-field properties with white noise. Many neurons were orientation tuned with gratings presented to either eye. White noise analysis recovered receptive fields that were confined to a small location ~1 deg in diameter. We found neurons that are highly selective for disparity. A subset of neurons increased firing rate from 0 to 50 spikes/s within a range smaller than 1 deg disparity. Our results suggest that the tree shrew V1 is an excellent model for dissecting circuit mechanisms of binocular combination.

Title: Spontaneous traveling waves are an intrinsic feature of ongoing cortical dynamics and regulate perceptual sensitivity

Authors: *Z. W. DAVIS[1], G. B. BENIGNO[2], T. J. SEJNOWSKI[1], J. H. REYNOLDS[1], L. MULLER[2];

Abstract: Neocortical activity is highly variable, fluctuating from moment-to-moment, with broadly distributed spectral energy (Shadlen and Newsome, J Neurosci, 1998). In multielectrode array recordings made in area MT of the common marmoset, we find that these fluctuations are neither fully random nor synchronous across space: rather, they are often spatiotemporally organized into traveling waves. As they traverse the cortex, these waves modulate spontaneous and stimulus-evoked spiking activity and perceptual sensitivity as measured in monkeys trained to detect faint visual targets. To gain insight into the neural mechanisms underlying traveling waves, we study a large-scale spiking network model with conductance-based synapses, biologically realistic topographic connectivity and action potential propagation speeds consistent with those observed in unmyelinated horizontal fibers (Girard et al., J Neurophysiol, 2001). We find that these properties are sufficient to generate spontaneous waves across the entire range of network parameters that produce asynchronous-irregular spiking dynamics (Brunel, J Comput Neurosci, 2000; Renart et al., Science, 2010). Further, we find that neuronal participation in these waves is sparse, enabling traveling waves to coexist with asynchronous-irregular spiking activity without necessarily inducing correlations, which have been found to impair perception (Nandy et al., eLife, 2019). This sparse-wave network regime remained sensitive to feed-forward driving input and modulated the strength of stimulus-evoked responses in a manner similar to that observed in cortex. This was in contrast to smaller scale networks that produce dense spike coupling to traveling waves, which drove strong pairwise correlations and rendered the network insensitive to feed-forward driving input. We conclude that the presence of traveling waves in cortical dynamics can be explained as a natural consequence of activity propagating along unmyelinated horizontal fibers. Traveling waves, which improve perceptual sensitivity in MT (Davis et al., Nature, 2020), appear to be an intrinsic feature of cortical dynamics, and they therefore likely impact the moment-to-moment processing of information throughout the brain.

Abstract: How the duration of a visual stimulus affects its perceived brightness is not well understood. To uncover the neural mechanisms of duration on brightness perception, we recorded from single cells in non-human primates. We (1) located V1 neurons, (2) mapped its receptive field (RF), and (3) presented Gabor stimuli, with variable duration across trials, in the RF of the identified V1 neuron.
For each recorded cell, we recorded the entire response and analyzed both onset and termination responses to the visual stimuli. We present the electro physiological results and several models, aimed to characterize the relationship between onset and termination responses, as a function of stimulus duration. The results reveal a strong correlation between the timing of the onset and the termination responses to the visual stimulus, suggesting that it is unlikely that either response is derived by feedback signals from downstream areas.

Title: Distinct representation of prediction signals in excitatory and inhibitory populations during a visual task

Authors: *F. NAJAFI, M. GARRETT, A. PIET, D. OLLERENSHAW, I. YAVORSKA, N. PONVERT, P. GROBLEWSKI, S. MIHALAS, S. R. OLSEN;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Predictive coding states that the brain constantly generates and updates predictions about sensory inputs. Previous studies have shown that excitatory neurons in the visual cortex detect oddball stimuli, potentially mediated by SST and VIP inhibitory neurons, as well as the neuromodulatory system. While these studies have begun to illuminate the cell types involved in predictive coding, many questions still remain. In particular, it is unclear how predictive signals arise in each cell type. A change in an animal's internal state or in top-down and bottom-up inputs may underlie predictive signals in distinct cell types. Here, we seek to address these questions by studying the activity of distinct excitatory and inhibitory neurons in a visual task under different internal states and sensory contexts. The visual task involved repeated image

presentations interspersed with rare image omissions. To assess the role of internal state, images were presented either passively or while animals were engaged in the task. Moreover, animals received two image sets across sessions: one familiar set that mice were trained on, and another novel set that they had never seen, which allowed studying how novel context affects predictive signals in each cell type. We used Multiplane Mesoscopes to simultaneously image multiple cortical layers and areas. To characterize sensory and prediction signals in our dataset, we fit a GLM to the activity of each neuron. Our results indicate that excitatory, SST and VIP neurons are modulated by omissions. Additionally, we found that novel context strongly affects omission coding in excitatory and VIP cells, and to a lesser extent in SST cells. Next, we performed a series of population decoding analyses to investigate omission-related signals at the ensemble level. First, we used a binary classifier to decode the presence of omissions, and found that omissions are strongly represented in all populations. Next, we used multi-class classification to study if the omission-evoked signal encoded image identity. Interestingly, we observed a slow steady increase in image selectivity following omissions in excitatory and SST populations. In contrast, the omission response was not image selective in the VIP population. Our results indicate that excitatory and SST neurons may carry stimulus-selective prediction signals, while VIP neurons represent a non-selective signal following unexpected events. Moreover, excitatory neurons seem to be more influenced by novel context compared to SST neurons. Overall, our findings suggest that separate cell types encode distinct prediction signals that vary in their stimulus specificity and modulation by context.

Title: Automated characterization of neuronal arbors from brightfield images in a multimodal dataset

Authors: *O. GLIKO, M. MALLORY, R. DALLEY, R. GALA, S. SORENSEN, U. SÜMBÜL;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Recent advances in integrated methods, such as Patch-seq, assessing gene expression, electrophysiology and neuroanatomy at the single cell level provide a multi-modal approach to neuron classification leading to deeper understanding of the brain cell type diversity. Motivated by the relatively low throughput of morphological characterization in the Patch-seq experiment

due to manual tracing, we developed a fully automated reconstruction pipeline for in-slice brightfield images of biocytin-filled neurons. The pipeline performs automated segmentation of dendritic and axonal arbors followed by post-processing to produce digital representations of neuronal geometry and topology (e.g., swc file). On a large set of manually reconstructed neurons, we apply a topology-preserving variant of the fast marching algorithm to generate volumetric labels. Using these labels as the training set and employing multiple data augmentation strategies, we train a convolutional neural network (U-Net) to produce accurate segmentations. We post-process these segmentations by removing background noise, connecting broken segments and assigning separate labels to apical and basal dendrites. The overall pipeline can produce neuron reconstructions in the swc format from raw images at a rate of 100 cells/day using 16 GPUs. We have so far processed more than 3500 inhibitory and excitatory cells from the mouse visual cortex, including 1000 neurons with manual traces used to assess reconstruction accuracy. Bringing the throughput of anatomical characterization closer to that of transcriptomic and/or electrophysiological aspects of the multi-modal Patch-seq experiment enables data-driven analyses of the anatomical correlates of gene expression and response characteristics.

Title: Recording the activity of transcriptomic cell types in mouse primary visual cortex

Authors: S. BUGEON[1], T. HAULING[1], J. DUFFIELD[1], D. NICOLOUTSOPOULOS[1], D. ORME[1], I. PRANKERD[1], Y. ISOGAI[2], M. CARANDINI[1], K. D. HARRIS[1];

Abstract: Cortical computations rely on microcircuits that involve multiple neuronal subtypes. While cortical neurons have been classically subdivided into broad subtypes (i.e. Vip, Sst and Pvalb positive interneurons), transcriptomic analysis has revealed many more subpopulations of finely distinguished cortical neurons (Tasic et al., Nature 2018). To decipher the functional properties and network activity of these fine cell types in primary visual cortex (V1), we have applied post-hoc in situ transcriptomic analysis to cortical neurons after imaging their activity in vivo. We first recorded the activity of V1 neurons using two-photon calcium imaging in awake freely running mice, during visual stimulation. The visual stimuli comprised drifting and static

gratings, and natural scenes. We also recorded V1 neuronal activity during navigation in a virtual corridor containing visual landmarks. After these recordings, we collected consecutive brain slices which were registered to a reference z-stack from the in-vivo recording, using multiple landmarks. We then matched each individual cell between the in vivo recordings and the brain sections. These brain sections were then processed for post-hoc transcriptomic analysis using in situ sequencing (Qian et al., Nature Methods 2020), a multiplexed single RNA detection procedure. This method allows us to characterize the expression of 73 different genes at the single cell level. Based on this single cell gene expression, we then assigned a transcriptomic cell type to each recorded cell. To confirm that this procedure can reveal the functional properties of transcriptomic cell types, we reproduced findings on the size tuning of different V1 cell types, and their modulation by locomotion (Dippopa et al., Neuron 2018). Importantly, while these results were previously obtained using Cre lines to record activity of one cell class at a time, we can record the different cortical cell types in a same animal and in a same recording session. Thus, this method provides a high-throughput approach to characterize the in vivo activity of fine transcriptomic cortical cell types.

Title: Electrophysiological assessment of marmoset primary visual cortex during free locomotion

Authors: *J. P. LISKA, C. BADILLO, J.-O. MUTHMANN, A. HUK;
Univ. of Texas at Austin, Austin, TX

Abstract: The emergence of the mouse model system in visual neuroscience has produced a number of novel findings in early visual cortex. One notable example is the observation of significant firing rate modulations in primary visual cortex (V1) when mice are allowed to freely locomote. While there has been continued investigation into this effect in mice, it is not known whether this phenomena is also present in the visual cortex of primates. It has traditionally been infeasible to allow awake primates to safely locomote in a laboratory environment during invasive data acquisition, but the common marmoset allows us to leverage the experimental flexibility of a rodent in an animal with the visual system of a primate. We have therefore created an immersive VR environment allowing for linear locomotion for use with the common

marmoset. A dome-shaped projection surface is used to present stimuli ranging from simple oriented gratings to immersive, naturalistic stimuli across 180+ degrees of the marmoset's visual field while it is allowed to locomote freely on a treadmill which can be yoked to control the stimulus. We have recorded activity from ensembles of V1 neurons using chronically-implanted multi-electrode arrays. Recording quality maintains high SNR even during locomotion, allowing for single unit isolation and quantification of conventional V1 tuning properties via spike sorting. V1 neurons (N=15 per session) were reliably activated by high contrast orientated gratings placed in particular locations in the virtual environment. Neuronal response patterns were also similar between nearby neurons. These results confirm the basic functional properties and organization of V1 despite being recorded in a complex naturalistic environment with ongoing locomotion behavior.

Title: Images associated with reward resist surround suppression in macaque area V2

Authors: ***M. CARR**[1], N. WILLIAMS[2], C. R. OLSON[2];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: It is possible that images associated with reward elicit enhanced visual responses from neurons in low-order visual cortex of primates. Recent fMRI-based studies have indicated that reward-associated images elicit enhanced BOLD responses in low-order visual areas of humans (Serences, 2008). However, enhanced BOLD activation need not indicate enhanced spiking activity since the signal is driven by both excitatory and inhibitory synaptic events. Moreover, fMRI lacks the temporal resolution to distinguish enhanced visual response strength from delayed activation related to reward anticipation, as observed in mouse V1 (Shuler & Bear 2006). We set out to resolve this issue by monitoring the activity of neurons in area V2 of a rhesus macaque monkey trained through repeated passive exposure to associate certain natural images with large reward and others with small reward. On each training trial, while the monkey maintained central fixation, a single image was presented for 300 ms, following which, after a delay of 300 ms, the associated reward was delivered. Each image subtended 3° of visual angle and was centered in the lower quadrant of the visual field opposite the hemisphere destined for recording. Training involved more than a hundred exposures to each image over a period of weeks. Upon completion of training, we measured the visual responses of V2 neurons to "good" and "bad" images presented in superimposition on their classical receptive field. The timing of each trial was the same except for stimulus presentation, which lasted 600 ms. On average, good images and bad images elicited responses of indistinguishable strength. However, it seemed possible that under more naturalistic testing conditions, differences in efficacy might emerge. To test this idea, we monitored neuronal responses to displays consisting of a good or bad image centered on the neuron's classical receptive field and a reward-neutral concentric annulus with a 4° inner diameter and a 8° outer diameter. Under these conditions, we observed a marked difference between good and bad images. Surround suppression, measured as a reduction in response strength induced by the annulus, occurred robustly for bad images but was minor or absent for good images. The difference emerged around 75 ms after image onset, a latency shorter than that commonly associated with top-down effects. It persisted during sessions in which reward amount was fixed regardless of image identity and thus reflected the impact of long-term associations rather than short-term expectation. We conclude that images repeatedly paired with large reward do not elicit stronger responses in V2 but do acquire immunity to surround suppression.

Title: Optogenetic stimulation of Primate V1 induces activity across cortical layers and elicits a visual percept

Authors: *B. AGAYBY[1], S. RIMA[2], M. ORTIZ-RIOS[3], M. HAAG[2], M. C. SCHMID[2,1]; [1]Biosci. Inst., Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Dept. of Neurosciences and Movement Sci., Univ. of Fribourg, Fribourg, Switzerland; [3]Functional Imaging Lab., German Primate Ctr. (DPZ), Göttingen, Germany

Abstract: Optogenetics has been successfully used to examine perceptual processing along the columnar architecture of the primate primary visual cortex (V1) [1–3] and to induce saccadic eye movements[4]. However, it remains to be determined how optogenetic stimulation affects activity across V1 layers and whether such activation induces a visual percept ('phosphene').To address these two questions, we injected AAV9-hSyn-ChR2-eYFP across multiple depths and sites in the opercular part of V1 of a macaque monkey. Laminar probes with an embedded optical fibre were used to record multiunit activity (MUA) across the layers of the cortex as well as for light delivery. Across 19 sessions, 354 out of 380 contacts showed a significant increase in firing rates in response to a blue light (473nm) pulse. The averaged laminar profile showed significant activation across all contacts covering the cortex in line with an expected non-specific expression of the construct. Examining the latency of the activation elicited by lower light intensities revealed that the earliest responses were located in putative layer 2/3 & L4A, which may indicate a higher expression of the opsin in these layers or could be due to the location of the optical fibre. To examine if optogenetic stimulation could induce a visual percept we trained a monkey on a two-alternative forced-choice task. The macaque reported, via a saccade-based perceptual detection, whether a visual or optogenetic stimulation was present or not (catch trials). The performance showed exceeded chance levels across all three task conditions: visual, optogenetic and catch. Interestingly, by comparing the success rate, reaction times and saccade velocities of the optogenetic trials to those of the visual trials, we were able to infer that the animal perceived a "phosphene" stimulus that is similar to a weak visual stimulus. Taken together, our results demonstrate that optogenetic stimulation could be used to induces wide-spread activation across the cortical layers of V1 demonstrating its suitability for generating phosphenes.

Title: Differential responding of cortical cell-types for novelty detection

Authors: *C. G. GALLIMORE, J. M. ROSS, J. HOLMES, A. D. FERRELL, J. P. HAMM; Neurosci., Georgia State Univ., Atlanta, GA

Abstract: The processing of stimuli in their spatial and temporal context is a core function necessary for an organism's survival. Contextual modulation of sensory processing is known to be present in neocortical circuits, whereby neural responses differentiate contextually novel stimuli from those which are predictable, or redundant. This allows the organism to update its internal model of the world, appropriately allocating resources for ongoing processing or goal-directed action. However, it is unclear how specific cell-types give rise to this modulation. Here, we examined the activity of various cell-types in mouse primary visual cortex (layers L2-4) during a visual oddball paradigm, in which orthogonal square-wave gratings are presented to the animal in conditions of varying contextual salience: novel ("deviant"), predictable ("redundant"), or neither. Using type-specific Ca^{2+} indicator expression (GCaMP6s), we were able to selectively monitor the activity of excitatory pyramidal cells (PYRs) and two classes of inhibitory interneurons (INs; SST, VIP) with high spatiotemporal precision using fast two-photon Ca^{2+}-imaging (28 Hz). Results revealed two underlying contextual modes of neural responses: stimulus-specific adaptation (SSA), a suppression of cortical responses to redundant stimuli, and deviance detection (DD), an augmented response to deviant stimuli, reminiscent of "prediction-error". Excitatory PYRs displayed SSA across all cortical layers observed, though only displayed DD in supragranular L2-3. This response profile was robust, and is consistent with the predictive coding framework. Inhibitory INs, however, displayed dynamics broadly consistent with their mutually inhibitory influences on one another. For example, L2/3 SSTs showed some evidence of DD, whereas those in L4 did not. And SSTs at all depths showed ongoing SSA, such that subsequent redundant gratings elicited decreasing response magnitudes. Conversely, VIPs showed no evidence of DD at any layer, and tended to ramp up their responses to redundant repetitions preceding a deviant stimulus - an inverse relationship to SSTs. Our L2/3 SST observations are consistent with the notion that their primary input source is local PYRs, as well as past work showing chemicogenetic suppression of SSTs eliminates DD in PYRs. We propose that a competitive disynaptic inhibitory motif between PYRs of opposite preferred orientation, mediated by L2/3 SSTs, gives rise to DD in cortical circuits. However, future work is needed for a more complete picture of circuit dynamics, incorporating measurements of the PV IN class, as well as teasing apart the contributions of feedback from higher cortex.

Title: Stimulus dependence of theta rhythmic activity in primate V1

Authors: *P. FANYIWI[1], B. AGAYBY[1], R. KIENITZ[2,3], M. HAAG[4], M. C. SCHMID[4,1]; [1]Biosci. Institute, Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Ernst Strüngmann Inst. for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany; [3]Epilepsy Ctr. Frankfurt Rhine-Main, Ctr. of Neurol. and Neurosurgery, Goethe Univ., Frankfurt, Germany; [4]Fac. of Sci. and Medicine, Univ. of Fribourg, Fribourg, Switzerland

Abstract: A growing body of psychophysical research suggests that perceptual sampling of complex environments might occur at a theta rhythm (3-8 Hz)[1]. Electrophysiological recordings point to a neural origin of this theta-rhythmic sampling mechanism in higher level cortical areas[2,3], often associated with exerting top-down attentional influences on perception[4]. However it remains unknown whether theta oscillations can be observed in primary visual cortex (V1) and to what extent their emergence might depend on stimulus properties. To address these questions, we recorded multi-unit activity (MUA) and single unit activity (SUA) from the V1 of two macaque monkeys passively viewing a visual stimulus with variable properties. Analysis of the MUA showed that among the visually responsive electrode sites (n = 107 in Monkey 1 and n = 78 in Monkey 2), more than 50 % showed a statistically significant theta oscillation when the stimulus appeared compared to a baseline period without a stimulus. Doing the same analysis for single units (n = 38 in Monkey 1 and Monkey 2), we found that more than 80 % of the sampled visually responsive units showed a statistically significant theta oscillation. Theta power varied depending on size, contrast, and orientation of the stimulus. Within each of these stimulus property domains (e.g. size), there was usually a single stimulus value that induced the strongest theta. The present study shows that a highly stimulus dependent neuronal theta oscillation can be elicited in V1 at the earliest level of visual cortical processing. Stimulus driven theta oscillations in visual cortex might be an additional mechanism for perceptual sampling that occurs at the same frequency range.

Title: Investigating structural covariance of the human optic tract and primary visual cortex in a neuroimaging dataset

Authors: *T. MIYATA[1,2], N. C. BENSON[3], J. WINAWER[4], H. TAKEMURA[2,1];
[1]Grad. school of Frontier Biosci., Osaka Univ., Suita, Japan; [2]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol., Suita, Japan; [3]eScience Inst., Univ. of Washington, Seattle, WA; [4]Dept. of Psychology and Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The relationship between the size of human brain structures within a population can inform our understanding of the organization and development of the nervous system. A previous post-mortem study demonstrated a correlation between the size of the optic tract and primary visual cortex (V1) across human individuals (Andrews et al., 1997), suggesting that the development of these structures is coordinated. In this study, we aimed to investigate covariance between structural properties of the optic tract and V1 in living human populations, by analyzing retinotopic maps from the Human Connectome Project Retinotopy dataset (N = 178; Benson et al., 2018) and diffusion MRI (dMRI) data acquired from the same human participants. We first calculated the surface area of V1 estimated by combining the fMRI dataset and a retinotopic atlas (Benson et al., 2018). We then identified the optic tract from all participants by using probabilistic tractography (Sherbondy et al., 2008) on dMRI data. For each optic tract, we measured the cross-sectional area and fractional anisotropy (FA; Basser & Pierpaoli, 1996). We initially analyzed FA estimated from dMRI data acquired with b = 2000 s/mm^2, and used dMRI data acquired with other b-values as replication datasets. We did not find a significant correlation between optic tract size (cross-sectional area) and V1 surface area (R = 0.04), in contrast with the previous post-mortem study. However, we found a small, but statistically significant negative correlation between FA of the optic tract and V1 surface area (R = -0.19, P = 0.009). The correlation was most prominent along the middle portion of the optic tract. This result was replicated in dMRI dataset acquired with different b-values (R = -0.15, P = 0.048 for b = 1000 s/mm^2; R = -0.16, P = 0.007 for 3000 s/mm^2). These results reveal a modest correspondence between tissue properties of the optic tract and the size of V1, suggesting that properties of retinal ganglion cells have some impact on the development of human V1. Further work is needed to understand why the size correlations differ from the prior post-mortem report.

Title: Testing the molecular anchors hypothesis in human and macaque visual cortex

Authors: M. MARTYNEK[1], S. KASTNER[2], M. S. LIVINGSTONE[3], *M. J. ARCARO[1]; [1]Univ. of Pennsylvania, Philadelphia, PA; [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]Harvard Med. Sch., Boston, MA

Abstract: The adult primate visual system comprises a series of retinotopically organized areas. These areas are present in every individual and have a stereotypical spatial organization across the cortical surface. While these areas are present at birth (Arcaro & Livingstone 2017), it has been proposed that the visual cortex develops sequentially with primary visual area V1 acting as an anchor and extrastriate areas V2, V3, and V4 self-organizing around V1 (Rosa, 2002). This hypothesis is difficult to test directly in primates given the limited tools available for manipulating early map formation. However, this hypothesis, predicts that features of extrastriate maps such as areal extent are tied to the map of V1. Here, we test this hypothesis by measuring the sizes of retinotopic maps in a large group of human and macaque subjects.

We used fMRI to map the retinotopic organization of the visual system in 53 adult humans (Wang et al. 2015) and 7 juvenile macaques (Arcaro & Livingstone, 2017). We mapped polar angle and eccentricity representations using a traveling wave paradigm and created individual cortical surface models from high-resolution anatomical MRIs. From these measurements, we identified 25 retinotopic maps in humans and 21 retinotopic maps in macaques. We measured the cortical extent of each area in each subject.

In both humans and monkeys, V1 had the largest cortical area and the sizes of extrastriate areas progressively decreased moving anterior from V1. Across subjects, the size of V1 was correlated with the sizes of V2, V3, V4, and MT in both humans and macaques. In general, correlations between V1 and more anterior areas along both dorsal and ventral visual pathways were weak in both species. Correlations in areal size between V1 and extrastriate areas were strongest for matching (e.g. dorsal V1: dorsal V3) than non-matching (e.g., dorsal V1: ventral V3) visual field representations. Together, these data provide empirical evidence in support of the molecular anchor hypothesis (Rosa 2002) and indicate that the development of extrastriate areas is directly tied to the visual field map of V1. In addition, the relatively weak correlations between V1 and anterior areas indicates that additional factors substantially contribute to the map development of higher order visual maps. Lastly, the correlation in areal size between V1 and MT is notable given the relatively large cortical distance between the two areas in both species. Given the early development of area MT (Bourne & Rosa 2006), this may reflect common thalamic constraints on development.

Title: Cortex exhibits microstructural tissue growth that proceeds hierarchically within the visual processing streams during the first 6 months of human life.

Abstract: The topology and chronology of postnatal human brain development have been of great interest for more than a century. Since Flechsig's seminal 1901 paper, the predominant focus has been on the maturation and myelination of white matter tracts, suggesting that projection fibers to primary sensory cortical areas are more mature at birth than those to other cortical areas. However, how cortical tissue develops postnatally is largely unknown. By combining T_1 relaxation time from quantitative MRI and mean diffusivity (MD) from diffusion MRI in 13 infants, we tracked cortical tissue development within individuals across three timepoints (newborn, 3 months, and 6 months, N=10 at each timepoint). Lower T_1 and MD indicate higher microstructural tissue density associated with more developed cortex. Our data reveal three main findings: First, primary sensory/motor areas (V1: visual, A1: auditory, S1: somatosensory, M1: motor) have lower T_1 and MD at birth than higher-level cortical areas. However, all primary areas show significant reductions in T_1 and MD in the first six months of life, illustrating profound tissue growth even after birth. Second, systematic and significant reductions in T_1 and MD from newborns to 6 month-olds occur in all visual areas of the ventral and dorsal visual streams. Strikingly, this development was heterogenous across the visual hierarchy: Earlier areas were more developed at birth (lower T_1 and MD) than higher-level areas, and also had a slower rate of T_1 and MD development as observed by a negative relationship between cortical tissue properties at birth and developmental rate. Third, a detailed look at regions that will become selective for faces and places by adulthood, reveals that face areas display at a faster rate of development than place areas, suggesting a fine-grained and functionally relevant developmental trajectory within higher-level areas. Finally, analysis of transcriptomic gene data that compares gene expression in postnatal vs. prenatal tissue samples shows strong postnatal expression of genes associated with myelination and synaptic signaling. We hypothesize that these cellular structures contribute to profound postnatal cortical tissue growth, which we observed with *in-vivo* T_1 and MD measurements. We propose a novel principle of postnatal maturation: development of cortical tissue proceeds in a fine-grained, hierarchical manner within cortical streams. We hypothesize that this hierarchical development

enables the cortical microcircuitry of lower-level areas to develop first, which, in turn, provides the necessary scaffolding for efficient signal conduction, tunability, and learning.

Title: Cytoarchitecture, not function, determines a visual region's connectivity profile in childhood

Authors: ***E. KUBOTA**[1], M. GROTHEER[1], J. GOMEZ[2], V. NATU[1], D. FINZI[1], A. REZAI[1], H. KULAR[1], M. NORDT[1], K. GRILL-SPECTOR[1];

Abstract: Ventral temporal cortex (VTC) contains regions involved in the processing of ecologically relevant stimuli that fall in consistent anatomical locations across individuals. However, the principles underlying the relationship between the topography of these domain-selective regions in VTC and brain structure are unclear. Here, we tested if white matter tracts that connect to functional regions in VTC are organized by cytoarchitecture, domain, or both, using functional MRI and diffusion MRI in 29 children (ages 5-12) and 28 adults (ages 22-29). To test these hypotheses, we quantify in each participant, the distribution of white matter fascicles ("connectivity profiles") of VTC domain-selective regions that have been previously shown to be located in different cytoarchitectonic areas. We find that across both children and adults, the connectivity profiles are similar between ROIs within the same cytoarchitectonic area, even if they are selective for different domains, e.g. face (mFus-faces) and word (mOTS-words) selective regions in cytoarchitectonic area FG4 have similar connectivity to the posterior arcuate (pAF), arcuate fasciculus (AF), and inferior longitudinal (ILF). In contrast, we find that connectivity profiles are significantly different between ROIs in different cytoarchitectonic parcellations even if they are selective for the same domain, e.g. mOTS-words in FG4 has particularly strong connections to the pAF, while pOTS-words in FG2 has particularly strong connections to the vertical occipital fascicle (VOF). This finding challenges the idea that regions selective for different domains have unique white matter connectivity profiles that support domain-specific processing. Interestingly, in adults but not children, mOTS-words has a greater percentage of fibers connecting to the AF compared to mFus-faces. This finding is important because mOTS-words is a brain region involved in reading and the AF is considered to be a language tract. Moreover, this increased connectivity is a result of mOTS-words shifting closer

to the AF from childhood to adulthood. Together, these findings suggest that large scale white matter connectivity is organized by cytoarchitecture early in development, whereas domain-specific connections emerge in response to reading experience.

Title: Human visual cortex is organized by an OFF-dominated map: evidence from multivariate analyses of magnetoencephalography (MEG) data

Authors: *S. R. SINGH[1], B. R. CONWAY[2];
[1]Natl. Eye Inst., Bethesda, MD; [2]NIH, Bethesda, MD

Abstract: The lateral geniculate nucleus relays to visual cortex information at each retinal location about luminance increments and decrements. These ON and OFF signals converge on cortical neurons to create multiple overlapping maps, including those that represent the visual field, ocular dominance, and orientation. Single-cell electrophysiology and optical imaging in cats and tree shrews show that the topographic constraints of each map are satisfied by a precise spatial arrangement of thalamic inputs, with the OFF inputs forming the scaffolding (Kremkow et al., and Lee et al., Nature, 2016). However, it is not known whether OFF inputs also govern the organization of visual cortex in humans, or of any primate. We tested this hypothesis by: (1) simulating the impact of small eye movements on the spatial representation across the cortex of ON and OFF inputs; and (2) directly measuring the extent to which ON versus OFF signals could be decoded from the spatial pattern of responses measured with MEG. The simulations suggest that small eye movements produce less variability in the pattern of activation for OFF versus ON, implying that responses are more precise for darks compared to lights. This prediction was supported by the multivariate analyses of MEG data, which showed that the spatial pattern of responses to darks were more consistent than those to lights. Participants (N=18) were shown brief flashes (116ms; 1s ISI) of spiral-shaped stimuli (spanning 10°) of 26% luminance contrast as increments and decrements, while measuring MEG activity (Elekta Triux system, 306-channel probe). Univariate responses to darks and lights were not significantly different. The precision of the maps was assessed with representational similarity analyses. For each 5-ms time bin, we determined the extent to which the pattern of activity across the array of sensors was correlated in independent data sets. The correlation matrix was compared to two models, one in which patterns elicited by dark stimuli were more correlated than the patterns elicited by light stimuli, and one in which patterns elicited by light stimuli were more correlated. The results showed that

the spatial patterns elicited by darks were initially more correlated, with an onset latency of 75-ms (peak at 95-ms), followed by higher correlation for lights (peaks at 145 ms and 195-ms), and another peak for darks at 245-ms. The early time of the onset latency suggests the correlation structure reflects the initial OFF-dominated wave of thalamic activity recorded in visual cortex. These results provide the first evidence we are aware of showing that the topographic structure of visual cortex in humans is governed by an OFF-dominated map.

Title: A psychophysical signature of Y like neuronal responses in human vision

Authors: *A. L. RAMIREZ HERNANDEZ[1], A. ROSENBERG[2], C. L. BAKER[3];
[1]McGill Univ., Montreal, QC, Canada; [2]Neurosci., Univ. of Wisconsin - Madison, Madison, WI; [3]Ophthalmology, McGill Vision Res. Unit, Montreal, QC, Canada

Abstract: Establishing the contributions of the different types of retinal ganglion cells (RGCs) to visual perception has been challenging. In cats, X and Y RGCs have been neurophysiologically well characterized. These cell types are similar to primate Midget and Parasol cells, respectively. Y-cells (and Parasol cells) are distinguished by a nonlinear response at higher spatial frequencies (SFs) and higher temporal frequencies (TFs), but the functional roles of these nonlinear responses in human visual perception are not well understood. Subcortical Y-like inputs are thought to mediate cortical responses to contrast modulation (CM) patterns, which consist of a high SF grating carrier whose contrast is modulated by a low SF sinewave envelope. Here, we leveraged the Y-like carrier response properties of cortical neurons to CM patterns to demonstrate a novel psychophysical approach to revealing the function of Y-like RGCs.CM as well as luminance modulation (LM) patterns were viewed monocularly by subjects with normal vision, at 2.1, 4.3, 6.4, and 8.5 degrees of eccentricity. In each stimulus trial (120 msec duration), a CM pattern or a LM pattern was presented. The CM stimuli had a contrast-reversing carrier and a drifting sinewave envelope with a SF of 0.25 cycles/deg (cpd) and a TF of 3 Hz. The psychophysical task was to report the perceived direction of motion of LM gratings or CM envelopes. Within each block of trials, SF (for LMs) or carrier SF (for CMs) was varied with a method of constant stimuli for different values of TF (LMs) or carrier TF (CMs).We found that the ability to correctly perceive envelope direction of motion with CM patterns was bandpass with carrier SF, exhibiting best performance at relatively high carrier SFs (1.5 to 3.0 cpd), and high carrier TFs (15 to 20 Hz). For CM patterns, the performance at the highest carrier TF (20 Hz) did not decrease uniformly with eccentricity. In contrast, for LM patterns, the best

performance at 1.5 to 3.0 cpd was at low TFs (5-10 Hz), and the performance decreased systematically with eccentricity. Because the linear mechanisms of RGCs respond best at lower TFs, whereas the nonlinear subunit responses of Y-like cells respond well at higher TFs, the measured psychophysical performance for CM patterns likely reflected nonlinear subunits. In addition, the good performance at SFs that are high for peripheral vision and relatively independent of eccentricity was more consistent with the responses of small nonlinear subunits than with linear mechanisms. Therefore, the performance for CM patterns with high carrier SFs and TFs likely arises from Y-like cells such as Parasol cells.

Title: Motion and Stereopsis Are Encoded by Distinct Mesoscopic Channels in Human Extrastriate Cortex

Authors: *S. NASR[1], B. KENNEDY[2], R. B. H. TOOTELL[1];
[1]Massachusetts Gen. Hospital, Harvard Med. Sch., Charlestown, MA; [2]Radiology, Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: BACKGROUND: The encoding of stereopsis and motion involves much of visual extrastriate cortex in humans, including thick-type columns in V2, V3, and area V3A. Many of these sites are reported to be strongly influenced by the magnocellular stream. However, it remains unclear whether motion and stereopsis are processed diffusely within a common magnocellular-influenced channel, or instead, within smaller scale ‘sub-channels’ within it.

METHODS: We used high-resolution fMRI (1 mm isotropic), collected in a 7T scanner, to localize motion- and stereo-selective columns in the human extrastriate cortex (n = 14), based on the response to moving-vs-stationary (Tootell and Nasr, 2020) and 3D-vs-2D (Nasr and Tootell, 2018) stimuli, respectively. As a control, color-selective 'V2/V3 'thin' stripes were also localized in the same subjects, based on their response to color-vs-luminance varying stimuli (Nasr et al., 2016). Finally, we studied the functional connectivity between these columns by measuring their spontaneous fMRI fluctuations during the resting-state (eyes closed).
RESULTS: In areas V2 and V3, motion- and stereo-selective activity clusters were localized *between* the color-selective 'thin' stripes. Regions with overlapping "motion-and-stereo" selectivity (~5% of V2/V3 area) showed a relatively strong selective response to both visual cues. In contrast, regions with overlapping "motion-and-color" or "stereo-and-color" selectivity showed relatively weak selectivity to either one of the visual cues. This suggests a more gradual shift in stimulus selectivity between stereo-vs- motion selective columns, and a relatively sharper segregation between color-vs-motion and/or color-vs-stereo selective columns. In V3A, motion- and stereo-selective activity formed larger clusters compared to V2/V3 with little overlap. Color-selective clusters were rare in this region. We also found a stronger functional connectivity between columns with alike (e.g. motion- to motion-selective) rather than unlike selectivity (e.g. motion- to color-selective) in either ipsilateral or contralateral hemispheres.
CONCLUSION: Within a well-described magnocellular-influenced stream, our evidence suggests the existence of a mesoscopic 'sub-stream', which responds selectively to motion or stereopsis.

Title: Depth perception by anti-correlated random-dot-stereograms in central visual field

Authors: *L. ZHAOPING;
Max Planck Inst. For Biol. Cybernetics.

Abstract: In a random dot stereogram (RDS), object surfaces in a three-dimensional scene are generated by images presented to left and right eyes that comprise interocularly corresponding random black and white dots. The spatial disparities between the corresponding dots determine the depth of the object surfaces. When a black dot in one monocular image corresponds to a (contrast-polarity reversed) white dot in the other, the RDS is called anti-correlated. Neurons in the primary visual cortex (V1) respond to such RDSs as if their preferred disparities become non-proferred and vice versa, thereby reversing the disparity signs reported to higher visual

areas. Humans can perceive such reversed depths in peripheral but not in central vision (Zhaoping & Ackermann 2018). According to the central-peripheral dichotomy in recognition (Zhaoping 2017, 2019), V1 signals are fed forward to higher visual areas to suggest initial perceptual hypotheses about scenes; in central but not in peripheral vision, top-down feedback from higher to lower visual cortical areas aid recognition using analysis-by-synthsis, so that the would-be visual input for each hypothesis (e.g., a depth order) is fed back to V1 to verify whether it matches the actual visual input, and the hypothesis yielding a good or poor match is boosted or suppressed, respectively, this is termed the Feedforward-Feedback-Verify-reWeight (FFVW) process for recognition. Accordingly, V1's reversed depth signals are perceived peripherally, but not centrally since, by FFVW, they disagree with the would-be inputs expected by the brain from past experience.
In this work, I show that the typically invisible reversed depth signals can influence depth perception in central vision in RDSs containing polarity-matched dots, polarity-reversed dots, and noise dots which are inter-ocularly independent. To report whether a central disk is in front or behind the surrounding ring in a noisy RDS, observers can see the defined depth order by the polarity-matched dots more (or less) clearly when the depth order in the reversed depth signals by the polarity-reversed dots is the same as, or opposite to, the defined depth order. Accordingly, the threshold signal-to-noise level needed in a noisy RDS to see depth can be lowered or raised respectively by adding congruent or incongruent reversed depth signals. The reversed depth signals are more perceptually more influential in dynamic RDSs with brief stereo-frames to make top-down feedback in FFVW less effective. Hence, the feedforward reversed depth signals from V1 can influence percept in central vision when the feedback veto can be reduced by brief inputs or mitigated by normal depth signals.

Title: Event-related phase synchronization propagates as waves in human ventral visual cortex

Authors: *O. WOOLNOUGH, K. J. FORSETH, P. S. ROLLO, Z. J. ROCCAFORTE, N. TANDON;
UT Hlth., Houston, TX

Abstract: Electrophysiological studies have revealed that visual stimuli evoke spreading waves of cortical activity in primary visual cortex, a presumed manifestation of the intrinsic connectivity of hierarchically organized early visual cortex. However, it unknown if this

phenomenon occurs in higher-order visual cortex, where inputs from early visual cortex integrate with semantic, attentional and memory inputs. To probe the organizational principles of higher visual cortex we performed intracranial recordings in 90 individuals, with >2,000 electrodes in ventral visual cortex, while they performed visual tasks of varying visual, cognitive and attentional complexity (word reading, face naming and scene classification). We tracked the spatiotemporal progression of changes in theta (4 - 8 Hz) inter-trial phase coherence (ITC), theta power, event related potentials (ERPs) and gamma (70 - 150 Hz) power across the cortical surface. Strong phase modulation was noted almost ubiquitously across ventral occipitotemporal cortex; from occipital pole to anterior fusiform in all tested visual tasks. Visual onsets and offsets induce posterior-to-anterior travelling waves of phase and power modulation across the entire ventral occipitotemporal cortex. Spread of ITC and gamma power was well correlated with spatial location (>20% variance explained) and demonstrated propagation velocities of 1-1.1 m/s for ITC and 0.4-0.5 m/s for gamma power. Phase modulation, but not oscillatory power, was strongly predictive of the ERP amplitude at each electrode, suggesting that ERP is at least partially a manifestation of phase reset. Importantly, attentional modulation, within task, resulted in a dissociation between ITC and ERP, with attentional modulation showing unique patterns of modulation of the time course of ITC, ERP, theta and gamma power. In conclusion, this is novel evidence for the existence of posterior-to-anterior travelling waves of theta phase modulation and gamma power, spreading from calcarine cortex to visual associative areas in fusiform cortex. We provide multiple strands of evidence to reveal that while phase, power and ERP are correlated, they index distinct processes in the visual system. We propose this theta-centric travelling wave could represent sequential cortico-cortical integration across the ventral visual pathway.

Title: Laminar processing of border ownership in primate extrastriate visual cortex

Authors: *T. P. FRANKEN, J. H. REYNOLDS;
Salk Inst., La Jolla, CA

Abstract: Gestalt psychologists have known for over a century that the primate visual system compulsorily assigns contrast edges to objects, i.e. edges are perceived as being owned by foreground objects. Early primate extrastriate visual cortex contains neurons that encode border

ownership, providing border ownership signals which occur even when the visual stimulus features that distinguish foreground object from background fall well outside the neuron's classical receptive field (Zhou et al., 2000). It is unresolved whether the information that establishes border ownership selectivity is mediated through feedforward, horizontal or feedback pathways (e.g. Zhaoping, 2005; Sakai and Nishimura, 2006; Zhu et al., 2020). These pathways have distinct laminar connectivity patterns. Here we mapped the timing of border ownership signals across cortical layers, using 32-channel laminar probes. We recorded responses from well-isolated units in extrastriate visual area V4 in two behaving macaques. By replacing the native dura with a transparent artificial dura we were able to position the probes orthogonally to the cortical surface. We used current source density analysis of stimulus-evoked local field potentials to identify the granular (input) layer as the current sink with the shortest latency, and locate the units recorded from to supragranular, granular or infragranular layers. We then measured spiking activity evoked by square stimuli presented on a uniform background. The stimuli were positioned such that only one border of the object fell within the classical receptive field of each neuron. Border ownership was thus defined by stimulus features outside of the classical receptive field. We quantified border ownership selectivity using the reliability metric introduced by Zhou et al. (2000). Our data confirm earlier reports of a dominant presence of border ownership signals in V4. In contrast to the hypothesis that border ownership signals in V4 are inherited from V2, we find that border ownership selectivity rises first in the infragranular layer, before it appears in the granular and the supragranular layers (bootstrap latency analysis $p<0.05$). Our data thus suggest that border ownership signals are not inherited in a feedforward manner from upstream areas. Rather, they appear either to be established in V4 deep layers, or they may arrive through cortical feedback from downstream visual areas. Deep layers include neurons that project to upstream cortical areas, raising the possibility that these early border ownership signals in deep layers are part of the cortical feedback projecting to upstream areas.

Title: A model for the origin of ocular dominance columns in primary visual cortex

Authors: A. SOMARATNA, *A. W. FREEMAN;
Univ. of Sydney, Sydney, Australia

Abstract: Introduction. Ocular dominance columns are a prominent feature of carnivore and primate primary visual cortex. Their visual function (if any) and origin are, however, little understood. We modelled ocular dominance columns to explore their contribution to binocular vision. **Methods.** We extended an existing monocular model of the cat's upstream visual system (Nguyen, Freeman, 2019) by adding a second eye. Both eyes supplied the cortex with multiple

channels, each of which comprised a photoreceptor, bipolar cell, ganglion cell and lateral geniculate nucleus cell. Each neuron was represented by a differential equation, and all equations were simultaneously integrated to calculate responses. Ganglion cells were distributed across the retina so as to reproduce the spatial statistics of real arrays (Wässle et al., 1981). The geniculocortical synaptic strength of each channel developed with a Hebbian process that reduced destructive interference between neighbouring on- and off-channels, and thereby produced orientation-selective cortical neurons. Critically, the starting values of these weights was set proportional to the interocular difference of local retinal ganglion cell densities. **Results.** Ocular dominance was assessed for each cortical neuron by drifting an optimally oriented sinusoidal grating across its receptive field. A neuron's ocular dominance index was calculated as the normalised interocular difference in the fundamental Fourier component of impulse rate, with values ranging from pure contralateral to pure ipsilateral drive. The ocular dominance index was mapped across the simulated patch of visual field; not surprisingly, the map closely replicated interocular differences in retinal ganglion cell density. More importantly, the map was reminiscent of measurements in cats (Löwel et al., 1988). In particular, the periodicity of this map was 1.1 mm, which is within the empirical range. Other cortical properties in the model also tallied well with experiment: the interocular difference in preferred orientation was small, with a standard deviation of 8 deg; interocular differences in receptive field location were variable, leading to preferred stimulus locations nearer than, on, or beyond the fixation plane. **Discussion.** There is debate whether ocular dominance columns result from molecular interactions between geniculate axons and cortical cells, or from activity-based changes in innervation. We have avoided this debate by assuming that the columns depend, in both cases, on the relative densities of afferents from the two eyes. This assumption leads to a model that reproduces several of the well-known properties of binocular vision.

Title: Performance in even a simple visual task depends on mouse secondary visual areas

Authors: *H. C. GOLDBACH, B. AKITAKE, C. E. LEEDY, M. H. HISTED;
NIMH, Bethesda, MD

Abstract: Primary visual cortex (V1) in the mouse projects to numerous brain areas, including several secondary visual areas, frontal cortex, and basal ganglia. While it has been demonstrated that optogenetic silencing of V1 strongly impairs visually-guided behavior, it is not known which

downstream areas are required for visual behaviors. Here we trained mice to perform a contrast-increment change detection task. For this task, substantial information is available in V1 to allow a perceptual decision to be made -- V1 neurons show contrast-dependent changes in firing rate. Therefore, it could be that animals perform this task by using V1 information directly and bypassing secondary visual areas, or alternatively, secondary areas might be used even in this simple contrast-step task. Via optogenetic silencing of visual responses in V1 and secondary visual areas, we found that secondary areas' activity is required. First, we verified that inhibition of V1 at even low light intensities greatly affects performance during this task (mean 100% crossing point; the light required to increase contrast threshold by 100%: 0.42 mW/mm^2, bootstrap 95% CI 0.30 - 0.55 mW/mm^2, N = 9). Inhibition of control locations outside visual areas produced significantly weaker effects (mean 100% crossing point 4.2 mW/mm^2, bootstrap 95% CI 2.1 - 6.8 mW/mm^2, N = 5). Inhibition of areas lateral to V1 (LM, AL, RL) produced effects that were, in some cases, even larger than those seen with inhibition of activity in V1 (mean 100% crossing point 0.37 mW/mm^2, bootstrap 95% CI 0.20 - 0.57 mW/mm^2, N = 7). Inhibition of area PM produced effects that were significantly smaller than those seen during V1 inhibition (mean 100% crossing point 1.87 mW/mm^2, bootstrap 95% CI 0.65 - 3.08 mW/mm^2). In vivo electrophysiology and widefield GCaMP imaging showed that, although inhibiting secondary visual areas could produce some feedback effects in V1, the principal effect was profound suppression at the location of the optogenetic light. The results show that pathways through secondary visual areas are necessary for even perhaps the simplest visual behaviors that involve V1.

Abstract: Finding regularities in the environment and utilising them is important in this complex, yet structured world. Perceptual decisions, therefore, not only depend on current sensory input, but are also influenced by previous experience.
To investigate history effects during visual perceptual decision-making, we trained head-fixed

mice to perform a lick-left/lick-right orientation discrimination task. We used logistic regression to estimate the contributions of task-relevant (current stimulus) and task-irrelevant factors (past stimuli, past choices) on the animals' decisions.
Mice learned the task and reached stable performance in 6-8 weeks. Examining model weights during learning, we found that progress in learning was paralleled by increasing weights assigned to the current stimulus ($r = 0.87$). After learning, average performance was $67.5\% \pm 0.9\%$. To better understand the overall sub-optimal performance, we focused on response times (RTs), and separated trials with short or long RTs, using as boundary each animal's median RT - 0.5 s. Performance was at chance level for trials with short RTs ($50.7\% \pm 2.8\%$) but better for trials with long RTs ($71.8\% \pm 0.4\%$). To account for variability related to response time, we included RT as a predictor, which improved model performance. Model weights for current stimulus were negligible for trials with short RTs, suggesting that on these trials, animals failed to use relevant sensory evidence to guide decisions. Irrespective of RT, significant weights were assigned to past stimulus and choice, indicating that history effects influence decisions across all trials.
To investigate how mice trade off stimulus-related and contextual information, we introduced blocks of trials with stimulus-specific imbalances of reward. Here, mice showed a consistent bias towards the response side associated with larger reward. Under these conditions, the weight assigned to the current stimulus decreased compared to blocks with balanced rewards. This suggests that mice integrate information regarding expected reward size into their visually driven choice.
We conclude that, even for simple visual stimuli well above threshold, perceptual decision-making in mice is influenced not only by the current visual stimulus but also by the history of past trials and the context of reward. In addition, not accounting for trial-to-trial variability in the speed of the response will likely underestimate behavioural performance.

Title: The spatial structure of feedforward information in mouse primary visual cortex

Authors: ***J. ZHUANG**, N. OUELLETTE, R. LARSEN, K. TAKASAKI, T. DAIGLE, B. TASIC, J. WATERS, H. ZENG, R. REID;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Location-sensitive and motion-sensitive units are two major functional types of feedforward projections from lateral geniculate nucleus (LGN) to primary visual cortex (V1) in

mouse. The distribution of these inputs in cortical depth remains under debate. We systematically mapped the spatial organizations of location-sensitive and motion-sensitive LGN inputs in V1 of awake mice by imaging their axonal calcium activities. Although both types distributed similarly across cortical depth, we found notable organizations specific to each type: the motion-sensitive axons showed a depth-dependent bias in motion direction while the location-sensitive axons showed a depth-independent OFF dominance. By grouping boutons into axon segments, we showed the motion-sensitive axons had greater horizontal bouton spread than location-sensitive axons. While, within each type, the bouton spread was relatively uniform, indicating the spatial organization was determined by the axon distribution. Overall, our results suggest a new model of receptive biases and laminar structure of thalamic inputs to V1.

Title: Functional interlaminar connectivity in mouse primary visual cortex

Authors: *M. A. ROSSA[1,2], E. M. CALLAWAY[1];
[1]Salk Inst. for Biol. Studies, La Jolla, CA; [2]Neurosciences Grad. Program, Univ. of California-San Diego, La Jolla, CA

Abstract: One of the defining characteristics of the cerebral cortex is its organization into 6 layers, each distinguishable by a unique composition of cell types and representing a fundamental component of sensory information-processing. Most of what we know about functional interlaminar connectivity is from paired recordings in slice preparations which, due to cut axons, dramatically underestimate the rate of interlaminar connections. This leaves us with an incomplete understanding of how cortical circuits transform sensory information across layers. In this study, we use an optogenetic approach to bypass the issue of cut axons and comprehensively characterize relative synaptic input strength between cortical layers 2/3, 4, 5, and 6. We use transgenic mouse lines and viral vectors to restrict Channelrhodopsin-2 expression to excitatory cells within a single layer in mouse primary visual cortex. We then pair optogenetic stimulation of axon terminals (including live, cut axons) with *ex vivo* intracellular recordings in neurons across cortical layers and measure the monosynaptic input strength from the stimulated cell population to the recorded cell. This enables us to compare postsynaptic responses between cells recorded in different layers and thereby quantify the proportion of excitatory input from each cortical layer to other layers. Preliminary results suggest input strength from a given layer

to a particular cell depends strongly on both the input layer and the laminar location of the recipient cell. Consistent with previous research, L4 (the primary layer receiving sensory input relayed from thalamus) provides most of its input to L2/3, and L2/3 provides strong input both within L2/3 and to L5. We also find that interlaminar input strength varies by cell type; while extratelencephalic (ET) neurons in L5 primarily provide input to other cells in L5, L5 intratelencephalic (IT) neurons provide the majority of their input to L2/3. Interestingly, inputs from L6 ET neurons are evenly distributed between L4, L5, and L6. We also expect functional input strength to differ between excitatory cells and inhibitory cells and are further examining how each layer-specific population provides input to excitatory versus inhibitory cells within a particular layer. Together, our results provide a more complete picture of the relative distribution of excitatory synaptic input from each layer to other layers within a single cortical region.

Title: Long-term stability of neuronal ensembles in mouse visual cortex during spontaneous and visually-evoked activity

Authors: *J. PÉREZ-ORTEGA, T. ALEJANDRE-GARCÍA, R. YUSTE;
Columbia Univ., New York, NY

Abstract: Neuronal ensembles, i.e. coactive groups of neurons, are thought to participate in the internal representations of memories, perceptions, and mental states. New insights from experiments *in vivo* demonstrate their causal role in perception and behavior, but it is still unknown how stable they are over time. We performed two-photon volumetric calcium imaging of layer 2/3 of visual cortex of awake mature adult mice (TIGRE2.0 GCaMP6s/f, n = 6) ranging from 3 - 6 months in age. We imaged and tracked over weeks the activity of the same neurons in response to visual stimuli and spontaneous activity. Less than 20% of neurons remained active across weeks. Analyzing them, we found both stable ensembles, lasting up to 46 days, and transient ones, observed during one single session. Most visually-evoked ensembles were stable, whereas spontaneous ensembles were both stable and transient. Stable and transient ensembles had similar number of neurons and functional network density, but stable ensembles were more robust and more than 60% of their neurons still belonged to the same ensemble after weeks. These core cells had stronger functional connectivity than neurons that stopped belonging to the ensemble. Our results demonstrate that spontaneous and evoked neuronal ensembles can last

weeks, providing a neuronal mechanism for long-lasting representation of perceptual states or memories.

Abstract: Color is an important feature in guiding visual behavior in animals. Mice are dichromatic; they express short (S) and medium (M) wavelength-sensitive opsins. While true S-cones are distributed relatively uniformly across the mouse retina, M-cones co-express S-opsin with increasing co-expression gradient towards the ventral retina [1]. This results in a green-sensitive dorsal and UV-sensitive ventral retina. Despite this uneven opsin distribution, behavioral studies have demonstrated that mice can discriminate colors [2] in the upper visual field [3]. Here, we investigate retinal correlates of this behavior by analyzing chromatic processing in mouse retinal ganglion cells (RGCs).
To systematically examine how RGCs encode chromatic information, we used two-photon calcium imaging with visual stimulation. First, we employed a set of artificial stimuli such as a UV and green center-surround flicker stimulus to analyze chromatic preference of RGC receptive fields. Our study [4] on > 8,000 recorded ganglion cell layer cells confirmed that the dorso-ventral opsin expression gradient determines the spectral sensitivity of RGC center responses. Interestingly, we found that the surround chromatic preference of ventral RGCs was systematically shifted towards green, resulting in color-opponent center-surround antagonism. This stands in line with behavioral experiments showing that color vision in mice seems more prominent in the upper visual field [3].
Next, we investigated how chromatic information is processed in RGCs with more naturalistic stimuli. For that, we used “mouse natural movies” capturing the two color channels relevant for mice and the natural visual statistics of their environment more closely than artificial stimuli. We

probed RGC responses by displaying sequences from upper and lower visual field of these movies. To estimate spatial and temporal RGC receptive fields and to model RGC responses, we implemented a convolutional neural network (CNN) [5]. The CNN's architecture is inspired by the tiling of RGC types: features learned in the core are shared among all cells, and a cell-specific readout determines the combination of features and location in space. This approach enabled to predict RGC responses to naturalistic stimuli, capture their functional diversity and generate optimal stimuli (most exciting inputs, MEIs). Additionally, analyzing chromatic preferences reflected in spatial and temporal structures of MEIs allows to investigate how RGCs encode chromatic information present in the natural environment.

Munich, Munich, Germany

Abstract: Pressures for survival make sensory circuits adapted to a species' natural habitat and its behavioral challenges [1]. Thus, to advance our understanding of the visual system, it is essential to consider an animal's specific visual environment, by capturing natural scenes, characterizing their statistical regularities, and using them to probe visual computations. Mice, a prominent model system for vision research, have salient visual specializations, i.e. being dichromatic with enhanced sensitivity to green and UV in the dorsal and ventral retina, respectively. However, the characteristics of their visual environment that likely have driven these adaptations are rarely considered. Here, we built a gimbal-stabilized, UV-green sensitive

camera to record natural scenes from the habitat of mice. Analysis of the spectral channels revealed that chromatic contrast greatly diverged in the upper but not in the lower visual field. Models that were trained to encode the natural scenes suggest that this environmental difference might have driven the emergence of superior chromatic opponency in the ventral mouse retina, supporting color discrimination in the upper visual field [2,3]. In addition, we found that the upper visual field was biased towards dark contrasts implied in aerial predator detection, in particular for the UV channel, and this bias was paralleled by a higher frequency of large-receptive field, light-offset sensitive (Off) ganglion cells in the ventral retina. Together, our findings lend further support to the idea that, during evolution, natural scene statistics shaped retinal circuit processing [4]. The recorded footage is meant as a resource for mouse vision research and will be made publicly available. **References** [1] Simoncelli EP and Olshausen BA. Title: Temporal contrast modulates burst activity in the lateral geniculate nucleus

Authors: *A. N. SANCHEZ[1], H. J. ALITTO[1], W. USREY[2];
[1]Ctr. for Neurosci., UC Davis, Davis, CA; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Bursting is a ubiquitous feature of thalamic neurons and is well documented for visual neurons in the lateral geniculate nucleus (LGN). While bursts are often associated with states of drowsiness, they are also known to convey visual information to cortex. The occurrence of thalamic bursts depends on the inactivation state of T-type Ca^{2+} channels, which become de-inactivated and primed to evoke bursts following periods of increased membrane

hyperpolarization. Given the time/voltage relationship that underlies the production of bursts, it is reasonable to assume that bursts are influenced by the temporal contrast of visual stimuli. We therefore recorded the spiking activity of LGN neurons in the anesthetized cat while presenting drifting sine-wave gratings that varied in contrast. Spikes were categorized as tonic or bursts using established criteria, and comparisons were made between these categories under different contrast conditions. For high-contrast stimuli, we predicted the null phase of the stimulus would cause a deeper and more sustained hyperpolarization of relay cells than would occur with low-contrast stimuli, and that this difference would affect burst activity. Results show that burst rate increased significantly with high-contrast stimuli compared with low-contrast stimuli, as did the tonic spike rate; however, a more detailed analysis confirmed that the increase in burst rate was not simply due to an overall increase in firing rate. Further, bursts were more reliable and more temporally precise for the preferred phase of the stimulus cycle during high-contrast stimulation than during low-contrast stimulation. These results support the hypothesis that stimulus contrast and the biophysical properties underlying the state of T-type Ca^{2+} channels interact to influence the reliability and precision of geniculate bursts, presumably to facilitate stimulus detection. More subtle aspects of stimulus discrimination are best conveyed by tonic spikes.

Title: Target facilitation precedes competitive selection in a dragonfly visual neuron

Authors: ***B. H. LANCER**[1], B. J. E. EVANS[1], J. M. FABIAN[2], D. C. O'CARROLL[3], S. D. WIEDERMAN[1];
[1]The Univ. of Adelaide, Adelaide, Australia; [2]Flinders Univ., Adelaide, Australia; [3]Lund Univ., Lund, Sweden

Abstract: Animals that rely on pursuit predation to feed must be able to identify and track moving targets throughout a highly cluttered world, often amongst swarms of distractions. Despite this computational complexity, dragonflies are highly successful aerial predators, whose capture success is unperturbed by larger swarms of prey. How is the dragonfly nervous system able to achieve such success under such complex conditions? We have recorded intracellularly from an identified neuron in the dragonfly optic lobe, known as 'Centrifugal Small-Target Motion Detector 1,' ('*CSTMD1*'). Previously, CSTMD1 has been shown to display complex winner-takes-all selective attention enabling it to selectively single-out a chosen target from a pair. Additionally, CSTMD1 exhibits a predictive gain modulation, both enhancement (termed

‘facilitation’) and surround suppression which is thought to drive the neuronal response to a target to saturation in order to minimise the effect of distraction. However, CSTMD1 also exhibits dynamic switching between competing target stimului. In a total of 20 wild-caught, male dragonflies (*Hemicordulia sp.)* we tested whether all targets are facilitated, before one is selected; or whether a single selected target is then facilitated. By analysing the neuronal response to targets that were preceded by either an attended or non-attended target, we observed that in either case the tested probe displayed facilitatory gain enhancement. This reveals that neuronal facilitation is a lower-order computation applied to all targets, before selection is committed. By driving responses towards saturation when the target is within the receptive field for some time, facilitation blocks out transiently salient distractions. Thus, behaviourally important stimuli that persist over several hundred milliseconds (target trajectories) are given the competitive boost to drive selection and switching.

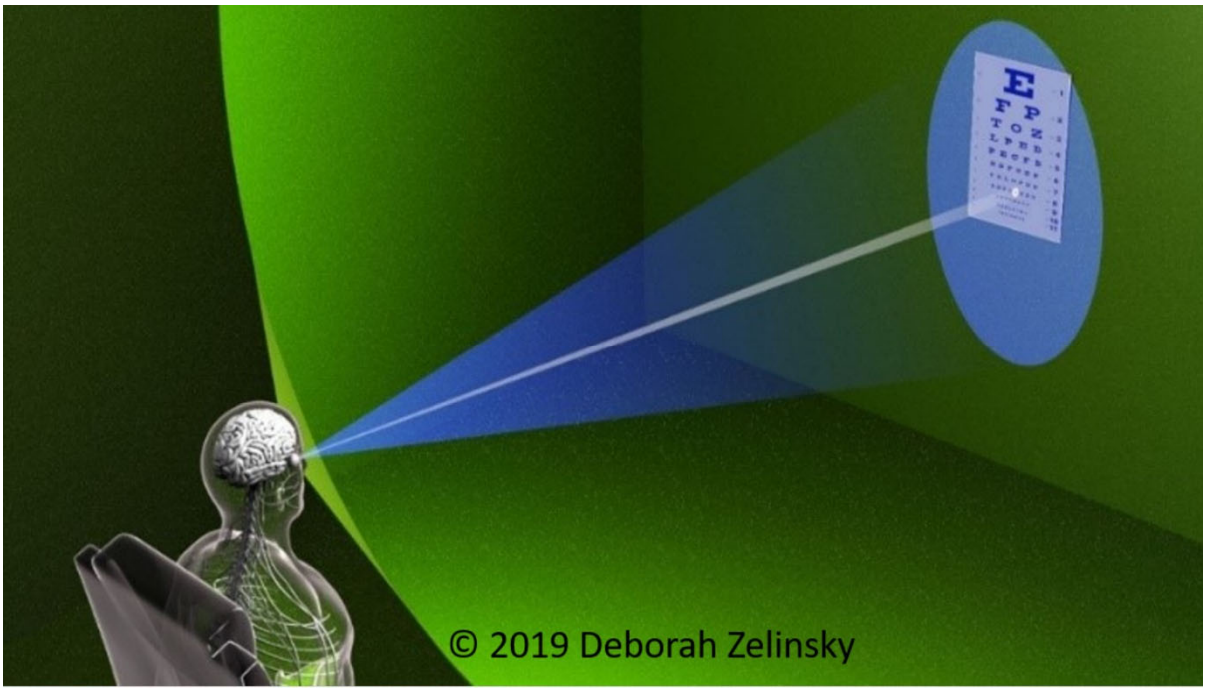
Title: From Moment to Memory: The Life Span of a Visual Signal

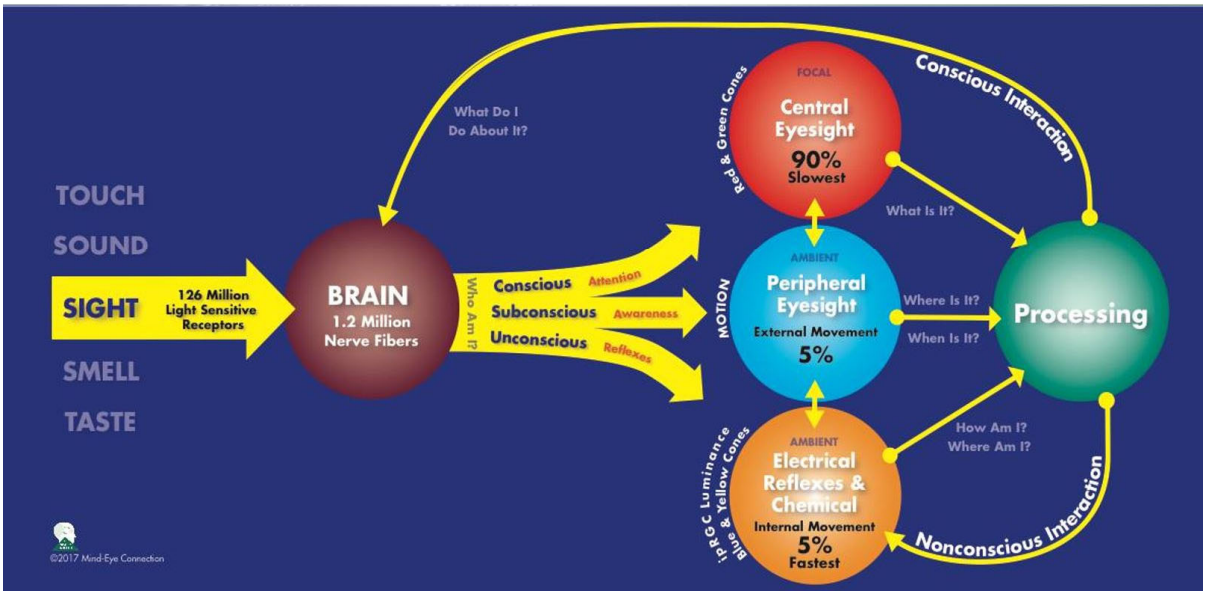
Authors: *D. G. ZELINSKY;
The Mind-Eye Connection.

Abstract: Retinal tissue is comprised of brain tissue and is considered part of the central nervous system as an interface between internal and external environments. It is nourished by blood flow from the inside, while processing light input from the outside. In order to pay attention to a target, 94% of the surroundings has to be tuned out via processes requiring coordination among many chemical and electrical systems.



The life of a visual signal starts by activation of one of 126 million light-sensitive receptors involved in retinal circuitry. After being filtered into 1.2 million exiting signals, each signal travels through a specific pathway, including fast "highways" to and from the limbic system & brainstem, as well as slower pathways to and from the cortex. The 94% of peripheral eyesight is represented by 200 thousand ganglion axons; the other 6% representing central eyesight is represented by 1 million axons. Optometry is beginning to use individualized Brainwear™ (eyeglasses designed for the 94%, rather than the 6%) to selectively activate brain circuitry. This novel use of retinal stimulation for neuromodulation is an important upgrade to the current, outdated eye examination.

21st Century Optometric Viewpoint



Sensory systems are integrated -not separate- so the future optometrist is envisioned as a primary healthcare provider who can selectively stimulate neuroendocrine functions while enhancing subconscious awareness of surrounding space, forming a link between orientation, navigation and identification skills in addition to memory.

Title: Visual cortex is hardly auditory

Authors: *C. BIMBARD, T. SIT, A. LEBEDEVA, P. COEN, K. HARRIS, M. CARANDINI; Univ. Col. London, London, United Kingdom

Abstract: Sensory cortices are increasingly thought to encode multisensory information. For instance, mouse primary visual cortex (V1) appears to be influenced by auditory inputs, which have been suggested to provide global inhibition or loudness- and frequency-specific information. However, sounds can also evoke unsolicited behavioral responses, and such behavioral responses are now known to elicit neural activity across the brain. Thus, multisensory

studies may suffer from a potential confound between acoustic-related and movement-related activity. We measured the neuronal responses to natural movies and natural sounds in V1 using chronically implanted Neuropixels probes, thus recording the activity of hundreds of units. At the same time, we filmed the behavior of the mice. We replicated previous results showing that sounds could evoke neural activity in V1. Though sound-evoked responses were weak compared to video-evoked responses, we could significantly decode sound identity from population activity. However, we also observed that in response to the sounds the mice performed stereotypical, unsolicited movements. These movements induced activity in the V1 population activity. Removing it significantly reduced the responses to sounds. We conclude that a significant part of sound-evoked responses in V1 comes from indirect behavioral responses, and that a careful characterization of auditory inputs to sensory areas requires controlling sound-induced changes in behavioral state.

Title: Behavioral and neuronal effects of predictability in multi-sensory objects

Authors: *O. D. GILDAY, A. MIZRAHI;
The Edmond and Lily Safra Ctr. for Neurosci., The Hebrew Univ., Jerusalem, Israel

Abstract: Perception is constantly shaped by non-sensory effects such as expectation, attention and context. Experimental studies have shown that such effects also modulate activity in sensory cortical neurons. Based on the theory of predictive processing such modulation is a result of top-down innervation from higher cortical regions. Evidence for such top-down effects, and specifically the effect of expectation, and its relation to perception, however, is scarce. In order to investigate these questions, we designed a behavioral task for mice that is a derivative of the "Go-No-Go" task. In this paradigm the "Go" and "No-Go" cues are auditory, and the extent to which their presentation is predictable is modulated by preceding olfactory cues. We show that although mice correctly use the auditory cues to maximize their rewards and minimize their punishments, their behavior is affected by the prior probabilities formed by the preceding olfactory cues. We also show examples of activity in the Auditory Cortex (ACx) of awake behaving mice, that although is not responsive to odor, is nonetheless modulated by the predictability of sounds that follow olfactory cues. Given that olfactory information is not coded in ACx, we propose that this modulation is a result of a top-down innervation of ACx, and suggest this behavioral paradigm as a fertile ground for research of predictability in multi-sensory objects.

Abstract: Neuronal circuits in the primary visual cortex undergo significant reorganization during the critical period. In mice, this reorganization corresponds with an experience-dependent convergence of ipsilateral and contralateral eye inputs onto neurons in the binocular region of the primary visual cortex (bV1). How synaptic inputs onto bV1 neurons, reflected in the responses of individual spines, change across development remains unknown. We compared the functional properties of synapses on L2/3 bV1 neurons between critical period and adulthood, using two-photon calcium imaging of dendritic spines in awake mice during monocular and binocular presentations of visual stimuli. We find that adult neurons have a significantly higher fraction of spines with a stronger bias to either the ipsilateral or contralateral eye than during the critical period, when spines are more binocular. Some spines in adult neurons that exhibit a preference towards one eye during monocular stimulation show reduced responses to binocular stimulation, indicating that these spines are either directly or indirectly suppressed by the non-preferred eye. To determine how dendritic spine responses evolve over development, we imaged the same spines and dendritic segments at different time points. Our preliminary findings show that some visually responsive spines shift their relative responses to each eye and develop binocular suppression, indicating dynamic changes in eye-specific drive onto individual spines. These changes can arise from presynaptic inputs onto spines or can be constructed at individual spines, potentially reflecting changes in excitatory inputs from one eye and development of inhibitory inputs from the other eye. To further probe mechanisms of binocular suppression in spines, our ongoing work employs a novel tissue expansion technology, Magnified Analysis of the Proteome (MAP), that allows super-resolution measurement of the synaptic composition of dendritic spines from L2/3 bV1 neurons. We hypothesize that the enrichment and distribution of inhibitory and excitatory synapses onto spines could provide a mechanistic explanation for the emergence of inter-ocular suppression across development.

Title: High-throughput analysis of layer specificity of plasticity in visual cortex after monocular deprivation

Authors: ***J. BOTTORFF**, G. TURRIGIANO;
Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: Hebbian and homeostatic forms of plasticity are crucial for efficient learning and information storage, and experimental and theoretical evidence suggest they may be segregated temporally to avoid possible interference. Monocular deprivation (MD) is a well-established protocol that induces a biphasic change in firing rates of excitatory neurons in the deprived hemisphere of rodent monocular visual cortex (V1m), while neural activity in the control hemisphere remains unchanged. In deprived neurons, Hebbian mechanisms cause a depression of firing rates in the first few days after MD, while homeostatic mechanisms return this activity to baseline in the next few days; further, our lab has shown that the homeostatic rebound is gated by wake behavioral states. However, the cellular and molecular mechanisms, including many aspects of cell-type specificity, underlying these phenomena are unknown. We developed a method using viral expression of CaMPARI2, a calcium and UV-dependent photoconvertible fluorescent protein, and *ex vivo* imaging in critical period rats to study layer and cell-type specific activity changes after MD (Trojanowski et al. 2019, biorxiv). By photoconverting CaMPARI2 *ex vivo* at different times after MD and measuring the ratio of converted (red) to unconverted (green) CaMPARI2 in deprived vs. control hemisphere V1m, we can quantify the time course of activity changes in neural subgroups after MD. We found that this method is sensitive enough to detect the known early drop and later rebound in deprived activity after MD. After 3 days MD, red/green ratios of excitatory, deprived neurons were significantly lower than control, but after 6 days MD, the ratios in each hemisphere were indistinguishable (MD3: $p = 1x10^{-12}$; MD6: $p = 0.83$, Mann Whitney-U test; $n > 800$ cells from 5-6 animals per condition). Interestingly, these dynamics were layer-dependent; on MD3, the median red/green ratio of deprived cells in cortical layer 2/3 (L2/3) dropped to 75% of control, in L4 the median deprived ratio was 64% of control, but in L5/6, the median deprived ratio remained at 97% of control. Thus, we can track layer and cell type-specific changes in activity after MD, and we found that the established biphasic changes in deprived activity do not occur in the same way in L5/6. These results suggest that CaMPARI2 is a valuable, high-throughput tool with which to further

dissect the cellular and molecular mechanisms regulating distinct neural dynamics after MD. This will also enable investigation of mechanisms underlying the observed wake-specific gating of the homeostatic rebound via manipulations of behavioral state-specific neuromodulators during discrete phases after MD.

Title: Visual recognition is heralded in V1 by shifts in local oscillatory activity and inhibitory networks

Authors: *D. J. HAYDEN[1], D. P. MONTGOMERY[1], S. F. COOKE[2], M. F. BEAR[1];
[1]MIT, Cambridge, MA; [2]King's Col. London, London, United Kingdom

Abstract: Filtering out familiar, irrelevant stimuli is a major step to ease the computational burden on the cerebral cortex. Inhibition is a candidate mechanism in this filtration process. Oscillations in the cortical local field potential (LFP) serve as markers of the engagement of different inhibitory neurons. In awake mice, we find pronounced changes in LFP oscillatory activity present in layer 4 of V1 with progressive stimulus familiarity. Over days of repeated stimulus presentation, low frequency (alpha/beta) power increases while high frequency (gamma) power decreases. This high frequency activity re-emerges when a novel stimulus is shown. Thus, high frequency power is a marker of novelty while low frequency power signifies familiarity. Consistent with their role in the generation of gamma oscillations, two-photon imaging of parvalbumin-expressing inhibitory neurons reveals disengagement with familiar stimuli and reactivation to novelty, whereas somatostatin-expressing inhibitory neurons respond to familiarity but disengage to novelty, indicating a contribution to the emergence of lower frequency oscillations. We also reveal that stimulus familiarity and novelty have differential effects on oscillations and cell activity over a shorter timescale of seconds. Taken together with previously published results, we propose a model in which two interneuron circuits compete to drive familiarity or novelty encoding.

Title: Integration of new skills does not perturb preexisting function in primary visual cortex

Authors: *B. B. JEON[1], S. M. CHASE[1], S. J. KUHLMAN[2];
[1]Biomed. Engin., [2]Biol. Sci., Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The ability to learn and practice new skills applies to the computation of abstract properties such as geometric form and neuroprosthetic control, as well as physical actions. We trained adult mice to successfully use an optical brain-computer interface (BCI) device so that we could assess the extent to which abstract skill learning disrupts previously acquired cortical function. We found that animals used multiple neural strategies to gain volitional control of the BCI device, and continued to do so after additional training. Despite significant engagement of local neural activity during BCI performance, tuning properties and stimulus encoding were not perturbed by new skill acquisition.Successful integration of new skills into an existing network requires balancing maintenance of perception and action with the acquisition of new function. New skill learning, whether it is perceptual, motor, or abstract, involves changes in cellular physiology that are distributed across the brain (Koralek et al., 2012; Allen et al., 2017; Neely et al., 2018; Roth et al., 2020). Locally, up to 50% of the neurons within a circuit are recruited during task-specific behaviors, and it is observed that synaptic plasticity is pervasive among the activated neurons, particularly in the early phases of training (Wang et al., 2016; Roth et al., 2020). The extent to which these widespread adaptive changes disrupt or otherwise impact existing circuit function is not known. Although addressing this issue is fundamental to understanding the biological constraints on learning, it is challenging to investigate because it requires identifying the neurons responsible for improved performance and monitoring these same neurons longitudinally throughout learning, as well as monitoring existing network function before and after new skill acquisition. We met these challenges by combining 2-photon calcium imaging with a behavioral paradigm in which mice were trained to perform a *de novo* task wherein they earned a reward by modulating the activity of a selected set of sensory neurons in a user-defined pattern. Stimulus tuning and discriminability were quantified before and after skill acquisition to assess maintenance of visual function. The use of a genetically encoded sensor, which was expressed specifically in excitatory neurons, allowed the same neurons to be tracked throughout training.These results indicate that flexible selection of neural strategies during goal-directed practice may facilitate the integration of new skills with existing function.

Title: Development of natural scene representation in primary visual cortex continues past the peak of the critical period for ocular dominance plasticity

Authors: T. FUCHS, B. JEON, ***S. J. KUHLMAN**;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: The development of the visual system is known to be shaped by early-life experience. To identify response properties that contribute to enhanced natural scene representation, we recently performed calcium imaging of excitatory neurons in the primary visual cortex (V1) of awake mice raised in three different conditions (standard-reared, dark-reared, and delayed-visual experience) and compared neuronal responses to a small set of highly similar natural scene images relative to simpler grating stimuli that varied in orientation and spatial frequency. We assessed population selectivity in V1 using decoding methods and found that natural scene discriminability increased by 75% between the ages of 4 to 6 weeks. Both natural scene and grating discriminability were higher in standard-reared animals compared to those raised in the dark. This increase in discriminability was accompanied by a reduction in the number of neurons that responded to low-spatial frequency gratings. Light exposure restricted to a 2-4 week window during adulthood did not induce improvements in natural scene nor in grating stimulus discriminability. Our results demonstrate that early visual experience enhances natural scene discriminability by directly increasing responsiveness to natural scene features (Kowalewski et al. 2020, Current Biology in press).
Notably, these results establish that natural scene discriminability continues to develop past the peak of the critical period for ocular dominance plasticity, and might not rely on the refinement of low-level feature representations. We hypothesize that natural scene representation in V1 becomes sparser with visual experience, and that visual experience continues to play a role in shaping natural scene responsiveness past the critical period for ocular dominance plasticity. To determine whether lifetime sparseness and population sparseness continue to develop past this critical period, we expanded our natural scene stimulus set to include 60 natural scenes and are currently testing whether visual experience is both required and sufficient to improve natural scene discriminability specifically during the ages of 4-6 weeks.

Title: Examining changes in spontaneous activity and functional connectivity in the human visual system following deprivation and increased use.

Authors: *L. L. FLEMING, P. DEMIRAYAK, M. DEFENDERFER, K. M. VISSCHER; Neurobio., Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: It is well known that different types of experiences, such as increased use and decreased use due to sensory deprivation, can have measurable impacts on brain structure and function. Adaptation to different types of experiences like deprivation and increased use may involve multiple, simultaneous modes of plasticity. As a result, an outstanding question in the field is how different forms of plasticity may operate in response to different types of experiences. Here, we examine experience-dependent plasticity in macular degeneration (MD), a disease that allows for the observation of the separate effects of both sensory deprivation and increased use in the adult brain. MD is characterized by retinal lesions often resulting in bilateral central vision loss. This forces individuals to rely on peripheral vision for everyday visual tasks. As such, MD serves a model for examining the relationship between experience and neural plasticity. Here, we use resting-state fMRI to measure functional outcomes of experience-dependent plasticity in MD. We focused on cortical representations of three parts of the visual field: the area of deprivation (lesion projection zone, LPZ), the area of increased use (preferred retinal locus, PRL), and a control region that remains relatively intact but is not preferentially used (un-preferred retinal locus, URL). Using resting-state data obtained during complete darkness with eyes open, we examined functional connectivity between these regions in early visual cortex and specialized regions that fall later in the visual system hierarchy. We found that the PRL region in MD patients showed greater functional connectivity to fusiform face area, a region that is selectively responsive to faces. Surprisingly, functional connectivity to middle temporal area, a region selectively responsive to motion, displayed stronger connections toward both the PRL and URL. This finding suggests that using peripheral vision for motion detection causes an increase in connectivity to peripheral regions overall. These findings are consistent with the notion that changes in functional connectivity reflect a history of repeated co-activation been brain regions (i.e. – Hebbian plasticity). Additionally, we examined the amplitude of spontaneous activity during complete darkness. Spontaneous activity in the PRL was lower in MD patients, suggesting a possible homeostatic change that results from increased daily use of that region. Together, these results provide evidence that different outcomes of neural plasticity in the human brain can be differentially impacted by different types of long-term changes in experience.

Title: Population receptive fields in human visual cortex during active vision

Authors: *J. H. FABIUS, K. MORAVKOVA, A. FRACASSO;
Univ. of Glasgow, Glasgow, United Kingdom

Abstract: To adequately localize sensory events, the brain must have an accurate representation of the receptor topography. In the visual system this is achieved with an organization that preserves the retinotopic topography of photoreceptors. However, because receptors can move with respect to other parts of the body, the mere topography of receptors is not sufficient for localization of external objects. In the case of vision, eye movements change the orientation of the entire retina with respect to the head and body. A computational solution to this problem is a modulation of response gain based on receptor orientation (e.g. based on eye position). In theory, gain fields allow for the transition from a purely retinotopic to an eye position invariant representation of visual space. Evidence for gain fields in the visual system comes primarily from neurophysiological studies with non-human primates. Still, it is not clear how and to what extent the gain field mechanism is implemented in the human visual hierarchy. Here, we measure high resolution functional MRI data while participants actively made guided eye movements. In our analysis, we first estimated population receptive fields (pRF) using data from a standard moving-bar paradigm. Next, we assessed to what extent these pRF estimates can account for the data from the eye movement paradigm. Finally, we will estimate population gain fields on top of pRFs, testing whether eye-position based gain modulation increases the explained variance of the predicted contrast-based pRF response. Moreover, we will assess how reliably eye-position can be decoded from different areas along the visual hierarchy. These results will shed new light on how receptor position modulates sensory processing in the human brain, and our methods provide a new way of access to the computational code behind that modulation, potentially accessing the large-scale organization of gain-field properties in human neocortex.

Title: Oculomotor-related measures but not distance visual acuity are predictive of reading ability in first graders

Authors: *A. PORTNOY[1], S. GILAIE-DOTAN[1,2];
[1]Optometry and Vision Sci., Bar Ilan Universty, Ramat Gan, Israel; [2]UCL, London, United Kingdom

Abstract: Vision screenings in junior schools around the globe are often limited to distance visual acuity (dVA). We hypothesize that dVA is not crucial for comfortable and efficient acquisition of effective reading skills and that a basic prerequisite for successful reading is that the ocular sensory-motor functions involved (fixation, saccades, accommodation and fusional vergences) perform in flawless harmony with effortless automaticity. Oculomotor dysfunction (OMD) is an umbrella term that includes abnormalities in comfortable and accurate control of the oculomotor system (fixation, pursuits and saccades). We speculated that OMD has a profound effect on all reading acquisition, all the more so with regard to transparent orthographies (Hebrew, Arabic). In order to assess these in the general population, we retrospectively assessed the results of an extensive optometric screening examination of an ordinary class of 28 first graders (17 boys and 11 girls) and compared them to independently obtained standardized reading evaluations (blind to the optometric results). Good or normal dVA was not indicative of reading performance (speed or accuracy), while poorer dVA was correlated with better reading speed and accuracy. As we hypothesized, performance on optometric OMD tests were predictive of reading speed and accuracy. Specifically, performance on optometric oculomotor tests (such as DEM or NSUCO) were predictive of reading test performance according to the standardized national reading norms. Our results suggest that there is a need to reevaluate which visual skills should be evaluated when assessing visual readiness in preparation for scholastic achievements such as reading acquisition. We suggest including OMD assessments and possibly other visual skills unrelated to acuity as part of a paradigm shift in the screening of vision skills in early readers. Furthermore, potential treatment protocols for those pupils struggling to acquire efficient reading skills should possibly be reassessed.

Title: Investigating perception of facial expression emotional valence at parafoveal locations

Authors: *V. AKSELEVICH[1], S. GILAIE-DOTAN[1,2];
[1]Fac. of Life Sci., Bar Ilan Univ., Ramat Gan, Israel; [2]Inst. of Cognitive Neurosci., UCL, London, United Kingdom

Abstract: Facial emotion perception is typically studied at central visual field, and peripheral investigations mainly focus on locations to the right or left of fixation. Faces, however, can appear in different locations of the visual field. Furthermore, a recent study shows that parametric investigations of visual functions at parafoveal locations can be informative about the underlying mechanisms. Thus we have examined how emotional valence and eccentricity

modulate emotion perception. A group of 28 participants kept fixation while categorizing emotional valence of face photos with positive, negative, or neutral valence. Images were presented for 200 ms at fixation or at one of 8 parafoveal locations (2°, 4°) across the visual field. Since mouth regions may provide distinctive facial expression cues, we used open-mouth photos for positive and negative valence. Eye movements were monitored. As expected, performance accuracy decreased and RT increased with growing eccentricity. Furthermore, a significant effect of emotion was found with highest performance for positive emotions and lowest for negative ones, and error analysis revealed that this was not a result of response biases towards a certain valence. An interaction between valence and eccentricity was evident by negative emotions being the most influenced by eccentricity (accuracies of 83.68% at centre decreased to 52.14% at 4°) and positive emotions the least (mean accuracy of 93.87% at centre and 76.9% at 4°). Additionally, we found that performance within-valence type (but not across-valence types) was correlated across eccentricities, suggesting that these may be supported by dissociated mechanisms. Our results suggest that perception of different types of emotional valence may have different sensitivities which peripheral vision may shed a light on.

Title: Presaccadic visual stimulus affects postsaccadic neural activity during realistic detection task

Authors: *A. D. STANKOV[1], J. TOURYAN[2], S. GORDON[3], J. KI[1], L. C. PARRA[1];
[1]City Col. of New York, New York, NY; [2]CCDC Army Res. Lab., Adelphi, MD; [3]DCS Corp., Alexandria, VA

Abstract: Little is known about visual processing during free viewing in realistic dynamic environments. Free viewing is characterized by frequent saccades, which generate large neural responses that have been linked to enhanced visual processing during the subsequent fixations. While visual input is inhibited during the saccade, we do know that the content of fixation prior to a saccade can modulate post-saccading processing. To better understand these processes in a realistic setting we study here saccades and neural responses elicited by the appearance of visual targets in a realistic virtual environment. While subjects are being driven through a 3D virtual town they were asked to detect targets that appear on the road. We found that the presence of a target elicits saccades with stronger saccade-evoked potentials at 125ms and 195ms as well as capturing potentials associated with button presses 250-750ms after the start of the saccade. Both times (125ms and 195ms post saccade) are modulated by the visibility of the target, albeit the

former being marginal in comparison to the former, suggesting that it is related to target processing and not the saccade itself. Its spatial distribution over central scalp electrodes is reminiscent of the classic P300 reorienting response. When targets appeared in peripheral vision, they elicited larger eye movements as compared to targets in central vision. However, contrary to our expectations, targets elicited similar saccade-related responses regardless of where they appeared in the visual field and resulted in similar reaction times. Together these results suggest that during natural viewing neural processing of the visual stimulus, including reorienting, starts before a saccade and continues throughout the saccade, unencumbered by saccadic inhibition.

Title: An fMRI investigation into the cortical correlates for transsaccadic perception of object orientation vs. shape

Authors: *B. BALTARETU[1], W. S. STEVENS[1], E. FREUD[1], J. CRAWFORD[2];
[2]Ctr. for Vision Res., [1]York Univ., Toronto, ON, Canada

Abstract: Recently, Dunkley et al. (*Cortex*, 2016) showed modulations in parietal cortex (i.e., supramarginal gyrus, SMG) for transsaccadic changes in object orientation. However, this result did not generalize to other features, such as spatial frequency (Baltaretu et al., *J Vis*, 2016). We hypothesized that the fundamental difference between these results was the detection of transsaccadic changes in object orientation vs. shape. To test this, we used a double-dissociation fMRI task. Participants fixated a small cross 15.4° left or right of centre, where an object was subsequently presented (rectangle, barrel-shaped, or hourglass-shaped), oriented at ±45° from vertical. After this, the fixation cross either remained in the same position (Fixation condition) or shifted to the other side (Saccade condition). Then, either the *same object* would appear at the *orthogonal orientation* (Orientation change condition) or *one of the other two objects* would appear at the *same initial orientation* (Shape change condition). Button press was used to indicate whether object orientation or shape had changed across the two stimulus presentations in a given trial. Results indicate that cortical modulations were larger for saccades (than fixations) when orientation changed in medial early occipital regions (e.g., cuneus), extending into later occipitotemporal regions. Activation for changes in object shape was larger for saccades (than

fixations) in regions similar to those for orientation changes, but were also found in medial parietal regions (e.g., precuneus and superior parietal lobule). When looking for a feature change (Orientation > Shape) specifically in cortical regions showing saccade-related (Saccade > Fixation) preferences, we found modulations within medial occipital/occipitotemporal cortex, also extending dorsally toward the parietal cortex border. These preliminary results suggest that differences in object features that occur across saccades may also appear at the cortical level (predominantly within medial occipital cortex, extending in both directions toward parietal and temporal cortex).

Title: Functional brain network of transsaccadic integration: Evidence from fMRI and graph theory analysis

Authors: *G. TOMOU[1], B.-R. BALTARETU[1], A. GHADERI[1], J. CRAWFORD[2];
[1]York Univ., Toronto, ON, Canada; [2]Ctr. for Vision Res., York Univ., North York, ON, Canada

Abstract: While the brain regions involved in transsaccadic integration have been established, the networks comprised of these regions are not well understood. We formed functional brain networks from functional magnetic resonance imaging (fMRI) data collected during a task designed to dissociate saccade activity from object feature activity and evaluated the network properties between conditions. Participants (N=17) maintained fixation on a cross either at the left or right of center for 7.5 s, after which one of three objects was presented at one of two orientations (45º clockwise or counterclockwise from vertical) in the center of the display for 3 s. Following the initial presentation period, the fixation cross either remained in the same location or was displayed at the opposing side of the center (fixation vs. saccade conditions). Subsequently, an object was once again presented at the center location for 3 s; the two objects were the either the same with the second presentation at the contrary orientation (orientation change condition), or the objects were different while the orientation remained the same (identity change condition). Participants were asked to indicate which change had occurred (orientation vs. identity). Graph theory analysis was applied to identify clustering coefficient, local efficiency, global efficiency, and small world propensity. Pairwise t-tests indicated significantly higher values for clustering coefficient, local efficiency, and global efficiency for saccades relative to fixation, suggesting enhanced segregation and integration of the identified network

during saccades. These enhanced network properties suggest increased speed of information distribution during saccades. No significant differences in these measures were found for orientation vs. identity conditions, indicating that the analyzed network specializes in transsaccadic integration and is not involved in discrimination of object orientation and identity.

Title: Ap2s1 is required for modulation of visually guided behavior in zebrafish larvae

Authors: *H. DOLL[1], A. LABORDE[2], M. ORGER[2], R. JAIN[1];
[1]Haverford Col., Haverford, PA; [2]Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Given that many neuropsychiatric conditions have a significant genetic component, investigating the underlying mechanisms of behavior selection could illuminate pathogenesis. In humans, sequence variants in *ap2s1* have been linked to cognitive disruption and autism spectrum disorder, among other conditions. *ap2s1* is a subunit of the AP-2 Complex, which is involved in clathrin-mediated endocytosis. We previously identified the gene *ap2s1* to be involved in acoustic behavior modulation through a forward genetic screen in zebrafish larvae. We also observed a strong expression pattern in components of the visual system, suggesting the gene could modulate behavior in other modalities, such as the visual system. Elucidating the role that *ap2s1* plays in visually-guided behavior will help paint a clearer picture of where and how the gene impacts complex behaviors. Here, we used motion tracking and bout-based tracking in several behavioral assays to examine visual acuity and visually-guided behaviors in *ap2s1* mutant zebrafish. Though *ap2s1* mutations enhance escape responses to acoustic stimuli, the mutants failed to perform escape responses to threatening visual stimuli. However, the mutants did respond to visual stimuli in the whole-field lighting changes and optomotor (OMR) stimuli, strongly indicating that the mutants are not completely blind. Mutants displayed altered kinematics during these assays and unexpectedly showed enhanced accuracy in responding to OMR stimuli as compared to non-mutant siblings. Overall, we found a complex and unexpected role of *ap2s1* in the visual system which could lead us to better understand the gene's role in human behavior.

Title: Cortical recycling in high-level visual cortex during childhood development

Authors: *M. NORDT[1], J. GOMEZ[2], V. NATU[1], A. A. REZAI[1], D. FINZI[1], H. KULAR[1], K. GRILL-SPECTOR[1];
[1]Stanford Univ., Stanford, CA; [2]Princeton Univ., Princeton, NJ

Abstract: Human ventral temporal cortex (VTC) contains category-selective regions that respond preferentially to ecologically-relevant categories such as faces, bodies, places, and words and are causally involved in the perception of these categories. How do these regions develop during childhood? Here we used functional MRI to measure longitudinal development of category-selectivity in VTC in individual school-age children (n=29, initial ages: 5-12 years). During fMRI participants viewed images of faces (child/adult), body parts (limbs/bodies), characters (words/numbers), objects (cars/string instruments), and places (houses/corridors) while performing an oddball task. Using data from 128 functional sessions collected over the course of 5 years, we surprisingly find both increases and decreases of category-selectivity during childhood development: From young childhood to the teens, face- and word-selective regions in VTC expand and increase in their respective category-selectivity, but limb-selective regions in VTC shrink and lose their preference for limbs (Fig 1). Critically, as a child develops, increases in their face- and word-selectivity are directly linked to decreases in limb-selectivity. These data show that during childhood limb-selectivity in VTC is repurposed into word- and face-selectivity providing the first empirical evidence for cortical recycling during childhood development. These results suggest a rethinking of prevailing hypotheses that cortical development involves sculpting of new representations upon general-purpose cortex. Instead, our results propose a new hypothesis that during development VTC representations adjust to changes in the salience and social relevance of visual inputs, which has important implications for both typical and atypical brain development.

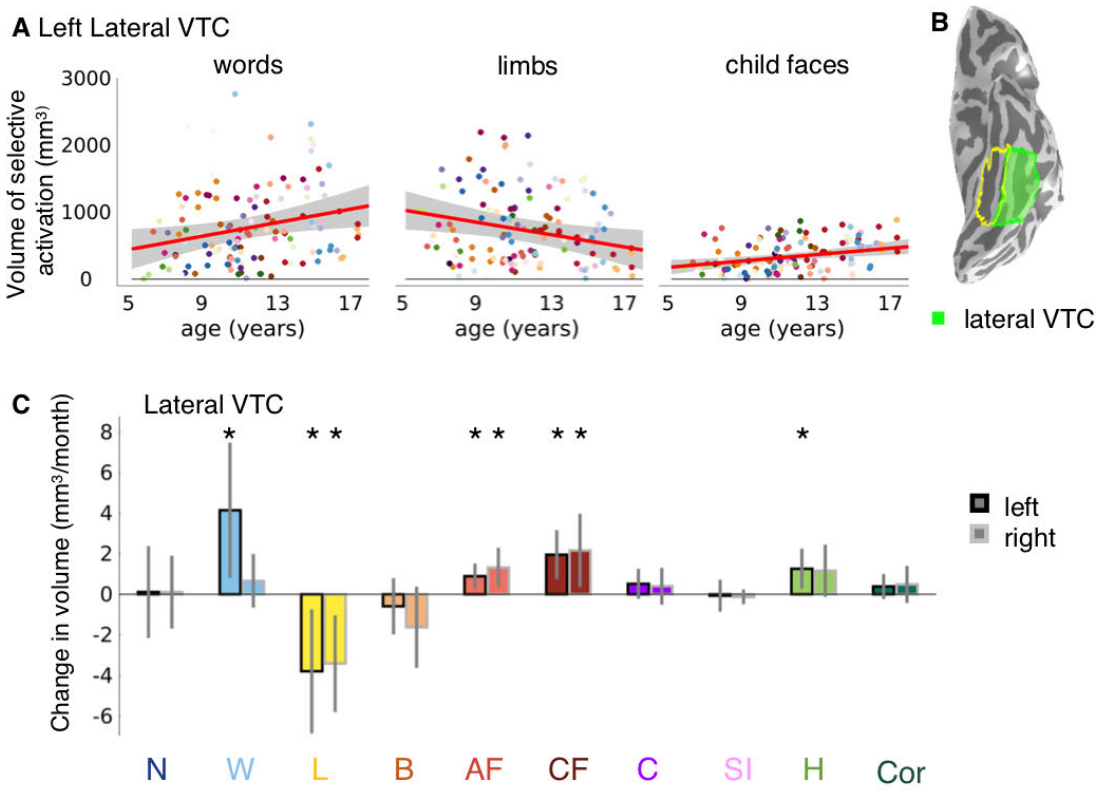

Fig 1. Developmental increases and decreases in category-selective activation in lateral VTC.

Title: Face, body and object representation in the human and canine occipito-temporal cortex

Authors: *M. BOCH[1,2], I. C. WAGNER[1], S. KARL[3], L. HUBER[3], C. LAMM[1];
[1]Dept. of Cognition, Emotion, and Methods in Psychology, Univ. of Vienna, Vienna, Austria; [2]Dept. of Cognitive Biol., Univ. of Vienna, Austria, Austria; [3]Comparative Cognition, Messerli Res. Inst., Univ. of Vet. Med. Vienna, Vienna, Austria

Abstract: A large body of research revealed neural representations for faces, bodies, and objects in the human brain over the last years. However, much less is known on how our (social) environment shapes the neural bases of face, body and object processing. The emerging field of canine neuroscience allows us to close this gap non-invasively by studying a longstanding, close companion of humans. Here, we test and compare the neural underpinnings of face, everyday objects and body processing in pet dogs (*Canis familiaris*) and humans for the first time. Fifteen dogs (11 females, 4-11 years) and 26 humans (14 females, 19-28 years) underwent MRI scanning. All dogs received extensive training; they were awake and unrestrained during MRI. Across two runs, both dogs and humans viewed faces (F) and bodies (B) of dogs and humans, everyday objects (O), and a visual control (scrambled images; S). Univariate results in dogs, revealed partially overlapping face and body sensitive caudal temporal regions compared to scrambled images (B > S; F > S), but we only found a specialized sub-region for bodies (B > F + O + S) not faces (F > B + O + S). We did not replicate previously reported differences due to species in dogs. In line with previous research, univariate results in humans replicated specialized processing regions for faces (F > B + O + S) and bodies (B > F + O + S) in occipito-temporal regions. Comparing species, human (> dog) stimuli led to increased activation in similar ventral temporal regions, vice versa (dog > human) we found increased activation in occipital regions (e.g., V1). Investigating the neural representation in dogs (representational similarity analysis: whole-brain, searchlight), the results indicated increased similarity for all object categories (F x B x O > S) in caudal and ventral temporal regions, the occipital lobe and the frontal lobe. Within these regions, we partly observed increased similarity for animate compared to non-animate objects (F x B > O). Finally, we found sub-clusters for dog (> human) bodies in a part of the specialized region for body processing along with the insula, piriform lobe and caudal temporal regions. In humans, we again replicated previous findings. In sum, our results indicate object representations and sensitivity in occipito-temporal regions of both species, while dogs seem to specialize more on bodies, not faces, different from humans. Taken

together, we provide first comparative insights into categorical object representations yielding an evolutionary perspective on how such neural representations are shaped by the environment.

Title: Self-supervised natural image reconstruction and rich semantic classification from fMRI

Authors: ***G. GAZIV**[1], R. BELIY[1], N. GRANOT[1], A. HOOGI[1], F. STRAPPINI[1], T. GOLAN[2], M. IRANI[1];

Abstract: Reconstructing seen natural images from a subject's evoked fMRI response and decoding their semantic class is a milestone towards brain-machine interfaces and for the study of consciousness. Unfortunately, acquiring sufficient (Image,fMRI) "paired" training data to span the huge space of natural images and their semantic classes is prohibitive, resulting in limited generalization power of today's decoders. We present a novel self-supervised approach that overcomes the inherent lack of training data, simultaneously for both tasks -- image reconstruction and large-scale semantic classification. Specifically, we impose cycle-consistency using two networks, Encoder (E) & Decoder (D), and train on additional "unpaired" data from the image and the fMRI domains. Concatenating those two networks back-to-back, E-D, allows for unsupervised training on unpaired images (i.e., images without any fMRI recordings) - e.g., 50,000 natural images from 1000 ImageNet semantic classes in our experiments. Such self-supervision adapts the network to the statistics of novel images and their diverse novel categories. Similarly, reversely concatenating our two networks, D-E, allows for unsupervised training on additional unpaired fMRI samples (i.e., fMRI recordings without images). Moreover, imposing high-level perceptual reconstruction criteria within the self-supervision on unpaired images results in a leap improvement over top existing methods, achieving unprecedented image-reconstruction from fMRI of never-before-seen images (evaluated by image metrics and human testing), and large-scale semantic classification (1000 diverse classes) of categories that are never-before-seen during network training (exceeding chance level accuracy by more than 100-fold). To our best knowledge, such large scale semantic classification (1000 classes) from fMRI data has never been exhibited before. We further visualize the receptive field underlying our decoder and show the emergence of classic retinotopic organization. These results support the biological plausibility of our model.

Title: Unraveling the temporal cortical dynamics of indoor scene navigation using behavioral and deep neural network models

Authors: ***M. P. BALODE**[1,2], K. DWIVEDI[2,3], G. ROIG[3], R. M. CICHY[2];
[1]Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [2]Dept. of Educ. and Psychology, Freie Univ. Berlin, Berlin, Germany; [3]Dept. of Computer Sci., Goethe Univ., Frankfurt am Main, Germany

Abstract: Humans have to process scene information rapidly in order to navigate through their immediate environment. How does the rapid cascade of neural processing elicited by viewing a scene enable navigational planning? We addressed this question by comparing human electroencephalography (EEG) responses with computational models representing distinct levels of scene processing and a behavioral model capturing navigational planning. We recorded EEG (N = 16, 7 females, mean age 28.9 ± SD 5.6) while participants viewed 50 indoor scene images and engaged in a navigational task during which they had to respond whether the exit path displayed on the screen corresponded to any of the exit paths from the previous trial (Fig. 1A). As for the computational models, we used activations from 18 deep neural networks (DNN) (Zamir, 2018) optimized for different visual tasks that were grouped into 3 categories (2D, 3D, semantic) corresponding to low-, mid- and high-level scene features, respectively. To model navigational planning we used the navigational affordance map (NAM) model (Bonner < Epstein, 2018) that was constructed from participants' responses in a behavioral task in which they had to draw possible navigational paths on the same set of images.We computed the unique variance of EEG data explained by each of the models by comparing the Representational Dissimilarity Matrices (RDMs) of EEG for every 10 ms from -200 to +800 ms relative to image onset (Fig. 1B) with RDMs of DNN (Fig. 1C) and NAM (Fig. 1D) data.The results revealed a different temporal pattern of unique variance for each of the models (Fig. 1E). Navigational affordance representations peaked significantly (t-test, FDR-corrected, $p < 0.05$) later (NAM: 326 ms) than high- (semantic: 177 ms), mid- (3D: 154 ms) and low- (2D: 126 ms) level visual representations (Fig. 1F).Taken together, our findings describe the time course with which the processing of different scene features precedes navigational affordance representations, suggesting that the processing of 2D, 3D, and semantic scene features facilitate navigation planning.

Figure 1

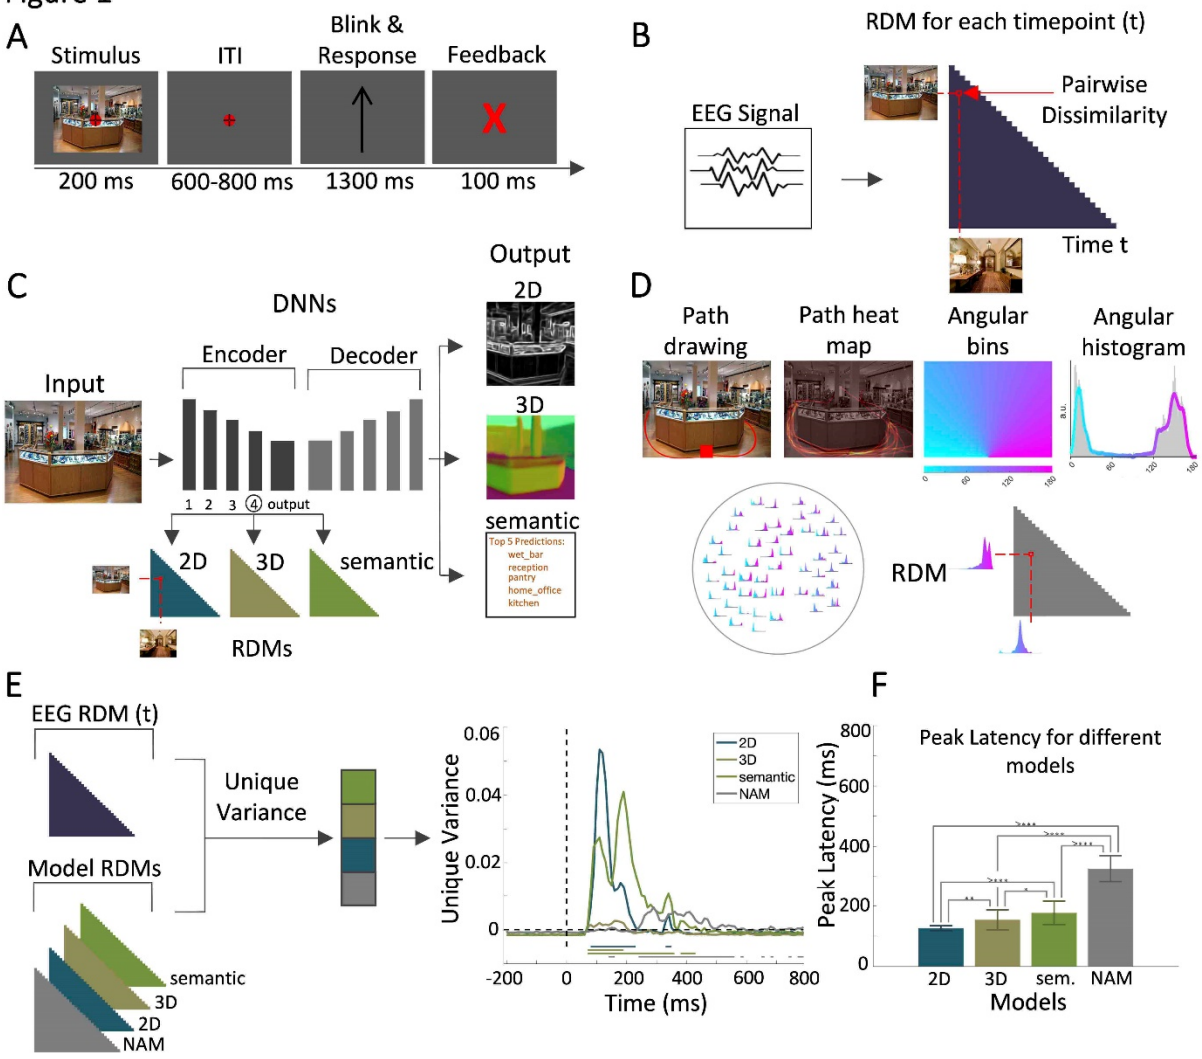

Figure 1: A) EEG paradigm. The participants viewed 50 images of indoor scenes and were asked to mentally plan possible exit paths through the scenes. After a varying number of image trials the participants had to respond whether the exit path displayed on the screen corresponded to any of the exit paths from the previous trial. **B) EEG RDMs.** We computed the RDMs for each EEG time point (every 10 ms from -200 to +800 ms with respect to image onset) using pairwise decoding accuracy. **C) DNN RDMs.** We calculated the RDMs from the 4th encoder block of 2D, 3D and semantic DNNs, corresponding to low-, mid- and high-level scene features, respectively. **D) NAM model and RDM** (Bonner and Epstein, 2018). **E) Unique Variance.** We calculated the unique EEG variance explained by each of the models revealing different temporal activation patterns. Lines below the plots indicate significant times using t-test (FDR corrected $p < 0.05$). **F) Peak latencies of different models.** 2D: 126 ms, 3D: 154 ms, semantic: 177 ms, NAM: 326 ms. Error bars indicate standard deviation for 16 subjects. Stars above bars indicate significant differences across different models (*$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, t-test FDR corrected).

Title: Robust Representation of Natural Scenes within Columns of Primary Visual Cortex

Authors: *X. CHEN[1], K. BAI[3], S. ZHU[4], R. XIA[1], N. KONG[2], S. WEINGARTNER[4], A. NORCIA[2], T. MOORE[4,1];

Abstract: The visual system is believed to have adapted to the statistical properties of the natural environment. However, the stage at which sensitivity to naturalistic structure emerges during visual processing is controversial. To address this, we recorded in macaque V1 using high-density electrode arrays (Neuropixels probes, IMEC) and investigated the neural representation of images in macaque primary visual cortex (V1) using three sets of images that varied in their higher order image statistics: natural scenes (NA), synthetic natural texture (ST) images, and phase-scrambled synthetic noise (SN) images. We measured the response from hundreds of V1 neurons across the columnar structure of V1. We first examined the sensitivity of single neurons for natural images and found that V1 neurons responded more vigorously to NA than to SN and ST images within the first 50 ms of the visual response. This sensitivity to natural image structure was robustly observed throughout all cortical layers, including neurons in the input layer 4C. We next examined the population coding of V1 neurons for natural scenes. We found that V1 neurons showed high population sparseness and high lifetime sparseness for natural scenes. Moreover, individual neurons were less synchronized with the overall population activity for images containing more natural statistical components. In addition, the neural ensembles showed higher discriminability for natural scenes. Lastly, we examined the activity patterns of an ImageNet-trained deep convolutional neural network model (DCNN) in response to the same set of stimuli. This analysis shows that higher sensitivity to natural scenes also emerges early in this feedforward artificial visual system. Taken together, these results revealed a distinct coding preference for natural images starting at the earliest stages of visual cortex. In addition to feedback modulation from higher visual cortex, these results suggest a feed forward sensitivity to natural scenes during cortical visual processing.

Title: Toward a benchmark test that selectively measures shape recognition competence

Authors: *J. W. NAM[1], A. S. RIOS[1], B. W. MEL[2,1];
[1]Neurosci. Grad. Program, [2]Biomed. Engin., USC, Los Angeles, CA

Abstract: Deep networks (DNs) trained on object recognition tasks achieve high performance on standard benchmarks, but unlike biological vision systems, which rely heavily on shape information for classification, DNs mainly depend on local color and texture features. An ongoing impediment to creating a more human-like recognition system that generalizes based on shape similarity is the lack of a benchmark that specifically tests shape recognition competence. We are developing such a benchmark, where performance is measured by ordering similarly matching scores for each object view in the database against all other object views (our database currently contains ~12,000 total views). A correct match is scored when for a given object view, the closest (eligible) matching view of the same object has a higher matching score than that of any view of any other object in the database. Task difficulty is controlled through the use of "exclusions" - the removal from contention during matching of any view of the same object that is "too similar", whether in viewpoint, contrast, or other viewing parameters. Our first task was to challenge a state-of-the-art pre-trained DN using this benchmarking approach. On a database containing only 10 objects (~600 views each), shape-matching performance of a Resnet 50 pre-trained on ImageNet was already poor under an exclusion condition involving a only a contrast reversal and a modest change in 3D viewpoint. Error rate began at 25% for contrast reversal alone, and climbed rapidly as the viewpoint exclusion increased. Our near term goal is to increase task difficulty by growing the database to 100 objects, which will significantly increase the density of distractors during matching, and to implement several more types of exclusions designed to frustrate OR systems that lack a strong internal shape representation.

Abstract: Naturalistic stimuli offer a unique opportunity to study the interaction of low level visual stimulus features and higher level features of narratives. Specifically, scene cuts in commercially produced movies are designed to guide the narrative of a story and are accompanied by strong changes in visual contrast. Here, we investigate the neural responses to scene cuts that reflect a change of camera position ('camera'), in contrast to the responses to scene cuts that are related to semantic changes in the narrative of a movie ('semantic'). We analyzed electrophysiological data from over 4400 intracranial electrodes from 19 patients with medically refractory epilepsy. The patients watched a total 53 min of short clips of commercially produced movies, ranging from animations to documentaries, while simultaneous eye tracking and intracranial EEG data was recorded. We find that a larger share of electrodes respond to 'semantic' scene cuts than to 'camera' scene cuts. While electrodes in the occipital cortex respond indiscriminately to any type of scene cuts, electrodes in the parietal, temporal and frontal cortex show more specific responses to either 'camera view' or 'semantic' scene cuts. This effect was seen in the broadband local field potential as well as in the power of particular frequencies: theta (4-7 Hz), alpha (8-14 Hz), beta (15-30 Hz) and broadband high-frequency amplitude (70-150 Hz). Additionally, we observe that both types of scene cuts elicit an increase in saccade rates. The saccade rates are not significantly different after 'camera view' or 'semantic' scene cuts. In conclusion, we find a more widespread response to scene cuts that represent semantic changes of the narrative, as compared to simple changes in camera view position. This contrast increases in higher order cortical lobes and is independent of saccades that cluster after scene cuts.

Title: Fmri adaptation and multi-voxel pattern classification support different conclusions about hippocampal pattern separation

Authors: *K. M. FERKO, A. KHAN, S. KÖHLER;
Western Univ., London, ON, Canada

Abstract: Pattern separation is a neural computation thought to underlie our ability to form distinct memories of similar events. It involves transforming overlapping inputs into less overlapping outputs. Research on pattern separation has primarily focused on transformations of

representations between entorhinal cortex and the dentate gyrus (DG) of the hippocampus. Evidence for pattern separation in human neuroimaging research has primarily come from fMRI adaptation (fMRIa) paradigms, in which repetition suppression and novelty signals are used to make inferences about pattern separation for activity in DG associated with targets and similar lures. Multivariate pattern-analysis (MVPA) techniques provide a more direct way to measure the separability of patterns of activity in DG for similar items. There is evidence suggesting that similar scenes matched for degree of novelty can be classified based on activity patterns in DG. At present it is unclear whether comparable separation can be observed for objects. Given that many extant findings obtained with fMRIa in DG have involved visual presentation of objects it is important to determine whether pattern-based analyses confirm the role of DG in pattern separation for this stimulus class. In the present study, we directly compared fMRIa and MVPA classification in combination with ultra-high resolution image acquisition. Hippocampal subfields and other medial temporal-lobe regions were segmented with ASHS, including a region that captured DG/CA3. Participants (N=23) performed a modified 1-Back paradigm with similar exemplars from multiple real-world categories (e.g, apples, flowers) that required identification of repetition at the exemplar or at the category level. fMRIa analyses of activity revealed evidence for pattern separation between objects from the same category in DG/CA3 and perirhinal cortex (PrC), a structure that has been implicated in object discrimination in many prior studies. Specifically, similar objects that followed exemplars from the same category elicited higher levels of activity (i.e. less adaptation) in both regions when compared with exact repetitions of the same objects. In contrast, MVPA classification revealed separable patterns of activity for exemplars from the same category only in PrC, but not in DG/CA3, when novelty status of exemplars was matched. In other words, fMRIa on DG/CA3 revealed evidence of the kind that is typically interpreted as pattern separation whereas MVPA did not. By contrast, in PrC findings from both methods converged. The divergence of conclusions drawn from both methods about DG in the same data question the notion that they get at the same computation.

Title: Feature-reweighted RSA: a general purpose method for increasing the fit between vision models and brain data?

Authors: *P. KANIUTH, M. N. HEBART;
Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: Representational Similarity Analysis (RSA) has emerged as a popular tool in cognitive neuroscience to compare representations of different modalities, species, and models (e.g., brains or deep neural networks, DNNs). RSA works by comparing representational dissimilarity matrices (RDM), which characterize the dissimilarity between all pairs of conditions (e.g., visual stimuli). However, classical RSA assumes that individual features of measured representations or models (e.g., brain voxels, DNN units) all contribute equally to the final similarity estimate. This is a strong assumption and contrasts with other common methods, such as multivariate decoding, that allow for a linear reweighting of individual features. Recent developments counteract this by reweighting features of DNN models for use in RSA, and indeed find improved performance (Jozwik et al., 2017; Peterson et al., 2018; Storrs et al., 2020). Here, we systematically evaluated the degree to which this feature-reweighted RSA (FR-RSA) can serve as a general purpose method for improving the sensitivity of measured representations. To this end, we used three publicly available datasets of real-world object images (84, 92, and 118 conditions, respectively), testing the correspondence between DNNs, behavior, fMRI, and MEG for MEG-fMRI fusion. For all datasets and models, we found that FR-RSA consistently increased the correspondence of pairs of RDMs, sometimes doubling the amount of shared variance. Sanity checks and the fitting algorithm's design ensured that this was not due to overfitting. RSA is commonly deployed to estimate how well different models capture how the brain represents relations between stimuli or conditions. FR-RSA could become a general purpose method that further refines this process, ultimately facilitating the selection between competing models.

Title: Behavioral state-dependent modulation of medial Lateral Posterior (LP) thalamic visual input to the Anterior Cingulate Cortex (ACC)

Authors: *Y. N. LEOW, B. ZHOU, M. SUR;
Dept. of Brain & Cognitive Sci., MIT, Cambridge, MA

Abstract: Selective attention is a critical cognitive process to adaptively highlight task-relevant stimuli while gating indiscriminate stimulus responsivity. Functional connectivity between the reciprocally connected pulvinar and frontal areas like the anterior cingulate cortex (ACC) is associated with impaired sensory filtering and over-responsiveness to stimuli. We sought to

examine how the lateral posterior (LP) thalamic nucleus, the rodent homologue of the pulvinar, may exert behavior state-dependent gating of its visual-associated input to ACC. Using two-photon calcium imaging of LP axons in ACC of head-fixed mice presented with visual stimuli, we demonstrate that visual responsiveness and feature tuning to the same stimuli are highly correlated with spontaneous fluctuations in behavioral state as well as direction of self-motion. We also find dissociable contributions of pupil-linked arousal and locomotion. As ACC simultaneously receives visual input from primary visual cortex and other higher visual areas, state-dependent gating by LP could in turn influence the visual information integrated at ACC or bias ACC-dependent top-down modulation of visual inputs.
To identify neural sources that may convey such behavioral states, we performed monosynaptic rabies tracing of brain-wide inputs to LP-ACC projections and its top-down complement, ACC-LP projections. This revealed a convergence of multi-sensory and motor input upon LP-ACC neurons, in contrast to ACC-LP neurons, which mainly receive visual and frontal inputs. In addition, the most prominent subcortical input source to LP-ACC neurons is the superior colliculus (SC) — particularly from the intermediate and deep layers which do not receive direct retinal input. With the shared involvement of ACC, LP and SC in visuomotor functions, orienting and coordinating attentional priority, LP can thus serve as one of the pathways for feedback from SC to ACC.

Title: Robust visuomotor transformations in the multi-unit activity of the monkey frontal cortex

Authors: ***S. SEO**[1], V. BHARMAURIA[1], A. SCHÜTZ[2], F. BREMMER[2], X. YAN[1], H. WANG[1], J. D. CRAWFORD[1];
[1]York Univ., Toronto, ON, Canada; [2]Philipps-Universität Marburg, Marburg, Germany

Abstract: Neurons work in coordination and form networks with each other to encode a stimulus or behavior. Therefore, there is an increasing trend toward analyzing the activity of several simultaneously recorded neurons. Multiunit activity (MU), which refers to the average firing of neurons recorded within the close proximity of a microelectrode is being increasingly studied in neuroscience as it contains accurate estimations of neural populations dynamics related to a stimulus or task [1]. Here we examined the spatial structure of simultaneously recorded MU activity from the frontal (FEF) and supplementary eye fields (SEF). We employed a cue-conflict

memory-guided saccade task (where a target-fixed landmark shifted during the delay) to record spiking activity (visual, memory, and motor) in head-unrestrained monkeys (*Macaca mulatta)*. Then, we isolated the single unit (SU) and MU [by simply rethresholding[2]] activity from the raw recorded signals. Using a model fitting approach on the SU and MU response fields (RF), along a target (T) to gaze (G) continuum, we then calculated if the MU activity contains the same information compared with the SU activity. In both areas, we found that the MU possesses similar visual-to-motor transformation as the SU activity [3,4]. Specifically, the MU visual (FEF = 88; SEF = 45) and motor (FEF = 90; SEF = 49) activities also encoded the target-in-eye (Te) and future gaze-in-eye (Ge) coordinates, respectively. Along the spatiotemporal domain that spanned the visual-memory-motor activity, we noticed a progressive transition from T to G coding. Finally, the FEF MU activity of motor neurons better predicted the gaze than SU activity ($p < 0.05$) implying the robust transformation in population signals. We conclude that: 1) neurons work in coordination for a common gaze goal, and 2) MU activity is a reliable marker of visuomotor transformations with potential for translational purposes in medical settings.

Title: Predictive integration of visual landmarks in the neural activity of the monkey frontal cortex

Authors: *V. BHARMAURIA[1], A. SCHÜTZ[2], H. WANG[1], X. YAN[1], F. BREMMER[2], J. D. CRAWFORD[1];
[1]York Univ., Toronto, ON, Canada; [2]Philipps-Universität Marburg, Marburg, Germany

Abstract: A major goal of the brain is to predict future events and it does so by constantly updating internal models of the environmental inputs, thus keeping us prepared for future action. Can the brain incorporate visual landmarks predictively in the gaze system and what are the neural underpinnings thereof? To investigate this question, we recorded the behavior and concurrent neural activity from two head unrestrained monkeys (*Macaca mullata*) in two important gaze areas, the frontal (FEF) and supplementary eye fields (SEF), during a cue-conflict delayed memory task. In this task, the cue-conflict was realized by a quasi-predictably shifting landmark (it shifted after a mask) during delay. Recently, in this task, in these two areas we documented that the landmark shift influenced the memory and motor activity [1,2]. In this study, we first analyzed the behavior and then all spatially tuned neurons recorded in the FEF (n = 147) and SEF (n=68). Due to the cue-conflict and quasi-predictable nature of the paradigm, we assumed the behavior as well as the neuronal activity to be driven by three components — 1) egocentric and allocentric memory/information, 2) prediction and 3) reward. To investigate this hypothesis, we modelled the behavior as the result of a random process based on these three components. We found that the behavior was best described by integration of all three components. We then fit neural response fields (RFs) against a target-to-gaze (T-G) continuum in eye-coordinates and tracked their evolution in the spatiotemporal domain (from visual response onset until the mask-off/landmark-on). A sudden predictive shift (before mask-on) toward gaze was noticed in the SEF but not the FEF responses. Collectively, these results along with our previous findings [1,2] suggest that in the gaze system the SEF provides control signals to the FEF for the final gaze command. First, the SEF detects the quasi-predictive information (while weighing the future reward) in its neural activity and then relays it to the FEF for incorporating the final gaze command through closely knit visual-visuomotor-motor circuitries between both areas with opposing roles.REFERENCES1.Bharmauria, V. *et al.* Spatiotemporal coding in the macaque supplementary eye fields: landmark influence in the target-to-gaze transformation. *bioRxiv* 2020.06.25.172031 (2020). doi:10.1101/2020.06.25.1720312.Bharmauria, V. *et al.* Integration of eye-centered and landmark-centered codes in frontal eye field gaze responses. *Cereb. Title: Prefrontal cortical inhibition of innate orienting responses of the superior colliculus in perceptual choice

Authors: *K. CRUZ[1], R. HUDA[2], A. SULLINS[1], M. SUR[1];
[1]Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Rutgers - New Brunswick, New Brunswick, NJ

Abstract: The natural world contains stimuli as varied and complex as the possible actions we can take to interact with them. While reflexive processes are sufficient for selecting responses to passively salient stimuli, competing environmental cues necessitate a means for selective control over perceptual choices in accordance with internal goals. While the prefrontal cortex has been broadly implicated in modulating perceptual processes, it is yet unclear how its control signals selectively drive or suppress the activity of downstream structures to obtain specific behavioral outcomes. Emerging evidence finds that one subdivision of the prefrontal cortex, the anterior cingulate cortex (ACC), plays a critical role in coordinating visually driven behaviors. Its projections to the superior colliculus (SC), a key midbrain region well known for its role in visuomotor action selection, provide a candidate pathway to investigate circuit mechanisms for the top-down modulation of goal-oriented choices. We have established a task that requires mice to move a trackball left or right to report the location of a visual cue. Using the DeepLabCut algorithm, we have identified an analogous forepaw-to-body relationship during spontaneous turning in freely moving mice and ball rotations in head-fixed mice. These findings support the validity of this task design as a model to study orienting behavior in head-fixed mice. Using this task, we previously found a role for the ACC and SC in mediating visuomotor responses to individually presented stimuli. We have now examined the relative contributions of these structures to perceptual decisions and action selection. Mice were simultaneously presented with a target and distractor cue of differing luminance, necessitating a categorical judgement and response. This behavioral design allowed us to identify the contributions of the ACC, SC, and ACC-SC projections to specific components of the resulting psychometric function. Our optogenetics results so far suggest that the SC and ACC play opposing but complementary roles in this task. We find that the SC promotes contraversive orienting in both trained and untrained mice, without affecting the likelihood of a response. While areal inactivations reveal a complex role for the ACC in several aspects of perceptual decision-making, we find that the ACC-SC projection specifically inhibits the innate function of the SC during this behavior to bias action selection in a stimulus-dependent manner. Our findings suggest that the prefrontal cortex exerts top-down inhibitory control over collicular orienting circuits to facilitate the selection of specific actions mediating perceptual choice.

Abstract: To produce timely responses, animals must conquer delays from visual processing pathway by predicting motion. Previous studies [1] revealed that predictive information of motion is encoded in spiking activities of retinal ganglion cells (RGCs) early in the visual path. In order to study the predictive properties of a retina in a more systematic manner, stimuli in the form of a stochastic moving bar are used in experiments with retinas from bull frogs in a multi-electrode system. Trajectories of the bar are produced by Ornstein-Uhlenbeck (OU) processes with different time correlations (memories) induced by a butter-worth low-pass filter with various cut-off frequencies. We then investigated the predictive properties of single RGC by calculating the time shifted (δt) mutual information (MI(x,r;δt)) between spiking output (r(t)) from RGCs and the bar trajectories (x(t)). Intuitively, the peak position of MI(δt) is typically negative when considering the processing delay of the retina. Our measured peak positions of MI(δt) for some RGCs were characterized by both positive and negative peak position under low-pass OU (LPOU) stimulus. This finding indicates that some RGCs (P-RGCs) are predictive while the others are non-predictive (NP-RGCs). For LPOU with various correlation times, the MI peaks from the P-RGCs are positively correlated with the correlation times of the stimuli while those from the NP-RGCs are always around a fixed negative number (-50ms). In order to further understand the mechanism of prediction, we develop a negative group delay model which is based on Voss's [2] paper to generate anticipative responses. We extend our model to one dimension and use the same stimulation condition as we use in experiments. The model indicates that delayed negative feedback is crucial for producing MI(x,r;δt) similar to those observed in experiments. Besides, we also show feedforward inhibition can also generate similar prediction dynamics. To sum up, we presume horizontal cells' feedback inhibition and amacrine cells' feedforward inhibition may participate in this prediction phenomenon. Reference:1. Title: Modeling facilitation and suppression of motion perception in humans in the single moving stimulus design for two possible opposite motion directions

Authors: *T. TZVETANOV[1,2];
[1]NEUROPSYPHY SASU en cours de formation, Colmar, France; [2]Sch. of Information Processing, Hefei Univ. of Technol., Hefei, China

Abstract: Human perception of a single moving pattern is related to the motion sensitive area V5. Specifically, size and contrast of the stimulus give counter intuitive results (Tadin et al., Nature, 2003, 424:321-315): at low contrast increasing size decreases the amount of stimulus presentation for correct direction discrimination, while at high contrast when increasing size people need longer presentations. It is attributed to the center-surround structure of motion sensitive neurons coding direction, contrast, and size. Models were proposed in the literature but their theoretical foundations and derivations are unsatisfactory (Tzvetanov, 2018, biorxiv-465807). Here, these foundations are clearly stated, i.e. the low-level neuronal responses coding all stimulus dimensions (direction, contrast (c), size (s), presentation time (t_{stim})) with two possible variants of excitatory/inhibitory pooling (subtractive or divisive inhibition), and the decision stage part (signal detection theory and drift-diffusion model). They are written as (Equation 1) with R_0-noise level, E()-excitatory and I()-inhibitory drives, S()-transducer, σ-constant, N()-normal distribution of unit variance, A-DDM's decision boundary height, and R^+() and R^-() the neuronal population responses with opposite preferred directions of motion. With a simple assumption (Equ.2), perceptual thresholds are derived for each case (Equ.3; $C_{decision}$-constant). The equations show that, if the mathematical functions for excitatory and inhibitory drives are the same for both low-level variants, these two variants can predict exactly the same thresholds. Thus, this experimental design cannot dissociate between the two theoretical assumptions. In addition, experimental data allow to discard some model parametrization as unrealistic. By using published functions for $E(c,s)$ and $I(c,s)$, it is demonstrated how the equations can be used to extract quantitative parameters from published psychophysics data, and how they correctly match corresponding neurophysiological reports of motion sensitive neurons.

$$(Equ.1)\begin{cases} R_{sub}(c,s,t_{stim}) = R_0 + S\Big(E(s,c,t_{stim}) - I(s,c,t_{stim})\Big) \\ R_{div}(c,s,t_{stim}) = R_0 + E(s,c,t_{stim})/\big(\sigma + I(s,c,t_{stim})\big) \\ P_{SDT}(+|c,s,t_{stim}) = \int_0^{+\infty} N\left((R^+ - R^-)\,/\left(\sqrt{Var(R^+) + Var(R^-)}\right)\right) dx \\ P_{DDM}(+|c,s,t_{stim}) = 1/\left(1 + \exp\left(-2A(R^+ - R^-)\right)\right) \end{cases}$$

$$(Equ.2)\begin{cases} R(t_{stim}) \propto t_{stim}^n/(t_{stim}^n + t_{50}^n) \\ E(s,c,t_{stim}) = R(t_{stim}) \times E(s,c) \\ I(s,c,t_{stim}) = R(t_{stim}) \times I(s,c) \end{cases}$$

$$(Equ.3)\begin{cases} \text{Subtractive inh.} : t_{stim}^{thr} = t_{50}\left(\frac{C_{Decision}}{E(c,s) - I(c,s) - C_{Decision}}\right)^{1/n} \\ \text{Divisive inh.} : t_{stim}^{thr} = t_{50}\left(\frac{\sigma C_{Decision}}{R_{exc}(c,s) - C_{Decision} R_{inh}(c,s) - \sigma C_{Decision}}\right)^{1/n} \end{cases}$$

Title: A single neuron correlate for long-range motion in ventral visual area V4

Authors: *A. BIGELOW, T. NAMIMA, T. KIM, W. BAIR, A. PASUPATHY;
Univ. of Washington, Seattle, WA

Abstract: When a stimulus jumps intermittently across the visual field with large spatial (dX) and temporal (dT) steps, it induces a strong illusory motion percept known as long-range apparent motion. However, direction selective neurons in visual cortical areas V1 and MT are strikingly insensitive to the direction of this long-range motion. Psychophysical studies have argued that long-range apparent motion perception relies not on dorsal stream areas but instead on ventral stream areas dedicated to higher-order object tracking with large windows of spatiotemporal integration. Such an object-tracking process may be critical for the perception of object motion behind occluders, commonly seen in natural vision. To test the hypothesis that ventral stream areas are involved in processing long-range motion, we studied the responses of single neurons in primate area V4, an intermediate stage in the ventral visual pathway, known to be strongly inter-connected with dorsal stream visual areas MT and LIP. Our stimulus set included Gabor (sinusoidal) and Julesz (binary white noise) patches that were intermittently displaced across the visual display (dX > 0.5 deg; dT = 100 ms) in 8 directions at 45-degree increments to induce long-range motion percepts. The Gabor stimuli were either static or included local drift in the same or opposite direction as the long-range motion signal. We found that ~30% of V4 neurons (33/115), showed tuning for long-range apparent motion using a standard direction index (DI) metric (DI $\geq$ 0.5). When a range of step sizes were tested, spanning short to long-range motion, a larger fraction of V4 neurons (35/83; ~42%) exhibit direction selectivity. Many of these neurons are surprisingly insensitive to drifting grating stimuli presented within a static aperture. In control experiments, we found that tuning for long-range motion direction was consistent across positions within a single RF and consistent between equiluminant colored bars and Julesz patches, both being second order motion stimuli. To further characterize V4 direction selectivity in terms of spatiotemporal integration, we varied dT while keeping dX constant, i.e., systematically increasing the stimulus speed. We found compelling evidence in a subset of neurons that motion direction selectivity emerges based on integration over a fixed duration of time. Our results identify the first single neuron correlate of long-range

motion in the primate visual system and they support the hypothesis of a complementary motion system in the ventral stream that relies on second-order cues and large spatiotemporal windows for tracking objects in natural vision.

Title: Visual processing circuits in a basal chordate

Authors: ***C. BORBA**[1], M. J. KOURAKIS[2], S. SCHWENNICKE[3], E. NEWMAN-SMITH[2], W. C. SMITH[1];
[1]Molecular, Cellular, and Developmental Biol., [2]Neurosci. Res. Inst., [3]Col. of Creative Studies, Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: To date, there are only two completed connectomes; the most recent one being from the tunicate Ciona tadpole larvae. The simple Ciona larval central nervous system (CNS) has a common structure with those of vertebrates, its close chordate relatives, and although it only has 177 neurons, it elicits complex behaviors. Ciona larvae have two distinct photomotor behaviors, negative phototaxis and a looming shadow response. These two behaviors are controlled by two distinct neural circuits arising from the group I and group II photoreceptors (PR-I and PR-II), respectively. The objective of this study is to further assess the minimum visual circuits predicted from the connectome with behavioral assays, mutant lines, and pharmacology. The PR-Is are glutamatergic and detect the direction of light. The PR-Is project to two groups of interconnected relay neurons (RNs): the cholinergic prRNs, which project to secondary interneurons and then to motor neurons, and to the GABAergic pr-AMG RNs. The PR-IIs are GABAergic and are responsible for detecting changes in ambient light. They project to pr-AMG RNs to evoke swimming, likely through a disinhibitory pathway. We find that the magnitude of the looming shadow and negative phototaxis responses, as measured by swim time, follows the rules of fold-change detection (FCD), rather than absolute light levels. The response to light-dimming exhibits other characteristics of FCD, including absolute adaptation, and fold-change-dependent response times. We hypothesize that all, or most, of the fold-change transformation of visual input occurs at the level of the RNs, as the interconnections between the excitatory prRN and the inhibitory pr-AMG RN appear to match known FCD circuits. The PR-I circuit forms an incoherent feedforward loop, while a nonlinear integral feedback loop is present in the PR-II circuit. As further evidence for the processing roles of these circuits, we observed that pharmacological alteration of the modulator neurons in the circuit resulted in disrupting FCD,

but not the overall response. The proposed FCD circuits are found in the posterior brain vesicle (pBV), a brain region we hypothesize has homology to the vertebrate midbrain. The Ciona pBV expresses a suite of genes associated with the vertebrate midbrain, and is situated anteriorly of a region of the brain previously hypothesized to be homologous to the vertebrate hindbrain. Functionally, the pBV appears to be similar to the vertebrate midbrain as it is the primary recipient of input from the photoreceptors. In summary, the simple Ciona larval CNS may provide insight into ancestral chordate sensory processing circuits and the evolution of the midbrain.

Title: Frontal eye field activity is correlated beyond the similarity in the response to behavior

Authors: *N. LARRY, M. JOSHUA;
Edmond & Lily Safra Ctr. for Brain Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Neuronal activity, as well as behavior, varies even when attempting to repeat the same action. These trial-by-trial fluctuations in firing rates are correlated between neurons. The fraction of correlated activity in motor areas that contributes to behavioral variability depends on the properties of the decoding of the neural state into action. We used a novel method to estimate the contribution of correlations in the frontal eye field (FEF) to pursuit eye-movements in monkeys. We applied a sequence of shuffles to the neuronal response. In the first shuffle in the sequence, we match each trial with the most behaviorally similar trial. In each step in the sequence, we loosened the constraints, allowing trials to be matched with increasingly distant trials. We then calculate the correlation between the activity of one of the neurons with the activity from a second neuron shuffled according to the behaver similarity. We found that although neurons in the FEF covaried in behaviorally similar trials, the correlations were strongly reduced when applying even the most constrained shuffle. Thus, only a small fraction of FEF correlations affect the behavior. Model simulations validate our approach, showing that our method can estimate the effect of correlations on behavior. Furthermore, our method has relatively modest assumptions and is general for different FEF model. We use the simulations to show that the reduction in correlation could be caused by downstream noise or the decoder of FEF activity.

Title: Signals from parietal area 5 to superior colliculus for coordination of gaze with strides

Authors: ***W. U. NILAWEERA**[1], I. N. BELOOZEROVA[2];
[1]Des Moines Area Community Col., Des Moines, IA; [2]Sch. of Biol. Sci., Georgia Inst. of Technol., Atlanta, GA

Abstract: The parietal cortex receives both visual and movement-related information, and is involved in the control of limb movements, including accurate steps during locomotion. The activity of parietal area 5 neurons projecting to the pyramidal tract changes when the animal steps over an obstacle (Andujar et al. 2010), and lesions in the area compromise step accuracy (Lajoie & Drew 2007). Accurate steps on a complex terrain rely on visual information about it, and gaze behavior is coordinated with strides (Matthis et al. 2018; Zubair et al. 2019). The spinal locomotor CPG plays a significant role in the coordination (Combes et al. 2008), and vestibular signals resulting from head movement during locomotion also contribute. The contribution of the brain's visual and motor centers to the coordination of the gaze with strides remains poorly understood. In this study, we investigated the activity of parietal area 5 neurons projecting to the rostral pole of the superior colliculus, the midbrain center for gaze control, as the cat walked on a flat surface and horizontally placed ladder. Walking on the flat surface does not require vision, while accurate stepping on the ladder does. Comparing neuronal activity between these two tasks allows identification of components of the activity that are related to gaze control and visual processing vs. limb movement. We investigated the activity of 30 neurons projecting to the superior colliculus (a5-SCs) and thus presumably contributing to the gaze control; the activity of 33 pyramidal tract projecting neurons (a5-PTNs), which presumably contributing to the control of limbs; and the activity of 130 unidentified neurons (noIDs), all recorded in cortical layer V of the same or neighboring microelectrode tracks through the most rostral area of the suprasylvian gyrus. We found that, as reported earlier for area 5 noIDs (Beloozerova & Sirota 2003), the activity of the majority of a5-SCs and a5-PTNs was step-related. On the flat surface, the depth of the activity modulation was higher in a5-PTNs. Upon transition to the ladder, most neurons in all groups changed one or more of: the discharge rate, depth of its modulation, stride phase distribution. The a5-SCs, however, changed the distribution of the activity much more often than the a5-PTNs, and as a group, increased the depth of the activity modulation. This indicated that the activity of a5-SCs on the ladder was significantly influenced by visual information. We concluded that a5-SC neurons may contribute to the coordination of gaze with limb locomotor

movements by conveying to the superior colliculus visual information from the cortex that is superimposed on the locomotion rhythm-related discharge.

Title: Mechanisms for integrating allocentric and egocentric information for goal-directed movements: a neural network approach

Authors: *P. ABEDI KHOOZANI[1], V. BHARMAURIA[1], A. SCHÜTZ[4], R. WILDES[1,2], D. CRAWFORD[1,3];
[1]Ctr. for Vision Res. (CVR) and Vision Sci. to Applications (VISTA), [2]Electrical and Computer Engin., [3]Departments of Psychology, Biology, Kinesiology & Hlth. Sci., York Univ., Toronto, ON, Canada; [4]Dept. of Neurophysics, Philipps-University Marburg, Marburg, Germany

Abstract: Numerous studies have shown that allocentric and egocentric information are combined for goal-directed movements toward visual targets. Specifically, behavioural studies suggested that this combination follows Bayesian integration; e.g. decreasing the stability of visual landmarks decreased the reliance on allocentric information (Byrne et al., 2010; Klinghammer et al., 2017). Additionally, neural recordings found landmark-specific coding in supplementary and frontal eye fields when monkeys performed saccades toward a remembered visual target (Schütz et al., 2020; Bharmauria et al., 2020). Nevertheless, the intrinsic coordinate representation and underlying processes for this combination remain a puzzle, mainly due to inadequacy of current theoretical models to explain data at different levels (i.e. behaviour, single neuron and distributed networks). In response, we aim to build a theoretical framework to tackle this challenge. In particular, we propose a physiologically inspired neural network with two major components. First, a Convolutional Neural Network (CNN) is used to extract the allocentric and target information: Our CNN performs repeated (2 layers) convolution, rectifications, and normalization to first extract low-level features from input images. With the features extracted, the challenge is to combine them to generate an abstract representation (allocentric cues and target position). We address this challenge by training a feature pooling layer at the end of our CNN network. Second, a Multi-Layer Perceptron network (MLP) is used to combine allocentric (extracted feature maps from the CNN) and egocentric information (initial gaze position fed to the network as an additional input): Our MLP consists of three fully connected hidden layers. These three layers incrementally transform the allocentric and egocentric representations into an integrated motor response. Finally, following the MLP, an additional layer transforms motor responses into final gaze positions. We were able to train these

physiologically inspired networks to achieve good correspondence with a test dataset (MLP: R^2 = 0.94). Additionally, the activity of hidden layer units in the MLP was similar to experimentally recorded neural response fields in monkeys (Bharmauria et al. 2020) and was modulated by varying landmark positions. These results suggest that our framework provides a suitable tool to study the underlying mechanisms of allocentric and egocentric integration.

Title: Visual feedback and attentional deficits are associated with altered visual strategy during a pinch force-steadiness task in some older adults

Authors: *B. HEINTZ WALTERS[1], W. E. HUDDLESTON[2], K. O'CONNOR[2], J. WANG[2], M. HOEGER BEMENT[3], K. G. KEENAN[2];
[1]Kinesiology, Seattle Univ., Seattle, WA; [2]Kinesiology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [3]Marquette Univ., Milwaukee, WI

Abstract: Introduction. Visual information processing and associated eye movements may play a critical role in age-related dexterous impairments, yet no comprehensive analysis to date has evaluated the effect of visual strategies and attentional capabilities on changes in manual dexterity. The purpose of this study was to determine the relations among visual strategies associated with altered visual feedback, attentional deficits, and decreased force steadiness in older adults. **Methods.** Eye movements were recorded from 21 young (age 20 - 38 years; 11 female, 10 male) and 21 older (age 65 - 90 years; 11 female, 10 male) adults during a submaximal pinch force-steadiness task while viewing force feedback with higher and lower gain and while performing a visuospatial dual task. Participant's force appeared as a line that moved left to right across the screen relative to a horizontal target line. Performance on standardized tests of attention (The Test of Everyday Attention and Trail Making Test) was also measured. **Results.** All participants gazed near the target line and used a series of saccades from left to right during the higher and lower gain conditions without the visuospatial task. Older adults made fewer saccades than young adults (23.6 ± 4.4 and 21.0 ± 2.9 saccades, respectively) and all made fewer saccades during the higher vs. lower gain conditions (23.7 ± 3.5 and 20.9 ± 4.0 saccades, respectively). Most participants used the same visual strategy when simultaneously performing the dual task though a subset of older adults (n = 7) used an altered visual strategy;

gaze did not stay near the target line and did not travel exclusively left to right. Performance on the standardized measures of attention was impaired in this subset compared to older adults who did not use the altered visual strategy. **Conclusions**. Results demonstrate that the amount of visual feedback influences visual strategy during force-steadiness tasks in older adults and reveal unique eye movement patterns in a subset of older adults when allocating attention across multiple tasks. Given that this subset demonstrated impaired performance on measures of attention, this may be a maladaptive visual strategy used by older adults performing near their attentional capacity. Future work could examine why some older adults use an altered visual strategy and whether this could serve as an indicator of motor and/or cognitive impairments in older adults and other patient populations.

Title: Evaluation of vocabulary acquisition by pupillary response

Authors: *T. HIRATA[1], K. MISHIMA[1], K. FUKAYA[1], *Y. HIRATA[2];
[1]Chubu Univ. Col. of Educ., Aichi, Japan; [2]Chubu Univ. Col. of Engin., Aichi, Japan

Abstract: Vocabulary learning is one of the most crucial elements for second language (L2) acquisition. A general method for measuring a leaner's vocabulary size and learning achievement is a form-meaning matching test. Recent studies demonstrated that pupil sizes of L2 learners change during retrieval of paired associations from Hungarian to English (Pajkossy et al, 2019). This line of evidence suggests that the pupil can be used to evaluate vocabulary comprehension of L2 learners as an alternative to general exams. Presently, we pursued this possibility by measuring pupillary responses of L2 learners when they were learning new words. Fourteen L2 learners (12 males, 2 females) with normal or corrected vision participated in this study. Their first and second languages were Japanese and English, respectively. We selected 30 English nouns whose meanings were unknown and Japanese meanings can be written with two Japanese words. The experiment consisted of 3 parts: before (Control), during (Study), and after learning (Test) that were repeated 5 times. In Control trials, the 30 English words were presented for 3 sec in a random order on a PC monitor. Participants were asked to look at the word without blinking. A 3-sec gap was given between successive word presentations during which blinking was allowed. In Study trials, each of the 30 Japanese words was presented in random order for 3 sec, followed by the corresponding English word for 3 sec. Participants were instructed to memorize

the Japanese meaning of the English word. A 3-sec gap was given between Japanese and English word presentations. In Test trials, the 30 English words were randomly presented for 3 sec during which participants tried to retrieve their Japanese meanings. After this period, they answered verbally. A 5-sec gap was given between successive word presentations. We measured participants' pupil diameters using EyeSeeCam (EyeSeeTech, Germany) at a sampling rate of 220 Hz while English or Japanese words were presented for 3 sec in all the three parts. The results demonstrate that significantly greater pupil dilation was observed while participants viewed the English words they were failed to remember than those successfully remembered in both the Study and Test phases. Interestingly, in Control trials, greater dilation responses were observed while the participants were seeing the English words whose meanings they acquired with less repetition (< 2 times) than for those that took more repetition (> 4 times) to learn, before even knowing their Japanese meanings. These results support the idea that quantitative evaluation of pupillary responses may provide useful information on L2 learners vocabulary comprehension.

Title: Internally and externally driven oscillations in anterior cingulate, amygdala and cerebellum during acquisition of trace eyeblink conditioning in rats

Authors: *H. E. HALVERSON, J. KIM, J. H. FREEMAN;
Dept. of Psychological and Brain Sciences, Iowa Neurosci. Inst., Univ. of Iowa, Iowa City, IA

Abstract: Eyeblink conditioning is a simple form of associative learning where a conditioned stimulus (CS), e.g., a tone) is repeatedly paired with an unconditioned stimulus (US, e.g., a periorbital shock) to yield a cerebellum-dependent conditioned response. Cerebellar learning during trace eyeblink conditioning, when there is a temporal gap between the CS and US, requires mossy input from the CS and persistent mossy fiber input from the forebrain. The amygdala has also been shown to modulate cerebellar learning during eyeblink conditioning, through modulating mossy fiber inputs necessary for learning. The necessity of the serial circuit from forebrain to cerebellum for acquisition and expression of trace eyeblink conditioned responses has been well-established, however, dynamic network-based interactions with this serial circuit during learning have not been investigated. The current experiment used simultaneous tetrode recordings in anterior cingulate (right), amygdala (right) and anterior interpositus nucleus (left) during acquisition of trace eyeblink conditioning (250 ms tone/500 ms

trace interval) to investigate the evolution of dynamic interactions among these necessary structures during forebrain dependent cerebellar learning. Spectral analysis revealed changes in externally (CS/US) and internally (conditioned response) driven oscillations during the learning process. When aligned to external events (CS onset), spectral power increased across multiple frequencies during acquisition. Aligning oscillations to conditioned response onset revealed a large increase in power across multiple frequencies in parallel to the increase in behavioral responding across sessions. Aligning oscillations to the US also suggests a dynamic interaction throughout the learning process. These results suggest network based interactions in oscillatory activity may be facilitating the serial circuit from forebrain to cerebellum necessary for trace conditioning.

Title: Distributed memory consolidation of vestibulo-ocular reflex gains acquired by a frequency competitive visual-vestibular mismatch paradigm

Authors: T. IKEDA[1], *R. BAKER[2], Y. HIRATA[1];
[1]Robotic Sci. and Technol., Chubu Univ. Grad. Sch. of Engin., Kasugai, Japan; [2]Neurosci., New York Univ. Langone Med. Ctr., New York, NY

Abstract: The vestibulo-ocular reflex (VOR) stabilizes our vision during head movements by counter-rotating the eyes in the orbit. It has been a popular model system to study cerebellar roles in motor control and learning. VOR gain, defined as eye velocity divided by head velocity in the dark, can be modified by applying a visual-vestibular mismatch paradigm in which head and visual pattern stimulations are rotated at the same frequency in either the same (gain-down) or opposite (gain-up) directions. In both cats (Kassardjian et al., 2005) and monkeys (Anzai et al., 2010) it has been shown that after a short-term (<2 hours) VOR gain-down training the modified memory is temporally stored in the cerebellum and long-term (>3 days) training is consolidated in the vestibular nucleus. By using short-term frequency competitive visual-vestibular mismatch paradigms in which head and visual pattern rotations were presented in-phase at one frequency and anti-phase at the other it was demonstrated in both monkeys (Hirata et al., 2002) and goldfish (Soga et al., 2020) that VOR gains could be modified in opposite directions. Computationally, this form of motor memory requires frequency dependent nonlinear signal transformations that are possible in the cerebellar cortical neural network (Inagaki and Hirata, 2017), but such consolidation for long-term memory might not occur in the vestibular

nucleus with an elementary network structure than the cerebellum. Herein, we explored long-term memory of oppositely modified VOR gains by training 12 goldfish for 2 hours a day successively for 7 days with a frequency competitive paradigm of gain-up at 0.5Hz and gain-down at 0.1Hz. We found that most of the VOR gains at both frequencies were modified after 2-hour daily trainings, but were lost by the next day; however, fractions remained and accumulated gradually for 7 days resulting in significant simultaneous gain-up at 0.5Hz and gain-down at 0.1Hz. We conducted cerebellectomy on day-7 after 2-hour daily training in 6 animals, and found the increased gain-up at 0.5Hz to decrease back to the daily pre-training value. The modified gain-down increase at 0.1Hz was not only lost, but also it exceeded the daily pre-training and day-1 values settling close to the cerebellectomized gain-up at 0.5Hz. These results indicate that long-term memory of frequency competitive VOR motor learning can be consolidated with the increased VOR gain stored outside, and that decreased stored within, the cerebellum. Thus, the gain-down changes are actually much larger because they need to counteract the gain-up shift stored outside of the cerebellum.

Title: Heterogeneous neural correlates of short-term oculomotor learning in cerebellar Purkinje cells

Authors: *A. KIRJNER[1], B. J. BHASIN[2], J. L. RAYMOND[3];
[1]Dept. of Statistics, [2]Dept. of Bioengineering, Stanford Univ., Stanford, CA; [3]Dept. of Neurobio., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The oculomotor cerebellum provides a powerful system for analyzing how information processing in a neural circuit changes over the course of learning. During adaptive calibration of the gain of the vestibulo-ocular reflex (VOR), observed changes in the response of Purkinje cells in the cerebellar flocculus are thought to contribute to the learned increase or decrease in the eye movement response to a vestibular stimulus. Such changes have generally been studied over the course of hours to days, yet more recent work has shown that this neural correlate of learning may be observed over time scales as short as a single trial. We analyzed the changes in Purkinje cell responses in two rhesus monkeys during brief training periods of 60-90 seconds, focusing on the horizontal gaze velocity Purkinje cells (HGVPs), which have previously been implicated in VOR learning. 45 Purkinje cells were characterized as HGVPs based on their

responses during sinusoidal smooth pursuit and VOR cancellation: these cells increased their firing rate during smooth pursuit when the eyes moved ipsiversively and the head remained fixed, and during VOR cancellation when the head moved ipsiversively while the eyes remained nearly stationary on a target that moved with the head. To induce learning, vestibular stimuli consisting of pulses of rapid acceleration of the head to a constant velocity were paired with a visual stimulus that moved exactly with the head (VOR-decrease training) or exactly opposite the head (VOR-increase training). We analyzed spiking during the first 100 ms after the onset of acceleration in each trial, the period before visual feedback influences the eye movement response. We found unexpected heterogeneity in the baseline (pre-learning) responses of the HGVPs, with some cells increasing their firing and others decreasing their firing in response to the same visual-vestibular training stimulus. This suggests that there are subclasses of Purkinje cells with different signal content within the classically defined population of HGVPs, whose responses are not well-captured by the standard classification method. Additionally, cells that exhibited different baseline responses to a visual-vestibular training stimulus showed different learned changes in this response over the course of 60-90 sec of training. Contrary to the hypothesis that HGVP cells contribute to oculomotor performance and learning in a uniform fashion, our results suggest that HGVP cells carry different signals within the VOR circuit, as individual cells systematically respond differently even under the same training conditions.

Title: Assessment of functional benefits afforded by a sensory-enabled prosthesis to an individual with upper-limb amputation

Authors: A. SHELL[1], D. AGUILAR[1], B. HILLEN[1], L. RINCON GONZALEZ[1], J. J. ABBAS[2], *R. JUNG[1];
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Ctr. for Adaptive Neural Systems, Arizona State Univ., Tempe, AZ

Abstract: Commercially-available prostheses are limited in their ability to provide users with direct sensory feedback, which results in increased demands on vision to perform daily tasks and poor embodiment of the prosthesis. To address these limitations, we have developed the Neural Enabled Prosthetic Hand (NEPH) system to provide task-relevant sensations to upper-limb prosthesis users. The system delivers stimulation via implanted electrodes/electronics that are wirelessly controlled by prosthesis-mounted sensors and electronics. With sensory feedback,

users may be afforded the benefit of graded control to confidently perform daily functional tasks and an improved ability to manipulate objects with reduced attentional demands. The first subject enrolled in the first-in-human clinical trial of the NEPH system (NCT 03432325) underwent surgery to install the implanted components, was fit with the external components, has undergone a series of tests, and has been using the system in real-world environments for more than two years. We used the Southampton Hand Assessment Procedure (SHAP) to compare the subject's performance of functional tasks under conditions with and without stimulation. The SHAP consists of three categories of functional tasks: 6 lightweight object grasping tasks, 6 heavyweight object grasping tasks and 14 activities of daily living (ADL) tasks. A self-timed assessment was conducted in which the subject performed each task using the NEPH system; once with stimulation-induced sensory-feedback and once without at three time points in the period of 18 months post-surgery. One ADL task (cutting while holding the knife with the prosthesis) was found to be extremely difficult for the subject to complete and was excluded from all statistical analyses. To assess the effects of stimulation on each day, we used a paired t-test on the completion times for each task. To investigate the effects within each task group and time post-surgery, we used a two-way repeated measures ANOVA with time (session number) and stimulation condition as factors. Results indicated that, across the full set of tasks, completion times were statistically lower with stimulation than without stimulation in the session at 18 months ($p=0.012$). Additionally, for the set of lightweight objects, performance was marginally improved ($p = 0.076$) with sensation, and performance marginally improved over the study time period ($p = 0.057$). These results suggest that the SHAP can be used to evaluate the benefits of sensory feedback to prosthesis users, however further investigation with more subjects is required to determine the true benefits afforded by a sensory-enabled prosthesis.

Title: Combination training and latching filter improve activities of daily living and user experience with a bionic arm

Authors: *M. PASKETT[1,2], M. R. BRINTON[5,1], T. C. HANSEN[1], J. A. GEORGE[1,2,3], T. S. DAVIS[4], C. C. DUNCAN[3], G. A. CLARK[1];

Abstract: This work compares continuous bionic arm control using performance-based and user-focused outcomes in real-world tasks. Advanced prostheses can restore function and improve quality of life for individuals with amputations. Unfortunately, most commercial control strategies do not fully utilize the rich control information from residual nerves and musculature. Continuous decoders can provide more intuitive prosthesis control from multi-channel neural or electromyographic recordings. Three components influence continuous decoder performance: the data used to train the algorithm, the algorithm, and smoothing filters on the algorithm's output. As individual groups often focus on a single decoder, very few studies compare different decoders using otherwise similar experimental conditions. Additionally, control improvements are often demonstrated with offline data or in virtual settings, which do not necessarily translate to real-world usage.

We completed a two-phase head-to-head comparison of 12 continuous decoders using activities of daily living. In phase one, we compared two training types and a smoothing filter with three algorithms (modified Kalman filter, multi-layer perceptron, and convolutional neural network) in a clothespin relocation task. We compared training types that included data with only individual digit and wrist movements vs. combination movements (e.g., simultaneous grasp and wrist flexion). We also compared raw vs. nonlinearly smoothed algorithm outputs. In phase two, we compared the three algorithms in fragile egg, zipping, pouring, and folding tasks using the combination training and smoothing found most beneficial in phase one. In both phases, we collected objective, performance-based (e.g., success rate) and subjective, user-focused (e.g., preference) measures.

Phase one showed that combination training improved prosthesis control accuracy and speed, and that the nonlinear smoothing improved accuracy but generally reduced speed. In phase two, user-focused metrics favored the convolutional neural network and modified Kalman filter, whereas performance-based metrics were generally similar among all algorithms.

These results confirm that state-of-the-art algorithms, whether linear or nonlinear in nature, functionally benefit from training on more complex data, and demonstrate that smoothing the output improves control. These studies will be used to select a decoder for a long-term take-home trial with implanted neuromyoelectric devices. Overall, clinical considerations may favor the mKF as it is similar in performance, faster to train, and computationally less expensive than neural networks.

Title: A Self-Aware Bionic Hand that Autonomously Detects Nearby Objects and Dexterously Grasps Them with Minimal Force

Authors: *T. C. HANSEN[1], J. L. SEGIL[3], R. PATEL[4], R. F. F. WEIR[5], D. J. WARREN[1], J. A. GEORGE[2];
[1]Dept. of Biomed. Engin., [2]Div. of Physical Med. and Rehabil., Univ. of Utah, Salt Lake City, UT; [3]Biomed. Engin. Program, [4]Dept. of Computer Sci., Univ. of Colorado, Boulder, CO; [5]Dept. of Bioengineering, Univ. of Colorado Denver | Anschutz Med. Campus, Aurora, CO

Abstract: Multiarticulate bionic hands are now capable of recreating the endogenous movements and grip patterns of the human hand. However, it is difficult to intuitively control the many degrees of freedom associated with these bionic hands, and up to half of upper-limb amputees abandon their prostheses due to limited and/or unintuitive control. One approach towards more dexterous and intuitive control is to create an autonomous self-aware bionic hand that can synergistically aid a human with complex tasks. To that end, we have developed a bionic hand that can automatically detect and grasp nearby objects with minimal force. We embedded four digits (D1 - D4) of the TASKA Hand (TASKA Prosthetics, Christchurch, New Zealand) with infrared and pressure sensors. The infrared sensors can detect objects within 5 cm and the pressure sensors can detect up to 50 N. Each digit is self-aware such that each digit independently and autonomously maximizes non-zero infrared intensity (i.e. proximity) while minimizing non-zero pressure. The ability to grasp nearby objects with minimal force uniquely enables the self-aware hand to autonomously complete dexterous tasks such as holding a fragile object. We evaluated performance using a fragile egg task in which the hand must transfer a 43.7 g object over a barrier while keeping compression forces below 6.7 ± 0.1 N (mean ± standard deviation). A healthy intact arm participant completed the task with 100% accuracy (no breaks) in 0.83 ± 0.11 s. The self-aware bionic hand was able to complete the task with 100% accuracy within 3.40 ± 0.17 s. In contrast, a naïve intact participant controlling the bionic arm with a state-of-the-art surface electromyographic (sEMG) control algorithm (Paskett et al., SfN Global Connectome 2021) was unable to complete the task (0% accuracy) and spent a significantly longer time attempting the task (11.67 ± 11.26 s; $p < 0.05$).The embedded sensors provide unique insight into the differences between human sEMG and machine control. There were no significant differences in the time taken to approach the object (human: 0.93 ± 1.43 s, machine: 1.66 ± 0.13 s; $p = 0.12$), but the machine applied significantly less pressure to the object (human:

~15.33 ± 7.36 mbar, machine: ~3.55 ± 0.50 mbar; $p < 0.0001$). For both metrics, the machine was also significantly more precise (smaller variance; $p < 0.0001$). These preliminary results suggest that self-aware bionic hands can operate at near-human speed with greater-than-human sEMG accuracy and precision. Future work involves sharing control between the human and the computer; we anticipate there will be an optimal level of shared control to maximize performance while still maintaining human autonomy.

Title: Optimizing and decoding limb stiffness for reaching with functional electrical stimulation

Authors: *T. JOHNSON[1,2,3], S. MORALLE[1], D. M. TAYLOR[1,2,3];
[1]Cleveland Clin., Cleveland, OH; [2]VA Northeast Ohio Healthcare Syst., Cleveland, OH; [3]Case Western Reserve Univ., Cleveland, OH

Abstract: Functional Electrical Stimulation (FES) uses electrical stimulation to reanimate muscles that have been otherwise disconnected from the brain through injury or disease. This technology, when utilized in the upper limbs, gives paralyzed individuals the potential to perform reaching tasks which can significantly improve their independence and quality of life. During normal arm movements, people actively modulate the amount of 'cocontraction' or the degree to which opposing muscles are simultaneously active. Increasing cocontraction helps stiffen our limbs and makes them more resistant to external perturbations while decreasing cocontraction minimizes energy use and facilitates rapid movements. Optimizing the degree of cocontraction is particularly important when restoring arm function via FES because excess cocontraction can lead to muscle fatigue and faster battery drain. Conversely, too little cocontraction can lead to poorly controlled movements that are prone to perturbations from the environment. Our goal is to optimize ways to dynamically modulate cocontraction when controlling arm movements via FES. To that end we are using simulations of a virtual arm model where we can easily compare the pros and cons of various methods. Our current work demonstrates how an automated method of adjusting cocontraction based on decoded velocity and acceleration can improve arm control while balancing the need to conserve power and avoid fatigue.

Title: Control task cognitive load during continuous EEG neuro-robotic use affects cortical fatigue

Authors: *D. SUMA[1], J. MENG[1], B. J. EDELMAN[2], B. HE[1];
[1]Biomed. Engin., Carnegie Mellon Univ., Pittsburgh, PA; [2]Dept. of Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: During our recent experimentation demonstrating continuous noninvasive electroencephalographic (EEG) brain computer interfacing (BCI) of both the one and two

dimensional control of virtual cursors and neuro-robotic arms, we observed distinct behavioral responses to the introduction of a physical device. To better understand the dynamics of and improve continuous noninvasive control, we investigated the interactions between task complexity, spatial and temporal cursor-target interactions and the indirect effects of the introduction of a physical interface within an extended human subject population using both multi-level ANOVAs and ANCOVAs. Nine healthy human subjects participated in five sessions of one-dimensional (1D) horizontal (LR), vertical (UD) and two-dimensional (2D) continuous neural tracking utilizing EEG. Here, subjects controlled either a robotic arm or a virtual cursor to continuously track a Gaussian random motion target via kinesthetic hand motor imagery (MI) induced sensorimotor rhythm modulation. Control signals were estimated via online source imaging of each subject's cortical activation using high density (128 Channel) EEG and subject specific regions and frequencies of interest. Sessions consisted of 24, one minute continuous tracking tasks, broken down into a variable number of LR, UD, and 2D tasks, split evenly and block-wise randomized across interface (robotic arm or virtual cursor). Within trial fatigue rates were estimated via the slope of the mean-squared error (MSE) corresponding to three 20 second non-overlapping windows. These fatigue rates were found to be lower for control tasks with lower cognitive demand (UD, both hands MI and rest) compared to those with higher cognitive demand (LR, left- and right-hand MI). Spatial error analysis emphasizing target location, cursor location and error direction revealed that a reduction in tracking quality during robotic arm use was contingent upon visual obfuscation of the target by the physical device. In fact, robotic arm performance was significantly superior to virtual cursor control when the users' visual field was unobstructed. These results emphasize the need to take into account the physical footprint of devices, training complexity, and the synergy within control strategies when designing interfaces for practical real-world control.

Title: Decoding of eye movement trajectory by neuronal ensembles in cerebral cortex

Authors: B. LIU[1], *J. MAYO[2];
[1]Neurobio., Duke Univ., Durham, NC; [2]Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The vast majority of BMI (brain-machine interface) research has focused on decoding arm movement signals in primary motor cortex to control external prosthetic devices. Despite recent progress in BMIs, questions remain about the recorded cortical signals and how best to translate them into movements. The eye has fewer degrees of freedom so, in principle, it should be easier to develop a BMI for dynamic motor control using neural signals from oculomotor or possibly visual cortex. Here, we investigate the plausibility of an oculomotor BMI by analyzing

the relationship between cortical activity and eye movement trajectories in behaving macaques. We recorded ensemble neuronal activity in the frontal eye fields (FEF) in prefrontal cortex and visual area MT via laminar probes while a male monkey tracked moving visual targets. Using multiple decoding algorithms as well as modern neural network methods, we show that eye movements can be accurately decoded with relatively high precision. In an example session with 69 simultaneously recorded neurons (45 FEF; 24 MT), a neural-network decoder accounted for 87% variance of eye position over time (correlation coefficient between decoded trajectories and data is 0.94, $p<0.001$), with an average position error of 0.84 degrees. The reconstructed eye motion trajectories were successfully reproduced on 84% of the trials with an error constraint of 6 degrees (compared to 3 degrees in behavior). Our results demonstrate the feasibility of a gaze BMI, identify an adequate cortical substrate for its implementation, and supply a novel framework for investigating questions in oculomotor control.

Title: A Multimodal Neuroprosthesis: combining virtual reality and neurostimulation for treating sensory neuropathies

Authors: *G. VALLE, G. PREATONI, L. CHEE, S. RASPOPOVIC;
ETH Zurich, Zurich, Switzerland

Abstract: Because of sensory loss diabetic peripheral neuropathy (DPN) patients are prone to falls, incorrect balance/walking and consequent foot ulcers, which increase the risk of amputations. They also suffer neuropathic pain (pDPN), associable to the aberrant sensory inputs. The most urgent need for people with diabetic neuropathy is the recovery of correct sensations from the leg/foot and its proper brain integration, with consequent gait/balance amelioration and pain suppression. The aim of the study was to develop the first multimodal neuroprosthesis restoring close-to-natural foot sensations, through transcutaneous electrical nerve stimulation (TENS) and combining it with immersive visual digital technology delivered to the brain through the virtual reality (VR). We tested whether coherent multisensory visual-tactile neural stimulation (VTNS) would positively impact on gait, balance and pain of patients with the pDPN. Physiologically plausible stimulation targeting lower-limb nerve holds promise to restore sensory feedback that will improve balance and walking, and decrease periphery-induced pain. VR-based integration of a realistic foot representation will ameliorate the balance/walking and help in CNS-based component of pain. Combined, they should constitute the multimodal neuroprosthesis improving the overall origins of pPDN. It has never been proved

that the electrical stimulation of the lower limb diabetic nerve by arrays of the multi-pad electrodes could induce stable and reliable sensations from a diabetic foot with reduced sensitivity. Portable VR-based approach has been exploited in the pain and walking treatment of pDPN patients. Finally, experiments are performed to prove that this multimodal neurotechnology would trigger beneficial effects in the pDPN population. Virtual reality system was implemented and programmed with modes for the pain suppression and gait/balance training. The system was successfully tested with subjects suffering the pDPN. Our study showed: i) an effective device to achieve therapeutic and quality of life benefits for highly disabled pDPN subjects, who are currently affected by important functional and psychological problems ii) to augment the overall knowledge about the use of electrical stimulation and VR on in pDPN, iii) an assessment tool and rationale for the future extensive clinical study.

Title: Viral targeting of inhibitory interneurons in the spinal cord of wild type rats using the mDlx promotor

Authors: *J. KAUR, R. BERG;
Neurosci., Univ. of Copenhagen, Copenhagen, Denmark

Abstract: So far, genetic targeting of inhibitory interneurons has primarily been viable in transgenic animals. In recent years, viral approaches have been extensively utilized to transport transgenes into the neurons. Moreover, they can infect various cell types in the nervous system and act as a versatile tool to avoid breeding expensive transgenic animals which are available for small number of species. It would be beneficial to have a promotor that targeting inhibitory interneurons in the wild-type animals. In fact, such a promotor, called mDlx, has been developed and tested in the forebrain. Nevertheless, it was not tested in the adult spinal cord, and so far, specificity is unknown for the spinal interneurons in the adult mammalian system. Here, we used the adeno associated virus (AAV) with mDlx promotor with green fluorescent protein (GFP) reporter to target inhibitory neurons in the lumbar spinal region of adult wild- type rats. Laminectomy was performed and the virus was injected with a glass capillary (with a fine tip) at the lumbar spinal region. 3-4 weeks later, the virus expression was investigated by perfusing the rats with paraformaldehyde and sectioning the spinal cords. The sectioned cords were immediately inspected under the fluorescent microscope to verify the expression of GFP. Immunohistochemistry was performed to test the specificity of the virus to inhibitory interneurons. We found that the mDlx enhancer primarily targeted GAD-65 expressing neurons

in the dorsal, central and ventral region of the adult spinal cord whereas very few if any GAD-67 neurons, which are abundant in laminae I-III were infected by mDlx. To contrast the expression of inhibitory neurons using mDlx enhancer, we also used AAV virus with CamKIIa promotor to infect excitatory and hSynapsin to target all the neurons in the adult lumbar spinal cord. We noticed that cells infected with the CamKIIa enhancer has shown colocalization with some GluA1 and VGluT1 neurons, indicating glutamatergic neurons whereas, hSynapsin has shown to target 90% neurons in the dorsal and about 95% neurons in the central and ventral spinal regions. Our targeting of specific inhibitory interneurons in the adult spinal cord of wild-type rats demonstrates the potential of using a viral strategy with mDlx promotor in the mammalian sensory-motor system.

Abstract: Internal-switches of a central pattern generator for scratching in the cat
Gutiérrez-Ojeda J, Hernández LF, De la Torre Valdovinos B, Huidobro N, Manjarrez E
Instituto de Fisiología, Benemérita Universidad Autónoma de Puebla, México
The spinal neurons exhibit an ON-OFF and OFF-ON firing activity related to the central pattern generator (Cuellar et al., 2018, Front Cell Neurosci 12:68). However, this activity was only examined around the "postural stage" of fictive scratching, disregarding the firing behavior during and at the end of the scratching episodes. Here we extended such observations to include the analysis of the whole episodes. The experiments were performed in two decerebrate cats, following the National Institutes of Health Guide for the Care and Use of Laboratory Animals (85–23) and the Mexican regulations (NOM-062-ZOO-1999). We recorded the multiunit neuronal activity from the lumbar dorsal horn and the intermediate nucleus, as well as the electroneurographic activity from the flexor and extensor nerves. A spike sorting software was employed to select the unitary spikes from 743 neurons. The scratching episodes were divided into three stages: "before," "during," and "after." We found the following firing patterns associated with the whole scratching episodes at those stages: 1) ON-OFF-ON, 2) OFF-ON-OFF, 3) ONstart-OFF-ONend, 4) OFFstart-ON-OFFend, 5) ON-OFF-OFF, and 6) OFF-OFF-ON. Because these patterns resemble "switches" or "gates" turning ON or OFF the flow of firing

electrical activity, we suggest that they could be useful to develop new models of neural computation for the central pattern generator.

Title: Dorsal root site activated by nmda triggers limb pattern generators

Authors: *J. T. HACKETT;
Univ. of Virginia, Charlottesville, VA

Abstract: It is well established that the spinal cord contains the neuronal circuit for rhythmic locomotion, and application of NMDA can trigger this circuit. The site of action of NMDA remains to be established. In search for this site, we discovered that NMDA acts quickest and at lowest concentration if applied to the spinal dorsal roots. This finding may have clinical significance, because it allows for the application of agents to promote locomotion outside the CNS.

Title: Rhythmic movement by spinal motor networks is governed by rotational population dynamics

Authors: *R. W. BERG[1], P. C. PETERSEN[3], M. VESTERGAARD[4], H. LINDÉN[2];
[1]Dept. of neuroscience, Univ. of Copenhagen, Copenhagen, Denmark; [2]Dept. of neuroscience, Univ. of Copenhagen, KBH N, Denmark; [3]Neurosci. Inst., NYU Langone, New York Univ., New York, NY; [4]Dept. of Neurosci., Max-Delbrück Ctr. for Mol. Med. in the Helmholtz Assn. (MDC), Berlin, Germany

Abstract: While the orchestration of movements is accomplished by motor cortex and the brainstem, networks in the spinal cord are responsible for the detailed muscle commands,

including the generation of rhythmic movements such as locomotion. Although spinal neurons are well characterized at the cellular level, the mechanisms underlying rhythmic generation is largely unknown. It is known that the motor cortex exhibits rotational dynamics associated with movement (Churchland et al, 2012), i.e. the neural populations follow a rotating trajectory through their state space, but it is unknown whether the spinal cord has similar dynamics. To investigate this issue, we analyzed simultaneous multi-electrode recordings from the spinal cord of hundreds of neurons and discovered similar low-dimensional rotational dynamics characterized by a wide phase distribution in relation to the muscle activation. This is in opposition to alternation, which is predicted by the half-center theory (figure). To further appreciate how such slow population dynamics can yield rotational dynamics in the spinal cord, we develop a new theory, briefly involving firing rate dynamics of networks of recurrently connected excitatory and inhibitory spinal interneurons. By analyzing the spectrum of the linearized effective coupling matrix of the rate dynamics we illustrate how a tonic supraspinal drive can induce rhythmic network activity if two conditions are met: 1) the real part of the maximum eigenvalue of the effective coupling matrix is larger than a critical value, and 2) this eigenvalue has a non-zero imaginary part. Using numerical simulations of networks fulfilling these two conditions we show that the resulting population activity is largely determined by the eigenvector corresponding to the largest eigenvalue, displaying rotational dynamics with wide phase distributions consistent with the experimental data. Finally, we demonstrate how such population states can be flexibly modulated via a selective drive to allow multi-functional motor output patterns including multiple gaits.

Title: A rostro-caudal map of V1 inhibition in axial spinal circuits

Authors: *M. SENGUPTA, V. DALIPARTHI, M. BAGNALL;
Washington Univ. In St Louis, Saint Louis, MO

Abstract: The structure of neuronal connectivity is key to function. In cortex, the structure of inhibitory circuits influences synaptic gain, spike timing, and membrane potential oscillations. Though the spinal cord is responsible for most motor output, the organization of inhibitory networks within it is much less clear. Most spinal interneurons project axons along the rostro-caudal (R-C) axis of the cord, yet connectivity along this axis remains ill explored owing to the inaccessibility in mammalian models. In this study, we use larval zebrafish to map connectivity of a major inhibitory population: V1 (En1+) neurons that send ascending axons rostrally. They directly inhibit both motor and sensory targets, and some V1 neurons function as Renshaw cells, with a role in flexor/extensor alternation. Suppression of V1 neurons results in slower locomotor speeds, in both fish and rodents. To investigate whether V1 neurons are important in R-C coordination, we generated a broad map of connectivity, along the R-C axis, from V1 neurons to both motor and sensory targets, using single cell labelling, optogenetics and electrophysiology *in vivo*. We find that V1 neurons exhibit long axons running approximately 6-7 segments rostrally and exclusively ipsilaterally. To test connectivity, we recorded IPSCs in post-synaptic targets while optogenetically stimulating V1 neurons in different positions in the spinal cord with a DMD. We first looked at a classical V1 target: motor neurons (MNs), both fast and slow. Surprisingly, V1 neurons formed only local connections with motor neurons (up to 2 segments and 3 segments for fast and slow MNs respectively), despite the long reach of V1 axons anatomically. V1 connectivity to V2a neurons, a major excitatory driver of locomotion, extended more distally than MNs (up to 5 segments) but the strength of this synaptic inhibition diminished rapidly beyond 1-2 segments. This pattern of short range connectivity was also observed for other motor targets, including V2b neurons and commissural pre-motor neurons. In contrast, V1 neurons made robust inhibitory contacts throughout the rostral extent of their axonal projections (up to 7-9 segments) onto Commissural Primary Ascending neurons (CoPAs), a dorsal horn sensory population. This connectivity was specific to the CoPAs. Overall, these data demonstrate that V1 neurons systematically connect to different targets along the R-C axis, inhibiting motor targets locally, and shifting to sensory targets, distally. The implications for such a unique pattern of connectivity to functions of V1 neurons is still unknown. Current work involves building a computational model to test these functional implications.

Title: Anatomical and functional investigation of the diversity of reticulospinal neurons controlling movements

Authors: *G. USSEGLIO, E. GATIER, A. HEUZÉ, C. HÉRENT, J. BOUVIER;
Univ. Paris-Saclay, CNRS, Gif-sur-Yvette, France

Abstract: Orienting behaviors require multiple motor adjustments, notably of the head to displace the sensory apparatus, and of the limbs to modulate locomotor speed and when needed, to change trajectory. Brainstem reticulospinal (RS) neurons are key candidates for funneling sensory and goal-directed orienting signals to the executive motor circuits of the spinal cord. However, the intermingled organization of the reticular formation has hindered the identification of the RS subtype(s) specifically linked to orientation. Additionally, whether distinct motor actions are controlled synergistically by a unique RS population or instead by dedicated subtypes is still unresolved.

To address this we examined, in mice, the function and diversity of a genetically circumscribed class of glutamatergic RS neurons, the V2a neurons (expressing the transcription factor Chx10). First, using rabies-based transsynaptic tracings, we reveal that V2a neurons receive abundant synaptic inputs from the contralateral superior colliculus, making them a candidate relay of orienting commands. Second, we show that unilateral photo-activations of V2a neurons evoke multiple orienting-like motor responses, including a yaw rotation of the head and the snout and a displacement of the body axis towards the stimulated side. During locomotion, such activations lead to a transient locomotor arrest followed by a striking change in path trajectory. Next, using retrograde tracers and circuit optogenetics we reveal that these multiple motor actions are supported by distinct projection-defined V2a subsets, with at least 1) a lumbar-projecting subset whose activation, even unilaterally, arrests locomotion but neither impacts trajectory nor evokes orienting movements, and 2) a cervical-projecting subset dedicated to head orientation and whose activation suffices to change the animal's trajectory. This argues that the impact of V2a RS neurons on path trajectory owes to their capacity to impose the head orientation. Our ongoing experiments further indicate that cervical projecting V2a neurons might be neck pre-motoneurons and also hints at the existence of yet additional projection-defined V2a subsets that may drive other components of orientation.

Our work hence places medullary V2a neurons as important orchestrators of orienting movements. It also highlights that, while the reticular formation may be organized in functional modules defined by transcription factors (i.e. V2a RS neurons for orienting), a further specialization within modules following a muscle-group connectivity framework may allow the versatile expression of individual components of multi-faceted behaviors.

Abstract: Serotonergic (5-HT) pathways to the spinal cord have been shown to play an important role in locomotion. Additionally, a shared region of the medulla is a key site providing sympathetic input to support systems for locomotion, such as the cardiovascular system. Our lab has demonstrated that electrical stimulation of 5-HT neurons within the parapyramidal region (PPR) in the brainstem can elicit locomotion in an in vitro, neonatal rat preparation. We have also presented preliminary evidence that chemogenetic stimulation of these neurons can increase ENG activity and blood pressure in adult rats (Armstrong et al., SFN 2019). The aims of this study were to determine the contribution of serotonergic neurons to the initiation and/or the facilitation of locomotion in adult rodents. For the selective excitation of 5-HT neurons, excitatory DREADDs (n=9) were stereotaxically injected into the PPR using AAV viral vectors in adult Tph2-cre female rats. After a recovery period (21-97 days), experiments were performed in decerebrated (un-anesthetized) rats while recording lumbar cord dorsum potentials, hindlimb ENGs and arterial blood pressure. Mesencephalic locomotor region stimulation was used to induce fictive locomotor activity in order to assess changes after applying the clozapine-N-oxide (CNO) via intracerebral (i.c.) injections. Both ENG output and blood pressure increased after i.c. injections of CNO. The i.c. saline injections (n=4) or CNO injections into non-DREADD-infected controls showed no facilitation of ENG or blood pressure. Additionally, optogenetic constructs (ChR2) were targeted to this same region (n=6) and light stimulation-induced facilitation of blood pressure and hindlimb ENG activity was also achieved in these preparations. The injection site was verified post-hoc in frozen-sectioned tissue by mapping the fluorescent reporter protein for DREADDs (mCherry) or for ChR2 (eYFP). The utilization of the fluorescent constructs as tracers for the projections of PPR 5-HT neurons in our animals showed diverse branching of 5-HT terminals both in the thoracic and lumbar segments from the transfected subpopulation of neurons in most animals. These results suggest origin of a shared 5-HT network simultaneously regulating locomotor and cardiac control.

Title: Large-scale optical recording of respiration-modulated neurons in ventrolateral medulla reveals cycle-to-cycle variability consistent with multifunctionality

Authors: B. GOUREVITCH[1], T. PITTS[2], K. E. ICEMAN[3], ***N. M. MELLEN**[3];
[1]Unite de Genetique et Physiologie de l'Audition, Inst. Pasteur, Paris, France; [2]Kentucky Spinal Cord Res. Ctr., [3]Univ. of Louisville, Louisville, KY

Abstract: Respiration-modulated neurons form a distributed network in ventrolateral medulla. The post-inhibitory complex (PiCo) dorsal to the facial nucleus (VIIn), the parafacial respiratory group (pFRG), ventral to the VIIn, and the pre-Botzinger Complex (pre-BötC) are all endogenously rhythmic, and are hypothesized to mediate respiratory rhythm generation, but their interactions are poorly understood. All three networks can be recorded optically in the sagittally-sectioned rodent hindbrain (SSRH) preparation. In this study, neonate (P3-P5) mice in which the genetically-encoded Ca^{2+} indicator GCaMP6F was expressed in all cells due to spontaneous germline recombination were used, enabling an inclusive sampling of hindbrain respiratory networks. We recorded respiration-modulated networks along the ventral respiratory column at sampling rates fast enough (100 Hz) and recording epochs long enough (600 s) to robustly characterize the intrinsic cycle-to-cycle variability in both motor output and neuronal onset times relative to motor output (lags) and burst duration. The assumption behind these experiments was that constituents of a dedicated respiratory motor pattern generating network would consistently be among the earliest neurons active in each cycle. We found no anatomical parcellation of earliest neurons. Using Kendall's tau to quantify cycle-to-cycle lag variability, we found that although in aggregate pFRG neurons were significantly earlier than neurons in other regions, subsets of neurons from all regions were active earliest, and varied cycle-to-cycle. In part, variability in onset times could be accounted for by system-level variables: significant correlations between preceding expiratory durations and lags was observed for large subsets of neurons along the neuraxis. In addition, in a subset of experiments, non-parametric methods identified consistent "synfire chain" activation patterns associated with the shortest preceding

expiratory durations. The observation that inspiratory bursts arise out of the action of a diffuse network of neurons extending over a millimeter, whose constituents vary on a cycle-to-cycle basis is incompatible with the prevailing view that these are motor pattern generating networks. Rather, we propose that these networks are multifunctional, regulating the coordination of orofacial, ingestive, and respiratory behaviors, as well as blood-gas homeostasis.

Title: Microrna-206 acts in cerebellar purkinje cells to regulate sensorimotor gating and fear-related behaviors

Authors: ***M. P. HEYER**[1], M. ISHIKAWA[3], P. J. KENNY[2];
[2]Neurosci., [1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The cerebellum is primarily known for its roles in motor learning and coordination. Emerging evidence suggests that the cerebellum also regulates more complex behaviors related to cognition, affect, and reward, and dysfunction in this brain structure may contribute to schizophrenia and other neurodevelopment disorders. The cerebellum shares extensive reciprocal connectivity with the neocortex, basal ganglia and hindbrain nuclei, and is thought to convey sensory experiences that shape cortical development and function. Nevertheless, the genes, cells, and circuits that govern cerebellar interactions with higher-order brain systems are poorly understood. Using brain-wide in situ hybridization, we find that the schizophrenia-associated microRNA, miR-206, is specifically enriched in cerebellar Purkinje cells. Mice with a targeted deletion of miR-206 exhibit impaired pre-pulse inhibition, an endophenotype of schizophrenia, stress-induced hypolocomotion, impaired extinction of fear memories, and sex-dependent cognitive deficits. Pre-pulse inhibition impairments were recapitulated by conditional deletion of miR-206 in parvalbumin-expressing cells, including Purkinje cells, suggesting that altered cerebellar output may contribute to these behavioral abnormalities. Consistent with this possibility, the spontaneous firing frequency of Purkinje cells was increased in miR-206 null mice. High-throughput sequencing of RNA isolated by crosslinking immunoprecipation after miR-206 deletion in Purkinje cells revealed potential target mRNAs in pathways related to neuronal excitability, glutamate signaling, and dendritic morphology & development. Together, these findings suggest that miR-206 regulates the function of cerebellar Purkinje cells and that this action controls sensorimotor, cognitive, and affective behaviors that are relevant to schizophrenia.

Title: Cerebellar modulation of the hypothalamus

Authors: ***N. S. CAYLA**, J. WILLET, M. OÑATE, K. KHODAKHAH;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Although it constitutes a mere 10% of the total volume of the human central nervous system, the cerebellum contains more than half of our neurons. It is well-known for its involvement in motor control and coordination, but recent observations made on patients suffering from a myriad of mental disorders, or those with cerebellar lesions have led to a growing appreciation for its roles in the regulation of cognitive and somatic functions as well. To delineate the non-motor functions of the cerebellum it is important to have a detailed map of its connectivity with other brain regions, through anatomical neuronal tracings, we studied monosynaptic projections from the deep cerebellar nuclei (DCN). To do so, we used an AAV1-cre virus in the DCN of a reporter mice (called RCE:LoxP), in which neurons require Cre to express GFP. This virus possesses transsynaptic spread properties and allows the labelling of the somas of target-cells from monosynaptic projections. We observed the labelling of DCN target-cells in several hypothalamic regions: in the Medium Pre-Optic Area (MPOA), in the Lateral Hypothalamic Area (LHA), and in the Paraventricular Nucleus of the Hypothalamus (PVH). Immunohistochemistry and *in situ* RNA hybridization also revealed that some of the PVH cells which receive a DCN input also express oxytocin and vasopressin. These results suggest that the cerebellum may have a modulatory role in the hypothalamus. In future experiments, we plan to characterize this novel brain circuit by combining cell-type specific neuroanatomical tracing with in vivo and in vitro electrophysiological assays combined with behavioral tasks paired with live neuronal activity recordings in freely behaving mice.

Title: Cerebellar Purkinje cell activity determines the latency and precision of sensory-driven motor initiation

Authors: ***S. TSUTSUMI**[1,2], O. CHADNEY[1], T.-L. YIU[1], E. BÄUMLER[1], L. FARRAGIANA[1], M. BEAU[1], M. HÄUSSER[1];
[1]Univ. Col. London, London, United Kingdom; [2]RIKEN Ctr. for Brain Sci., Saitama, Japan

Abstract: The cerebellum receives a variety of sensory and motor information to shape precise behavior. However, the cerebellar cortical mechanisms realizing the timed initiation of sensorimotor behavior remain largely unexplored. Here we invented a behavioral paradigm which requires animals to rapidly discriminate multi- vs. uni- sensory information to generate quick motor responses, to probe for the active sensorimotor timing. We investigated the role of Purkinje cell activity in the left folium Crus I, a hemispheric lobule implicated in sensorimotor integration, by combining optogenetic manipulation of simple spikes, high density electrical recordings (Neuropixels) of both simple and complex spikes, and two photon calcium imaging of complex spike signals in head-fixed mice (> P60) during the task. Optogenetic manipulation of simple spikes either abolished (N = 4 mice; 98 ± 1 vs. 55 ± 8% initiation, P = 0.0023) or delayed (N = 4 mice; 210 ± 30 vs. 360 ± 20 ms latency, P = 0.00091) the sensory-driven motor initiation. The magnitude of short latency (~100 ms) simple spike aberration was correlated with the delay and abolition of the initiation. Two photon calcium imaging across the entire Crus I revealed that task-relevant complex spike signals were organized into highly conserved alternating parasagittal stripes (zones). Coherent complex spike signals within these zones represented the salient sensory information. The complex spike coherence was specifically enhanced before the sensory-driven motor initiation, but not before the voluntary motor initiation. Moreover, the presence of the coherent complex spike signals after the sensory stimuli predicted the temporal precision of motor initiation. Finally, the enhancement of sensory-evoked complex spike coherence upon associated motor initiation was acquired together with the temporal precision in the sensory-driven motor initiation. These results reveal the complementary cerebellar cortical systems in controlling the precise sensorimotor timing: simple spikes in Crus I determine whether and when to initiate the sensory-driven motor behavior, whereas the acquired enhancement in sensory-evoked complex spike coherence in Crus I zones contributes to its temporal precision.

Title: Mechanism of action of ethanol in EA2: the δ-subunit containing $GABA_AR$ hypothesis

Authors: *J. O. TINDI, K. KHODAKHAH;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Loss of function mutations in the *CACNA1A* gene in humans, which encodes the P/Q-type voltage-gated calcium channel (Cav2.1), cause episodic ataxia type 2 (EA2). EA2 is characterized by attacks of severe ataxia and dystonia that are triggered by stress, caffeine or alcohol. There are several mouse models of EA2, including the tottering mouse which has a mutation in the pore-forming subunit of Cav2.1, resulting in reduced channel current density. These mice exhibit baseline ataxia and episodes of severe dyskinesia and dystonia (motor attacks) that are also triggered by stress, caffeine or alcohol. Our lab reported previously that the baseline ataxia is due to decreased precision in the pacemaking of cerebellar Purkinje cells (PCs). The lab has also shown that stress and caffeine trigger motor attacks by acting on cerebellar α1 adrenergic receptors and A1 adenosine receptors, respectively, resulting in PC burst firing *in vivo* and increased PC irregularity *in vitro*. Although ethanol produces similar firing *in vivo* and *in vitro,* the mechanism by which it triggers attacks is unknown. In fact, the mechanism by which ethanol produces the multitude of reported neurobehavioral, cellular and molecular effects in humans and rodents remains an open question. One of the main hypotheses is that ethanol potentiates the activity of δ-subunit containing γ-aminobutyric acid type A receptors (δ-$GABA_ARs$). We test this by asking whether the δ-$GABA_AR$-specific agonist THIP is sufficient to produce attacks in tottering mice. While ethanol administered via intraperitoneal (IP) injections at 1.5 g/kg triggers attacks in tottering mice, we found that IP injections of THIP up to 4 mg/kg, does not. Ethanol causes ataxia in wild type C57BL6 mice, as assessed by performance on the balance beam, and this effect is exacerbated by THIP at 4 mg/kg. However, THIP alone does not produce ataxia. As a positive control, THIP at 10mg/kg reduces locomotor activity and causes sedation in wildtype mice. Given these results, we conclude that ethanol-triggered motor attacks and ethanol-induced ataxia in wild type mice are not mediated by δ-$GABA_ARs$. The cellular effects of ethanol are known to be species-specific and in C57BL6 mice, ethanol can directly inhibit α6-subunit containing $GABA_ARs$ (α6-$GABA_ARs$) in cerebellar granule cells. We tested this possibility by inhibiting these receptors with IP furosemide at 10m/kg. We found that this was not only insufficient to trigger motor attacks in tottering mice, but also insufficient to cause ataxia in wildtype C57BL6 mice. We therefore conclude that ethanol neither triggers motor attacks in EA2 nor produces ataxia in wildtype C57BL6 mice by acting on δ-$GABA_AR$ or α6-$GABA_AR$.

Title: Differential cortical and pallidal inputs to the striosome and matrix compartments in the rat striatum

Authors: *F. KARUBE, F. FUJIYAMA;
Grad. Sch. of Med., Hokkaido Univ., Sapporo, Japan

Abstract: Differentiation of striatal two compartments, the striosome and matrix, is not yet fully understood. Specific neural inputs to these compartments can drive their local circuits. We explore here compartment-dependent excitatory and inhibitory inputs using adeno-associated virus (AAV) and conventional neural tracers in 8-12 weeks male rats (N>3 rats and N=2-4 sections for all morphological experiments). As shown in earlier reports, the primary motor (M1) and secondary motor (M2) area projected to the striatum (Str). Both motor areas projected to the dorsolateral regions, although M2 projection was frequently found in the more medial Str. M1 preferentially projected to the matrix, whereas M2 equally projected to the striosome and matrix. Since the matrix also receives thalamic inputs more frequently than the striosome, what inhibitory inputs balance with these rich excitatory inputs? Regarding inhibitory inputs to Str, GP is one of the main sources. Thus, we visualized GP projection to Str using anterograde or retrograde AAVs, and discovered that GP densely projected to the matrix, whereas only small amounts of axons are observed in the striosome. Since many axonal fibers pass through GP, some axons from other brain regions could be also labeled. To label GP neurons projecting to Str more specifically, we applied a combination of injection of retrograde AAV encoding Cre (AAV-rg-Cre) to Str and injection of another AAV to GP, which expresses fluorophores in a Cre-dependent manner. Again, GP projection preferred the matrix to the striosome. Recently, it is known that GP projection neurons consist of two types: one type also projects to STN, as well as Str, whereas another type projects only to Str. To reveal whether both types prefer the matrix, the STN-projecting-GP neurons were labeled with injection of AAV-rg-Cre to STN followed by another AAV injection to GP. We found that their axons also preferred the matrix, although axon density in Str was small. It strongly suggests that both GP projection neuron types selectively project to the matrix. Therefore, rich excitatory inputs from M1 and thalamus to the matrix can be balanced with selective inhibitory inputs from GP.In summary, we found that M1 and M2

differentially projected to the striosome/matrix compartments of Str. In addition, GP selectively project to the matrix. Altogether, biased excitatory and inhibitory neural projections from the motor cortical areas to Str, and from GP to Str can affect the matrix-specific local neural circuitry, and take important roles to prepare and conduct appropriate motor behaviors.

Title: Dopamine modulates the size of striatal projection neuron ensembles

Authors: *M. MALTESE, J. R. MARCH, A. G. BASHAW, N. X. TRITSCH;
NYU Neurosci. Institute, NYU Langone Hlth., New York, NY

Abstract: Dopamine (DA) is a critical modulator of brain circuits that control voluntary movements. However, our understanding of its influence on the activity of target neurons in vivo remains limited. Here, we use two-photon Ca2+ imaging in the striatum of behaving mice to simultaneously monitor the activity of direct and indirect pathway spiny projection neurons (SPNs) during acute and prolonged manipulations of DA signaling. We find that DA strongly and differentially regulates the number of direct and indirect pathway SPNs recruited during behavior, and that chronic loss of DA neurons profoundly alters SPN responses to DA. Our results extend existing models of DA modulation and provide novel insights into the pathophysiology of Parkinson's disease.

Title: 2-arachidonoylglycerol mobilization following brief synaptic stimulation in the dorsal lateral striatum requires glutamatergic and cholinergic neurotransmission

Authors: *D. J. LIPUT[1], H. PUHL[1], A. DONG[2], K. HE[2], Y. LI[2], D. LOVINGER[1];
[1]NIH/NIAAA, Rockville, MD; [2]Peking Univ., Beijing, China

Abstract: The endocannabinoid (eCB) system is a major source of synaptic modulation in the dorsal lateral striatum (DLS) and is required for proper motor output and striatal-dependent learning. Several forms of eCB-dependent plasticity have been described in the DLS, however most experimental protocols used to induce plasticity do not recapitulate the firing patterns of striatal-projecting pyramidal neurons in the cortex or firing patterns of striatal medium spiny neurons. Therefore, it is unclear if current models of eCB signaling in the DLS provide a reliable description of mechanisms engaged under physiological conditions. To address this uncertainty, we investigated mechanisms of eCB mobilization following brief synaptic stimulation that mimics *in vivo* patterns of neural activity in the DLS. To monitor eCB mobilization, the novel genetically encoded fluorescent eCB biosensor, GRABeCB2.0, was expressed in corticostriatal afferents of C57BL6J mice and electrically-evoked eCB transients were measured in the DLS using a brain slice photometry technique. We found that brief bouts of synaptic stimulation induce long lasting eCB transients that are modulated by stimulation frequency and duration. Inhibition of monoacylglycerol lipase, but not fatty acid amide hydrolase, increased the amplitude and prolonged the duration of the eCB transient, suggesting that 2-AG is the predominate eCB generated following brief synaptic stimulation. 2-AG transients were robustly inhibited by the muscarinic M1 receptor (M1R) antagonist, VU 0255035, and augmented by a M1R positive allosteric modulator, VU 0486846 (VU'846), indicating that acetylcholine (ACh) release is required for 2-AG production. Additionally, the dopamine D2 receptor (D2R) agonist, quinpiriole, inhibited the 2-AG transient. Combined, these results suggest that cholinergic interneurons (CINs) are required for 2-AG production and D2Rs expressed on these neurons limit production by inhibiting ACh release. To test this hypothesis, we generated transgenic mice lacking D2Rs specifically on CINs. In slices from these mice, quinpirole did not inhibit 2-AG production, confirming that D2Rs on CINs can control the magnitude of 2-AG production. Interestingly, the AMPA receptor (AMPAR) antagonist, DNQX, also robustly inhibited 2-AG production and blocked 2-AG augmentation by VU'846. These results suggest that converging glutamatergic and cholinergic signals are required for efficient 2-AG production following brief synaptic stimulation. Collectively, the present study provides new insights on circuit and cellular mechanisms controlling 2-AG mobilization in the DLS.

Title: Dopamine depresses lateral inhibition in the nucleus accumbens through a noncanonical mechanism

Authors: *D. A. BURKE[1,2], V. A. ALVAREZ[1];
[1]NIAAA, NIH, Rockville, MD; [2]Brown Univ., Providence, RI

Abstract: The nucleus accumbens (NAc) is a brain region that subserves healthy motivated behaviors and is an important site of dysfunction in addiction and depression. Acting as a "limbic-motor interface," projection neurons in the NAc, medium spiny neurons (MSNs), integrate excitatory glutamate signals from cortical and limbic regions with dopamine (DA) signals from midbrain to facilitate motivation and reward learning. However, NAc also contains an extensive network of inhibitory GABA synapses between MSNs, which remains understudied. It is currently unknown how DA interacts with this network of MSN GABA synapses. By modulating synaptic strength within this network of lateral inhibition, DA is situated to influence NAc information processing by shifting the balance of excitation/inhibition at the micro circuitry level. MSNs express two types of dopamine receptors: either G_{olf} coupled D1 receptors or $G_{i/o}$ coupled D2 receptors (D2MSNs). Here we ask: how does DA acutely affect GABA transmission from D2MSNs onto neighboring MSNs? We hypothesize that endogenously released DA from the midbrain can inhibit local GABA transmission from D2MSNs to neighboring MSNs. Using a dual optogenetic approach to test this hypothesis in mouse brain slices, we show that DA neuron stimulation preceding D2MSN GABA release by 500-1000ms acutely depresses GABA transmission from D2MSN synapses. To further probe this depression, we applied exogenous DA and found the IC_{50} for the depression of GABA transmission to be in the micromolar range, an order of magnitude higher than that of previous studies using heterologous systems. We next hypothesized that this DA depression of D2MSN GABA transmission is mediated presynaptically by D2Rs expressed on D2MSNs. Through a series of pharmacological and uncaging studies, we indeed found that this depression is driven presynaptically. However, to our surprise the depression is only partially explained by D2R activation. Genetically deleting D2Rs or pharmacologically blocking D2-like receptors only prevented ~50% of the DA mediated depression. Moreover, D1-like receptor antagonists had no effect on this DA mediated depression, suggesting a novel target of DA. Current experiments are aimed at determining this novel mechanism by which dopamine inhibits synaptic transmission. Taken together, these results shed light on the actions and mechanisms by which DA acutely modulates the lateral inhibitory network in the NAc. This insight is necessary for understanding how DA shapes NAc circuitry and information processing to promote motivated behaviors, both in health and disease.

Title: Mechanisms of presynaptic modulation of striatal efferents by $G\alpha_{i/o}$ coupled GPCRs

Authors: *G. SITZIA[1], D. LIPUT[1], K. P. ABRAHAO[2], G. M. CALANDRA[3], D. M. LOVINGER[1];
[1]NIAAA, Lab. for Integrative Neurosci., Rockville, MD; [2]Univ. Federal de São Paulo, São Paulo, Brazil; [3]Deutsches Zentrum fur Neurodegenerative Erkrankungen (DZN), Munich, Germany

Abstract: Dorsal striatal control over basal ganglia (BG) output nuclei is required for appropriate action selection and performance. Presynaptic modulation of SPN terminals plays a role in determining net striatal output and is disrupted in models of BG dysfunction. Potential mediators of presynaptic modulation at SPN terminals are the $G\alpha_{i/o}$ coupled GPCRs, $GABA_B$ and CB1, however the exact mechanisms by which these receptors modulate neurotransmitter release are unclear. Further, which calcium (Ca^{2+}) channel subtypes contribute to presynaptic Ca^{2+} influx at SPN terminals is unknown. Here, we studied Ca^{2+} channel subtype contributions to presynaptic Ca^{2+} influx and GPCR modulation of presynaptic Ca^{2+} transients (preCaTs) and transmission in the direct pathway SPN (dSPN) terminals in the SNr, dSPN collateral terminals in the GPe and indirect pathway SPNs (iSPN) terminals in the GPe. Brain slice photometry was used to measure electrical stimulation-evoked preCaTs in slices from transgenic mice expressing the genetically encoded Ca^{2+} sensor, GCaMP6f, in dSPNs or iSPNs. In parallel experiments, optically-evoked IPSCs (oIPSCs) were recorded in slices from transgenic mice expressing channelrhodopsin in dSPNs or iSPNs. Bath application of N- or P/Q-type Ca^{2+} channel blockers (ω-conotoxin GVIA and ω-agatoxin IVA, respectively), but not a L-type Ca^{2+} channel blocker (Nifedipine), decreased the amplitude of presynaptic Ca^{2+} transients in all three sets of SPN terminals. Bath application of the $GABA_B$ receptor agonist, baclofen, significantly reduced the amplitude of preCaTs and the amplitude of oIPSCs at all three sets of SPN terminals. Interestingly, applying CGP55840 after baclofen reversed the effect of baclofen on preCaTs to baseline amplitudes at iSPN terminals in the GPe, while increasing the amplitude of the preCaT above baseline at dSPN terminals in the GPe and dSPNs in the SNr. Combined, these results suggest that presynaptic $GABA_B$ receptors couple to N- and/or P/Q-type Ca^{2+} channels to inhibit neurotransmitter release at dSPN and iSPN terminals, and $GABA_B$ receptors may tonically inhibit presynaptic calcium channels in dSPN but not iSPN terminals. Surprisingly, bath application of the CB1 receptor agonist WIN55212-2 did not significantly inhibit preCaTs, but strongly reduced the amplitude of oIPSCs in all three sets of SPN terminals, suggesting that CB1 receptors might inhibit neurotransmitter release at dSPN and iSPN terminals through mechanisms independent of presynaptic Ca^{2+} influx. Overall, our results contribute to unravelling the specific mechanisms underlying presynaptic modulation of SPN terminals in the SNr and GPe.

Abstract: Basal ganglia dysfunction is central to diverse neurological disorders including Huntington's disease, Parkinson's disease, Obsessive compulsive disorder, and addiction. Among the basal ganglia structures, the striatum integrates synaptic inputs from diverse brain regions and plays a major role in regulating motor output and reward. Neuron populations in the striatum include medium spiny neurons (MSNs), diverse local GABAergic interneurons, and large cholinergic interneurons. Of particular interest, striatal MSNs consist of two functionally distinct but intermingled populations: those that send axon projections to the substantia nigra (SNr) forming the direct pathway (dMSNs), and those that send axon projections to the globus pallidus externa (GPe) forming the indirect pathway (iMSNs). Understanding the balance between these distinct pathways is critical and may lead to breakthroughs in the treatment of movement disorders.

Transgenic lines for *in vivo* targeting of striatal cell types are well established in mice, and have been invaluable for genetic dissection of intrinsic properties, synaptic connectivity, and circuitry basis of behavior. However, these tools are restricted to the mouse model and can't be leveraged for cross-species studies, including functional studies in non-human primates (NHPs) or potential therapeutic applications in human patients. To address this crucial gap, we developed adeno-associated viral vectors (AAV vectors) with compact cell type-specific enhancer elements to target several important neuron classes and subclasses in the striatum including iMSN, dMSN, pan-MSN, and cholinergic interneuron populations. Putative striatal cell type enhancers were identified from published or open access human and mouse epigenetic datasets and genome browsers and cloned into AAV vectors for functional testing.

We characterized brain-wide expression patterns of our novel AAV vectors in mice and present multiple lines of validation on labeling specificity. Importantly, many of these cell type enhancer AAVs also drive transgene expression in macaque *ex vivo* putamen slice cultures and *in vivo*

following stereotaxic injection. As a final validation of labeling specificity and demonstration of a functional application, we have performed targeted Patch-seq recordings to measure electrophysiology, morphology, and transcriptomes of virus labeled neuron types in mouse and monkey brain slices. These novel viral tools will facilitate additional detailed functional characterization of striatal cell types across mammalian species, with possible applications for human gene therapy to treat disorders of the basal ganglia.

Abstract: In the classical model of the basal ganglia two segregated and functionally opposing pathways arise from the striatum to regulate motor control. Direct pathway striatal projection neurons (dSPNs) expressing dopamine D1 receptors (D1R) project monosynaptically to the substantia nigra (SNr) to promote movement while indirect pathway SPNs (iSPNs) expressing D2R project monosynaptically to the globus pallidus externus (GPe) to oppose movement. Recent functional studies, however, reveal that during native movements both pathways are activated. Moreover, anatomical and physiological studies have put into question the organization of the basal ganglia. For instance, we and others have shown that a large fraction of

dSPNs possess axon collaterals within the GPe. These “bridging” collaterals are plastic in the adult animal and regulated by D2Rs and neuronal activity. These findings, though indirect, suggested an important role of dSPN bridging collaterals in regulating the balance of the direct and indirect pathway and motor function. Here, we used a combination of genetic targeting, in vivo calcium imaging, dSPN terminal-specific manipulations (chemogenetics, optogenetics) and behavioral tracking (DeepLabCut) to determine the role of dSPN bridging collaterals in motor function. We found that dSPN bridging collaterals were activated during specific movements in the rotarod. dSPN terminal inhibition also decreased locomotion and impaired rotarod performance. Recent physiology work shows that dSPNs preferentially target the non-canonical, striatal-backprojecting, arkypallidal Npas1 neurons in the GPe. We here found that stimulation of dSPNs inhibited native Npas1 signals in awake behaving mice. Finally, we found that Npas1 stimulation recapitulated the effects of dSPN inhibition by decreasing locomotion and rotarod function. We propose a model by which dSPN bridging collaterals support movement via inhibition of Npas1 neurons in the GPe. Thus, direct pathway GPe terminals act in concert with the canonical terminals in the SNr by inhibiting a potential stop signal going back to the striatum. Future work on bridging collaterals is expected to inform applications to disease states characterized by basal ganglia imbalances, such as Parkinson’s disease or Huntington’s.

Title: Motor skill learning and execution in a distributed brain network

Authors: *S. B. WOLFF, A. DHAWALE, R. KO, B. ÖLVECZKY;
Harvard Univ., Cambridge, MA

Abstract: The remarkable capacity of the brain to acquire and execute motor skills depends on a distributed motor network. While many components have been identified, less is known about their specific roles and interactions during skill learning and execution. Here we probe this network through the lens of complex, spatiotemporally precise motor sequences we train in rats. We focus on the basal ganglia and the contributions made by their main inputs, from motor cortex and thalamus, respectively. Using electrophysiological recordings, we find that the dorsolateral striatum (DLS), the main motor-related input nucleus of the basal ganglia, encodes the detailed kinematic structure of the learned motor sequences. We further show that a loss of the DLS renders animals unable to execute the learned idiosyncratic motor patterns, causing them to revert to simple species-typical behaviors. In addition, we find that not only the DLS, but also its motor cortical inputs are necessary for learning the skills we train. This very same pathway, however, becomes dispensable after the behaviors are acquired. In line with this, the loss of motor cortical inputs leaves the DLS activity encoding the kinematic structure of the behavior largely unaffected. In contrast, thalamic inputs to the DLS remain crucial for the generation of the learned skills and loss of these inputs disrupts performance akin to DLS lesions, causing a reversion to the same species-typical behavior. Together, our results suggest that the basal ganglia can play a role in the control of complex learned behaviors which goes beyond traditional models of basal ganglia function. They further suggest that motor cortex 'tutors' sub-cortical motor circuits during learning, potentially by guiding plasticity at thalamostriatal synapses. Such adaptive reprogramming of lower-level motor circuits may broaden their flexibility and allow them to store and generate complex learned motor skills.

Title: Optogenetic activation of the inhibitory nigro-collicular circuit evokes orienting movements in mice

Authors: *C. A. VILLALOBOS, M. A. BASSO;
Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA

Abstract: In contrast to predictions from the current model of basal ganglia (BG) function, we report here that increasing inhibition from the BG to the superior colliculus (SC) through the substantia nigra (nigra) using *in vivo* optogenetic activation of GABAergic terminals produces contralateral orienting movements in freely moving mice. Orienting movements resulting from

activation of inhibitory nigral terminals are unexpected because decreases and not increases in nigral activity are generally associated with orienting movements. To determine how orienting movements may result from activation of inhibitory terminals, we performed a series of slice experiments and found that the same optogenetic stimulation of nigral terminals used *in vivo*, evoked post-inhibitory rebound depolarization and spiking in SC output neurons *in vitro*. In addition, only high frequency (100Hz) stimulation evoked contralateral movements *in vivo* and triggered rebound spiking *in vitro*. Furthermore, the latency of orienting movements relative to the stimulation *in vivo* was similar to the latency of rebound spiking *in vitro*. Taken together, our results point toward a novel hypothesis proposing that inhibition from the BG into the SC may play an active rather than passive role in the generation of orienting movements in mice.

Title: Dynamic dopaminergic activity controls the moment-to-moment decision of when to move.

Authors: *A. E. HAMILOS[1], G. SPEDICATO[1], Y. HONG[1], F. SUN[2], Y. LI[2], J. A. ASSAD[1,3]; [1]Harvard Med. Sch., Boston, MA; [2]Peking Univ., Beijing, China; [3]Inst. Italiano di Tecnologia, Genoa, Italy

Abstract: Parkinson's disease has long suggested a vital role for dopamine in movement initiation, but there is surprisingly little evidence connecting the activity of the endogenous dopaminergic system to movement onset. Although "standard" stimulus-response paradigms have not revealed a clear role for dopaminergic activity in movement initiation, most natural movements are not short-latency reactions to abrupt stimuli. Intriguingly, Parkinson's patients struggle to *self-initiate* movement more than to react to sensory cues (a phenomenon known as "paradoxical kinesia"), which suggests a role for dopamine might be revealed by instead examining movements that rely on an internal generative process to decide when to move. One type of self-generated movement is self-timed movement, in which subjects must decide *when* to move in the absence of overt cues, and pharmacological studies have suggested that exogenous dopamine can affect the timing of these movements. We hypothesized that dopaminergic activity may influence movement initiation by guiding its moment-to-moment timing. We recorded

dopaminergic system activity with fiber photometry in gender-balanced cohorts of mice as they prepared to initiate self-timed movements (GCaMP6f in genetically-defined dopamine neurons (n=12); the novel dopamine indicator dLight1.1 (n=5) or DA2m (n=4) in striatal neurons). We controlled for optical/movement artefacts with co-expressed tdTomato fiber photometry, neck EMG, back mounted accelerometer, and high-speed video. We found that even when accounting for movement, task variables, and trial history, dopaminergic signals were highly predictive of single-trial movement timing via a slow "ramp-up" that unfolded over seconds between the start-timing cue and the self-timed movement, reminiscent of a ramp-to-threshold process. Moreover, optogenetic activation of dopamine neurons systematically early-shifted movement timing (n=12 mice), whereas inhibition caused late-shifting (n=4 mice), and no-opsin stimulation caused no consistent behavioral effect (n=5 mice). Optogenetic stimuli were subthreshold for generating/preventing movement outside the task, suggesting that dopaminergic activity influenced movement onset by adjusting the moment-to-moment probability of a planned movement. Applying a reward-prediction error model for dopaminergic activity recapitulated the dopaminergic signal in our task and explained puzzling findings from a recent perceptual timing task, suggesting a unifying interpretation for the role of dopaminergic activity across timing paradigms.

Title: Developmentally regulated pathways for motor skill learning in songbirds

Authors: ***A. CHUNG**, S. W. BOTTJER;
USC, Los Angeles, CA

Abstract: During motor skill learning, cortico-basal ganglia circuits mediate comparisons between self-generated motor actions and a goal behavior that the animal is trying to learn; the results of these comparisons guide refinement of the animal's own behavior towards the goal motor pattern. Information stemming from copies of motor commands - efference copy - may play an essential role in guiding this learning process. Vocal learning in songbirds serves as a powerful model for investigating mechanisms of motor skill learning, because, like humans, juvenile songbirds learn complex vocal motor patterns by copying the song of an adult tutor (the

goal behavior). Juvenile song production is mediated by a projection from the cortical nucleus $LMAN_{core}$ to RA, a region of the motor cortex that directly drives vocal motor output. $LMAN_{core}$→RA neurons send a collateral projection to AId, a region adjacent to RA, in juvenile birds during early vocal development. Both RA and AId neurons project to the thalamic nucleus DLM, which forms a feedback pathway to cortico-basal ganglia circuitry. These projections from motor-command neurons in $LMAN_{core}$ to AId and RA and thence to the thalamus provide pathways by which information about vocal motor output could be reintegrated into cortico-basal ganglia circuitry, potentially aiding in the refinement of juvenile vocalizations. However, no studies have examined whether the strength of these efferent projections changes during the early stages of sensorimotor learning. We investigated developmental changes in these axonal pathways by conducting tract-tracing experiments to label the projections of $LMAN_{core}$ to AId and of RA to DLM in juvenile songbirds (35-50 dph). The volume and density of terminal label in AId stemming from injections into $LMAN_{core}$ (n=7) declines substantially between 35 and 45 dph, during the earliest stages of sensorimotor learning. In contrast, the projection from RA to DLM is consistently sparse during the early stages of sensorimotor learning and does not change in volume or density (n=15). The developmental decrease in connectivity between $LMAN_{core}$ and AId indicates a loss of efference copy in this pathway and suggests that substantial changes in the neural substrate are intertwined with changes in learning: projections that are present only during early stages of sensorimotor learning may mediate unique, temporally restricted processes of goal-directed learning.

Title: The mTOR pathway impacts motor learning skills in mice

Authors: *A.-S. ALLAIN[1], M. CYR[2];
[2]Med. Biol., [1]Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada

Abstract: The mammalian target of rapamycin (mTOR) is known to play a central role in cognitive memory function. For instance, the underlying changes in biological processes that are associated with Alzheimer's disease, a condition with progressive decline in cognitive function as a primary clinical symptom, are associated with mTOR dysfunctions. (Hoeffer and Klann, 2010) However, whether mTOR play a role in motor memory processes is still under investigation. Recent study have shown that mTOR is using molecular partners like ribosomal protein S6 kinase beta-1 (p70-S6K) to initiate formation of new neuronal connections. (Graber et

al., 2013) Our study investigates the role of mTOR and p70-S6K during the learning of a complex motor skill by using selective pharmacological inhibitors. The effect of systemic treatments with rapamycin and PF4708671, inhibitors of mTOR and p70 S6K respectively, were investigated during the accelerating rotarod test on day 1, 2 and 3, using three cohort of mice (N=84). The first cohort (n=36) was injected 1 hour or 15 minutes before trainings to study intra-sessions effect. The second cohort (n=30) was injected after trainings to examine inter-sessions effect. The third cohort (n=18) was injected before day 4, with no injections on day 1, 2 and 3. This last cohort was also tested for motor strength and coordination. Preliminary results with first cohort demonstrated significant differences between mice treated before training with vehicle and those treated with PF4708671 on day two and three, but no significant effect with rapamycin. The experiments using the second and third cohorts revealed that injections of rapamycin or PF4706871 had no effect on motor learning when injected after trainings, and that both treatments were not affecting general motor capacity such as muscular strength. In conclusion, our data suggest that p70-S6K function is important during motor learning sessions (intra-sessions effect). However, we didn't observe significant impact of mTOR inhibition during motor learning. Our results also indicate that activation of those two proteins might not be crucial after trainings (inter-sessions effect). The way mTOR pathway impacts motor learning skills is important in order to better understand the basis of neurophysiology and neurodegenerative diseases. GRABER, T. E., MCCAMPHILL, P. Title: What you see vs. what you need: How reliance on visual information changes in response to sequence motor learning

Authors: *A. CATES, K. GORDON;
Northwestern Univ., Chicago, IL

Abstract: Vision supplies vital feedback information for motor execution and feedforward information for motor planning. As individuals learn a motor task, how the nervous system uses visual information to control movements will change. However, little research has examined how the role of feedback and feedforward information changes in relation to motor learning. In the present study, participants completed an online "video game" with a sequence-learning task during which small objects dropped downward on the monitor and traveled through 1 of 4 vertical channels at a constant velocity. As the object(s) crossed a target located at the bottom of

the vertical channel, the participant was instructed to press a keyboard key(s) corresponding to the correct target(s). The dropping objects appeared in a 10-object repeating sequence (i.e. a fixed spatiotemporal relationship between the 10 individual objects) and participants received auditory feedback following accurate responses to help accelerate motor learning. Participants completed 8 trial blocks (practice, baseline, 5 training blocks, and post testing). The repeating sequence was included in the 5 training blocks and in post testing where the 10-object sequence was repeated 15 times per block. Participant reliance on feedback and feedforward visual information was probed by either blacking out object trajectories in the upper (feedforward) or lower (feedback) half of the game screen with the same expectation for participants to press the correct keys as the object crossed the target locations. We hypothesized that at baseline, before practicing the task, accuracy would decrease more when visual feedback information in the lower half was removed as compared to feedforward information at the top half, signifying a greater reliance on feedback. We also hypothesized that following motor learning, performance would decrease more when feedforward visual information at the upper half was removed, signifying a greater reliance on feedforward information. The results support our hypothesis with performance decreasing by 73% without feedback compared to 7% without feedforward information at baseline. Following the motor learning paradigm, performance dropped 30% without feedback and 33% without feedforward visual information. These results suggest that participants shift reliance from feedback to feedforward visual information following sequence learning.

Title: Effect of local vibration on finger force production during isometric pressing tasks

Authors: *W. ZHANG[1], F. BRUYER-MONTÉLÉONE[1,3], E. SHI[1], V. APADAYLO[1], L. SOLOVEYCHIK[1], S. IMOKE[2], A. ZOU[1,4], Z. AHMED[1];
[1]Physical Therapy, [2]Neurosci. Program, Col. of Staten Island / City Univ. of NY, STATEN ISLAND, NY; [3]Dept. of Biomechanical Engin., Univ. de Technologie de Compiègne, Compiègne, France; [4]Computer Engin., Boston Univ., Boston, MA

Abstract: Vibration stimulation has been studied to analyze the neural and mechanical connections that lie underneath the limbs control. It has been evidenced that long-time vibration exposure produced nerve and muscle injuries (Krajnak et al., 2013; Barcenilla et al., 2011). However, more recent investigations using vibration applied to either upper or lower limbs revealed an enhancement of human performances such as jumping height, extension strength, speed, grip force etc (Arpinar-Avsar et al., 2013). Direct stimulation has been proved to activate the muscles at both primary and secondary endings leading to the tonic vibration reflex effect

(TVR) (Luo et al., 2005). TVR showed an enhancement of the muscle's force on the flexor side indicating activation on the agonist muscle (Eklund 1978). However, it is unknown if the muscle response the same during voluntary (maximal and low force tasks) and involuntary contractions. It appears that vibration provides both temporal and spatial aspects that need to be further evaluated. In this study, we investigated the effect of vibration stimulation on finger forces during voluntary contraction and resting tests. We hypothesize that the vibration stimulation effect is dependent on muscle voluntary activation status. In addition, the effect of vibration on muscle responses is interacted with the stimulation site, as well as the enrolled finger combination. 12 healthy adult subjects participated and performed isometric pressing tasks by right four fingers in 2 separate sessions: vibration and control sessions. In vibration session, 5 vibrators (MicroPrecision, 100Hz frequency) were attached at 4 distal sites for fingers and 1 proximal site for the wrist, to stimulate both agonist and antagonist muscle tendons (flexor and extensor respectively). Individual finger forces have been recorded by force/torque sensors (ATI nano17) under 3 force conditions: voluntary maximal force (MVC), voluntary sub-maximal force (sub-MVC), and resting. Each force condition was performed by each individual finger (1D: I, M, R or L) or the four fingers together (4D), resulting in 76 pseudo-randomized trials. Our results showed that MVC is significantly decreased by vibration stimulation on flexor side, while the involuntary forces during resting condition from same side presented significant higher values with vibration compared to control session. Our findings suggest that the additional sensory stimulation of muscle vibration pose opposite effect toward to muscle activation, that is, an inhibition effect upon agonist muscle tendon during voluntary contractions, yet an activation effect on muscle tendon during resting period.

Title: Involvement of Dorsal and Ventral Premotor cortices in online updating to reach and grasp perturbations

Authors: *M. P. FURMANEK, M. YAROSSI, M. MANGALAM, K. LOCKWOOD, E. TUNIK;
Dept. of Physical Therapy, Movement and Rehabil. Sci., Bouvé Col. of Hlth. Sciences, Northeastern Univ., Boston, MA

Abstract: Dexterous and robust control of reach-to-grasp involves rapid sensorimotor updating for online adjustments to changing external goals (e.g., perturbations of objects we interact with) in order to interact with objects in the surrounding environment seamlessly. It is now well-established that nodes within the dorsolateral pathway involving the ventral premotor cortex (PMv) are involved in sensorimotor processing of hand preshaping, and nodes within the dorsomedial pathway involving dorsal premotor cortex (PMd) processing the reach component during reach-to-grasping actions. Recent evidence, however, that neural populations in both pathways respond to both reach- and grasp-related aspects of the movement suggest that neural control of reach-to-grasp may not be as parcellated as previously thought. In this investigation, we test the degree to which PMv and PMd mediate online updating to transport and grasp perturbations during reach-to-grasp action. Seven healthy right-handed subjects (26.2 ±7.7 years old), after providing informed consent, performed reach-to-grasp movements in a virtual environment. Movements were performed in unperturbed conditions toward a 3.6 cm (small) virtual object located 24 cm (near) from the starting hand position. In a minority of the trials (25%), either the object size (small-to-large, 3.6-7.2 cm) or distance (near-to-far, 24-36 cm) was unexpectedly perturbed (early-100 ms or late-300 ms after movement onset), requiring subjects to make online compensatory responses to grasp (aperture) and reach (transport). Transcranial magnetic stimulation (TMS) was used to perturb processing in PMv and PMd (50% of trials, 120% of RMT) at the time of object perturbation. Movement kinematics of grasp aperture and wrist transport were analyzed using standard parametric statistical tests. Our preliminary data revealed two main findings: (i) TMS to PMv delayed the latency of corrective response in aperture (50 ms, $p = .001$) for late transport perturbation condition (despite there being no perturbation of grasp); (ii) TMS to both PMv (20 ms, $p = .013$), and PMd (30 ms, $p = .003$) delayed the latency of corrective responses of aperture to perturbations of object size when the perturbation was applied early into the movement, and in the case of PMv, the effect held for late perturbations as well (40 ms, $p = .003$). These preliminary findings provide evidence that PMv and PMd may both integrate grasp and transport information at different stages of the reach-to-movement. If true, the data warrant a reevaluation of the classical two-streams model of information processing for reach-to-grasp. We are currently investigating this in a larger sample size.

Title: The dose-response effectiveness of active music therapy for upper extremity stroke rehabilitation: a systematic review and meta-analysis study

Authors: S. ARCHER, A. TOMLIN, G. WARREN, ***Y.-A. CHEN**;
Georgia State Univ., Atlanta, GA

Abstract: Background. Previous studies have found that active music therapy (AMT) can improve upper extremity (UE) function in people with stroke. Actively playing a musical instrument is highly motivating compared to rote exercises due to the engaging music features. When playing instruments, such as a piano, the affected UE can be naturally involved in practice, which leads to functional improvements. To investigate the effects and the optimal dosage of AMT in improving UE function in stroke, we conducted a systematic review and meta-analysis.
Methods: Our systematic review included searches in PubMed, Cochrane, MEDLINE, Embase, CINAHL, and ProQuest, with three key categories terms: stroke, music-based therapy, and upper extremity. The review process were conducted by two individuals separately with a third person involved if agreement was not achieved. For meta-analysis, data were extracted from the commonly-used assessments for UE function and finger dexterity in the field, including Action Research Arm Test and Nine Hole Pegboard Test. The intervention dosage in total minutes was also extracted from each article.
Results: Twenty-one articles were selected from the systematic review. Thirteen studies remained in the meta-analysis after excluding duplicate or missing data set (n=2), studies without the common assessments (n=4), and single subject studies (n=2). Two meta-analyses were conducted: one included studies with a stroke control group (n=5) and one without (n=8). While the effect size of most selected studies were not significant, both meta-analyses showed a significant overall effect of AMT on UE function post-intervention (p=0.021 and $p < 0.000$). This indicated the potential benefit of AMT in stroke. There was no heterogeneity in either meta-analysis, suggesting a low variability among studies. Further meta-regression also demonstrated no dosage-response effect (p=0.663 and p=0.231). Greater treatment time did not associate with better motor outcomes.**Conclusion/Discussion:**Our findings suggest that AMT has the potential to UE motor function in stroke survivors, compared to control treatments and pre-intervention performance. However, with the small number of articles and mostly non-randomized controlled trails (n=10), more high quality of research is needed to conclude a solid suggestion. In addition, the majority of the selected articles included AMT for a total of 5-10 hours (n=10). The low variability did not provide enough information for understanding optimal dosage of AMT. Music-based therapy is a developing but promising intervention. Future research should continue focusing in this area to help recovery for stroke survivors.

Title: Effects of aging on rapid grip force during bimanual manipulation of an active object

Authors: *H. HIBINO[1], N. WATSON[2], S. L. GORNIAK[1];
[1]Dept. of Hlth. and Human Performance, [2]Dept. of Biol. and Biochem., Univ. of Houston, Houston, TX

Abstract: Reports of an age-related deterioration in rapid grip force responses, which may be attributed to declined somatosensory and cognitive functions, are limited to a one-hand condition despite the higher frequency of using two hands together in daily living of older adults and the higher risk of dropping objects. Unexpected perturbations during bimanual movements elicit goal-oriented and cortically-meditated bilateral rapid motor responses. As aging is associated with declined somatosensory and cognitive functions, bilateral rapid motor responses may differ between young and older adults, such that older adults exert stronger grip forces following perturbation and the unperturbed hand is more involved in stabilizing the object in older adults. We tested this hypothesis by comparing the rapid grip force responses of both hands in young and older adults. A total of 13 right-handed young adults (24.2 ± 4.0 years old, 5 men) and 13 right-handed older adults (68.7 ± 7.1 years old, 5 men) performed a bimanual grip-lift movement, in which subjects held and leveled an object using thumbs and index fingers of both hands. Two different magnitudes of unpredictable pulling loads were applied to the right side of the object while subjects were leveling the object. Measures of rapid motor response included: latency, maximal grip force (MGF), ΔGF (difference between MGF and stabled grip force at pre-perturbation), peak grip force rate (PGF rate), and maximal grip-to-slip forces ratio (G/S ratio) of both hands. Additionally, the equivalence between left and right hands from kinetic data was quantified (L/R ratio). Regardless of age, the latency of the left hand was slower than the right hand, while the hand difference depended on perturbation magnitudes ($p < 0.05$). Older adults had higher values of MGF and PGF rate compared to young adults ($p < 0.05$). The analyses of MGF, ΔGF, and PGF rate demonstrated hand difference regardless of age; the magnitude of hand difference was dependent on the perturbation magnitude only in young adults but not in older adults ($p < 0.01$). The analysis of G/S ratio demonstrated that older adults exerted grip force three times higher than the slip force in both hands, while such relation between grip and slip forces was seen only in the right hand in young adults ($p < 0.005$). The analyses for L/R ratio suggested that the indirectly perturbed (left) hand was more involved in stabilizing the object in older adults compared to young adults ($p < 0.05$). The study extended the understanding of age-related changes in rapid grip force responses to unexpected perturbations. The age differences may be due to both declined peripheral and central nervous systems with aging.

Title: Are primates just big frogs? Forelimb force direction and amplitude are independently controlled by spinal motor modules

Authors: *A. YARON[1], D. KOWALSKI[2], H. YAGUCHI[1], T. TAKEI[3], K. SEKI[1];
[1]Natl.inst.Neurosci., Tokyo, Japan; [2]Drexel Univ., Philadelphia, PA; [3]Grad Sch. of Med., Kyoto Univ., Kyoto, Japan

Abstract: Modular organization of the spinal motor system is thought to reduce the cognitive complexity of simultaneously controlling the large number of muscles and joints in the human body. Although modular organization has been confirmed in the hindlimb control system of several animal species, it has yet to be established in the forelimb motor system or in primates. Expanding upon experiments originally performed in the frog lumbar spinal cord, we examined whether co-stimulation of two sites in the macaque monkey cervical spinal cord results in motor activity that is a simple linear sum of the responses evoked by stimulating each site individually. Similar to previous observations in the frog and rodent hindlimb, our analysis revealed that in most cases (77% of all pairs), the directions of the force fields elicited by co-stimulation were highly similar to those predicted by the simple linear sum of those elicited by stimulating each site individually. A comparable simple summation of EMG output, especially in the proximal muscles, suggested that this linear summation of force field direction was produced by a spinal neural mechanism whereby the forelimb motor output recruited by co-stimulation was also summed linearly. We further found that the force field magnitudes exhibited supra-linear (amplified) summation, which was also observed in the EMG output of distal forelimb muscles, implying a novel feature of primate forelimb control. Overall, our observations support the idea that complex movements in the primate forelimb control system are made possible by flexibly combined spinal motor modules.

Title: Visuo-proprioceptive realignment: Rate, retention, and conscious awareness

Authors: R. BABU, M. WALI, A. HSIAO, ***H. J. BLOCK**;
Indiana Univ., Bloomington, IN

Abstract: We estimate hand position via proprioception and vision, which may not agree. E.g., viewing the hand underwater: water refracts light, displacing the visual estimate of the hand from the proprioceptive estimate. The brain compensates by realigning one or both. We have previously studied this phenomenon by gradually displacing a visual indicator of fingertip position from the true, unseen fingertip position, with no performance feedback. The mismatch can reach 70 mm without most subjects noticing. Subjects realign both visual and proprioceptive estimates, but usually this compensation totals only about 45 of the 70 mm perturbation. In Experiment 1 we asked whether the rate of visuo-proprioceptive misalignment affects the magnitude of realignment. The Slow, Medium, and Fast groups experienced misalignment at a rate of 0.84, 1.67, or 3.34 mm every two trials, respectively. Once misalignment reached 70 mm, this mismatch was maintained for the remaining trials. Results suggest that realignment in the Fast and Medium groups was similar during the gradual misalignment phase: 61 and 56 mm in total. No further realignment was evident during the maintenance phase. The Slow group realigned only 43 mm in total, suggesting that a slower misalignment rate may be less effective at eliciting realignment. Experiment 2 asked whether direct vision of the hand and/or active movement of the hand could disrupt retention of realignment. Four groups of subjects experienced misalignment at the medium rate to a maximum of 70 mm. After the misalignment phase, the Active/Vision group was given direct vision of the misaligned hand and asked to trace circles with their index fingers. The Active/No Vision group traced circles, but with no visual information. The Rest/Vision group was given direct vision of the misaligned hand while resting the hand on their lap. The Rest/No Vision group rested their hand without vision. After 5 minutes, subjects performed more trials to assess how much visual and proprioceptive realignment was retained from the end of the misalignment phase. Preliminary data shows evidence of retention in all four groups. Experiment 3 asked how much misalignment must occur before subjects begin to notice. Subjects experienced misalignment at the medium rate for 8 blocks of trials, reaching a max of 140 mm mismatch. After each block, subjects were questioned about their perception of the mismatch. Once they noticed the mismatch, subjects reported awareness of only about half the true mismatch magnitude. This suggests that visuo-proprioceptive perception of the hand is flexible enough to accommodate considerable spatial perturbation.

Title: Evaluation of sensory integration and its impact on sensory-motor function post-stroke

Authors: *S. M. LINDER[1], Z. C. THUMSER[2], D. T. BECKLER[2], P. D. MARASCO[2];
[1]Physical Med. and Rehabil., [2]Biomed. Engin., Cleveland Clin., Cleveland, OH

Abstract: Introduction: Post-stroke motor recovery can be frustratingly intractable. Despite rehabilitative efforts that focus on motor recovery, functional deficits remain even when strength is restored. Normal motor control requires real-time feedback from the sensory system to operate effectively. However, current standard of care rehabilitation approaches and testing metrics simply ignore the sensory side of the sensory-motor equation. Recent work from our lab provides evidence that amplified proprioceptive sensory feedback improves post-stroke motor control in an upper limb reaching task. The aim of this study was to examine the use of new functional metrics for upper limb sensory-motor function to provide insight into the effects of somatosensory impairment on upper limb motor control. Methods: A cohort study was conducted in which participants (N=2) with chronic stroke and residual upper limb dysfunction completed the Fugl-Meyer Assessment (FMA) evaluating motor function and two recently developed tests evaluating sensory-motor function. 1) During the block sorting test, subjects are asked to identify, manipulate, and transfer polyurethane rubber blocks of varying stiffness (soft, medium, or hard). Outcomes include accuracy, alpha and beta error rates, foraging times, overall efficiency, and discrimination efficiency. 2) The grasping precision test requires participants to quickly and accurately achieve a desired grasp force. Fitts'-based outcomes of interest include speed and peak precision, and the relationship between speed and precision (throughput). Results: The participants performed comparably on the FMA; however, they demonstrated variable performance on sensory-motor testing. One participant was within normative ranges of speed and efficiency on the block test, demonstrating mild difficulty with discrimination accuracy (75% correct) while the other was unable to discriminate firmness (accuracy = 38%) and had deficits with speed (discrimination efficiency of 1.2 %correct/sec). Maximal grip was similar for both patients at 166 N and 185 N. Throughput during the grip test was below normative values for both at 0.87 bits/s and 0.67 bits/s. Conclusion: Although the FMA did not resolve differences between subjects, the grip and block tests revealed distinct differences in how participants integrated sensory information into function, indicating that data from both systems are necessary to provide comprehensive upper limb function assessments. Functional tests with high resolution that evaluate the integration of the sensory system can guide clinical interventions and measure the effects of training on sensory-motor function.

Title: Timing estimates are biased by viscous movement environments

Authors: *R. DE KOCK[1], *W. ZHOU[1], W. JOINER[1], M. WIENER[2];
[1]Univ. of California, Davis, Davis, CA; [2]Dept. of Psychology, George Mason Univ., George Mason Univ., Fairfax, VA

Abstract: Time perception is a phenomenon that is highly influenced by sensory and cognitive processes. However, there are surprisingly few investigations into the involvement of the motor system on timing. This is particularly important, as organisms rely on continuous sensorimotor feedback to navigate a world with rich temporal dynamics. Recent research suggests that movement parameters (e.g., speed and direction) can bias timing estimates, and more generally, that movement can improve timing sensitivity. While this work characterizes the role of volitionally modulated movement parameters, the influence of external modulation (e.g., environmental perturbations) is relatively unexplored. In this experiment, 18 right-handed participants (7 female, 11 male, M age = 21.5(4.1)) completed a temporal reproduction task in which intervals were timed during hand movement in viscous movement environments. We hypothesized that viscosity would restrict movement to shorter lengths, and likewise bias timing estimates to be shorter. Participants performed this task using a robotic arm manipulandum. During the encoding phase, they were instructed to continuously move their right arm through the two-dimensional workspace (i.e., “try not to stay still”) while listening to an auditory tone ranging from 1-4s. In each trial, one of four viscosity values (0, 12, 24, or 36 Ns/m²) was randomly applied to the robotic handle to increase resistance, and thus shorten movement. Next, they reproduced the duration in a central location (handle locked in place) by holding and releasing a button attached to the handle. Notably, including movement during encoding only allowed us to isolate observed movement effects to perceptual timing. Participants performed 280 trials, and trials were excluded if reproduction times were outside of 3 standard deviations from the mean. Our analyses confirmed that viscosity shortened movement in a graded way [$F(3,51)=149.82$, $p < 0.001$, $\eta 2p =0.898$]. By utilizing a Bayesian observer model, we isolated the individual components of the timing process (e.g., bias, estimation noise, and production noise), which revealed an effect of viscosity on perceptual bias (offset parameter) [$F(3,51)=3.72$, $p = 0.017$, $\eta 2p =0.18$]. This suggests that viscosity impacted perceptual, but not cognitive processes during timing. These results strongly indicate that further investigations into external movement influences are needed in timing research, and can help move research towards understanding time-keeping in real world settings where motor plans undergo continuous updating and encounter various environmental perturbations.

Title: Coordinated movement-related activity emerges across motor cortex and cerebellum during skill learning

Authors: *P. FLEISCHER[1], A. ABBASI[1], N. DANIELSEN[1], T. GULATI[1,2];
[1]Cedars-Sinai, Los Angeles, CA; [2]UCLA, Los Angeles, CA

Abstract: The control of forelimb movement and learning new motor skills is distributed across several regions of the brain. This allows for precise limb coordination that is mediated by appropriate descending commands as well as sensory feedback while executing a consolidated task. Cerebellum and the motor cortex (M1) are two densely interconnected regions that are linked to motor learning. Yet, little is known about how the network dynamics in these two regions change when learning a dexterous skilled motor behavior. We have performed simultaneous recordings in M1 and cerebellum in awake behaving rodents (n=3) and profiled the properties of cortico-cerebellar communication that develops while learning a skilled reach-to-grasp task.Single-unit and local field-potential (LFP) recordings were collected from the M1 and cerebellum's Crus II and paramedian lobules while the rats were trained in a skilled forelimb reaching task. We analyzed how the behavior changes from early days of training to late days and the associated power-spectral changes in M1 and cerebellum. We also analyzed movement-related neural coherence across the M1 and cerebellum and specifically, the changes in phase relationships between the spiking activity and the LFP frequency bands both within and between the two regions. Finally, we also explored the representation of neuron activity in M1 and cerebellum through Gaussian-process factor analysis (GPFA). Once the rats had become proficient we saw coordinated low-frequency (< 4 Hz) activity across the M1 and cerebellum that was closely related to the sub-movements in the reach-to-grasp task. Movement-related LFP coherence between M1 and cerebellar LFP also increased in the low frequency range. Furthermore, we also found that this low-frequency oscillatory activity in LFPs modulated the phasic spiking activity of the neurons in each region. GPFA analysis found more correlation within the low-dimensional factors representing population spiking activity in the M1 and cerebellum in individual trials as the skill consolidates. Our work suggests that coordinated low-frequency activity is present in cortico-cerebellar networks and that such rhythmic activity may allow for the coordination of neuronal activity across regions that sub-serves skill learning.

Title: The Effects of Musical Education in Rhythmic Perception and Production in Puerto Rican Adults with or without Musical Training

Authors: *A. F. EDWARDS-CINTRÓN[1], M. RODRÍGUEZ[1], D. PÉREZ[1], A. RAVIGNANI[2], A. MIQUELAJÁUREGUI[1];
[1]Inst. of Neurobio. at Univ. of Puerto Rico, Med. Sci. Campus, San Juan, Puerto Rico;
[2]Comparative Bioacoustics Group, Max Plank Inst. for Psycholingustics, Nijmegen, Netherlands

Abstract: Our remarkable musical abilities seem to be rooted in biological principles and the inherent capacities of the human brain. In this study, we seek to understand the intrinsic rhythmic capabilities in Puerto Rican adults, as well as consider how musical education influences these abilities. To account for these skills, Puerto Rican adults (over 21 years of age), with or without musical training, participated in a series of rhythmic perception and production tests. The tests were the following: Metronome Synchronization, Free Tapping and the Montreal Battery of Evaluation of Musical Abilities (MBEMA). The rhythmic outputs were quantified by measuring the Inter Beat Intervals (IBI). We expect that musicians will display less variability and more accuracy in both rhythmic perception and production. Although all participants reflected a consistent rhythmic output, preliminary data reflects less variability in musicians during the rhythmic production tests when compared to non-musicians. In addition, the participants obtained an overall score of 85% or higher in the rhythmic perception test. This supports that although there seems to be inherent capabilities for rhythmic abilities, musical training may enhance these skills. By characterizing rhythmic perception and production in Puerto Rican adults and children, we hope to shed light on the maturation of rhythmic abilities during brain development and adulthood.

Title: Visuomotor transformations in ventral premotor cortex during head-unrestrained reaches.

Authors: *V. NACHER, P. ABEDI-KHOOZANI, V. BHARMAURIA, H. ARORA, X. YAN, S. SUN, H. WANG, J. D. CRAWFORD;
York Univ., Toronto, ON, Canada

Abstract: Reaching involves a coordinated sequence of gaze, head, and arm movements toward a visual stimulus. Several studies have examined eye-head-hand coordination in the human, but the underlying neural mechanisms, especially those controlling head motion, have not been studied. We addressed this problem by recording single neurons from ventral premotor cortex (PMv) while two trained monkeys performed a reaching paradigm, that allowed unencumbered head motion and reaching in depth. Animals touched one of three central LEDs (different initial hand locations) at waist level while maintaining gaze on a central fixation dot (with a jitter of 7-10° from trial to trial) and were rewarded if they touched a target appearing at one of 15 locations in a 40° x 20° (visual angle) array. Preliminary analysis of 271 neurons in both monkeys showed an assortment of target/stimulus, gaze, pre-reach and reach related responses in PMv. Most neurons could be described as falling into three main groups. 'Early" neurons increased firing rate during the target presentation and gaze onset. "Early-late" neurons responded in a sustained way from target presentation until reach. Finally, "Late" neurons increased firing rate during the pre-reach and peak when the monkey reaches. We first tested for gaze, head and hand gain fields during the different neuronal responses and found in both animals that 38% of target, gaze, pre-reach and reach-aligned responses were gain modulated by initial hand position. A small fraction of neurons showed gain fields for initial eye position (4%), and for both initial eye and hand position (6%). After removing the gain field effects, we fitted the residual data against various spatial models and found that "Early" neurons best coded the target (T) during target presentation and, during gaze shifts, preferentially coded displacement of the arm (dA). This T-dA transformation occurred 150-200 ms after target onset. "Early-late" neurons coded dA from target presentation until reach and "Late" neurons best coded T during pre-reach and arm position in future space (Afs) during reach. A more complete analysis will aim to describe the complete coding and distribution of gaze, head and reach signals in this region.

Title: Acting alone or together? Measuring the cost of inter-individual motor coordination in non-human primates

Authors: *I. LACAL, A. SCHITO, L. CARATELLI, A. BATTAGLIA-MAYER;
Dept. of Physiol. and Pharmacol. "Vittorio Erspamer", Sapienza Univ. of Rome, Rome, Italy

Abstract: Motor coordination between individuals is costly but can also be advantageous when making a goal accomplishable. We previously showed (Visco-Comandini et al, Cortex, 2015) that monkeys engaged in a joint action task pay their cost to achieve a common goal, by adjusting the motor behavior to coordinate with their mates. We now study monkeys' attitude to act together, when allowed to freely choose whether to achieve a goal individually or jointly, on the basis of the payoff of each option. Two rhesus monkeys, using an isometric joystick, guided each a cursor shown on a screen from its center to one of two alternative targets (left/right) to gain the offered amount of reward, which was cued by a level bar inside each target. The targets' color instead cued the type of action (SOLO or TOGETHER) required to gain the offer. In the SOLO option, monkeys obtained the expected reward by moving their cursor alone, while in the TOGETHER one, the animals had to reciprocally coordinate their forces to bring jointly their cursors into the selected target and gain their treat. The rewards associated to the two options differed by 5 possible values (Δ_i, i=0, ⋯ ,4) equally spaced from 0 to 0.60 ml. As a control, monkeys were required to choose between two SOLO or two TOGETHER options, with different payoff.When choosing between targets associated to the same action type both monkeys aimed at the higher offer with similar probability. When facing the SOLO vs TOGETHER choice both animals showed an utter preference for the SOLO action regardless of the offer. This preference decreased without being reverted just for a reward difference higher than 0.15 ml in favor of the TOGETHER option, increasing the choice rate from 0% to about 40%, in both animals. We hypothesized that the offered payoff difference initially adopted was always insufficient to motivate monkeys to choose unequivocally the costly TOGETHER condition over the SOLO one, even when maximally rewarded (Δ_4). However, by doubling the Δ_i - thus ranging from 0 to 1.20 ml - the action condition preference drastically changed: the SOLO action was not always preferred, and 100% of choice rate in favor of the TOGETHER option was observed for a difference in the two options' values above 0.90 ml. The indifference point between the TOGETHER and SOLO offers was found at $\Delta = 0.30$ ml, indicating the perceived cost of acting together. In conclusion, when monkeys chose between acting alone or together, their choice was not merely dictated by the payoff value, but their economic evaluation was subdued to the high cost of motor interindividual coordination. Thus, monkeys can accurately estimate this cost and use it to decide whether to act individually or jointly with others.

Abstract: Previous work reported prolonged spatial planning deficits during eye-hand decoupling tasks in young adult non-athlete college students with a sport-related concussion history (CH) from adolescence. The individuals with CH displayed a larger initial direction error and a trend to fail more often to decouple the movement direction of the eyes and hand at response onset than controls with no concussion history. The previous work focused on performance across the whole series of trials. We now expand this work and investigate potential time-related changes of these deficits along this series of trials, to examine whether these eye-hand decoupling deficits are rather due to problems with adapting to new task constraints or with meeting ongoing task demand. We re-analyzed data from 21 CH participants (M=48 months post-concussion) and 20 controls with no-history of concussion (NoH) (M=21 yrs. in both groups). Participants performed two eye-hand coordination tasks, a direct task with vision and motor action in alignment, and an eye-hand decoupling (EHD) task where vision and motor action were spatially decoupled. Twenty trials were performed per task condition, with five movements from a central target to each of four target directions (up, down, left, right), thus, movement trials were split into five blocks of four trials (i.e., trial 1-4, 5-8, 9-12, 13-16, and 17-20). We analyzed movement planning (direction reversal error [DRE] at response onset, reaction time, initial direction error [IDE] 100 ms after response onset) and execution related variables (movement time, path length, endpoint error) across blocks (1-5) and groups (CH, NoH) in condition EHD.ANOVA revealed CH trended to perform more DRE than NoH in the EHD condition ($p=0.08$), independent of blocks. For IDE, ANOVA revealed a main effect of group ($p<0.001$), block ($p<0.01$), and a significant block x group interaction ($p<0.05$). Post hoc test revealed IDE was larger in CH than NoH in block 1 and 2 (both $p<0.01$) but not in block 3-5 (all $p>0.05$). All other variables did not show significant group or group x block effects in condition EHD (all $p>0.05$).The present results suggest that the previously reported spatial movement planning deficits of young adults with a concussion history from adolescence while performing a series of eye-hand decoupling trials relate to issues with adapting to new task constraints. Our findings also suggest a trend for ongoing inhibition control issues (i.e., a larger DRE) along a series of twenty trials in the CH group. The current work enhances our understanding of performance issues during eye-hand decoupling tasks in young adults with concussion history about four years post-injury.

Title: The importance of inhibition in grooming action choice

Authors: *D. S. SYED, J. H. SIMPSON;
MCDB, Univ. of California Santa Brabara, Santa Barbara, CA

Abstract: Complex behaviors such as courtship or catching food require series of coordinated actions. How nervous systems solve the problem of assembling flexible behavioral sequences is an important unresolved question. We study grooming behavior in the fruit fly, *Drosophila* as a model to investigate circuits that regulate sequential behaviors. Flies covered with dust select different motor programs among many competing choices. They clean only one body part at a time and prioritize anterior body cleaning over posterior (Seeds et al., 2014; Hampel et al., 2015, 2017). Here, we investigate the role of specific inhibitory interneurons in regulating the choice of grooming actions. Inhibition controls movement of limb joints (Grillner, 2006; Kiehn, 2011; Goulding et al., 2014) and regulates selection among different behaviors (Gaudry and Kristan, 2009; Stephenson-Jones et al., 2011; Mann et al., 2013). Humans and flies share Gamma-aminobutyric acid (GABA) as a major inhibitory neurotransmitter (Hosie et al., 1997; Ennel et al., 2007; Fei et al., 2010). Although inhibition is key for motor control, common design principles that enable execution of flexible motor sequences are not yet obvious.
We performed a targeted behavioral screen to identify specific inhibitory neurons that disrupt normal grooming. We use sensory cues to initiate grooming and test behavioral consequences of optogenetic activation of interneurons. We identified subsets of GABAergic lineage 13 neurons that are involved in both inter- and intra-segmental coordination. Lineage 13 consists of two hemilineages, 13A and 13B that project to the ipsilateral and contralateral regions respectively in a given segment of ventral nerve cord (VNC) (Harris et al., 2015). Some disrupt essential left-right limb coordination. Activation of other inhibitory neurons disrupts the grooming hierarchy, causing flies to prioritize posterior body cleaning over anterior. Inhibition could act directly at the sensory level, since RNAi knockdown of Rdl receptors in mechanosensory neurons results in a similar phenotype. Preliminary connectivity analysis using an electron-microscopy dataset (Maniates-Selvin et al., 2020) revealed interesting presynaptic connections. These include commissural interneurons, possibly involved in left-right coordination; descending neurons that project from brain to the VNC; and intersegmental neurons, possibly involved in sequential action selection. The neural circuit motifs identified in this study will provide insights into how a relatively simple nervous system coordinates the order and execution of sequential actions.

Title: Independent Adaptations of Movement Direction and Extent During Goal-directed Reaching

Authors: *D. PETERS[1,2], D. LANTAGNE[1,2], J. HOELZLE[1], D. THOMAS[2], L. A. MROTEK[1,2], R. SCHEIDT[1,3,4,2];

Abstract: Existing concussion assessments focus on symptoms, signs, and changes in overt behavior and measurement of cognitive performance that engage explicit memory systems but do not assess implicit motor memories. Recent findings (Brown JA et al, 2015) show that people with a history of concussion exhibit pronounced deficits in movement timing and accuracy relative to healthy controls when the brain has to resolve more than one level of decoupling between vision and action. Here we sought to develop a robust concussion assessment by establishing normative performance on a challenging reach task requiring simultaneous adaptations to distinct perturbations of movement direction and extent. Seven subjects performed 600 ballistic, 10 cm, out-and-back reaches to 5 targets at -60°, -30°, 0°, 30°, 60° from the participant's sagittal plane. Subjects moved a 2-joint robot handle outward in the horizontal plane against spring-like loads that changed unpredictably from trial to trial. Direct view of the arm was blocked. Subjects received feedback of hand location on a monitor in the vertical plane. Visual feedback was faithful during the first 150 trials (Baseline), a 30° visuomotor rotation was applied for 300 trials (Rotation) and then removed for 150 trials (Washout). Kinematic performance was quantified using reach direction error and extent error at the point of maximum extent. All subjects reached with minimal direction and extent errors during Baseline. At the start of the Rotation Block, both direction and extent errors increased, but the time course of subsequent error reduction differed markedly between the two error measures. Whereas direction errors were corrected within 10-15 trials, extent errors took more than 50 trials to return to baseline. On removing the rotation (Washout), direction errors showed clear aftereffects whereas reach extent was unaffected by removal of the imposed rotation. Because the rotation impacted movement direction but not extent, and the spring loads impacted movement extent but not direction, the results show that the sensorimotor compensations used to adapt movement direction are distinct from those mediating adaptation of movement extent. Thus, our findings support separate planning and control of reach direction and extent (Bhat RB & Sanes JN, 1998).

Future studies are planned to use this composite task to study the impact of concussion on these two aspects of sensorimotor control.

Title: Variability of Arm Kinematics in Hitting a Target with a Bull Whip

Authors: *M. EDRAKI[1], R. SHARIF RAZAVIAN[2], A. D. KROTOV[3], M. RUSSO[2], M. C. NAH[5], N. HOGAN[6], D. STERNAD[4];

Abstract: Over evolution, humans have become exquisitely adept at manipulating complex objects, ranging from chopping onions to spreading a tablecloth. However, to date motor control studies have focused on simple highly controlled motor tasks typically excluding contact or interaction to assure experimental control. As an overture to study the variety of skills that humans display in their daily actions, this study chose one of the most challenging motor skills: manipulation of a flexible underactuated object—a bull whip. We studied whole-body movements when swinging a 1.6m long bull whip to hit a target at ~2.2m distance with the tip of the whip. A first question was how different manipulation styles achieved hitting accuracy. Sixteen subjects were asked to throw a whip in two variants: hitting the target in a single-shot discrete movement and in a rhythmic action that kept the whip in the air. All subjects performed both styles for 5 blocks, each consisting of ~30 trials. Three-dimensional body and whip kinematics were tracked using a marker-based motion capture system. Seven joint angles of the arm were calculated.Performance was quantified by target hits and mean and variability of error. The 16 participants showed a wide range of performance success. However, all participants showed better hitting performance in the discrete style, although improvements across blocks only occurred in the rhythmic style. Based on this wide range of performance levels, the next focus was on how inter-joint coordination of the arm prepared an accurate whip throw. Given the redundancy of the multi-joint arm, principal components analysis assessed the dimensionality of the throwing movement evolving across the duration of the throw. We hypothesized that more

successful subjects reduce their variability as they approached the critical throw onset. We further hypothesized that, as subject improve, they learn to exploit the redundancy in the task and reduce joint angle variability in the latent dimensions that affect task performance. First analyses showed results consistent with these hypotheses.This analysis of a highly complex motor task aims to shed light onto how humans learn to adjust their joint coordination when interacting with a complex object. This study presents the first step in a new experimental paradigm that challenges current motor control notions and sets the stage for more hypothesis-driven analysis.

Title: Going through the motions: Evaluating the consistency of mouse-tracking derived measures of decision difficulty across three reach-decision tasks

Authors: *A. A. OUELLETTE ZUK[1], C. S. CHAPMAN[2];
[1]Neurosci. and Mental Hlth. Inst., [2]Fac. of Kinesiology, Sport and Recreation, Univ. of Alberta, Edmonton, AB, Canada

Abstract: As decisions require actions in order to have an effect on the world (Cisek & Kalaska, 2010), measures derived from movements can be used to provide a powerful index of decision-making processes (e.g. Gallivan & Chapman, 2014). Measures of trajectory curvature (interpreted as a competitive pull from the non-chosen choice; Spivey, Grosjean, & Knoblich, 2005), reaction time, and movement time obtained during mouse-tracked, reach-decision tasks thus provide a metric of the relative difficulty of decisions (McKinstry, Dale, & Spivey, 2008). While these measures of decision difficulty have been demonstrated across a variety of decision domains, they are reported in different studies with different groups of participants. To our knowledge, no study has determined whether the same measures of decision difficulty are consistent for an individual across different decision tasks. To that end, the current study aims to 1) replicate task-specific metrics of competition between choice options in three independent decision domains differing in choice stimuli, objectivity and processing requirements and 2) assess whether within-participant measures of decision difficulty remain consistent across the decision domains. Deploying a classic mouse-tracking, reach-decision paradigm, participants (n = 46) were asked to complete a numeric-size congruency (SC) task requiring objective perceptual judgements of which of two digits with different physical sizes was numerically larger (Faulkenberry *et al.*, 2016), a sentence verification (SV) task requiring semi-subjective

conceptual judgements about the truth value of statements varying in truth value and negation (Maldonado *et al.*, 2019), and a photo preference (PP) task requiring subjective judgements of preference between two images varying in pleasantness (Koop & Johnson, 2013). Broadly, task-specific results replicated previous work: SC: We found an increase in decision difficulty when digit choice options were incongruent in physical and numeric size; SV: Measures of decision difficulty increased when participants were asked to affirm negated sentences compared to non-negated sentences, with greater negation-driven difficulty effects for true statements than false statements; PP: Images matched in pleasantness showed increased decision difficulty compared to image options that differed in pleasantness. Ongoing analyses are examining 1) across-participant correlations to determine if participants exhibiting high degrees of decision difficulty are consistent across tasks and 2) within-participant correlations to examine how measures of mouse-derived decision difficulty are related.

Title: Computational limits on the speed of learning internal models for arm reaching

Authors: *V. R. BARRADAS[1], N. SCHWEIGHOFER[2], Y. KOIKE[1];
[1]Tokyo Inst. of Technol., Tokyo, Japan; [2]USC, Los Angeles, CA

Abstract: An important aspect of motor learning is the formation of internal models, which encode the physics of a motor task in the form of mappings between motor commands and actions (forward models), and vice versa (inverse models). Different learning algorithms such as feedback error learning, reinforcement learning and distal learning have been proposed to explain the formation of inverse models. These algorithms attempt to minimize errors by adjusting parameters of the inverse model. Here we used a distal learning-based model to investigate the aspects of isometric and kinematic arm reaching tasks that influence the speed of learning an inverse model of the task. Using convex optimization techniques, we analyzed the shape of the error surface in the space of the inverse model parameters. The eigenvalues of the Hessian of the error surface around a minimum describe the shape of the surface, which for gradient-following algorithms, also determines the maximum speed of learning for a given task. We show that for reaching tasks, the shape of the error surface and the speed of learning are determined by the shape of the manipulability ellipsoid of the arm, and by the distribution of targets in the task. In particular, the rounder the manipulability ellipsoid and the target distribution, the faster learning can take place. We tested these results experimentally in a virtual quasi-isometric reaching task where the force manipulability ellipse of the arm is controlled through a virtual squeezing mapping between arm forces and cursor movement. The results (5 subjects, 3 male) showed that rounder virtual force manipulability ellipses allow faster learning

of a 30° visuomotor rotation. This is consistent with our theoretical predictions. Furthermore, our analytical framework was able to predict the speed of learning in several experiments published in the literature. For instance, differences in the speed of learning incompatible and compatible virtual surgeries, and differences in the speed of learning a visuomotor rotation with different numbers of targets are well accounted for by our analysis. By identifying factors that influence the speed of learning, our results provide theoretical principles for the design of motor tasks that allow for faster learning.

Title: The effect of instructions on de novo learning and the mechanisms that distinguish it from motor adaptation

Authors: *R. Q. GASTROCK[1,2], B. M. 'T HART[1,2], D. Y. P. HENRIQUES[1,2];
[1]York Univ., Toronto, ON, Canada; [2]Ctr. for Vision Res., Toronto, ON, Canada

Abstract: The environments that people move in are constantly changing. Such changes may lead to movement errors, which we must process in order to produce correct movements. This error processing occurs regardless of whether people are acquiring a new motor skill (de novo learning) or adapting a well-known movement (motor adaptation). However, these two types of motor learning should develop differently. Furthermore, while reach aftereffects or the persistent deviation in reaches after perturbation removal are typically observed following adaptation, switching between response mappings in de novo learning should not lead to aftereffects. Here, we conducted two experiments that differentiate de novo learning from adaptation and explore the mechanisms of de novo learning further. In experiment 1 (N = 16), we distinguished the two motor learning types by having each participant train with two perturbations in counterbalanced order: a 30-degree visuomotor rotation and a reversal of cursor feedback in the opposite direction of a mirror axis. Importantly, we matched the movements required to reach the targets in both tasks. We found no order effects, suggesting that learning for one perturbation does not affect the other. Although participants countered for both perturbations by the end of only 90 training trials, learning for the rotation task was more gradual while variability in learning was greater for the mirror task. Participants generally took longer to initiate and execute reaching movements in the mirror task. Moreover, participants only exhibited reach aftereffects after completing the rotation task. In experiment 2, we developed an online version of the mirror task, with target locations placed farther from the mirror axis than in experiment 1. Here, we compared how learning progressed when either providing participants with explicit instructions about the nature

of the mirror reversal (N = 115) or not providing such instructions (N = 112). Surprisingly, learning occurred quickly, even for the non-instructed participants. Regardless of instructions, however, asymptotic learning of participants differed depending on target location and reach aftereffects were not observed. These results show how the development of de novo learning is distinct from adaptation, and future work should investigate the behavioural and neural processes underlying these two types of motor learning.

Title: Mapping of cervical spinal cord in humans shows stronger muscle responses to lateral than midline stimulation

Authors: *J. R. MCINTOSH[1,4], S. C. KARCESKI[5], O. MODIK[5], E. SHELKOV[5], N. PATEL[6], S. OH[1,2], J. L. GOLDBERG[4], N. Y. HAREL[7,8], M. VIRK[4], J. B. CARMEL[1,3];

Ctr., New York, NY

Abstract: When individuals who have had spinal cord injury are treated with continuous lumbar epidural spinal cord stimulation they are able to stand and walk, demonstrating the effectiveness of this technique for restoration of movement. However, the question of how best to deliver electrical stimulation for sustained arm and hand function recovery remains open. In particular, how epidural stimulation activates human cervical spinal cord circuits is poorly understood. Work in rats has indicated that stimulation delivered over the dorsal root entry zone recruits afferent axons more strongly than stimulation directly over the midline. Based on this, we hypothesized that in humans, stimulation applied more laterally, where afferents enter the spinal cord at the dorsal root entry zone, would produce stronger muscle responses compared to stimulation delivered over the midline. We mapped cervical spinal cord responses to epidural stimulation in 10 participants undergoing clinically indicated cervical laminectomy. EMG was recorded in multiple arm and leg muscles, and a hand-held bipolar electrode was used to stimulate the exposed dorsal spinal cord. We measured the threshold stimulation intensity required to evoke activation of a targeted muscle (triceps or ADM) at the midline of the most caudal surgically exposed segment (usually C7). Multiple rostrocaudal and midline-lateral sites were then stimulated at 120% of this threshold. Analysis was conducted on the area under the curve (AUC), calculated by integrating the evoked responses. Stimulating laterally produced

larger muscle activation than stimulating at midline across subjects (median midline AUC = 0.93μVs, lateral AUC = 2.30μVs, Wilcoxon signed-rank test, p = 0.014, n = 10), corresponding to a 131% increase. By demonstrating greater responses when stimulation was delivered directly over the dorsal root entry zone, our results are consistent with a growing body of work indicating that epidural stimulation of the spinal cord primarily activates afferents. More generally, this study paves the way for further work investigating associative plasticity that can be induced in the cervical spinal cord by combining brain stimulation and spinal epidural electrical stimulation to aid recovery in spinal cord injury.

Title: Decoding motor error correction and adaptation through phase and amplitude components of the EEG signal.

Authors: *L. STRUBER, M. BAUMONT, P.-A. BARRAUD, V. NOUGIER, F. CIGNETTI; TIMC-IMAG, Univ. Grenoble Alpes, CNRS, Grenoble INP*, Grenoble, France

Abstract: In order to achieve goal-directed movement, our brain simulates movement dynamics with an internal model. Error between actual and expected consequences of the movement drives update of this model, a.k.a. motor adaptation. Only a few studies focused on the oscillatory brain activities associated with recalibration of an internal model. We proposed here a sensitive data-driven multivariate approach to explore EEG signal characteristics and come up with an extended understanding of motor adaptation. To this end, 19 healthy subjects performed aiming movements with a joystick, while a visuomotor distortion (constant rotation) was applied between the joystick and the visual feedback. Two other experimental conditions were also considered, one without distortion, including neither error nor model update, and one with a random rotational perturbation in which errors were present but without model update. Oscillatory power and phase locking signals were estimated from 128-channel EEG through Hilbert transform. Then, a multiple kernel learning (MKL) approach with a high number of features was considered to decode early from late stages of visuomotor adaptation. Secondarily, adaptation condition was also classified against the other conditions to tease apart internal model update and error correction processes. MKL discriminated between early and late adaptation (accuracy: 87%; p = 0.002) from modulations of EEG power during post-movement.

Specifically, weights of the kernels revealed three frequency bands contributing to the discrimination: a theta band contribution in frontal and premotor regions, a beta band contribution in the supplementary motor area, and a gamma band contribution in motor regions, explaining respectively 29%, 18% and 30% of the classification. For all these band/region couples, adaptation process led to an increase of post-movement event-related synchronization. Further investigation showed a strong contribution of high frequency bands (beta and gamma, 46% and 41%) in the classification of the no perturbation vs. random perturbation conditions (accuracy: 74%; $p = 0.016$), between which only error size varied. Besides, classification of no perturbation vs. adaptation (accuracy: 82%; $p = 0.002$), in which both error and model update differed, showed a strong contribution of theta band (66%), and to a lesser extent of beta and gamma bands (11 and 15%, respectively). Altogether, our results indicate that post-movement frontal theta synchronization is most related to model update, whereas post-movement motor high-frequency beta and gamma synchronization is most associated to error processing.

Title: Neural correlates of visuomotor adaptation with workspace manipulation

Authors: *R. N. ADDISON, F. STEINBERG, A. W. VAN GEMMERT;
Sch. of Kinesiology, Louisiana State Univ., Baton Rouge, LA

Abstract: Background: Visuomotor adaptation tasks provide insights into how humans integrate sensory information to interact with our environment. Successful updates of motor plans ensues in visuomotor adaptation. Effective visuomotor adaptation might be workspace specific and associated neural activity, in particular the central and parietal areas, may differ due to adaptation within different workspaces. **Objective:** This study examines neural activity changes due to visuomotor adaptation to workspace location manipulation. **Methods:** Twenty right-handed healthy young adults were instructed to move a stylus from a home position to a target on a digitizer tablet using a stylus while visual feedback of the drawing trace was rotated 45 degrees on the monitor. Three different workspace location conditions were employed: 1) Digitizer located central to the body's midline (control condition; CON), 2) lateral to the body requiring the hand holding the stylus not to cross the participant's midline (NMC), and 3) lateral to the body requiring the hand holding the stylus to cross the participant's midline of the body (CML). Participants started and ended the experimental session with the CON condition, while NMC and CML conditions were counterbalanced across participants. During performance, neural activity through electroencephalography (EEG) with 32 electrodes was recorded and for each condition the power spectra of alpha and beta waves were computed. A repeated measures

ANOVA with workspace location as within factor was performed for five behavioral variables (Pathlength, movement time, resultant velocity, normalized jerk, and endpoint error), as well as for neural activity measures (alpha and beta waves). **Results:** All behavioral measures, except normalized jerk, and mainly the neural activity measures of the central and parietal areas were significantly affected by the workspace conditions. Tukey's test for post hoc analysis revealed differences in behavioral measures and neural correlates of the different workspace manipulation. Workspace condition differences of alpha waves were mostly observed unilaterally in the right hemisphere of the central and parietal areas (C4, CP2, CP6, P4, and P8), whereas beta waves showed bilaterally differences between workspace conditions (C3, CP1, CP2, P3, and P4). **Conclusions:** Workspace location affects alpha and beta neural activity of central and parietal areas together with behavioral performance measures when performing a visuomotor task. Therefore, this study supports the view that these brain areas are pivotal to process spatial information during the adaption process when novel tasks are performed.

Title: Beta Band Decreases in Hippocampus During Motor Execution in a Delayed Reach Task

Authors: A. M. TANG, R. MARTIN DEL CAMPO-VERA, K.-H. CHEN, A. S. GOGIA, R. SEBASTIAN, G. NUNE, C. Y. LIU, S. KELLIS, *B. LEE;
Neurosurg., USC, Los Angeles, CA

Abstract: Introduction:
The role of the hippocampus in motor planning and execution is a documented area of ongoing investigation. Much of previous research has focused on the hippocampal beta frequency band (13-30 Hz), particularly focusing on beta band increases and decreases during phases of movement planning and execution. During simple reaching tasks, the beta band has been shown to decrease during movement. Conversely, beta band increases have been observed during Go/No-Go tasks requiring movement inhibition. However, despite the increasingly clear relationship between movement and beta band modulation, it remains unclear if modulation is a reflection of planning or execution itself. In this study, a delayed reach task is utilized to elucidate the temporal properties of movement-related beta band modulation.

Methods:
Twelve participants with epilepsy underwent hippocampal stereo electroencephalographic (SEEG) implantation. Local field potentials (LFPs) were sampled throughout a delayed reach task, in which patients were cued on the movement destination, but were required to remain stationary for a 1-4 second delay prior to motor response. For each phase of the task, beta band

neural modulation was compared to baseline power levels during the fixation phase. Differences were assessed by observation of 95% confidence intervals for trial-averaged spectral power.
Results:
After artifact removal, eight patients were available for analysis. Five out of eight patients had decreases in beta power during the response phase. When compared to baseline, cue phase beta power increased in three out of eight patients. During the delay phase, three out of eight patients demonstrated beta power increases.
Conclusion:
This study found decreases in beta power during movement execution in a task that introduced a delay between cue and execution. This finding supports previous studies noting decreases in the beta band during movement execution itself and adds that the beta band has similar modulation when the planning component is forced to delay. Furthermore, during the delay requiring movement inhibition, increases in beta band were not generally observed. This finding suggests that the mechanism behind beta band increases in previous Go/No-Go studies requires continued investigation.

Title: An investigation of individual differences to anodal tDCS during practice with complex, whole-arm, implicit sequence task

Authors: *B. GREELEY;
Dept. of Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: While transcranial direct current stimulation (tDCS), a form of non-invasive brain stimulation, over the primary motor cortex (M1) has been demonstrated to improve motor learning, there is considerable individual variability in response to tDCS. For example, it is estimated that approximately 40-70% of individuals respond to anodal (excitatory) tDCS in an expected manner (e.g., tDCS enhances motor learning). Therefore, there is a need to identify sources of variability to tDCS in order to understand and predict tDCS efficacy. Here we investigate two potential sources of variability to tDCS efficacy: resting motor threshold (RMT) and the duration and quality of sleep following a single session of anodal (excitatory) tDCS. Using a within-subject design (3 day washout period), eleven (age range 20-35 years old, 3 males) healthy young adults received either sham or anodal tDCS (5x7cm electrodes, 2mA, 10 minutes) over the dominant M1 while practicing 4 blocks of the serial targeting task, a whole-arm implicit motor sequence task, on a KINARM robot. In the task, participants reached to a

series of targets that were arranged in a circular array. Targets were presented one at a time. Unknown to participants, a reoccurring 6-element sequence was embedded in the target presentations, flanked by the presentation of pseudo-random targets. To quantify learning the reaction time from the sequence targets was subtracted from the random targets. RMT was obtained via transcranial magnetic stimulation over the extensor carpi radialis motor "hotspot." Twenty-four hours following practice, participants returned and practiced 1 block of the serial targeting task without the application of tDCS to assess retention and completed a survey to assess sleep duration and quality. While a repeated measures ANOVA revealed that there was no difference in learning between the anodal and sham tDCS groups, cluster analysis indicated 54% of participants benefited from the application of anodal tDCS. Additionally, neither RMT or sleep duration or quality predicted motor retention. These preliminary results suggest that other approaches such as individualized current modeling or structural imaging methods may be more effective in accounting for sources of variability to tDCS.

Title: Temporal cortical regulation of motor behavior on a modified forelimb dexterity test

Authors: *H. MOHAMMED, Y. LI, P. DI GRAZIA, A. BERNSTEIN, S. AGGER, E. HOLLIS, II;
Burke Neurolog. Inst., White Plains, NY

Abstract: Hand and arm manual dexterity is a hallmark of humans and non-human primates. While rodents are less dexterous than primates, they provide powerful models for testing neural circuit function in behavioral output, including dexterous behaviors. In rodents, the single pellet reach task has been used extensively to study both dexterous forelimb motor learning as well as recovery from injury; however, mice exhibit high variability in task acquisition in comparison to rats and a significant percentage fail to learn the task. We have created a recessed version of the task that requires greater dexterity. This subtle modification increases both task difficulty as well as the proportion of mice that show an improvement with training. Furthermore, motor cortex inactivation shows a greater effect on the execution of the recessed forelimb reach task, with distinct effects on reach targeting vs grasping components depending on the timing of inhibitory activation. Kinematic analysis revealed differences in reach targeting upon transient cortical inhibition prior to reach onset. In summary, the recessed single pellet reach task provides a

robust assessment of forelimb dexterity in mice and a tool for studying skilled motor acquisition and execution.

Title: Pre-instruction about future action improves joint action performance in monkeys

Authors: I. LACAL, A. SCHITO, L. BABICOLA, L. NALBANT, R. GUPTA, ***A. BATTAGLIA MAYER**;
Dept. of Physiol. and Pharmachology, Sapienza, Univ. of Rome, Rome, Italy

Abstract: The ability to optimize collective behavior to achieve common goals is not a prerogative of our species, although humans exhibit exceptional skills in acting together, due to their capacity to predict a coagent's behavior and to flexibly adjust to it. We have shown (Visco-Comandini et al, Cortex, 2015) that monkeys engaged in a joint action task use different strategies to coordinate with each other. We now investigate under which conditions monkeys' dyadic performance can be facilitated. Three pairs of rhesus monkeys were trained to perform an isometric center-out task requiring a force application to guide visual cursors in 8 directions, either individually (SOLO) or jointly (TOGETHER) with a partner, in an intermingled fashion. Two different task structures were used: i) in the 'no Pre-Instruction' (no-PI) task the direction of cursor's movement and the action type (SOLO or TOGETHER), required to gain the reward, were cued simultaneously, by presenting a peripheral target in one location, its color signalling the action requested; ii) in the Pre-Instruction (PI) task the action type was prompted in advance by the color of the central target, during an ad hoc delay time, followed by the appearance of the peripheral target. The TOGETHER performance was always poorer than the SOLO one, reflecting the higher task demand due to the necessity of a reciprocal motor coordination. However, the presence of the pre-instruction about the action type favored the joint behavior, significantly increasing the dyadic success rate. Even though, as previously shown, reaction-times (RTs) were generally reduced in the TOGETHER condition respect to SOLO one, few exceptions confirmed that this was not always the adopted strategy. We hypothesized that the way each monkey copes with interacting contexts critically depends on the idiosyncratic motor behavior of the respective partner. We found that inter-individual differences in monkeys' action kinematics, as observed in SOLO condition, predict the quality of joint performance. Interestingly, this correlation was observed only for PI trials, i.e. when the pre-instruction about the future action type was provided. The presence of a PI period was associated to RTs'

decrease, that resulted in reducing the RTs differences between the interacting subjects and therefore in their synchronization. We conclude that pre-cueing the future action type facilitates inter-individual motor coordination during joint action, particularly in the temporal domain. It might provide an optimal 'kinematic setting' that ultimately induces the reduction of inter-individual differences, maximizing the chance of success between interacting partners.

Title: Estimating maximal muscle electromyographic activity from the relationship between muscle activity and voluntary activation

Authors: *J. DIONG[1], K. KISHIMOTO[1], S. C. GANDEVIA[2], J. E. BUTLER[3], M. E. HEROUX[4];
[1]The Univ. of Sydney, Sydney, Australia; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Neurosci. Res. Australia, Randwick, NSW, Australia; [4]Neurosci. Res. Australia, Sydney - Randwick, Australia

Abstract: Maximal muscle activity recorded using surface electromyography (EMG) is an important neurophysiological measure. It is often used to normalize EMG activity recorded during passive movement or active contractions. However, maximal muscle activity cannot be accurately measured in people with an impaired ability to voluntarily activate their muscles. In this study, we determined whether maximal muscle activity can be estimated from muscle activity produced during submaximal voluntary activation. Twenty-five able-bodied adults (18 males, mean age 29 yrs, range 19-64 yrs) participated in the study. Participants were seated with the knee flexed 90° and the ankle in 5° of dorsiflexion from neutral. Participants performed isometric voluntary ankle plantarflexion contractions to produce the following target torques, in random order: 1, 5, 10, 15, 25, 50, 75, 90, 95, 100% of maximal voluntary torque. Ankle torque, muscle activity in soleus, medial and lateral gastrocnemius muscles, and voluntary muscle activation measured using twitch interpolation were recorded. In all three muscles tested, there was a strong $\log_e$-linear relationship between measures of muscle activation and muscle activity. Linear mixed models were fitted to muscle activation and $\log_e$-transformed EMG data. Each 1% increase in muscle activation was associated with a mean increase in muscle activity of 0.027 ln(mV) [95% CI 0.025 to 0.029 ln(mV)] in the soleus muscle, 0.025 ln(mV) [0.022 to 0.028 ln(mV)] in the medial gastrocnemius muscle, and 0.028 ln(mV) [0.026 to 0.030 ln(mV)] in the lateral gastrocnemius muscle. The relationship between voluntary muscle activation and muscle activity can be described using simple mathematical functions, which could be later used to estimate maximal muscle activity to normalize recorded muscle activity.

Title: The neurophysiological effects of an acute exercise bout in young healthy individuals: a systematic review and meta-analysis

Authors: ***S. PHAN**[1], J. COLLINS[2], B. FRANCISCO[4], L. JOHNSON[5], A. ROMAIN[2], K. HAYWARD[6], J. L. NEVA[3,7];
[1]École de kinésiologie et des sciences de l'activité physique, Univ. De Montréal, Montréal, QC, Canada; [2]École de kinésiologie et des sciences de l'activité physique, Univ. de Montréal, Montreal, QC, Canada; [3]École de kinésiologie et des sciences de l'activité physique, Univ. de Montréal, Montréal, QC, Canada; [4]Univ. of British Columbia, Vancouver, BC, Canada; [5]Australian Catholic Univ., Melbourne, Australia; [6]Dept. of Physiotherapy, Univ. of Melbourne, Melbourne, Australia; [7]Ctr. de recherche de l'institut universitaire de gériatrie de Montréal, Montreal, QC, Canada

Abstract: Acute cycling exercise can modulate primary motor cortex (M1) excitability of the non-exercised upper-limb in young healthy individuals. Evidence shows that measures of intracortical excitability, via transcranial magnetic stimulation (TMS), are altered after an acute bout of exercise [1-4], with some studies showing enhanced corticospinal excitability [4-5]. However, it is unclear which M1 excitability measures are consistently altered after acute exercise and which exercise intensity elicits the greatest modulation [1-5]. We conducted a systematic review and meta-analysis to synthesize the current state of the literature to further understand the impact of acute exercise on M1 excitability (PROSPERO CRD42017065673). This work has three aims: (1) characterize the effects of acute exercise on M1 excitability, (2) determine which TMS measure shows consistent and robust effects and (3) examine which exercise intensity (i.e., low, moderate, high) elicits the greatest M1 excitability response. A literature search was conducted up to April 2020 using Medline Ovid, Embase, and PsychINFO. Eligible studies included healthy participants (aged 18-40), an acute bout of lower-limb cycling exercise and measures of M1 excitability of the non-exercised upper-limb using TMS. Screening of titles and abstracts was performed (3047 studies), followed by full text screening (61 studies), resulting in 22 included studies (n=457 participants). Data extraction was performed using a prespecified form. Descriptive statistics (mean, frequency) were used to characterize the impact of acute exercise on M1 excitability. Preliminary results demonstrated most studies included a measure of intracortical excitability (49%), with several including measures of corticospinal excitability (39%). Moderate-(43%) and/or high-intensity (39%) were the most common exercise

intensities included in the studies. Descriptive results suggest that acute exercise more commonly impacted intracortical excitability compared to corticospinal excitability, and moderate-to-high intensity exercise more frequently elicited these effects compared to low-intensity exercise. A meta-analysis of continuous data will be performed on the extracted data (mean, SD) to determine which TMS measure shows the greatest response to acute exercise and sensitivity analyses to control for exercise intensity. Title: The impact of acute high intensity exercise on transcallosal inhibition in older adults

Authors: *B. CHAU, B. GREELEY, C. B. JONES, L. A. BOYD;
Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Background: While studies have investigated the effect of exercise on corticospinal, intracortical, and interhemispheric processes in young adults, few studies have focused on older adults. Current evidence supports the hypothesis that there is a shift from predominantly inhibitory to excitatory interhemispheric interactions as we age. Other work suggests that changes observed in transcallosal inhibition (TCI) with age (i.e., reduced ipsilateral silent period (iSP) duration and area), may be mitigated by physical activity. Therefore, the main purpose of this experiment was to advance understanding of how high intensity interval exercise training (HIIT) alters patterns of interhemispheric excitability in the healthy older adult population. **Methods**: 41 healthy older adults participated in this study. 21 were pseudo-randomized into the exercise group (8 males, mean age = 66.8 ± 8.9) and 20 in the rest group (5 males, mean age = 65.8 ± 6.3). Participants in the exercise group completed an acute bout of HIIT on a recumbent bike. HIIT exercise began with a 5 min warm up (10 W), followed by three repetitions of 3-minute high intensity bouts of exercise (75% of their max power output as determined from their cardiac stress test) which were interspersed with 3-minute bouts of active recovery (at 10 W) for a total 23 minutes of exercise. Participants in the rest group sat for the same duration of time while their attention was controlled by watching a nature documentary. TCI of the upper limbs, indexed by iSP area, was assessed via transcranial magnetic stimulation while participants squeezed a dynamometer at 50% of their maximum voluntary contraction before (baseline),

immediately (Post 1), and 30 minutes (Post 2) following HITT or rest. **Results**: A mixed design ANOVA was performed with between group factor GROUP (exercise, rest), and within group factors: TIMEPOINT (baseline, post 1, post 2) and HEMISPHERE (dominant, non-dominant) to evaluate changes in iSP area. There was an interaction effect between timepoint and hemisphere ($F(2, 78)= 3.211$, $p= .046$). Post-hoc analyses using Bonferroni correction revealed that this interaction effect was driven by hemispheric differences within the Exercise group at timepoint Post 1; iSP area was significantly greater in the non-dominant compared to the dominant hemisphere ($p= .008$). **Conclusion**: The current study showed following HIIT, that there was a hemispheric difference in TCI in older adults. The present research provides insight on how exercise could be used to mitigate age related changes in the brain and informs how exercise therapies could be employed in association with rehabilitation in clinical populations.

Title: Characterizing changes in PMd-M1 interhemispheric inhibition across execution of simple unimanual and bimanual actions.

Authors: *R. DENYER, B. GREELEY, L. A. BOYD;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Understanding the influence of frontal cortical regions on primary motor cortex (M1) output during movement preparation and execution will inform hierarchical models of motor control and improve treatment of movement disorders. In the current study, single and dual stimulation transcranial magnetic stimulation (TMS) were used to measure the inhibitory influence of non-dominant dorsal premotor cortex (PMd) on dominant M1 at rest and in the pre-movement period of unimanual and bimanual simple reaction time tasks in heathy volunteers. Motor evoked potentials (MEPs) generated in the flexor dorsal interossei by single stimulation TMS over M1 (% maximum stimulator output that generated ~1 mV MEPs at rest) were used to track corticospinal excitability as participants prepared to execute button presses in response to a visual GO stimulus. The inhibitory influence of PMd on M1 was tracked by assessing the effect of a conditioning TMS stimulus over non-dominant PMd on MEPs generated by a test stimulus over dominant M1 (conditioning stimulus intensity = 110% of resting motor threshold, interstimulus interval = 9ms). MEPs were generated at rest, 50ms and 100ms after the presentation of the GO stimulus. In line with previous work, preliminary results showed that corticospinal excitability linearly increased as reaction time approached, for both unimanual and bimanual movements. In contrast, a release in inhibition from PMd to M1 was found at 50ms, but not at 100ms post GO stimulus in the unimanual task. PMd-M1 inhibition was not modulated in the bimanual task. These results tentatively support the notion that PMd is central to the early

shaping of motor programs generated in response to external cues, and that PMd modulates inhibitory output depending on whether unimanual or bimanual responses are required.

Title: Neuronal activity reorganization in motor cortex for successful locomotion after a lesion in the ventrolateral thalamus

Authors: *I. N. BELOOZEROVA;
Georgia Inst. of Technol..

Abstract: Thalamic stroke is a common disease that leads to ataxia if the cerebellum-receiving ventrolateral thalamus (VL) is affected. The compensation mechanism for this deficit and the contribution of different brain regions to the compensation are unclear. This slows development of rehabilitation approaches. The goal of this study was to clarify neuronal mechanisms of motor cortex that are involved in compensation for ataxia during locomotion when a part of the VL is inactivated or lesioned. In freely ambulating cats we recorded the activity of neurons in layer V of motor cortex as cats walked on the flat surface and horizontal ladder. Walking on the ladder is an accuracy demanding task that suffers if the VL is damaged. We first reversibly inactivated approximately 10% of the VL unilaterally using an AMPA/kaniate glutamatergic transmission antagonist CNQX and analyzed how neuronal activity in motor cortex reorganized for this 2-4 hour long small inactivation. We focused on pyramidal tract projecting neurons (PTNs) and on subpopulations of neurons with somatosensory receptive fields on different segments of the forelimb. We next lesioned 50-75% of the VL bilaterally with kainic acid and analyzed the activity of motor cortex neurons during the following month. We found that when a small part of the VL was inactivated, discharge rates of motor cortex neurons decreased but otherwise the activity was near normal, and cats walked fairly well. Individual neurons retained their ability to respond to the demand for accuracy during ladder locomotion, however, the great majority changed their response. In different neurons the changes were often opposite, so that only few net population changes were observed. When the VL was lesioned, the cat walked normally on the flat surface, but was ataxic on the ladder during several days post-lesion often missing crosspieces. When ladder locomotion normalized, neuronal discharge rates on the ladder were normal and the shoulder-related group was preferentially active during the swing phase of the stride rather than at the end of the stance phase. We concluded that motor cortex compensates for

a VL leason and contributes to maintenance of successful locomotion on a complex terrain by reorganizing responses of individual neurons and neuronal subpopulations to the accuracy demands during locomotion. These data may be useful for the development of new rehabilitation approaches for patients with thalamic stroke or lesion, approaches that assist the function of motor cortex at the level of single neurons and specific subpopulation of neurons.

Title: Decoding lingual-palatal contacts from population responses in primate orofacial sensorimotor cortex

Authors: *D. TANG[1], A. SIMONOFF[1], J. LAURENCE-CHASEN[1], B. J. SESSLE[2], C. ROSS[1], N. HATSOPOULOS[1], F. I. ARCE-MCSHANE[1];
[1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada

Abstract: Complex orofacial sensorimotor behaviors, such as feeding and speech, rely on precise control from the orofacial sensorimotor cortex (oSM). The ways in which tactile and proprioceptive feedback contribute to this process have yet to be characterized. We evaluated the presence of information on lingual-palatal contacts in oSM and how this was affected by absent tactile inputs while monkeys engaged in natural feeding. Neuronal activity from four chronically implanted microelectrode arrays in the primary motor (rostral M1 and caudal M1) and somatosensory (areas 3a/3b and areas 1/2 of S1) regions of oSM was recorded simultaneously with 3D tracking of tongue kinematics using bilateral videoradiography with the X-Ray Reconstruction of Moving Morphology (XROMM) workflow. To determine palate locations, we used a CT-scan based reconstruction of the cranium. Local anesthetic block of trigeminal nerve sensory branches knocked out tactile inputs from the palate, teeth, and tongue, while preserving proprioceptive inputs. We implemented two K-Nearest Neighbor (KNN) classifiers to evaluate the ability of spiking activity of M1 and S1 neurons to predict 1) contact of any part of the tongue to six palatal regions encoded by a sequence of six bits (total of 64 possible combinations) and 2) contact of tongue-tip to two anterior palatal regions. Classifier performance was assessed using classification loss for 10-folds of cross- validated data. For decoding multiple lingual-palatal contacts, we found that classifier performance was better than chance for all cortical regions, with M1 being the most reliable predictor of contact with (control) and without

tactile feedback. The removal of tactile inputs degraded performance when assessing spiking activity from areas 1/2. In contrast, performance improved for areas 3a/3b. For single lingual-palatal contact, the classifier correctly identified palatal regions above chance with and without nerve block. The weak effect of absent tactile inputs on decoding lingual-palatal contact suggests alternative sources of sensory information, possibly from proprioceptive inputs from the tongue. The robust representations of lingual-palatal contacts in oSM suggest that their cortical control plays an important role in vital and critical functions such as feeding. The results may have important implications for the evaluation and treatment of sensorimotor disorders affecting the orofacial system.

Title: Sensorimotor beta oscillations contribute to reward processing

Authors: ***T. YADAV**[1], D. FRANCIS[2], J. T. FRANCIS[1];
[1]Biomed. Engin., [2]Univ. of Houston, Houston, TX

Abstract: The role of beta oscillations in motor processing has been widely studied in both the animal and human sensorimotor cortices. However, whether these oscillations contribute to the processing of non-movement aspects of a motor task such as reward magnitude is not fully understood. In our previous work (An et al., 2019), we established that local field potentials (LFP) in the primary motor cortex (M1) are modulated by reward expectation. As a next step, the aim of present research is to study the influence of reward magnitude on LFPs specifically beta oscillations recorded from M1 and somatosensory (S1) cortices. For this, we trained a non-human primate (Female, Macaca mulatta) to perform planar center-out reaching movements to targets in 4 possible directions (0, 90, 180 and 270 degrees relative to horizontal line). For every successful trial, the monkey received a cued amount of juice reward (1/2/3 drops). Prior to the analysis, data collected from 17 sessions were pooled and matched for significant differences in reaction time, peak movement speed and time to reward (time from cue presentation to the start of reward delivery). A linear fixed effects model with two predictors namely reward level and time bin was used to fit beta amplitude during the hold period (0.7 sec), pre-movement period (0.5 sec) and movement period (0.8 sec) of each successful trial. A significant interaction between reward level and time bin was seen for both M1 and S1 (F-test, $p<0.05$). Post-hoc

analysis (Wilcoxon rank sum with false discovery rate, $p<0.001$) was used to identify significantly different reward pairs in each time bin. Reward-related distinction in beta amplitude began to appear 300ms and 450ms after the presentation of reward predicting cue in M1 and S1 regions respectively. Further, these differences continued to remain significant until the beginning of movement in M1 and end of movement in S1. The results of this study indicate that beta amplitude during hold on cue and pre-movement periods decreases with increase in reward magnitude in both regions. From these preliminary results, we have shown that sensorimotor beta oscillations indeed reflect processing of reward information.

Title: Convergence of proprioceptive and visual feedback on neurons in primary motor cortex

Authors: *K. P. CROSS, D. J. COOK, S. H. SCOTT;
Ctr. for Neurosci., Queen's Univ., Kingston, ON, Canada

Abstract: Sensory feedback plays a critical role in correcting motor actions such as when our arm is bumped while moving, or when the behavioural goal unexpectedly moves such as a glass tipping over. Vision plays a dominant role for identifying behavioural goals, while vision and proprioception provide feedback about the limb. Primary motor cortex (M1) plays an important role in generating corrections to sensory feedback, however, we know little about how these different sources of feedback are organized in M1 for online control. Here we examined two extreme hypotheses, the convergence and independent-input hypotheses. The convergence hypothesis assumes that 1) proprioceptive and visual feedback of the limb are redundant sources of information and should be optimally combined into a common limb estimate 2) a difference vector is computed between the visual location of the goal and the common limb estimate which is then converted to motor commands by M1. The prediction is that a common group of neurons in M1 should rapidly respond to proprioceptive feedback and visual feedback of the limb and goal. The independent-input hypothesis assumes that each feedback source is not integrated due to the computational complexities of combining multiple feedback sources. The prediction is that each feedback source will influence a random distribution of neurons in M1. We investigated these hypotheses by training monkeys to make goal-directed reaches to a target. On random trials a perturbation was applied that was either a jump to the visual feedback of the goal or limb or a mechanical load that displaced the limb off its intended trajectory (i.e. proprioceptive feedback). Monkeys were able to quickly counter the perturbations and recordings from M1 demonstrated

that each type of perturbation generated a robust change in activity in a subpopulation of neurons with 55%, 52% and 57% of neurons responding to the goal jump, cursor jump and mechanical loads, respectively. Across the subpopulations, there was significant overlap between the different perturbation types with many neurons responding to two or more different perturbations (Monkey M/A: χ^2 =113.9/68.1, df=4, p<0.001/<0.001). The magnitudes of perturbation-related activity were also highly correlated between the different perturbation types (goal with cursor r=0.90/0.97, mechanical with goal r=0.85/0.86, mechanical with cursor r=0.75/0.86) and the low-dimensional subspaces that perturbation-related activity resided in was highly conserved across the different perturbation types. Collectively, these results indicate M1 receives potent and highly convergent sensory feedback about the limb and goal during online control.

Title: Functional ultrasound neuroimaging reveals heterogenous organization of posterior parietal cortex in non-human primates

Authors: *W. S. GRIGGS[1], S. NORMAN[1], C. RABUT[2], C. DEMENE[3], T. DEFFIEUX[3], V. CHRISTOPOULOS[4], M. TANTER[3], M. SHAPIRO[2], R. A. ANDERSEN[1];

Abstract: The posterior parietal cortex (PPC) is an important area for the transformation of spatial information into accurate motor movements. PPC sub-regions such as the lateral intraparietal area (LIP) and the parietal reach region (PRR) are especially important for saccades and reaches, respectively. However, our understanding of these areas' functional organization is incomplete, in part due to technical challenges. While electrophysiology recordings can only record from small regions of the PPC at a time, fMRI and other 'whole-brain' techniques have insufficient spatiotemporal resolution. Now, functional ultrasound (fUS) is available as an innovative neuroimaging technique that measures cerebral hemodynamics with exceptional spatiotemporal resolution (<100 μm; ~100 ms) and a large field of view (several cm) – specifications ideally suited to recording detailed activity of entire cortical regions in parallel. In this study, we used fUS to record changes in cerebral blood volume (CBV) in PPC of two awake

behaving monkeys. Each monkey performed intermingled memory-guided saccades or reaches to targets throughout their visual field. We then analyzed the distribution of response fields within each coronal plane of PPC. We found that many subregions within the PPC, including within LIP, PRR, ventral intraparietal area (VIP), Area 5, and medial parietal cortex (MP), had effector-specific tuning curves. Specifically, activity in these areas was modulated by certain effectors and movement directions. These results address a fundamental gap in our understanding of PPC's functional organization by developing mesoscopic maps of effector and direction specificity previously unattainable with fMRI or electrophysiology methods. These mesoscopic maps reveal a highly heterogenous organization within each PPC subregion with many small patches of cortex encoding different combinations of effectors and directions.

Title: A comparison of cognitive-motor integration performance and resting state functional brain network connectivity in female athletes with and without concussion history

Authors: *A. PIERIAS[1], D. E. GORBET[1], M. WOJTOWICZ[1], A. PRIEUR[1], L. E. SERGIO[2]; [1]York Univ., North York, ON, Canada; [2]Sch. Kinesiol & Hlth. Sci., York Univ., Toronto, ON, Canada

Abstract: Structural neural changes following concussion are often not captured by standard imaging techniques. However, there is growing evidence that damage to white matter tracts and change in functional network connectivity may be observed following concussive injury. We investigated behavioural performance on a cognitive-motor integration (CMI) task in conjunction with alterations in resting state functional connectivity (rs-FC) in brain networks in a population of 30 female varsity athletes, with 16 having a previous history of concussion. Behavioural performance on accuracy, timing, and trajectory measures of a CMI task were assessed between the concussion history group and the control group. Rs-FC within the nodes of the Default Mode Network (DMN), Dorsal Attention Network (DAN), the Frontoparietal Network, and the Anterior Cerebellar Lobule Network, was assessed against performance scores on accuracy, timing, and trajectory measures. Main findings indicate no difference in behavioural performance ($p>0.05$) between those with concussion history and those without, in contrast to previous findings in a group of primarily male varsity athletes. In addition, no difference in rs-FC was noted in correlation with behavioural performance scores on either accuracy, timing, or

trajectory. These findings may suggest sex-related differences in performance on a CMI task, and a resiliency in both functional network connectivity and visuomotor skilled performance in varsity female athletes.

Med., Univ. of Ottawa, Ottawa, ON, Canada; [6]RIKEN Ctr. for Brain Sci., Tokyo, Japan

Abstract: Modern experimental neuroscience has sought to identify the neural correlates of free, or voluntary, actions largely focusing on instructed tasks in humans while recording neural activity via electroencephalography (EEG) or functional magnetic resonance imaging (fMRI). Multiple findings from human studies suggest that significant increases in neural activity (e.g. “readiness potential”-RP) precede both action initiation and awareness, and that behavior could be predicted well before action. These findings have been countered by more recent studies suggesting that only low-value actions (e.g. random pressing of a button) can be predicted and that voluntary action studies should focus more on high-value freely chosen actions (e.g. those involving reward).
Here we study voluntary behavior in mice engaged in a high-value action, i.e. a self-initiated water seeking task in water deprived animals, while recording large-scale neural activity from the dorsal cortex using widefield calcium imaging. Mice were trained to pull a lever to receive a water reward following a minimum of 3 sec of non-lever movement. We identified high-value free behaviors such as lever pulls, as well as low-value behaviors such as spontaneous limb movement or grooming, using DeepLabCut for behavioral tracking. We show that self-initiated lever presses are preceded by increases in widefield calcium activity in multiple cortical areas. Water-seeking behaviors as well as spontaneous movements can be decoded using linear and nonlinear methods by up to several seconds prior to movement (Fig. 1). We finally show that preparation of voluntary behavior is widely distributed across the dorsal cortex, with the hubs of activity being in the motor, retrosplenial and somatosensory cortex. Our findings support the pre-movement determination of behavior, with a detailed quantitative study showing that self-

initiated voluntary high-value actions may be prepared and can be decoded several seconds in advance of movement. Our work paves the way to future studies in humans on behavior prediction from neural activity.

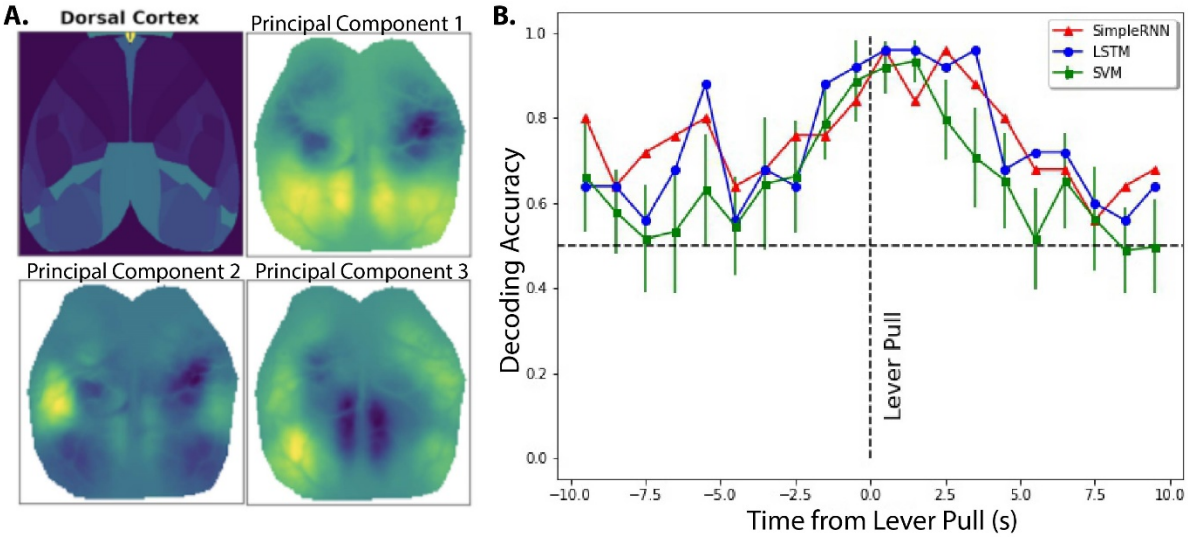

Figure 1. (A) Map of all mouse dorsal cortex areas visible during widefield imaging, and PCA loadings for the first three components activated during self-initiated behaviours. (B) Decoding accuracy of lever pull trials from random trials at various times before / after lever pull initiation, using Support Vector Machines (SVMs), and two different kinds of Recurrent Neural Networks (RNNs): Simple RNNs and LSTMs. Error bars show standard deviation across 10 folds.

Title: The association between masticatory performance and the parahippocampal volume varies as age increases in non-demented older people

Authors: ***C.-S. LIN**[1], J.-L. FUH[2];
[1]Dept. of Dent., Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Dept. of Neurology, Neurolog. Inst., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Cumulating evidence has suggested that in older people, oral sensorimotor performance is associated with not only the peripheral factors (e.g., tooth loss) but also brain signatures. The cross-sectional findings, however, do not clarify the dynamic association

between the brain and oral sensorimotor performance, which may vary as age increases. Atrophy of the volume of the medial temporal lobe, including the entorhinal and parahippocampal regions, is associated with normal aging. It has remained unclear if, in older people, the association between MP and the brain volume would vary as age increases. Here, we present novel evidence of the association between structural brain signatures and MP in a cohort followed up for at least one year. 31 non-demented older subjects (male:female=12:19, aged 50 to 78 years) were recruited and received T1-weighted magnetic resonance imaging (MRI) and oral examination, including assessment of the NMT and MP. MP was assessed using a color-changeable chewing gum test, with a higher score indicating a better oral mixing ability. The structural MRI data were processed using Freesurfer for extracting the regional volume of cortical and subcortical brain regions. To adjusted for individual variations in brain size, the regional volume was normalized by the intracranial volume on an individual basis. To quantify the association between MP and regional volume, Spearman's rho was used due to the non-parametric distribution of the NMT and MP. We find that (1) individual age is not significantly correlated with the NMT or MP. The NMT, MP, and brain volume of bilateral entorhinal or parahippocampal regions do not significantly differ between the initial and the follow-up stages. (2) Notably, at the initial stage, MP is significantly negatively correlated with NMT (rho=-0.45, p=0.015) and but not significantly correlated with the brain volume of bilateral entorhinal or parahippocampal regions. (3) In contrast, at the follow-up stage (1-1.5 year after), MP is not significantly correlated with the NMT (rho=-0.31, p=0.1) but significantly positively correlated with the brain volume of the right parahippocampal region (rho=0.41, p=0.023). The preliminary findings suggest that in non-demented older subjects, as age increases, the association between MP and the NMT may decrease, while the association between MP and the right parahippocampal region may increase. Such a dynamic association highlights the role of the CNS in an age-related change in oral functions, which would require further investigation.

Title: Sex, Song, and Estrogen: Vocal Learning Sufficient Gene Expression Specialization Following Estradiol Treatment in Female Zebra Finch

Authors: *M. DAVENPORT[1], H. CHOE[2], H. MATSUNAMI[2], E. JARVIS[1];
[1]The Rockefeller Univ., New York, NY; [2]Duke Univ., Durham, NC

Abstract: Zebra finches learn to sing by imitating heard vocalizations, a rare ability known as vocal learning. This vocal learning behavior demonstrates striking convergence with human speech in terms of developmental trajectory, neural circuit structure, and specialized gene expression in vocal motor control circuits. Unlike humans, the behavior is sexually restricted in zebra finch, with females limited to producing innate calls. The vocal learning brain regions and circuits form in both sexes during early post hatch life, but components of the circuit later atrophy in females. However, if female zebra finch are chronically treated with estrogen during development, they will develop a complete song system with mature connectivity, enabling them to vocally imitate male conspecifics. To better understand the genetic basis of zebra finch vocal learning and its sexual dimorphism, we chronically treated male and female birds with estradiol or saline from hatch until sacrifice at 30 days. Following sacrifice, we performed laser capture microdissection to isolate song nuclei and surrounding control regions, then short read sequencing on transcriptome libraries prepared from these samples. These RNAseq reads were mapped to a new zebra finch genome assembly, including the female restricted W sex chromosome. Using weighted gene co-expression network analysis, we found gene modules whose differential expression marks the song nuclei in vocal learning males and then examined module expression in females. While LMAN and RA song nuclei were similarly specialized in the females at post hatch day 30, HVC and Area X were unspecialized and absent respectively. Following estradiol treatment, HVC acquired a subset of the gene module specializations present in male HVC and Area X also appears as specialized. Intestingingly, the gene module specialized in female-estradiol HVC did not include the core vocal learning genes previously identified by convergent regulation in human vocal-motor cortex or involvement in human speech disorders. Our data instead indicate that vocal learning sufficient, estradiol induced specialization of female HVC is driven by the increased expression of certain Z chromosome genes, most strikingly the Growth Hormone Receptor, which are depleted in the untreated females.

Title: Identification and mitigation of technical challenges in experiments probing the cortical-basal ganglia speech network during awake Deep Brain Stimulation surgeries.

Authors: ***A. BUSH**[1], A. CHRABASZCZ[2], V. PETERSON[3], C. DASTOLFO-HROMACK[2], V. SARAVANAN[1], W. LIPSKI[2], M. RICHARDSON[1], M. RICHARDSON[1];

Abstract: Deep brain stimulation (DBS) surgery allows direct recordings from human basal ganglia and thalamus in awake patients, with adequate temporal and spatial resolution to explore the functional roles of these structures in speech production. However, neural signal contaminations in this setting have not been characterized. Here we report technical challenges encountered and applied solutions, focusing on the characterization of a speech induced vibration artifact in LFP recordings. We developed an intraoperative experimental approach which allows depth recordings from DBS targets, while simultaneously recording from selected cortical regions by means of high-density electrocorticography (ECoG) strips temporarily placed through the burr hole. A syllable repetition task using auditory stimuli was performed by 55 patients (36 males, mean age 66.8y, range 43-79) undergoing awake DBS surgery (# Target/Diagnosis: 28 STN/PD, 21 VIM/ET, 5 GPi/PD, 1 Gpi/Dystonia). We developed a well-documented data processing pipeline in Matlab for offline data synchronization, re-referencing, artifact characterization and rejection. We identified artifactual crosstalk between intra-cranial recording channels at the head-stage connector which could be corrected by custom re-referencing schemes. In addition to the physiological increase in high gamma (70-150 Hz) activity during speech production, time-frequency analysis revealed the presence of a narrowband component in the same frequency band, remarkably similar to the pattern observed in the spectrogram of produced speech. This component was present to different degrees in all types of LFP recordings: DBS leads, micro and macro mapping electrodes, and ECoG strips. We show that this component tracks the fundamental frequency of the participant's voice and speech intensity, correlates with the power spectrum of speech and has coherence with the produced speech audio. However, no corresponding component was identified in any neural channel during the listening epoch, ruling out the possibility of this component representing an auditory response. Attaching a vibration sensor to the stereotactic frame shows the presence of speech induced vibrations with the same pattern as observed in the LFPs. Taken together these observations suggest that speech-induced vibrations can affect the recorded neural signal, in line with observations from other groups. Speech production research in the context of DBS implantation surgery is a new and growing field. Identifying and accounting for potential sources and types of artifacts is crucial to achieve valid, reliable and reproducible results.

Title: Decoding tongue position and shape from population responses in primate orofacial sensorimotor cortex

Authors: *J. LAURENCE-CHASEN[1], C. F. ROSS[1], N. G. HATSOPOULOS[1], F. I. ARCE-MCSHANE[2];
[2]Dept. of Organismal Biol. and Anat., [1]Univ. of Chicago, Chicago, IL

Abstract: During feeding, drinking, and speech, the tongue both moves and deforms to assume a range of different postures. The extent to which the orofacial sensorimotor cortex encodes the different components of this behavior is not well understood. Here, we used XROMM (X-ray reconstruction of moving morphology) to quantify intraoral tongue movement and deformation while rhesus macaques (*Macaca mulatta,* n=2) fed on grapes and gummy bears. We employed an adaptive Kalman filter to decode either tongue position or tongue shape from cortical neuronal activity recorded from chronically-implanted microelectrode arrays in the orofacial region of the primary motor and somatosensory cortices. Specifically, the position variables comprised the X-, Y-, and Z- positions of four markers in the anterior region of the tongue, and the shape variables comprised the tongue's length, width, roll, and yaw. Each shape variable was computed from 4-6 dimensions of the 3D marker positions, and thus represented a multi-dimensional feature. To compare decoder performance across the range of positions and shapes, we compared the error expressed as a percentage of a given variable's total range. We found that the decoder predicted shape variables with similar accuracy as it did for position variables, as mean performance errors of approximately 20% remained consistent across all variable types. Such robust representations of both tongue position and tongue shape in the orofacial sensorimotor cortex suggest that their cortical control plays a role in critically important functions such as feeding and speech. The results may have important implications for the evaluation and treatment of sensorimotor disorders affecting the orofacial system.

Title: Modulation of task-related alpha power after motor learning is dependent on age and task difficulty

Authors: *M. BOOTSMA[1], S. R. CALJOUW[1], M. P. VELDMAN[3], N. M. MAURITS[2], J. C. ROTHWELL[4], T. HORTOBÁGYI[1];

Neuroplasticity Res. Group, Dept. of Movement Sci., KU Leuven, Leuven, Belgium; [4]Inst. Neurol, London, United Kingdom

Abstract: Although a general age-related decline in neural plasticity is evident, the effects of age on neural plasticity after a period of motor practice are inconclusive. Inconsistencies in the literature may be related to the nature of the experimental tasks, which differ in task-related variables such as task difficulty and the type of skill practiced. Therefore, the current study aimed to determine the effects of age and task difficulty on task-related brain activity before, immediately after, and 24-h after motor skill acquisition of a mirror star tracing task. Healthy younger (N=36, 19-24 yr) and older (N=36, 65-86 yr) adults practiced the task at one of three difficulty levels defined by the width of the wall of the star, while electroencephalography (EEG) was acquired. Task performance was assessed in terms of both performance speed and accuracy. On the behavioral level, task difficulty only affected motor skill acquisition in younger but not older adults. While young participants practicing at the low and high difficulty levels moved respectively 32% and 28% faster after practice, young participants practicing at the medium difficulty level predominantly improved tracing accuracy (43% improvement in accuracy, 12% improvement in speed). Furthermore, younger adults only consolidated improvements in speed (29% improvement pre-retention), whereas consolidation in older adults was limited to accuracy (18% improvement pre-retention). On the neural level, a significant decrease of task-related power in the alpha frequency band (8-12 Hz) after practice, indicative of early processes of neural plasticity, was present in practice groups that predominantly improved accuracy (35-85% decrease) but not in the groups that predominantly improved speed (7-18% decrease). Together, these data suggest that both age and task difficulty affect neural plasticity as well as the strategy to prioritize improvements in either speed or accuracy during the mirror star tracing task.

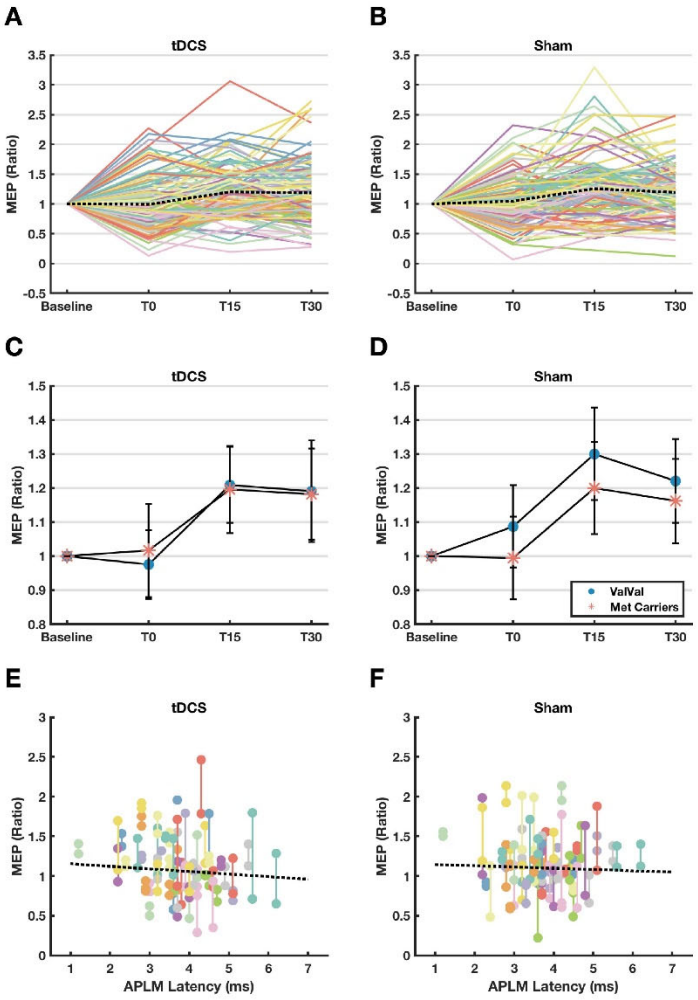
Title: No effect of anodal tDCS on motor cortical excitability and no evidence for responders in a large, double-blind, placebo-controlled trial

Authors: *C. GAISER[1], Z. D. JONKER[1], J. H. M. TULEN[2], G. M. RIBBERS[3], M. A. FRENS[1], R. W. SELLES[3];
[1]Dept. of Neurosci., [2]Dept. of Psychiatry, [3]Dept. of Rehabil. Med., Erasmus Med. Ctr., Rotterdam, Netherlands

Abstract: Rationale: *Transcranial direct current stimulation* (tDCS) has emerged as a non-invasive brain stimulation technique with potential applications in a variety of clinical fields.

However, it is not yet widely used in clinical settings as conflicting effects of tDCS have been reported. Some researchers have proposed that the variability in the literature is caused by a combination of underpowered studies and individual differences in sensitivity to tDCS. **Objective:** To test the effect of anodal tDCS on cortical excitability and the interaction effect of two participant-specific factors that may explain individual differences in sensitivity to anodal tDCS: the Brain Derived Neurotrophic Factor Val66Met polymorphism (BDNF genotype) and the latency difference between anterior-posterior and lateromedial TMS pulses (APLM latency). **Methods:** In 62 healthy participants, cortical excitability was measured before and after 20 minutes of anodal tDCS stimulation (2mA) in a pre-registered, double-blind, randomized, placebo-controlled trial with repeated measures. The main effect of tDCS and interaction effects of participant-specific predictors were assessed using a linear mixed model. Each participant was tested four times, with the first two and last two sessions constituting measurement pairs. In each measurement pair, a participant received one anodal and one sham tDCS stimulation, resulting in a total of two anodal and two sham sessions per participant. **Results:** We did not find a main effect of anodal tDCS, nor an interaction effect of the participant-specific predictors. Moreover, further analyses did not provide evidence for the existence of responders and non-responders. **Conclusion:** This study indicates that anodal tDCS at 2mA for 20 minutes may not reliably affect cortical excitability. Before tDCS can be used in a clinical setting, future research should focus on improving the tDCS technique, rather than continue the search for participant-specific predictors for the effect of tDCS in its current form.



Effects of tDCS on cortical excitability (N = 59).

A-B: Individual (colored lines) and mean (black dotted line) responses to anodal tDCS and sham stimulation over time (T1: 0 minutes after stimulation, T15: 15 minutes after stimulation, and T30: 30 minutes after stimulation). The evolution of cortical excitability is similar between tDCS and sham stimulation over different time points. ***C-D***: Responses of carriers (red asterisks) and non-carriers (blue dot) of the BDNF polymorphism to anodal tDCS or sham stimulation. Error bars indicate the 95% CI of the mean. The evolution is similar between carriers and non-carriers. ***E-F***: Relation between APLM latency and mean MEP ratio after anodal tDCS or sham stimulation. Connected dots illustrate responses of the same individual in two anodal tDCS and two sham conditions respectively. The black dotted line represents the regression line.

Title: Investigating the influence of sensory input on motor cortex organization

Authors: *C. V. TURCO[1], S. TOEPP[2], S. FOLGIA[2], P. DANS[2], A. J. NELSON[3];
[1]McMaster Univ., ; [3]Dept Kinesiol, [2]McMaster Univ., Hamilton, ON, Canada

Abstract: <Evidence indicates that prolonged periods of sensory input through peripheral nerve stimulation can induce changes in the organization of the primary motor cortex (M1). However, the mechanisms of such changes and the influence of cutaneous versus proprioceptive input are unclear. In this study, it is proposed that a Transcranial magnetic stimulation (TMS)-evoked phenomenon known as afferent inhibition may contribute to changes M1 organization induced by sensory enrichment. Short- and long-latency afferent inhibition (SAI, LAI) are TMS measures that reflect the excitability of neural connections between the primary somatosensory cortex (S1) and M1. Changes in SAI or LAI following a period of sensory enrichment may underly the neural mechanisms by which sensory input influences M1 organization. Therefore, we investigated the influence of sensory enrichment on afferent inhibition and on human M1 organization as assessed via maps created via TMS. Four right-handed, healthy humans (18-35 years) were recruited to participate in a pre- and post-intervention assessment. The following 45 min interventions were delivered on three separate sessions to create sensory enrichment: rest, digital nerve electrical stimulation or ulnar nerve electrical stimulation. Sensory enrichment was delivered at three times the perceptual threshold through a “burst” pattern of stimulation, where 20 Hz trains of electrical pulses were delivered for 1 s, with a 5 s rest between trains. Using fast-mapping TMS, the cortical representation of the right first dorsal interosseous (FDI) muscle was mapped pre- and post-interventions. 100 TMS pulses were delivered to pseudo-random locations within a 6x6 cm area centered over the FDI motor hotspot, at the intensity corresponding to 120% of the resting motor threshold with an inter-stimulus interval of 2 s. A MATLAB script was then used to construct a map of the FDI muscle representation from the peak-peak amplitude of the motor-evoked potentials (MEPs) and the location of stimulation registered with Neuronavigation. Measures of SAI and LAI were also acquired before and immediately following each intervention. To do so, digital nerve stimulation was delivered prior to the TMS pulse at an interstimulus interval of N20 + 2 ms for SAI and 200 ms for LAI. The preliminary results show no consistent pattern of intervention-induced changes in motor maps, SAI or LAI following any of the interventions.>

Title: Cortico-cerebellar adaptations associated with learning a cortically-controlled neuroprosthetic skill

Authors: *A. ABBASI[1], N. DANIELSEN[1], T. GULATI[1,2];
[1]Ctr. for Neural Sci. and Med., Cedars-Sinai Med. Ctr., Los Angeles, CA; [2]Bioengineering and Med., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Introduction: Brain-machine interfaces (BMIs) or neuroprosthetics have the potential to seamlessly merge the computational power of the motor system with that of artificial electronic systems. Previous studies have identified that learning to control a BMI involves an adaptive process in several cortical and subcortical regions of the brain. However, the cerebellar adaptations associated with neuroprosthetic learning remain incompletely understood. We have performed cerebellar recordings while rodents were trained on a cortically-controlled BMI, and analyzed the cortico-cerebellar adaptations associated with neuroprosthetic learning. **Methods:** We have recorded single units and local-field potentials (LFPs) by implanting microwire arrays in the primary motor cortex (M1) and silicon tetrodes in the cerebellum, while adult Long-Evans rats (n=4) performed a neuroprosthetic task. During the task, activity of experimenter-defined M1 neurons was transformed into the angular velocity of a feeding tube using a simple linear decoder. Rats have to modulate activity in these neurons, hereafter defined as 'direct' neurons, to obtain a reward. We analyzed how the activity in these direct neurons, as well as all other recorded (indirect) neurons in M1 and cerebellum changed while learning the neuroprosthetic task. We also analyzed band-limited oscillatory activity in both regions. **Results:** We found that learning a cortically-controlled BMI task led to indirect neurons showing a robust task-related modulation in the cerebellum and M1. Furthermore, we observed the emergence of task-related 3-6 Hz oscillatory activity in cortico-cerebellar LFPs, after neuroprosthetic learning. Also, task-related direct and indirect units' spike-field coherence (SFCs) were elevated in this frequency-band with learning. These changes were specific to robust BMI learning sessions and were not observed in poor learning sessions. **Conclusion:** Our work has identified cortico-cerebellar adaptations associated with learning a cortically-controlled neuroprosthetic task. This underscores the importance of optimal engagement of neural learning mechanisms in offsite motor regions while the neuroprosthetic task calls for modulation of only M1 activity.

Title: Common Patterns in Neural Learning and Optimization Across BCI Tasks

Authors: *A. M. MILLER[1], F. B. MCAFEE[2], Z. LIU[4], A. J. LAW[5], M. H. SCHIEBER[3], A. G. ROUSE[6];

[1]Neurosurg., Univ. of Kansas Med. Ctr., Kansas City, KS; [2]Biomed. Engin., [3]Neurol. and Neurosci., Univ. of Rochester, Rochester, NY; [4]MilliporeSigma, Burlington, MA; [5]Aerospace Res. Ctr., Natl. Res. Council Canada, Ottawa, ON, Canada; [6]Neurosurg., U of Kansas Med. Ctr., Kansas City, KS

Abstract: The study of brain-computer interfaces (BCIs) provides a unique opportunity to study the collective and individual learning properties of neurons. In this study we investigate, across three distinct task paradigms, the mechanism and patterns by which users modulate their neural activity and selectively optimize use of BCI control dimensions in order to improve task performance.

We analyzed neuronal data from 5 non-human primates who collectively performed three different BCI tasks. One task involved control of a virtual hand posture, a second task involved control of a cursor's position on a screen, and a third task involved control of a cursor's velocity on a screen. Between two and sixteen neurons, and between one and four BCI-control dimensions were used in each task. For each individual assignment, we analyzed the target independent, target dependent, and noise components of the neuronal firing rates. We then analyzed the magnitude and signal-to-noise ratio (SNR) of the firing rates over time. Magnitude was defined as the sum of target dependent variance, and SNR was defined as the ratio of the combined target independent and dependent variances to the total variance. Finally, we looked at optimization of neural modulation for each assignment, as measured by the difference between total firing rate magnitudes in BCI-output and non-BCI neural dimensions for each assignment. For each subject, we observed a pattern of increasing SNR and optimization over time across all assignments. A significant difference in their relative time courses was observed such that subjects reached peak SNR before peak optimization. Moreover, we observed that high SNR and optimization at the beginning of an assignment were associated with high SNR and optimization, respectively, at the end of an assignment, although low SNR and optimization were associated with greater increases in each over the course of an assignment.

Our results suggest a common pattern of BCI learning across distinct task types by which increases in signal-to-noise ratio of firing rates precedes increases in selective modulation of BCI-specific dimensions. Moreover, our results suggest that individual neurons differ in their capacity for adaptive BCI learning such that assignments with high performance early achieve higher end performance. Assignments with lower performance at the start had greater improvement in performance but did not reach the same peak performance as those with better starting performance.

Abstract: Implantable microelectrode arrays (MEAs) have created unprecedented opportunities to study brain function and treat neurological diseases. However, the rapid growth in use of these technologies has outpaced clear understanding of variable device longevity and performance caused by interactions with surrounding brain tissue. While gliosis and neuron cell death are well-known to occur following device implantation, the link between the tissue response and cell-specific changes in excitability are unknown. Our studies explore potential mechanisms of signal loss and instability by characterizing dendritic morphology and intrinsic excitability of pyramidal neurons in close proximity to an MEA. We employed fluorescence microscopy and patch-clamp electrophysiology in brain slice preparations containing a silicon or polyimide MEA device, harvested 1 week or 6 weeks after implantation into the primary motor cortex (M1) of adult Sprague-Dawley rats. Deep layer pyramidal neurons with somas <100 μm (Near-Device) and ≥500 μm (Distant-Device) from the implanted device were compared, with stab-injury and non-implanted controls also investigated. Morphology analyses show that Near-Device neurons at both time points have reduced dendritic arborization and reduced spine density. At 1 week, Near-Device neurons show a reduced density of filipodia (proto-spines), however that density is significantly increased after 6 weeks. Whole-cell intracellular recordings show that Near-Device neurons at 1 week show minimal differences in intrinsic properties or frequency of spontaneous excitatory postsynaptic currents (sEPSCs). At 6 weeks, Near-Device neurons show reduced sag amplitude (putative I_h), increased action potential half-width, and reduced sEPSC frequency. Our data suggest that after 6 weeks of implantation, Near-device neurons show a persistent reduction of dendrites, dendritic spine density, and excitatory activity. Additionally, these changes occur with both traditional, silicon-based devices and more flexible, polyimide-based devices. The results propose that a chronic, hypoexcitable network surrounding MEA devices could contribute significantly to MEA signal loss and instability.

Title: An Adaptive Model Predictive Control System for Functional Neuromuscular Stimulation Torque Control

Authors: ***W. M. THOMAS**[1], L. CAVALCANTI[2], V. MATHEWS[2], D. J. WARREN[1]; [1]Dept. of Biomed. Engin., Univ. of Utah, Salt Lake City, UT; [2]Sch. of Electrical Engin. and Computing Sci., Oregon State, Corvallis, OR

Abstract: Functional neuromuscular stimulation (FNS) is a well-established technique for reanimation of paralyzed limbs through electrical stimulation of muscles or nerves. Both open loop and feedback control techniques have been investigated in FNS systems to modulate stimulation to achieve a desired movement or torque production. We present here an adaptive model predictive control (aMPC) system for FNS and compare its performance to a proportional feedback controller (PFC). This aMPC system is designed around a dynamical model of the relationship between stimuli and neuromusculoskeletal system responses. Model predictive control systems have several advantages over feedback control techniques that include reduced response delays and complexity of gain tuning. Adaption mitigates the need for frequent recalibration of the model. We performed experiments with the aMPC system and a PFC to control isometric torque production, about the ankle in an animal model of paralysis, an anesthetized feline. A Utah Slanted Electrode Array (USEA) chronically implanted in the sciatic nerve was used to excite the lower limb muscles that produce torque. The aMPC system utilizes a linear twitch torque summation model based on single twitch recruitment curves (RC's) for each of the possible 96 electrodes. The RC relate the maximum twitch torque produced to the pulse width of a biphasic current pulse. Each sigmoidal-shaped RC was parameterized by the maximum torque, mid-point pulse width, and slope at the mid-point. The aMPC algorithm is composed of two parts: (1) a sequential determination of optimal stimuli based upon the twitch model and RC's and (2) online model recalibration by changing the parameters of each RC. For each experiment, the foot of the anesthetized feline was secured to the locked pedal of a custom torque monitoring device. The knee was also secured to ensure all torque measured came from the ankle. The evoked torque by the aMPC system for a 10 Ncm tall trapezoidal trajectory with a rise interval of 100 ms had a rise delay of 52 ± 34 ms (measured from the setpoint onset until the actual torque reached the setpoint) with a steady-state ripple of 1.4 ± 0.39 Ncm peak-to-peak, a steady-state error of 1.6 ± 1.1% and a overshoot of 41 ± 22% (n = 5). For the same trajectory, the PFC evoked a torque profile with a rise delay of 390 ± 130 ms, steady-state ripple of 0.93 ± 0.37 Ncm peak-to-peak, steady-state error of 1.3 ± 0.39 % and a overshoot of 27 ± 14 % (n = 5).The results currently demonstrate the reduction in response delay in the aMPC FNS system, with some minor compromises in steady state performance compared to the PFC. Overshoot remained high for both and is being addressed in future experiments.

Title: A novel method for creating electrolytic lesions using a microelectrode array

Authors: *I. E. BRAY[1], S. E. CLARKE[2], P. NUYUJUKIAN[2,3,1,4,5];
[1]Electrical Engin., [2]Bioengineering, [3]Neurosurg., [4]Wu Tsai Neurosciences Inst., [5]Bio-X, Stanford Univ., Stanford, CA

Abstract: Using multi-electrode arrays to record large populations of neurons has transformed motor systems neuroscience. Lesioning is another powerful method, as it offers strong causal insights. However, these two areas have not yet been combined; the effects of lesions have primarily been studied behaviorally. Combining chronic multi-electrode neuronal recording with lesional studies would enable causal investigation of the recorded population's role in generating skilled motor behavior over long timescales, while simultaneously providing unprecedented insight into neuronal reorganization after injury. In order to combine these methods, we need stable electrophysiology before and after the lesion and the ability to plan the lesion location and titrate its effect size. Although many lesioning methods exist, most are either invasive, potentially disturbing chronic electrodes, or the location and extent of the lesion is hard to control. We present a novel method for creating electrolytic lesions through chronically implanted multi-electrode arrays. We apply current through two electrodes of the array, using a custom-built current source to provide stable current in the face of changes in electrode impedance. Unlike conventional lesioning techniques, we avoid disruptive surgical procedures and can continue recording from the same population immediately after the lesion is performed. Electrode choice controls location, and by changing the duration and amount of current delivered, we can precisely control the extent of the injury. Calibration studies in ex-vivo and in-vivo porcine preparations allowed us to sweep a range of parameters, titrating to values that created damage without fully ablating the tissue. Our first nonhuman primate lesion in motor cortex resulted in a total estimated volume of 1.77 mm^3. Histology from this lesion was characterized by three qualitatively distinct zones: a lesion core of focal ablation, surrounding necrotic tissue from heat induced coagulation, and a periphery of rarefied tissue. The rarefied tissue at the periphery of the injury resembles the peri-infarct tissue after general hypoxic/ischemic trauma in humans, and it contains viable neurons whose survival and functional reorganization is hypothesized to play an important role in motor recovery. By comparing electrophysiology before and after the lesion, we have confirmed that the multi-electrode array continues to produce viable recordings and captures substantial changes in

neuronal population activity. We believe our new lesioning platform enables causal investigation of the relationship between activity of neuronal populations and behavior.

Title: Electrolytic lesion through multielectrode array alters population activity and impairs reach

Authors: *S. CLARKE[1], I. E. BRAY[2], P. NUYUJUKIAN[1,3,2,4,5];
[1]Bioengineering, [2]Electrical Engin., [3]Neurosurg., [4]Wu Tsai Neurosciences Inst., [5]Stanford Bio-X, Stanford Univ., Stanford, CA

Abstract: It is widely accepted that the coordinated activity of neuron populations in motor cortex generates voluntary movement, yet much remains unknown about the aspects causally necessary in the planning, production, and coordination of motor system output. Tremendous progress in understanding motor cortex has been made by simultaneously recording the action potentials of hundreds of neurons using multi-electrode arrays in awake-behaving non-human primates and applying multidimensional estimation techniques that reduce the complexity of the data. The resulting low-dimensional models of population activity capture both classic features of the neuronal code (e.g., directional tuning), as well as activity that deviates from traditional theories, but which features are necessary for the control of behavior? Here, we present the results from a novel electrolytic lesion technique that allows us to probe causality through permanent perturbations of a recorded population, while observing how the neuronal activity and task behavior subsequently evolve. The technique is performed painlessly in rhesus monkeys through chronically implanted arrays in motor cortex, allowing for months of undisturbed population recordings right before, and immediately after spatially precise lesions that target the neuronal correlates of the behavior. A data set of ten successive lesions over five months has been gathered from our first animal, demonstrating substantial changes in single neuron activity and population structure that accompanies slowed reaches. The behavior recovers in under a week, during which local neuronal reorganization is captured by the multi-electrode array. Changes in population activity are affected at distances beyond the physical boundaries of the lesion (one sixth of array surface area), indicative of decreased activity that may arise due to loss of co-activation in the local network, or increased inhibition from local and remote sources. By seamlessly integrating recording, electrical stimulation, and lesion capabilities on a single

chronic implant, we are in a unique position to causally assess invariance of neuron mappings into low dimensional state space, as well as how the state space evolves over time.

Title: Distinguishing Parkinson's Limb Tremor from Voluntary Movements in Neural Data

Authors: *D. TODOROV[1], A. SCHNITZLER[2], J. HIRSCHMANN[2];
[1]Ctr. De Recerca Matematica, Bellaterra, Spain; [2]Heinrich Heine Univ. Düsseldorf, Düsseldorf, Germany

Abstract: Many processes in Parkinson's disease, despite a long history of research, are still not completely understood. In particular, there is no clear understanding of how Parkinson's disease rest tremor is generated and even how it can be detected and distinguished from voluntary movements in neural recordings. Such a distinction is important for developing for tremor-guided adaptive deep brain stimulation. Previous studies mostly used LFP from deep brain electrodes in basal ganglia to detect tremor (distinguishing tremor time periods from quiet time periods). However distinguishing tremor from voluntary movements has been proven to be challenging using only LFP data. Here we employ several machine learning methods on multimodal data from the cortex (MEG) and basal ganglia (subthalamic nucleus LFP) to successfully distinguish tremor, quiet periods and two types of voluntary movements in the PD patients displaying intermittent tremor. Moreover we also describe which data features (frequency bands bands, cortical regions, cross-channels couplings) contribute most to the classification. Figure shows a nonlinear projection to 2D of the data from one of the patients, transformed by a linear classifier, where different colors correspond to different ground truth behavioral states (determined from EMG recordings): red=tremor, purple=voluntary hold, blue=voluntary grasp, green=quiet rest.

Title: Does learning alter neural decoders of motor cortex?

Authors: *M. BHATTACHARYA[1], S. MEAMARDOOST[1], E. HWANG[2], T. KOMIYAMA[3], C. MEWES[4], L. WANG[5], Y. ZHANG[6], R. GUNAWAN[7];

Engin., Univ. At Buffalo, Buffalo, NY

Abstract: The brain's motor cortex controls motor planning and motor tasks. Motor cortex has been shown to display a significant plasticity, in which neuronal activity of the motor cortex changes dramatically in a motor-skill learning. But, besides motor cortex, learning may also alter how motor cortex output is translated to voluntary movement - i.e., the motor cortex decoder. Here, we seek to elucidate alterations of the motor-cortex decoder in mice during new motor-skill by using long short-term memory (LSTM) recurrent neural network model. Deep neural network models have been demonstrated to be highly efficient in probing the functional outputs of the brain, and have been used as a powerful tool for Brain Computer Interfaces (BCIs). Here, we employ a data-driven approach to understand learning mechanisms. Neuronal activity of the motor cortex of mouse and the corresponding lever movement during a cue-driven reward-guided lever-press task has been used for the study. The mice are trained for 15 days to enable learning[1]. Preliminary analysis shows increasing trial-to-trial correlations between neuronal activity and lever movement[1] along with dynamic rewiring of connectome[2] inferred from neuronal activity, during motor skill learning. In this study, we use neuronal activity and corresponding lever movement data to model the motor cortex decoder. For elucidating the possible rewiring of the motor cortex decoder during learning, we built LSTM decoders for individual learning sessions and evaluated the accuracy of each session's decoder in predicting lever movements from motor cortex neuronal activity data from the corresponding session as well as other sessions. We further built a LSTM decoder using the cumulative data from all learning sessions and likewise, evaluated the performance of the cumulative decoder to predict lever movements. We observe stark changes from extreme naive to expert sessions and moderate alterations from one stage of learning to next with convergence towards the expert stages. The cumulative decoder is observed to be performing with comparable accuracy in all sessions as the individual decoders with performance improving towards later sessions due to highly correlated trial-trial neuronal activity and movements. Understanding the interplay of neural connectome rewiring across different brain's regions may lead to new architecture for interconnected AI.

Title: Electrocorticograph Signal Reconstruction with Recurrent Neural Network Autoencoders

Authors: ***M. NOLAN**[1], B. PESARAN[2], E. SHLIZERMAN[1], A. L. ORSBORN[1]; [1]Electrical & Computer Engin., Univ. of Washington, Seattle, WA; [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neural signal reconstruction and forecasting is a pragmatic means of approximating brain dynamics. Forecast signals can enable predictive algorithm design. Models of signal dynamics also enable unsupervised structure learning. We demonstrate electrocorticograph (ECoG) signal reconstruction using latent factor analysis for dynamical systems (LFADS) as a means of signal forecasting. LFADS has been used in prior studies to find task-relevant variable representation in latent factors within observed neural dynamics, but prior studies have done little to assess LFADS' neural signal reconstruction accuracy and have not yet applied the method to the reconstruction of field potential signals. Said studies have eschewed signal reconstruction performance assessments and instead focused on LFADS latent variable estimation capabilities, but signal reconstruction accuracy metrics are still needed for a robust model assessment. Seeking to bridge this gap, we report multichannel signal reconstruction using LFADS from non-human primate ECoG data collected continuously over a multiple day period and compare it to a best-fit linear autoregressive model. We find that LFADS provides substantially more accurate signal reconstructions than AR models in a relative prediction error (RPE) metric: AR models produce recreations with 0.827 +/- 0.094 RPE while LFADS model recreations achieve RPE values of 0.348 +/- 0.001. An RPE value of 0 indicates a perfect data reconstruction. While these results are promising, signals reconstructed by LFADS models were band-limited and incapable of recreating signal dynamics at frequencies higher than 40Hz (i.e. low and high gamma band frequencies). Further research into expanding LFADS representational capabilities will be needed for understanding how best to use LFADS-like approaches for reconstructing high-bandwidth neural data. We believe that these prediction accuracy improvements will enable novel predictive algorithm development and further enable unsupervised signal pattern learning through model latent space analysis.

Title: Latent state dynamics describe multiunit activity in premotor region of songbirds

Authors: *P. M. TOSTADO[1], D. E. BROWN, Jr.[2], E. M. ARNEODO[3], T. GENTNER[3], V. GILJA[2];
[1]Bioengineering, [2]Electrical and Computer Engin., [3]Psychology, UC San Diego, La Jolla, CA

Abstract: Brain Computer Interfaces (BCIs) hold promise to restore lost function to individuals with motor, speech and communication impairments due to injury or neurodegenerative disease. Traditionally, the primary research effort in this field has focused on studies of upper and lower limb motor control problems in rodents and non-human primates (NHPs). Despite recent heroic work in humans, more complex behaviors such as vocal production remain poorly understood. This is partly due to the lack of a well-established animal model for such behaviors. Thus, to better understand the neural mechanisms that enable complex motor-vocal behavior, we recorded the simultaneous activity of neurons in the sensory-motor nucleus HVC, a premotor region of the songbird brain, of male zebra finches (n=3) engaged in unconstrained vocal behavior during hours-long periods of time. We apply latent factor based models to describe the temporal dynamics of the recorded neural population. Complex, interdependent systems, such as biological neural networks, can often be captured by a lower-dimensional set of latent factors which describe how the observable output changes across time. Such latent representations of the system are typically robust to private noise present in measurements of its independent variables. Therefore, the understanding of the latent dynamics that emerge from activity across neural populations is crucially important in the design of robust, neurally-driven, chronic BCIs. We find that the temporal population dynamics of HVC correlate with specific features of the birdsong, including the onset of vocal production. Specifically, we observe a drop of up to 500% in the Fano factor in the majority of the channels recorded, which is time-locked to the start of periods

of vocalization and sustained across the song. The drop in neural variability happens in parallel with an expected x2 factor increase in the mean firing rates during vocal behavior relative to periods of inactivity. This visible reduction of neural variability prior to behavior onset is reinforced by a comparable reduction in shared variance in the latent space. Furthermore, we observe a temporal shift in the characteristic dynamics of the avian brain model and the behavior that may be informative of the functional connectivity across premotor and motor brain regions. These findings, originating from the latent-space modeling of brain activity in songbirds, are consistent with observations previously made in rodents and NHP during motor tasks.

Title: Trial-averaged neural trajectories display unique responses to unanticipated stimuli and can be used for online stimulus classification

Authors: *G. D. DISSE, B. NANDAKUMAR, K. A. MOXON;
UC Davis, Davis, CA

Abstract: Previous research into task-derived neural trajectories has often involved delayed-response tasks. However, motor brain machine interfaces (BMIs) must be able to react to complex, unpredictable scenarios. Thus, we sought to understand the low-dimensional neural dynamics associated with a task in which rats are subjected to unanticipated tilts. We then compared the performance of a classifier based on principal component analysis (PCA)-transformed data to that of a previously described classifier based on neural populations (i.e. peristimulus time histograms, PSTHs). **Methods:** Female Sprague-Dawley rats were placed on a platform that rotated along the frontal plane in two different directions and two different speeds to the same maximum angle at random intervals while neural activity was recorded in the hindlimb somatosensory cortex. Offline, we conducted PCA using the units as features and the first 200ms of spike data in 20ms bins from all trials as observations. Neural spike data was transformed using the output coefficients, and only the top three components were retained. Trajectories were found by plotting components against each other for each event type. Finally, to assess PCA-based classification of single trials, each event's trial-averaged PCA results were defined as templates, and a trial was assigned to the event with the smallest Euclidian distance to a given template. Classification performance was compared to that of a similar classifier that instead used PSTHs from all units. **Results:** Across animals, the first bin for each event trajectory was confined to a small state-space, suggesting similar baseline neural activity across

tilt types. However, these trajectories quickly diverged into four unique response profiles, with tilt direction being a large determinant of a trajectory's path and tilt speed determining trajectory length. These trajectories remained largely unchanged even after mid-thoracic spinal cord injury and over the course of 24 subsequent recording sessions. When comparing the classifier based off the first three components, offline performance remained largely unchanged compared to the full population, even when these first three components explained a small portion of the neural variance. **Conclusions:** Despite lacking an explicit motor planning component, visibly divergent, low-dimensional neural trajectories evolve over time when responding to unexpected postural perturbations, even after spinal cord injury. These trajectories can be used to classify single trials with a minimal loss of accuracy compared to classifiers based on full-population neural activity.

Title: Action Selection for Heterologous Control of a Continuous-Output Myoelectric Prosthesis

Authors: *S. SYLWESTER[1], D. J. WARREN[2], A. FERN[1], V. J. MATHEWS[1];
[1]Oregon State Univ., Corvallis, OR; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Movement intent decoding algorithms can interpret human surface electromyography (sEMG) signals to control prosthetic limbs with many degrees of freedom (DOFs). In this work, machine-learning algorithms are used to decode the human subject's sEMG signals into a continuous output for each DOF of the prosthesis. This paper presents an Action Selection algorithm to improve the decoder training process. While generally applicable, it is motivated by the case of heterologous control of a robotic hand in which the subject cannot activate the forearm muscles originally used to control a hand. The subject therefore needs to create a new, unintuitive muscle-to-movement mapping by deciding which heterologous muscle actions to correspond to the DOFs of the prosthesis. The presented approach tackles this additional motor learning challenge efficiently.
Given a prosthesis with m DOFs and a set of available muscle actions A, the Action Selection algorithm determines the size-m subset of A that minimizes the expected error of a decoder trained on the actions in that subset. Various error metrics are combined to evaluate the decoder's accuracy, consistency, and responsiveness. The algorithm begins by collecting a small amount of training data from each action. Cross-validation of a machine-learning algorithm is run on the data from each individual action to eliminate poorly performing actions, and on data from each pairwise combination of actions to eliminate actions that are too similar for the decoder to differentiate. This process is repeated with stricter thresholds until the number of

subsets is less than a preselected threshold. Finally, the algorithm evaluates each remaining subset offline and outputs the ranking.
The algorithm was validated through several experiments. To validate the action removal step, inconsistently performed and repeated actions were added to an example action set. The individual-action and pairwise-action cross-validations successfully eliminated the extraneous actions. Next, in an example in which 3 actions were chosen from 6 (20 possible subsets), the algorithm's subset ranking was compared to the ranking when trained on larger datasets for each subset and tested online. The rankings correlated, indicating that the Action Selection algorithm can successfully predict online decoder performance from offline analysis of a limited training dataset. Finally, results from intact test subjects showed that action subsets chosen via the Action Selection algorithm outperformed those chosen by a naïve algorithm that ranks subsets based only on the feature data distributions.

Title: Decoding of human identity by computer vision and neuronal vision

Authors: Y. ZHANG[1], *Z. M. AGHAJAN[2], M. ISON[4], Q. LU[1], H. TANG[5], G. KALENDER[2], T. MONSOOR[1], J. ZHENG[5], G. KREIMAN[5,6], V. ROYCHOWDHURY[1], I. FRIED[2,3,7]; [1]Electrical and Computer Engin., [2]Neurosurg., [3]Dept. of Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [4]Sch. of Psychology, Univ. of Nottingham, Nottingham, United Kingdom; [5]Children's Hosp., Harvard Med. Sch., Boston, MA; [6]Ctr. for Brains, Minds and Machines, MIT, Cambridge, MA; [7]Tel Aviv Med. Ctr. and Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel

Abstract: Computer vision (CV) guided by deep learning (DL) has made significant strides in the central challenge of recognizing a specific identity despite highly variable attributes. This indeed is the same challenge faced by the nervous system and partially addressed by the concept cells—neurons exhibiting invariant selective firing in response to specific persons/places, described in the human medial temporal lobe[1,2]. Given the firing pattern of such neurons, we can decode the concept presented in a discrete fashion[3]. Yet, the access to neurons representing a particular concept is limited due to these neurons' sparse coding. It is conceivable, however, that the information required for such decoding is present in small neuronal populations.

To address this question, we introduced an audiovisual sequence in the form of a movie, where a real-life changing narrative and several identities—movie characters—are presented with high variability. We recorded neural activity from multiple brain regions of ten neurosurgical epilepsy patients, implanted with depth electrodes, while they watched an episode of the TV series "24". We implemented two DL networks that used the time-varying population neural data as inputs and satisfactorily decoded the visual presence of the main characters in each frame. Before training and testing the DL models, we devised a minimally supervised CV algorithm (with comparable performance against manually labelled data[4]) to detect and label all the important characters in each frame. This methodology allowed us to compare "computer vision" with "neuronal vision", i.e., the footprints associated with each character present in the activity of a small number of neurons, and identify the brain regions that contributed to this decoding process. We then tested the DL models (trained on data during movie viewing) in a recognition memory task where subjects were asked to recognize clip segments from the presented episode and reject foil segments obtained from another episode they had not seen. Curiously, DL model activation was not only modulated by the presence of the corresponding characters but also by participants' subjective memory of whether they had seen the clip, and by the associative strengths of the characters in the narrative plot.
The described methodology can offer a novel way to probe the representation of concepts in time-evolving dynamic behavioral tasks. Further, the results suggest that the information required to robustly decode concepts is present in the population activity of a relatively small number of neurons in specific brain regions.

Title: The impact of dual task on step variability is influenced by stepping height during stepping in place without vision

Authors: *N. PAQUET[1], L. MICHAUD[2], N. POLSKAIA[2], Y. LAJOIE[2];
[1]Sch. of Rehabil. Sci., [2]Sch. of Human Kinetics, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background. The variability of spatiotemporal gait parameters is altered when under dual task conditions (motor task + cognitive task) in young adults (e.g., Dubost et al., 2008, Decker et al., 2016). When variability is higher in dual task, it can indicate that the two tasks compete for attentional resources (Woollacott & Shumway-Cook, 2002), whereas when it is reduced, it may reveal a more automatic gait pattern promoted through a shift of attention away from movement control (Lövdén et al., 2008). Recently, we found that during stepping in place without vision, the coefficient of variation (CV) of stepping frequency was significantly larger in dual task than in the single stepping task. The question is whether the effect of dual task on the CV of stepping frequency and step height is modulated according to stepping height, i.e. comfortable step height (CStep) vs. high stepping (HStep). **Methods.** Fourteen young adults were blindfolded and stepped in place for 50 steps at a preferred pace. The protocol consisted of two single-task conditions CStep and HStep (approx. 45° and 90° of hip flexion, respectively) and two dual task conditions, (CStep+CT and HStep+CT). The cognitive task (CT) required participants to identify the total number of times that one pre-determined target digit occurred during a sequence of three-digit numbers presented every two seconds. In the dual task conditions, participants self-reported how much attention they had allotted to the CT relative to the stepping task. The Vicon512^{TM} System was used to record 3D kinematic data at a frequency of 200 Hz from markers placed on the heel (calcaneus) and big toe (distal phalanx) on both sides. Repeated measures ANOVA with two within-person factors (CT: with, without; Stepping Height: comfortable, high) were performed on the CV of stepping frequency and step height. **Results.** The CV of stepping frequency was lower for CStep and HStep+CT than for CStep+CT and HStep (significant interaction between CT and Stepping Height, $p < 0.01$). The CV of step height was lower at high stepping (HStep and HStep+CT) than at comfortable stepping (CStep and CStep+CT; significant main effect of Stepping Height, $p < 0.01$). The mean percentage of attentional focus that was allocated to the CT was lower at high (56%) than at comfortable stepping (68%, $p < 0.01$). **Conclusion.** We found that stepping height can modulate the dual task effect on the variability of spatiotemporal stepping parameters. Indeed, the stepping frequency and step height CVs were lower at HStep+CT than at CStep+CT. It suggests that lifting the knees high promoted a more stable stepping pattern, despite the shift in attentional focus towards the stepping task.

Title: Coordination of sensed state body state and foot placement related muscle activation

Authors: *R. M. SPRAGUE, S. M. O'CONNOR;
San Diego State Univ., San Diego, CA

Abstract: The dominant strategy for maintaining frontal plane walking balance appears to be control of lateral foot placement based on sensed body state. Previously, measured body state at mid-stance has best correlated with subsequent foot placement location, but visual information from the preceding step also appears to inform subsequent foot placement location. Therefore, it is unclear when body state is predominately sensed in order to devise a motor plan for controlling swing leg motion and subsequent foot placement. The purpose of this study was to establish timing of body state sensing in relation to foot placement related muscle activation and we hypothesized that this sensing would occur early in the gait cycle up until muscle activation. Six healthy adult subjects (age = 21.8 +/- 1.5 years, male = 3, female = 3) walked on a large treadmill at a comfortable speed for four minutes. Body segment positions were recorded with optical motion capture and used to estimate center-of-mass position and velocity (P_{com}, V_{com}) and swing foot position and velocity (P_{foot},V_{foot}). Surface electromyography (EMG) signals were recorded on four frontal plane hip muscles of the dominant leg: Gluteus Medius (GM), Tensor Fasciae Latae (TFL), Gracilis (Gr), and Adductor Longus (AL). Foot placement control timing was assessed by determining when body state was best correlated with foot placement related EMG. This was calculated by measuring and averaging the body states (P_{com}, V_{com}, P_{foot}, V_{foot}) and EMG of the GM, TFL, Gr, and AL within each 2% increment of the gait cycle (50 time windows per stride). Then, coefficient of determination (R^2) values describing the correlation between the average body states: P_{com}, V_{com}, P_{foot}, V_{foot} (independent variables) and average EMG for the GM (dependent variable) were assessed across 200 strides using a multiple linear regression. R^2 values were determined for each 50x50 sensory-motor time window combination. This analysis was repeated for each muscle tested. The correlation between body states and GM EMG was largest (R^2 highest) for body states at 20% [8,24] (peak [range]) and EMG at 20% [18,24] of the gait cycle. For TFL, the correlation was largest for body states at 18% [14,22] and EMG at 24% [20,24] of the gait cycle. For AL, the correlation was largest for body states at 20% [2,20] and EMG at 20% [20,22] of the gait cycle. For Gr, the correlation was largest for body states at 20% [14,22] and EMG at 22% [22,24] of the gait cycle. Our findings indicate that body states are broadly sensed from the beginning of double-support phase into early swing phase and inform foot placement related muscle activation focused around 30% of swing phase.

Title: Differences in EMG activity of ankle plantarflexors and dorsiflexors during single and dual task walking in healthy older adults and people with Parkinson's disease

Authors: K. NAZARPOUR, ***L. ALCOCK**, L. ROCHESTER, A. PANTALL;
Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Background: Gait impairment in Parkinson's disease (PD) is characterised by decreased stride length, walking velocity and joint range of movement. Gait dysfunction is exacerbated during dual-task (DT) walking. Complex neural networks regulate activity and co-ordination of lower limb muscles essential for effective locomotion. Analysis of muscle activity may reveal underlying neural control mechanisms. However, current understanding of muscle activity during PD gait is limited (Islam et al. 2020).The aim of the study was to investigate: 1) distal lower limb muscle activity during walking in people with PD compared to healthy older adults (HOA) and; 2) the effect on muscle activity of adding an attentionally demanding cognitive task to single-task (ST) walking.**Methods**: We analysed muscle activity in 15 HOA (74 ± 6.9, m 8, f 7) and 30 people with idiopathic PD (71 ±5, m 19, f 11).Wireless surface electrodes recorded electromyographic (EMG) activity bilaterally from: tibialis anterior (TA), medial gastrocnemius (MG), lateral gastrocnemius (LG) and soleus (SO). Participants walked overground for 300 s (150 s ST, 150 s DT). Wavelet analysis was applied to the EMG signals to resolve them into time and frequency space. Eleven non-linearly spaced wavelets were used with centre frequencies from 7 Hz - 395 Hz (von Tscharner 2000). The wavelet transformed signals were segmented into gait cycles with gait events determined by a motion capture system and foot markers. EMG was time normalised to 100 timepoints and amplitude normalised to the mean maximum across gait cycles. EMG intensity and mean frequency (MF) were calculated. We applied linear mixed effect models which included walking task (ST/DT) and participant group (HOA/PD) as fixed effects.**Results:** Intensity of TA and SO decreased ($p<0.01$) during DT compared to ST whereas LG increased ($p<0.01$) in both groups. The PD group displayed a greater reduction in TA during DT walking ($p<0.01$) compared to the HOA. MF was lower during DT walking compared to ST in MG and SO for both groups with greater decrease for SO in the PD group.**Conclusions:** The decrease in EMG intensity during DT of uniarticular muscles TA and SO and increase in biarticular muscle LG may relate to the different motion demands and inhibitory effects of LG on SO (Prilutsky 2000). Greater reduction in TA activity in the PD group during DTW may be associated with changes in corticostriatal connectivity and sensorimotor impairment (Helich et al. 2015). As TA is important for foot placement, reduced activity during DTW may partially explain why people with PD experience greater falls. Reduction in MF during DT suggests changes in muscle fibre recruitment strategies.

Title: Adaptive dynamic balance Response in Degenerative Cervical Myelopathy

Authors: *T. F. BOERGER[1], L. MCGINN[1], S. LESSILA[1], M. WANG[2], B. SCHMIT[1], A. HYNGSTROM[1];
[1]Marquette Univ., Milwaukee, WI; [2]Med. Col. of Wisconsin, Wauwatosa, WI

Abstract: Introduction Degenerative cervical myelopathy (DCM) is the most common form of spinal cord dysfunction in adults and frequently causes gait and balance impairments. Degenerative changes in the cervical spine may narrow the spinal canal and chronically and progressively compress the spinal cord. Despite surgical decompression, residual step width and balance impairments may persist. A better understanding of balance impairments and neuroadaptive capacity in this population will aid the development of rehabilitation interventions that improve balance in people with DCM (PwDCM) and inform whether rehabilitation strategies should focus on compensatory strategies or normalization of balance responses. The purpose of this study was to investigate the locomotor adaptability to repeated lateral waist pulls during walking among PwDCM compared to controls. Methods Ten PwDCM (7F/3M, 58.80±12.37y, modified Japanese Orthopedic Association Scale: 14.6±0.81, 3.20±3.96y post op) and 10 older controls without myelopathy (7F/3M, 55.78±10.09y) completed gait testing on an instrumented treadmill with an adjacent robotic cable pulley system. The primary outcome variable was step width pre-, early-, late-, and post-adaptation. Participants completed 624 steps per trial with 208 steps (104 left/104 right) pre adaptation, 208 steps within cable pull adaptation task, and 208 steps post adaptation. Four adaptation task conditions were used (5% body mass pulls in-phase with velocity of the center of mass, 2.5% body mass in-phase, 5% body mass anti-phase, 2.5% body mass anti-phase). Locomotion data was captured with 8 Vicon cameras and processed off line in Vicon Nexus (Oxford UK). Clinical outcome data collected were Berg Balance Scale, Functional Gait Assessment scores and walking speed. Statistical results were computed in SPSS (IBM, Chicago, USA) using a mixed effects model for fixed effects of myelopathy, pull magnitude, and pull phasing with Sidak corrected post-hoc tests and alpha set a priori at 0.05. Clinical tests were compared with independent t-tests. Results PwDCM walked at slower self-selected speed ($p=0.04$), had lower Berg Balance scores ($p<0.01$), and Functional Gait Assessment scores ($p=0.01$) than controls. For step width there was an interaction between pull phase and adaptation timepoint ($p<0.01$). In-phase pulls increased step width in early-adaptation and post-adaptation whereas anti-phase pulls decreased post-adaptation step width. PwDCM walked with wider steps regardless of pull phase, magnitude, or trial timepoint ($p<0.01$). Conclusions
Due to similar adaptability to controls, PwDCM may benefit from locomotor balance therapies.

Title: Remote monitoring of motor performance via smartphone applications and markerless tracking

Authors: *E. QUARTA, G. VICHI, V. SORGENTE, R. BRAVI, E. J. COHEN, D. MINCIACCHI;
Univ. di Firenze, Firenze, Italy

Abstract: Motor control is usually studied by having test subjects coming to the lab to participate in experiments, often using dedicated instruments and setups. While this approach remains the gold standard for scientific experimentation, it is also important to develop methods for remote monitoring. This is especially relevant for populations with reduced mobility or that cannot easily access health professional consultancy. Moreover, due to the current pandemic, such a need is even more urging. Here we obtained movement data from healthy participants (n=9) that were either at their homes or, as a control condition, were tested in the lab. To collect data we leveraged on the fact that a large fraction of the general population (60.8%) owns a smartphone, especially those between the ages of 18 and 49 (more than 90%). In addition, appropriate data logger applications (app) are freely available. As a proof of concept, we tested postural control, which was performed remotely at the homes of the participants during a videoconference. The experimenter instructed the participant to install a free available app (i.e., AndroSensor, Fiv Asim, for Android devices or Physics Toolbox Sensor Suite, Vieyra Software, for iPhones) on their smartphone, which allowed to record tri-axial accelerations (sampling frequency 100Hz). Following that, participants were instructed to strap their phone to the lower back and “stand quietly while barefooted for 80 seconds”. The experiment was performed in several conditions in a randomised order which included: eyes open vs closed, bipodalic vs monopodalic stance. A control condition, in which the smartphone was placed on the ground, was also included. In selected trials, a concurrent video-recording of the trials (extracted from the videoconference; a sound cue was used for synchronisation) was performed by the experimenter, to be used for off-line markerless tracking of kinematic data which were later compared with the app data. Preliminary results indicate that remote monitoring of motor performance is similar to that obtained in the lab, with the great advantage of being low cost, time-effective and scalable which is a step toward a location-independent investigation of motor control/performance parameters.

Title: Robust Electromyographic Control During Active Exoskeleton Assistance Despite Non-Linear Reorganization of Locomotor Output

Authors: *J. A. GEORGE[1], A. J. GUNNELL[2], D. ARCHANGELI[2], G. HUNT[2], M. ISHMAEL[2], K. B. FOREMAN[3], T. LENZI[2];
[1]Physical Med. & Rehabil., [2]Mechanical Engin., [3]Physical Therapy & Athletic Training, Univ. of Utah, Salt Lake City, UT

Abstract: Robotic exoskeletons can assist humans with walking by providing supplemental torque at the joint level. Most assistive exoskeletons aim to provide supplemental torque proportionate to the user's muscle torque, which can be inferred by exploiting the relatively consistent torques generated during cyclic movements such as walking. Unfortunately, this control approach fails when the user performs non-cyclic movements (e.g., start walking, stop walking, change direction). In theory, electromyographic (EMG) control algorithms can overcome this challenge by estimating the user's muscle torque directly using EMG recordings from the muscles that generate the torque. However, EMG changes as a result of supplemental torque from an exoskeleton, resulting in unreliable estimates of the user's muscle torque during active exoskeleton assistance. Here, we present an EMG control framework for robotic exoskeletons that provides consistent muscle torque estimates across varying levels of assistance. Experiments with three healthy human subjects showed that using diverse training data (from different levels of assistance) enables robust control, and that a convolutional neural network (CNN), but not a Kalman filter (KF), can capture the non-linear transformations in EMG due to exoskeleton assistance. With diverse training, the CNN could reliably estimate muscle torque from EMG during zero, low, medium, and high levels of exoskeleton assistance (root mean squared error (RMSE) below 0.098). In contrast, without diverse training, RMSE of the CNN ranged from 0.103 to 0.147. RMSE of the KF ranged from 0.140 to 0.187 without diverse training, and did not improve with diverse training. When patient time is limited, training data should emphasize the highest levels of assistance first and utilize at least three full gait cycles. The average percent reduction in RMSE was 31.65% during the first three gait cycles and ~1% in all subsequent cycles (with performance still improving with 52 cycles). The results presented here constitute an important step towards adaptive and robust human augmentation via robotic exoskeletons. This work also highlights the non-linear reorganization of locomotor output when

using assistive exoskeletons; significant reductions in EMG were observed for the soleus and gastrocnemius, and a significant increase in EMG was observed for the spinae erector. Control algorithms that can accommodate spatiotemporal changes in muscle activity have broad implications for exoskeleton-based assistance and rehabilitation following neuromuscular injury.

Title: Inter-limb coordination in chronic stroke survivors

Authors: *T. SADO, Z. MOTZ, M. MUKHERJEE;
Biomechanics, Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Stroke is the leading cause of disability among adults and can cause major physical deficits including impaired gait, muscle weakness, and balance problems. Conventional rehabilitation practices often use assessments and therapy that target individual limb deficits and rarely does this therapy consider gait-coordination deficits. Although linear measurements have been the standard for measuring outcomes, they look at outcomes using averages and standard deviations, and in doing so only provides them with a snapshot of the behavior. Nonlinear measurements (e.g., cross recurrence quantification analysis (cRQA) and cross sample entropy (cSE), can be used to address this limitation, and complement current approaches by providing us a motion picture of inter-limb coordination. The goal of this project is to quantify the temporal structure of inter-limb coordination in chronic stroke survivors and healthy age-matched controls using nonlinear measurements. Thirteen chronic stroke survivors and thirteen healthy- age-matched controls walked on the treadmill for five minutes at their preferred walking speed, during which their kinematics were recorded via motion capture system. Inter-limb coordination was calculated via nonlinear methods cRQA (provides the variable 'Mean Diagonal Line Length' and corresponds to the average duration of coordination between the left- and right-legs) and cSE (describes the synchrony between the limbs during gait). Stroke survivors had significantly shorter mean diagonal line lengths than the healthy controls suggesting they had shorter duration of coupling between the two limbs. For cSE there were statistically significant differences between groups suggesting that the stroke survivors' gait was more repeatable, and possibly less adaptable to potential perturbations. Using cRQA and cSE, we have shown that the evolution of inter-limb coordination while walking is markedly different between healthy controls and chronic stroke survivors. Although even after a stroke, the two legs show coordinated behavior, the results show that this coordination is abnormal, may impede functional recovery and therefore could be a potential target when designing new rehabilitation paradigms.

Title: Step length adaptation imposes robust gait asymmetry in humans

Authors: ***E. HERRICK**[1], S. YAKOVENKO[2];
[1]Chem. and Biomed. Engin., [2]Human Performance, West Virginia Univ., Morgantown, WV

Abstract: Walking on a split-belt treadmill that imposes different speeds on each leg develops robust asymmetric aftereffects. The goal is to use this intervention as a rehabilitation approach. Yet, the difference in limb speeds is behaviorally related to turning and not to the limb preference, as seen in many gait pathologies. Here, we impose a stride length constraint using a wearable passive orthosis to modify limb dynamics independently from the limb speed. A group of young adults (N=3, 22.7±3 years) walked on a treadmill instrumented with force plates. Each session consisted of 3 blocks: unconstrained, constrained, and washout unconstrained locomotion at 0.8 m/s. The gait events corresponding to heel-contact and toe-off were detected from the ground reaction profiles for each limb, and each step cycle was described by four periods: leading double-stance, single stance, trailing double-stance, and swing. We observed temporal asymmetries during constrained stepping, shown by a large difference in magnitude between the leading and trailing double-stance compared to that in unconstrained stepping. To quantify this asymmetry, we calculated an asymmetric index (AI) as the difference between leading and trailing double-stance over the sum of the leading and trailing double-stance. A repeated measures ANOVA showed that there was a significant difference in mean AI between the unconstrained and constrained stepping, $F(1,2)=116.95$, $p<0.01$. The preliminary result indicates that this paradigm requires a period of deadaptation to return to symmetric locomotion. This supports the potential use of this task for the development of the intervention techniques for gait rehabilitation.

Title: Electrical Characterization of the Mesencephalic Locomotor Region in a Large Animal Model of Neuromodulation

Authors: *S. J. CHANG[1], A. J. SANTAMARIA[1], F. J. SANCHEZ[1], L. M. VILLAMIL[1], P. M. SARAIVA[1], Y. NUNEZ[1], J. P. SOLANO[1], J. D. GUEST[2], B. NOGA[1];
[1]Univ. of Miami, Miami, FL; [2]Neurolog. Surgery/Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Introduction: The mesencephalic locomotor region (MLR) is a functionally defined area in the midbrain, where electrical stimulation was discovered to initiate locomotion in several animals. Deep brain stimulation (DBS) of this region has been studied as a therapeutic target in rodent models of stroke, parkinsonism, and spinal cord injury. Clinical DBS trials have targeted the closely related pedunculopontine nucleus in patients with Parkinson's disease as a therapy for gait dysfunction, with mixed outcomes. Recent studies suggest that optimizing the MLR target could improve its effectiveness. **Objective:** We sought to determine if pigs have an MLR, and if stereotaxic targeting and DBS in the region was feasible to generate a large animal neuromodulation model of gait. We aimed to characterize optimal electrode positions and stimulation parameters to evoke locomotion, as well as any nearby off-target effects. **Methods:** We implanted electrodes into putative MLR structures in Yucatan micropigs to characterize the locomotor effects of acute DBS in this area, using EMG recordings, joint kinematics, and speed measurements on a manual treadmill. **Results:** MLR DBS robustly initiated and augmented locomotion in freely moving pigs. Effective locomotor sites centered around the Cuneiform nucleus and locomotor output depended on stimulation parameters. Off-target stimulation and high frequencies of stimulation evoked defensive and aversive behaviors in the animals. **Conclusion:** Pigs have an MLR and can be used to model neuromodulation of this gait-promoting center. Electrode position and stimulation parameters were critical to optimally evoke locomotor output while minimizing off-target effects. These results may provide insight to guide future clinical efforts.

Title: Evaluation and modeling of mechanosensory encoding of forces during walking using joint torques as 'naturalistic' stimuli

Authors: *S. N. ZILL[1], C. J. DALLMANN[2], ***N. SZCZECINSKI**[3];
[1]Biomed. Sciences/Anatomy, J.C. Edwards Sch. Med., Huntington, WV; [2]Physiol. and Biophysics, Univ. of Washington, Seattle, WA; [3]West Virginia Univ., Morgantown, WV

Abstract: Control of adaptive walking requires the detection and regulation of muscle forces and loads. This information is thought be derived from sensory receptors of the legs but the specific parameters that are encoded in walking have not been determined. We have studied how forces are signaled by mechanoreceptors (campaniform sensilla) of the legs of insects. We have also recently developed a model of signal transduction that accurately simulates many characteristics of the receptors. Previous studies have shown that application of forces using 'naturalistic' stimuli (waveforms of joint torques of freely walking animals calculated by inverse dynamics) produced graded activation of leg muscles and substantially reduced motor adaptation seen to conventional ramp and hold functions. The goal of the present studies was to elucidate and model the sensory mechanisms underlying these effects. Experimental application of waveforms of torques of the femoro-tibial joint in stick insects elicited discharges in tibial campaniform sensilla that strongly reflected the rate of change of force (dF/dt) throughout the stance phase, not merely at initiation of force application. These waveforms show no 'hold phase' and initial, non-linear, graded increases are most often followed by periods in which variations can occur, potentially due to gait and load transfer. We studied the initial component by application of forces with varying exponential rates of increase that reached a plateau. These studies showed that the delay of onset of sensory adaptation was correlated with the duration of positive dF/dt. Sensory discharges also showed substantial hysteresis (similar to many other proprioceptors) and were inhibited during transient or prolonged periods of force decrease, even when they occurred in periods of high sustained forces. We postulate that hysteresis can aid in the control of residual muscle tensions. Many of these characteristics of responses to 'naturalistic' stimuli were accurately simulated by our model, including time dependent components. The model output is the comparison between the instantaneous force stimulus and a low pass filtered copy of the stimulus. As a result, the model is "self-calibrating"; that is, it adapts to tonic forces, but responds strongly to rapid changes in force. Future studies will examine the effects of receptor properties in motor control. Our working hypothesis is that sensory discharges are tuned for the regulation of skeletal muscles. The dynamic and static sensitivities form a continuum of signals that could aid in adjusting motor activities in the generation of natural movements of animals or in the control of walking machines.

Title: Determining Transitions in Postural Sway Coupling between Visual Stimuli of Differing Complexities using Cross-Wavelet Coherence

Authors: Z. MOTZ[1], A. LIKENS[1], ***M. MUKHERJEE**[2];
[1]Biomechanics, [2]Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Introduction: Postural sway is affected by environmental changes and adapting to these changes allow us to maintain our upright stance. The ability to couple with changing environmental conditions provides insights into our ability to flexibly adapt to dynamic environmental states. Previous studies have shown that participants can transition coupling their postural sway from one stimulus to another when such stimuli are presented in sequence. Such coupling behavior comprises of postural dynamics that shows complex patterns that are related to the complexity of the stimulus. However, it is not clear how the dynamics of postural control change at the transition points between different stimuli. In this study, we used cross-wavelet coherence to determine the common power between postural sway and visual stimuli to understand how participants transition coupling from one stimulus to another. **Methods*:*** Fourteen participants performed a postural task in which they shifted weight mediolaterally on the frontal plane while matching their sway to a moving visual stimulus presented on a 180° virtual reality screen. Both deterministic (periodic and chaotic) and non-deterministic (random) stimuli were provided individually (baseline) and in combination. The combination trials comprised of either 20 second sections of the random stimulus followed by 20 seconds of the periodic stimulus, repeating for three minutes or the same structure with the chaotic stimulus instead of the periodic. The degree of center-of-mass to target coupling for the five seconds before and five seconds after the stimulus transition was quantified using cross-wavelet coherence. Cross-wavelet coherence represented the power relation between two time series in the time-frequency space. **Results/Discussion:** Transition points in postural sway coupling when switching between two external visual stimuli, show characteristic behavioral patterns that are different from postural sway dynamics during steady state stimuli. These transitions display hallmark characteristics of dynamical systems in that participants seem to settle into attractor states before and after the transition, and complexity appears to be the control parameter, as evidenced by an apparent hysteresis effect concerning the direction of the transition. Moreover, coupling during transitions is context dependent and based on both the high- and low-frequency components of the stimuli.

Title: Evaluating Associations Between Central Visual Field Loss and Conscious Movement Processing

Authors: N. SHANIDZE[1], R. LEE[1], W. R. YOUNG[2];
[1]The Smith-Kettlewell Eye Res. Inst., San Francisco, CA; [2]Sch. of Sport and Hlth. Sci., Univ. of Exeter, Exeter, United Kingdom

Abstract: Central visual field loss (CFL) due to diseases such as age-related macular degeneration (AMD) is a large and growing problem. While much is known about the visual limitations associated with this condition, one of its most dangerous and poorly understood outcomes is the increase in the risk of falls, which can be debilitating and even deadly. Recent studies suggest that older adults deemed to be at an increased risk of falls may alter their movement processing strategies (Wong et al. 2008). Specifically, heightened conscious movement processing and task-irrelevant ruminations are observed; both of which are linked to increased fall-related anxiety and increased movement errors when walking (Ellmers et al. 2019). These behaviors are also linked with maladaptive visual search strategies (i.e. reducing previewing of an intended walking path) during locomotion that may further increase the risk of trips, slips and falls. The current study sought to evaluate if similar conscious movement processes emerge in individuals with CFL and if these changes are related to the extent of visual deficit.
To assess changes in movement processing we used the Gait-Specific Attentional Profile (G-SAP, Young et al. 2020). Items on this scale were divided in to three sub-scales: conscious movement processing, anxiety, and rumination. The total score for each category was calculated separately for each participant and correlated with measures of binocular contrast sensitivity (MARS letter test) and visual acuity (VA) of the better eye. A total of 29 individuals with CFL (18 F) were surveyed for the study. We found binocular contrast sensitivity to be a significant predictor of increases in conscious movement processing during locomotion in individuals with CFL (linear regression, $p = 0.037$). Additionally, VA of the better eye was a strong predictor of an increase in anxious thoughts during locomotion ($p = 0.041$). The latter may be related to previously-reported increases in overall fear of falling in individuals with AMD (van Landingham et al. 2014). These findings suggest that further experiments are needed to investigate potentially dangerous behavioral changes in gaze strategies and posture in patients with CFL associated with increased conscious monitoring of movements during locomotion.

Title: Changes in cortical activity and gait parameters during dual task walking and after bi-anodal tDCS and treadmill walking in young and older adults

Authors: D. ORCIOLI-SILVA[1], A. ISLAM[2], L. ROCHESTER[2], L. T. B. GOBBI[1], ***A. PANTALL**[2];
[1]São Paulo State Univ., São Paulo, Brazil; [2]Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Background: Gait dysfunction is common in older adults. Studies indicate that transcranial direct current stimulation (tDCS) combined with treadmill walking (tDCS_TW) has potential to decrease gait dysfunction, particularly during dual-task walking (DTW). **Objective**: We investigated the effect of tDCS_TW on cortical activity and gait parameters in young adults (YA) and OA during DTW. **Methods**: Twenty-three YA and 21 OA were randomly allocated to receive active or sham tDCS. Participants performed 5 mins of treadmill walking (alternating 30 s bouts of single-task walking and DTW) before and after a 20 min intervention of tDCS_TW. Active anodal stimulation was applied to the left prefrontal cortex (PFC) and primary motor cortex (M1) using 9 cm^2 electrodes at 0.6mA. Cortical activity of the PFC, M1, premotor cortex (PMC), and supplementary motor area (SMA) bilaterally were recorded using a tethered functional near infra-red spectroscopy (fNIRS) system. An accelerometer measured gait parameters. We applied linear mixed effects models which included group (YA, OA) and intervention (sham, active) as fixed effects. **Results**: OA displayed higher activity bilaterally in the PFC and M1, and unilaterally in the right PMC during DTW compared to YA ($p<0.05$). Cadence was lower and gait variability higher in OA than YA. M1 activity decreased in both YA and OA following active tDCS. **Conclusion**: Increased activity in multiple cortical areas during DTW in OA may act as a compensatory mechanism to deal with increased task complexity during gait. In addition, tDCS_TW decreased M1 activity in both groups, suggesting active tDCS combined with treadmill walking may improve neural efficiency.

Title: Asymmetric precision walking task is controlled by the same synergies in rats

Authors: *K. HANNA[1], S. YAKOVENKO[1,2,3,4];
[1]Chem. and Biomed. Engin., [2]Human Performance - Exercise Physiol., [3]Neurosci., [4]Rockefeller Neurosci. Inst., West Virginia Univ., Morgantown, WV

Abstract: Walking with turning and precise limb placement is executed by a complex spatiotemporal pattern of muscle activations. The musculoskeletal high-dimensionality in walking is typically solved through the use of low-dimensional neuromuscular control signals, called synergies. Here, we test the composition of synergies in a precision walking task in symmetric and asymmetric conditions. Nine Sprague-Dawley rats were implanted with arrays of intramuscular electrodes to record EMG from the shoulder, elbow, and wrist flexors and extensors. Animals were trained to walk on a peg-way with movable bilateral individual pegs instrumented with force sensors. The asymmetric conditions were set so that animals walked either symmetrically with an overall preferred stride length of 15 cm or asymmetrically with either ipsilateral or contralateral limb forced to increase limb transfer during the swing and to exhibit limb preference during each stride. We extracted a low-dimensional structure in each condition from averaged EMG envelopes during the period from the onset of swing to foot contact identified from ground reaction forces. Using a dimensionality reduction algorithm, nonnegative matrix factorization (NNMF), we found four synergies explaining 99.95% of variability and temporally related to limb retraction, limb transfer, foot placement, and stance initiation. The weights representing the contribution of each temporal component are highly correlated across conditions ($r=0.96\pm0.04$) supporting the hypothesis that the same synergies generate movement across asymmetric conditions. This evidence provides further support that precise limb placement in symmetric and asymmetric stepping is controlled by the same control system in rodents, and it may be a therapeutic target for the rehabilitation of locomotor asymmetries.

Title: Predictive Impairments in Motor Skills in Children with Autism Spectrum Disorder

Authors: *S. F. BOND[1], S.-W. PARK[2], M. RUSSO[1], A. CARDINAUX[2], P. SINHA[2], D. STERNAD[1];
[1]Northeastern Univ., Boston, MA; [2]MIT, Cambridge, MA

Abstract: Anecdotal reports and selected research results suggest that individuals with autism spectrum disorder (ASD) exhibit difficulties in motor coordination, especially when interacting with dynamic objects, as in catching a ball. A theoretical framework from our group proposed that the distinct manifestations of ASD in multiple domains, including social interactions, cognition and motor coordination, have a common core: compromised temporal prediction (Sinha et al., 2014, PNAS). We tested this hypothesis in the motor domain: Would individuals with ASD show impaired motor coordination when intercepting a moving object as this task requires trajectory prediction? With this goal, we studied full body movements of ASD children while they attempted to catch balls launched towards them. To account for potential non-prediction related factors that could contribute to impaired catching performance, we conducted a series of matching control tasks. 16 children with ASD (aged 7-12 years) and 16 age- and IQ-matched neurotypical (NT) children participated in the experiment. They were asked to catch a ping-pong ball launched from a ball machine using one or two hands. 3D motion capture recorded joint kinematics of participants' arms and the flying ball. A set of control tasks assessed postural balance, reaction time when lifting both arms, and movement speed in reaching to a stationary ball. We hypothesized that in these control tasks, ASD and NT participants would not differ. Results showed that ASD participants indeed had fewer successful catches than NTs ($p=0.01$). Detailed kinematic analyses of ball and hand trajectories revealed that while NTs approached the ball with a relatively stable profile of hand velocity, ASDs exhibited a collision-like motion, suggesting insufficient prediction of the upcoming ball. In the control task of lifting both arms, ASDs and NTs showed similar reaction times ($p=0.18$). When reaching to a stationary ball, reaction times and movement speeds were also not significantly different ($p=0.789$). In addition, postural sway also did not differ ($p=0.45$). These lack of differences in basic aspects of motor coordination support the interpretation that it is the predictive demands that are likely responsible for the reduced performance of ASD participants when catching a flying ball. We conclude that in complex interactive motor tasks, performance of ASD children may be affected by reduced predictive motor control, consistent with our hypothesis. It remains to be seen whether this evidence of impairments in prediction will generalize beyond motor skills, enabling a more unified understanding of the complex autism phenotype.

Title: Relationship between cognitive and gait recovery at 2- and 12- months post-Traumatic brain injury

Authors: V. VUONG[1], K. K. PATTERSON[2], L. COLE[1], ***T. L. HENECHOWICZ**[1], C. SHERIDAN[2], R. GREEN[2], M. H. THAUT[1];
[1]Music and Hlth. Sci. Res. Collaboratory, Fac. of Music, [2]Toronto Rehabil. Institute, Univ. Hlth. Network, Univ. of Toronto, Toronto, ON, Canada

Abstract: Objectives/Rationale. This study examined the relationships between cognitive and motor functioning over time in a cohort of post-Traumatic Brain Injury (TBI) patients. Executive dysfunction is associated with slower walking speed (Yogev-Seligmann et al., 2008), increased incidence of falls (Persad et al., 2008), and increased stride time variability (Allali et al., 2008). However, investigations have yet to examine whether executive functioning predicts post-rehabilitation gait outcomes. We investigated if (1) measures of executive function correlate with gait outcomes and (2) if executive functioning at 2-months predicts gait at 12-months.**Methods.** N=93 TBI-patients underwent cognitive testing, Trail making B score (TMTB) and Digit Span Forward (DSF), and gait testing at 2- and 12-months post-injury. Six spatiotemporal variables were extracted: Step Length variability at Self Paced (SP) and Maximum Paced (MP), Step Time variability SP and MP, and Gait Velocity SP and MP. Spearman's correlation coefficients were calculated for gait and cognitive variables at concurrent time points and 2-month cognition with 12-month gait. Six Multiple Linear Regression models were fitted to assess whether 2-month cognition predicted 12-month gait. **Results.** 2-month TMTB correlated with 2-month Velocity MP ($r=0.28$, $p<0.01$) and SP ($r=0.33$, $p<0.01$), Step Time variability MP and SP ($r=-0.32$, $p=0.0326$; $r=-0.39$, $p<0.01$). 2-month Digit Span correlated with Velocity MP ($r=0.26$, $p<0.05$). At 12-months, TMT B and DSF were correlated with velocity SP. 2-month TMTB correlated with 12-month Step Length variability SP ($r=-0.51$, $p<0.01$), and Step Time variability SP (-0.53, $p<0.001$). 2-month Digit Span was correlated with 12-month Velocity SP and MP, ($r=-0.44$, $p<0.01$; $r=0.29$, $p<0.05$). 2-month TMTB was a significant predictor of 12-month gait in the models for Step Length variability SP ($p<0.05$), Step Time variability SP ($p<0.05$), and Velocity MP ($p<0.05$).**Conclusion**. Findings present evidence for correlations between the pre- and post-rehabilitation executive function and gait outcomes. Our prediction finding, TMTB (but not DSF) significantly predicted 12-month gait, suggests that future research in TBI rehabilitation should investigate motor and cognitive recovery in tandem rather than as distinct processes. Contrary to traditional approaches, an integrative approach to cognition and motor function should be considered when designing neurorehabilitation protocols.

Title: Effects of lighting and visual search on dynamic postural control in patients with peripheral field loss

Authors: *A. CHEONG[1], H.-Y. LAM[1], V. SUEN[1], C. TSANG[1], M. CHEUNG[1], G. WOO[1], J. CHO[2], J. KWAN[3], L. A. ABEL[4], P. LEE[1], W. TSANG[5];

Abstract: Introduction Due to reduced visual inputs, patients with vision loss have difficulty to maintain postural stability, in particular during challenging conditions. However, no studies have examined the impact of excessive lighting on dynamic balance function while engaging in a common daily task - visual search. This study was aimed to examine the effect of lighting and visual search on dynamic postural control in patients with and without peripheral field loss (PFL).
Methods Dynamic postural control for 10 patients with PFL due to retinitis pigmentosa (age: 61.1 ± 2.8) and 9 age-matched controls (age: 64.3 ± 0.8) were measured. Participants were required to walk a 4-metre pathway at self-pace, step onto a force platform (Bertec, OH, USA) at the end of walking path and maintain their posture for 20 sec for three levels of lighting (100 lux, 520 lux and 2100 lux). While walking, they were asked to either look at a stationary cross or perform a visual search task in which participants had to identify a target out of 5 distractors shown on 6 monitors located at 5-metre away, covering approximately 120 degree field of view. Each condition was repeated for 5 trials. Time to stabilize, maximal sway in anterior-posterior (AP) and medial-lateral (ML) directions, and total sway path length were analyzed.
Results Effect of lighting was only found in time-to-stabilize, in which significantly longer time was required to stabilize under the dimmest lighting condition (100 lux: 1.02s ± 0.06, 520 lux: 0.89s ± 0.05, 2100 lux: 0.91s ± 0.06; $p < 0.01$). The PFL group swayed significantly more than the control group, with significantly longer sway path length (148.0 cm ± 4.0 vs. 137.5 cm ± 2.8, $p<0.05$). Search task significantly affected their postural sway in AP (Fixation: 34.9 ± 1.5, Search: 37.5 ± 1.4; $p=0.02$) and ML (Fixation: 37.5 ± 1.8, Search: 52.3 ± 1.6; $p=0.02$) directions. However, no significant interaction effect of lighting-group, task-group and lighting-task-group was found ($p>0.05$).
Conclusion Our preliminary findings showed that the environmental changes (lighting), visual task (searching) and visual impairment (loss of peripheral vision) might cause detrimental impacts on dynamic postural control, but in different aspects. Changes in lighting (but not excessive lighting) affected the temporal domain of postural control (time-to-stabilize), while visual search and loss of visual input interrupted the spatial domain of postural control (sway path length, amplitudes in AP and ML sway). Further studies are needed to better understand the possible mechanisms of those environmental and daily life activities impact on dynamic postural control.

Title: Intranasal insulin rapidly alters ambulatory activity and neuronal calcium network in aged somatosensory cortex

Authors: R.-L. LIN[1], H. N. FRAZIER[2], K. L. ANDERSON[3], A. O. GHOWERI[4], ***O. THIBAULT**[1];
[1]Univ. Kentucky Med. Ctr., Lexington, KY; [2]Dept. of Pharmacol. and Nutritional Sci., [3]Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY; [4]Pharmacol. and Nutritional Sci., Univ. of Kentucky Med. Ctr., Lexington, KY

Abstract: With a 30-40% annual rate of fall, individuals over the age of 65 represent a population target with elevated injury-related morbidity and mortality among older adults, yet it is surprising that few strategies are available for the prevention of falls in the elderly. Non-medicinal approaches such as physical therapy, exercise interventions, use of braces or mobility devices, and even stretching, all appear capable of improving ease of movement and reducing falls; however, these are only moderately effective. Further, lack of adherence to these programs, along with their cost, significantly reduce their potential impact. Here we investigated the hypothesis that acute intranasal insulin (INI) delivery could have an impact on ambulatory performance in the aged F344 rat when delivered at a dose previously shown to improve memory processes. We also monitored the impact of acute INI on neuronal calcium network within the primary somatosensory cortex (S1) in aged animals treated with either insulin aspart or saline. Compared to controls, animals treated with INI moved through our 3-plane visualization ambulatory task (cumulative time required to walk 1 m down a corridor, and across 4 different surfaces) at a faster rate. Based on several task indices (*i.e.,* deviation from the center line, left, and right side coordination based on variability in x and y distances, and other coordination measures) INI treated animals showed a significant improvement on this task. Measures of network activation, synchronization and size within S1 revealed a rapid and significant drug effect within ~15 minutes post-dose. Together, these results show that INI rapidly enhances network communication in S1 and also improves coordination in an animal model of aging. We provide evidence that improved motor coordination may represent a new functional and relevant modality that is sensitive to INI. Given the numerous positive outcomes seen in response to INI in the clinic, including improvements in memory, cognitive and emotional functions, it is not

surprising that increased physical activity could also be a target of the hormone in the brain. These results align well with preclinical and clinical findings, and suggest motor behavior may be a new target of insulin in the brain.

Title: Upper limb protective responses during falls in complex environments by older adults

Authors: *N. SHISHOV[1], V. KOMISAR[1], D. S. MARIGOLD[1], J.-S. BLOUIN[3], S. N. ROBINOVITCH[1,2];
[1]Dept. of Biomed. Physiol. and Kinesiology, [2]Sch. of Engin. Sci., Simon Fraser Univ., Burnaby, BC, Canada; [3]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Falls cause up to 80% of traumatic brain injuries (TBI) in older adults (Fu et al. 2017 PLoS One). In the event of a fall, people often use upper limb protective responses to brace the fall and avoid impact and injury to the head. In laboratory studies, these responses are adjusted to the situational demands of the fall based on visual mapping of environmental features (Ghafouri et al. 2004 Exp Brain Res). However, it is unclear whether older adults, who are at the greatest risk for falls and TBI, tailor their protective responses to features of the environment in a functionally effective manner. In this study, we analyzed videos of real-life falls experienced by older adults in long-term care (LTC) to determine the portion of falls that involved object contacts (i.e. complex environments), and test the hypothesis that upper limb contacts to nearby objects reduced the risk of head impacts to objects.
We analyzed videos of 2746 falls using a valid questionnaire (Yang et al. 2013 BMC Geriatr) to characterize body part impacts, reach-to-grasp attempts and fall height. Falls were classified as occurring in complex environments if contact was initiated after fall onset between any body part with objects other than the floor. We used Chi-square to test whether, for falls in complex environments, the odds for head impact to objects was reduced by hand or elbow contact with objects.
We found that 46% of falls occurred in complex environments (n=1251), of which 51% involved upper limbs contacts with objects, and 33% involved head impacts with objects. When compared to falls from lower heights, falls from standing height (n=764) more often involved upper limb

contacts to objects (56 vs 44%), including successful reach-to-grasp of objects (35 vs 17%), elbow impact to objects (21 vs 28%) and hand impact to objects (14 vs 6%).
The probability of head impact to objects was lower in falls involving successful grasps compared to unsuccessful grasps or no attempt to grasp objects ($p<0.001$), in both falls from standing (17 vs 46 or 43%; $p<0.001$), and falls from lower height (12 vs 41 or 34%; $p<0.001$). In falls from lower than standing height, the probability of head impact to objects was reduced by hand or elbow impacts to objects compared to hand or elbow impacts with the ground or no hand and elbow impacts (19 vs 35 or 38%; $p<0.001$).
We found that nearly half of all falls by older adults in LTC occurred in complex environments, where upper limb interactions with objects reduced the risk for head impact to objects by nearly 3-fold. Our results suggest that older adults avoid head impact during falls through tailoring of upper limb protective responses to the immediate environment.

Title: Cognitive and motor perseveration are associated in older adults

Authors: *C. J. SOMBRIC[1], G. TORRES-OVIEDO[2];
[1]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA, [2]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Aging causes perseveration (difficulty to switch between actions) in motor and cognitive tasks, suggesting that the same neural processes could govern these abilities in older adults. To test this, we evaluated the relation between independently measured motor and cognitive perseveration in young (21.4±3.7 y/o) and older participants (76.5±2.9 y/o). Motor perseveration was measured with a locomotor task in which participants had to transition between distinct walking patterns. Cognitive perseveration was measured with a card matching task in which participants had to switch between distinct matching rules. We found that perseveration in the cognitive and motor domains were positively related in older, but not younger individuals, such that participants exhibiting greater perseveration in the motor task also perseverated more in the cognitive task. Additionally, exposure reduces motor perseveration: older adults who had practiced the motor task could transition between walking patterns as

proficiently as naïve, young individuals. Our results suggest an overlap in neural processes governing cognitive and motor perseveration with aging and that exposure can counteract the age-related motor perseveration.

Title: Effect of kinesiology tape on static postural control in non-athlete young adults with functional ankle instability

Authors: *L. MICHAUD, K. LY, Y. LAJOIE;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background**:** Kinesiology tape (KT) is often used to increase ankle stability and proprioception around the ankle of people with Functional Ankle Instability (FAI) during rehabilitation or physical activities (Williams et al., 2012). However, there is limited evidence of KT's effectiveness on static postural control, which can also be diminished by FAI. Furthermore, studies mainly focused on athletes thus limiting the possible inference toward a larger population. The effect of KT on static postural control is also mainly assessed using linear measures of the center of pressure (COP) displacement, which can be misleading since the COP displacement is nonlinear (Cavanaugh et al., 2005). Therefore, our objective was to determine if KT could improve static postural control of non-athletes with FAI using nonlinear COP measures. Method**:** Twenty young adults (23.4 ± 4.25 years) with FAI performed three standing tasks: unipedal stance on the leg with FAI, unipedal stance on the healthy leg and bipedal stance. Four trials of 45s were performed for each position and at three different times: before applying a KT on the unstable ankle (B), immediately after (I) and 24h later with the KT still on (24h). The COP displacement was obtained with an AMTI force platform at 500 Hz and analysed using two nonlinear COP measures: sample entropy and the contribution of specific frequency bands. The sample entropy measured the regularity of the signal in the anterior-posterior (AP) and medial-lateral (ML) direction. A discrete wavelet transform was applied to the signal, in both directions, to measure the contribution of four frequency bands related to different systems modulating the posture (medium: 1.56 to 6.25 Hz - proprioception, low: 0.39 to 1.56 Hz - cerebellum, very-low: 0.10 to 0.39 Hz - vestibular, ultralow: < 0.10 Hz - vision) (Quek et al., 2018). For the unipedal stances, two-way repeated measures ANOVA and MANOVA (leg x time) were performed on the sample entropy and wavelet data, respectively. For the bipedal stance, one-way repeated measures ANOVA and MANOVA (effect of time) were performed on the sample entropy and wavelet data, respectively. Result**:** Statistical analysis revealed only a main effect of time during the unipedal stance. Sample entropy was higher at B and 24h compared to I in both AP and ML. The low band in ML and the ultralow band in AP had higher contribution at I compared to 24h.

Conclusion**:** Our results suggest that KT didn't change the COP displacement dynamic during unipedal or bipedal stance. Although there was a main effect of time, there was no main effect of the leg side. This suggests that KT doesn't improve static postural control of non-athletes with FAI.

Title: Integrative measure of walking smoothness is associated with fear of falling, gait efficacy, and life-space in older adults

Authors: *A. SURI[1], A. L. ROSSO[2], J. VANSWEARINGEN[3], L. M. COFFMAN[3], J. S. BRACH[3], E. SEJDIC[1];
[1]Electrical and Computer Engin., [2]Epidemiology, [3]Physical Therapy, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Gait speed is a prime indicator of mobility ability, function and independence, but it incompletely captures the motor control of walking or gait quality. Accelerometry and instrumented walkway methods provide objective measures of gait quality. We examined the association of gait variability and smoothness to self-reported fear of falling (FOF), walking confidence, and life-space mobility. We used baseline data from community-dwelling older adult participants (n=231; age 77 ± 6 years; 65% females; 89% whites; 44% had more than a high school education) in a clinical trial to improve walking. Gait quality at usual pace was quantified by 1) smoothness (Harmonic ratio) calculated as the vector sum of vertical (V), anterior-posterior (AP) and medio-lateral (ML) directions; 2) gait variability (CoV) for step time, step length and stride width; combined variability computed as sum of CoV (step time, step length and step width); and 3) gait speed. Smoothness was derived from a tri-axial accelerometer during over-ground six-minute walking. Variability and speed were calculated for 6 passes of walking over a 4-m instrumented walkway. The association of gait quality with FOF, walking confidence (modified Gait Efficacy Scale), and life-space mobility (Life Space Assessment scale) was assessed using walking speed, age, and sex as covariates. ANCOVA compared gait quality between those with and without FOF and spearman correlations examined relations of gait quality to walking confidence and mobility. Individuals without compared to those with FOF had better gait quality: smoothness V (2.38 ± .58 vs 2.14 ± .73), combined smoothness (3.84 ± 0.89 vs 3.55 ± 0.97), and faster speed (1.10 ± .15 m/s vs 1.04 ± .17 m/s), all $p<0.05$. Greater

smoothness V (ρ_P=0.23), AP(ρ_P=0.13) and combined (ρ_P=0.17) and gait speed (ρ=0.42), were associated with a greater walking confidence, all p<0.05. Greater smoothness ML (ρ_P=0.16), AP (ρ_P=0.15) and combined (ρ_P=0.14), and walking speed (ρ=0.21), related to greater life-space mobility, all p<0.05. Controlling for gait speed, age and sex, no association was found for gait variability with FOF, confidence or mobility. In addition to walking speed in the older adults studied, gait quality, particularly smoothness, reflects psychosocial aspects of walking and community mobility. Identification of relevant gait quality aspects related to clinically important outcomes may help inform rehabilitation.

Title: The effects of tactile somatosensory therapies on walking rehabilitation for neurological disorders: a systematic review

Authors: *T. CORBET, S. N. EDD;
Gondola Med. Technologies, Epalinges, Switzerland

Abstract: Introduction: With a neurological disorder, walking often requires compensatory strategies to overcome the disability, demanding increased executive control. On the contrary, a healthy walking pattern is predominantly driven by automatic patterns with minimal executive control. One way to enhance automatic circuits and to reduce the executive involvement during walking may be through somatosensory feedback. Given that somatosensory information is essential for body representation and walking control, somatosensory therapies may be efficient for walking rehabilitation. The objective of this systematic literature review is to understand the effects of tactile somatosensory therapies on walking abilities in patients with neurological disorders.
Methods: Articles were included if they tested mechanical, tactile, or sensory electrical stimulation for walking rehabilitation interventions and tested participants with neurological disorders affecting gait. The literature search of articles published in English was performed in 4 electronic databases. Article selection followed the PRISMA methodology.
Results: The search yielded 1269 potentially relevant articles, leading to 28 selected articles, (including 15 randomized controlled trials). Among the selected articles, 12 tested the Automated Mechanical Peripheral Stimulation (AMPS) treatment (1), 6 studies tested textured insoles, 2 vibrotactile stimulation, 7 sensory electrical stimulation and 1 neuromuscular taping. Study populations were 64% Parkinson’s disease, 14% stroke, and 14% multiple sclerosis; one

study included infants with myelomeningocele and one tested an adult with a spinal cord tumor. Eighteen studies (including 11 studies with AMPS) reported a significant positive effect of tactile somatosensory therapies on walking abilities. The remaining ten studies reported no significant effect. No study reported a negative effect. Eight studies showed a significant increase in walking speed due to the intervention, but only studies using AMPS (n= 5) showed a clinically important change in walking speed (threshold of 0.10 m/s (2)). Regarding the underlying mechanisms, two studies showed that AMPS significantly increased brain connectivity and one study demonstrated increased BDNF after AMPS, suggesting synaptic plasticity.
Discussion & Conclusion: This systematic review highlights the possibility of using tactile somatosensory therapies for walking rehabilitation. AMPS therapy seems to be especially promising to improve walking function in patients with a neurological disorder.

Title: Mild Parkinsonian signs are associated with decreased cortical-striatal connectivity in executive control networks in healthy older adults

Authors: *J. B. HENGENIUS[1], T. J. HUPPERT[2], A. L. ROSSO[1], C. ROSANO[1];
[1]Epidemiology, [2]Electrical and Computer Engin., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Background: Mild Parkinsonian signs (MPS) may precede Parkinson's Disease (PD), but it is not known whether patients with MPS exhibit similar alterations of functional connectivity (FC) to those observed in PD. We hypothesize that MPS are associated with PD-like alterations of FC in the cortical-striatal-thalamic dopaminergic networks regulating sensorimotor, executive, and reward functions. Methods: Participants (N=272; mean age 83; 57% female; 41% African American) without PD completed structural and resting-state functional magnetic resonance imaging followed by the motor component of the Unified Parkinsonian Disease Rating Scale (UPDRS) within 6 months of scan. Risk factors for MPS included: gait speed, quadriceps strength, joint pain, body mass index, vision, lung function, and proprioception. To measure the FC between striatum and cortex in each network, we segmented both the striatum and cortex into sensorimotor, executive, and limbic regions using extant atlases. The thalamus (without functional subdivisions) was defined by existing atlas. After

regressing out mean white matter and cerebrospinal fluid signals, we computed correlations within each cortical-striatal network (e.g., between mean of sensorimotor cortex and mean of sensorimotor striatum). Total brain white matter hyperintensities (WMH) and gray matter volume (GMV) were normalized by total brain volume. Logistic regression tested the association of FC of each cortical-striatal network with MPS (UPDRS>0), adjusted for MPS risk factors first, then additionally for WMH and GMV. WMH by FC interactions were tested and analyses were repeated stratified by burden of WMH (median value cutoff). Results: Compared to those without MPS, those with MPS had significantly lower cortical-striatal FC in the left executive control function network (adjusted Odds Ratio [95% CI], p value: 0.188 [0.043, 0.824], 0.027). Association survived adjusting for MPS risk factors (0.151 [0.027, 0.860], 0.033) but was attenuated after adjusting for WMH (0.209 [0.036, 1.200], 0.079). In models stratified by WMH, left executive cortical-striatal FC was significantly associated with MPS for those with high WMH (0.077 [0.010, 0.599], 0.014) but not for those with low WMH (1.245 [0.128, 12.132], 0.850). Associations of MPS with FC in other networks were not significant. Conclusion: Cortical-striatal FC, especially in executive control networks, is lower for those with MPS. The association is independent of other risk factors but was stronger for those with high WMH, another central nervous system source of MPS. Future work should examine whether higher FC may protect against the influence of WMH on MPS.

Title: Distributed force feedback modulates the dependence of limb stiffness and inter-joint coordination on perturbation direction: a simulation study

Authors: *T. GOVINDARAJ[1], D. HOWLAND[4], G. SAWICKI[2], T. NICHOLS[3];
[1]Mechanical Engin., [2]Mechanical Engin. and Biol. Sci., [3]Biol. Sci., Georgia Inst. of Technol., Atlanta, GA; [4]Kentucky Spinal Cord Injury Res. Center, Dept. of Neurolog. Surgery, Univ. of Louisville; Res. Service, Robley Rex VA Med. Ctr., Louisville, KY

Abstract: Force feedback from Golgi tendon organs is more widely distributed than length-dependent feedback from muscle spindles, so force-dependent pathways are likely to have a more global effect on limb stiffness and inter-joint coordination. Limb stiffness is task-dependent and is decreased in downhill walking. To understand the role of force feedback in regulating limb mechanics for different terrains, we are developing a three segment feline hindlimb model

in Matlab, with realistic lengths and masses and rotational springs and dampers at all the joints to represent the intrinsic properties of muscles with integral stretch reflexes. Based on the known distribution of muscular mass, we set joint impedance to decrease from hip to ankle. In this initial model version, there is no provision for bi-articular muscles. Force feedback is represented by a matrix multiplying the joint torques. To simulate limb behavior during weight acceptance, a step input force equivalent to twice the body weight of a 3.5 kg cat is applied over one second, which is long enough for the model to settle to steady state. To simulate different kinds of terrain, the direction of the endpoint force is varied in even increments from the rostral to caudal aspects of the limb. For each perturbation, the stiffness, Kleg, is calculated along the direction of the limb for the following experimentally-observed inhibitory force feedback distributions: no force feedback, weak homonymous (i. e., each joint onto itself), strong homonymous, and three heteronymous (i.e., inter-joint) force feedback distributions (proximal to distal, distal to proximal, and balanced). Our hypothesis is that for each force feedback distribution, Kleg will be maximum for endpoint forces pointing directly to the hip (0 deg), and decrease for endpoint forces directed caudally or rostrally from the hip. We expect that Kleg will depend to the greatest extent on the direction of the endpoint force with homonymous feedback, but that the directional dependence will be attenuated significantly by inter-joint (i.e., heteronymous) force feedback. Preliminary results from a two segment model show that Kleg changes with the direction of the endpoint force in the expected manner, but the peak stiffness occurs for a rostrally-directed endpoint force (~-15 deg). Our results also indicate that inter-joint force feedback distributions significantly reduce the dependence of Kleg on the direction of an endpoint force, and that this effect is sensitive to the details of the feedback topology. However, in addition to the inter-joint distributions the results suggest that strong homonymous feedback attenuates the directional dependence of Kleg.

Title: Combining H-reflex conditioning and locomotor training enhances locomotor recovery in rats with incomplete spinal cord injury

Authors: *Y. CHEN[1], L. CHEN[2], X. YANG[2], J. R. WOLPAW[2], X. CHEN[2];
[1]Natl. Ctr. for Adaptive Neurotechnologies, [2]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the spinal stretch reflex or its electrical analog, the H-reflex (HR), changes brain and spinal cord (Curr Op Behav Sci 20:138-144, 2018 for review). In rats and humans with incomplete spinal cord injury (SCI), appropriate reflex conditioning improves locomotion (J Nsci 26:12537-43, 2006 & 33:2365-75, 2013). We are exploring the therapeutic impact of combining H-reflex conditioning with locomotor training (LT) after SCI. Under anesthesia, SD rats were implanted with EMG recording and nerve stimulating electrodes, and received a right lateral column lesion at T9; 20 d later, each was exposed for 60 d to right soleus HR up-conditioning plus 5 d/wk LT (CB rats, n=9), or LT alone (LT rats, n=7). Locomotor EMG and HRs, horizontal ladder crossing, locomotor kinematics were assessed before and after SCI, at the end of treatment (Rx), and 50 ds later. CB Rx increased the protocol HR (HR in the conditioning protocol); LT Rx did not. In CB rats, the protocol HR appeared to increase more quickly and more than in normal rats exposed to up-conditioning. CB, but not LT Rx also increased the locomotor HR (HR during locomotion). Horizontal ladder missteps were 0.11(±0.08SE) and 0.24(±0.10)/crossing for CB & LT rats, respectively (p=0.32, CB vs LT, t-test) before SCI, 6.24(±0.82) and 5.34(±0.58) (p=0.41) after SCI but pre-Rx, and 1.80(±0.51) and 5.14(±0.57) (p<0.001) post-Rx. In CB rats, missteps remained low 50 d post-Rx. Left and right hip heights (mm) were 53.6(±1.4) and 53.9(±1.6), respectively (p=0.20, right vs left, paired t-test) for CB rats and 55.0(±2.3) and 54.9(±2.2) (p=0.39) for LT rats before SCI, 58.1(±1.3) and 54.4(±1.1) (p<0.001) for CB rats and 57.3(±1.9) and 53.9(±1.9) (p=0.016) for LT rats after SCI and pre-Rx, and 56.8(±1.8) and 56.9(±1.9) (p=0.76) for CB rats and 61.6(±0.76) and 57.5(±1.0) (p=0.010) for LT rats post-Rx. In CB rats, hip heights remained symmetrical 50 d post-Rx. Step symmetry (right step duration as % of left) was 101.1(±0.4) and 100.5(±0.9) in CB and LT rats, respectively (p=0.99, CB vs LT, ANOVA) before SCI, 91.3(±1.0) and 88.5(±0.5) (p=0.99) after SCI and pre-Rx, and 97.9(±1.1) and 92.2(±0.5) post-Rx (p=0.001 CB vs LT; p<0.001 and p=0.11; pre- vs. post-Rx). In CB rats, steps remained symmetrical 50 d post-Rx. In rats with SCI, HR conditioning plus LT produces recovery superior to that of LT alone. Horizontal-ladder performance is better; right/left step and hip-height symmetries are restored. Improvements persist after Rx ends. The results are consistent with current human studies of therapeutic combinations (e.g., J Physiol 2019, https://doi.org/10.1113/JP278173), and can help guide their further development.

Title: H-reflex operant conditioning of the flexor carpi radialis

Authors: *J. J. S. NORTON[1], S. DEVETZOGLOU-TOLIOU[1], J. BRANGACCIO[1], D. E. GEMOETS[1], S. M. HECKMAN[1], T. M. VAUGHAN[1], N. J. HILL[1], J. S. CARP[1,2], J. R. WOLPAW[1,2];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Stratton VA Med. Center, Dept. of Veterans Affairs, Albany, NY; [2]Dept. of Biomed. Sci., Univ. at Albany, State Univ. of New York, Albany, NY

Abstract: H-reflex operant conditioning is a targeted new approach for rehabilitation of motor function following spinal cord injury and potentially stroke (Thompson et al., J Neurosci, 2013). In this protocol, participants learn to increase or decrease the size of abnormal reflex responses (as needed) triggering widespread beneficial plasticity that improves movement. H-reflex operant conditioning can complement existing therapies, is non-invasive, and has no known adverse side effects (Norton and Wolpaw, COBS, 2018). Previous investigations of H-reflex operant conditioning have focused on the soleus muscle in the leg (Thompson et al., J Neurosci, 2009; Thompson et al., J Neurosci, 2013). Here, we report on an ongoing research extending H-reflex operant conditioning to the flexor carpi radialis (FCR) in the arm and examining concurrent changes in brain activity—as measured using electroencephalography (EEG)—that occur during H-reflex operant conditioning.

The conditioning protocol we use in our study is based on the one described by Thompson et al. (J Neurosci; 2009). Participants are asked to complete 6 baseline and 24 conditioning sessions (3/wk over ~10 wks; EEG data recorded at ~2 wk intervals). During each session, participants complete a sequence of trials where they maintain a predefined level of FCR activity and H-reflexes are elicited using transcutaneous electrical stimulation. During conditioning sessions, immediate rewards occur when H-reflex size is below (down-conditioning) or above (up-conditioning) a criterion.

To date, 10 healthy participants (7 up- and 3 down-conditioned) have completed the protocol. For these participants, we compared average H-reflex size from the 6 baseline sessions to the average H-reflex size from the last 6 conditioning sessions. In 6 participants, H-reflex size changed in the rewarded direction (two-sample, one-sided t-test; $p<0.05$). In the other 4 participants, H-reflex size did not change. Analysis of the EEG data is underway; it is focusing on 8-13 Hz (*alpha*) and 20-30 Hz (*beta*) activity recorded over the contralateral sensorimotor cortex. These frequencies and locations are being targeted because the sensorimotor cortex is critical to H-reflex operant conditioning (Chen et al., J Neurophysiol, 2006) and there is a correlation between the size of sensorimotor rhythms in the alpha and beta bands and H-reflex amplitude (Thompson et al., Front Neurosci, 2018). Initial data indicate that operant conditioning of the FCR H-reflex is possible. Following confirmation of these initial results and further development we plan to investigate FCR H-reflex conditioning for motor recovery in Veterans who have had a stroke.

Title: Enhancing H-reflex operant conditioning using brain-computer interface (BCI)-based feedback

Authors: ***S. DEVETZOGLOU-TOLIOU**[1,2], M. ADAMEK[4,1], D. J. MCFARLAND[1], J. R. WOLPAW[1,3], J. J. S. NORTON[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Stratton VA Med. Center, Veterans Affairs, Albany, NY; [2]Electrical and Computer Engin., [3]Dept. of Biomed. Sci., Univ. at Albany, Albany, NY; [4]Neurosurg., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: We present ongoing research on the development of an H-reflex operant conditioning protocol that is enhanced with brain-computer interface (BCI)-based feedback. H-reflex operant conditioning is a promising new therapeutic approach for motor function recovery following injury or illness from spinal cord injury (SCI), stroke, or other neuromuscular disorders. In this paradigm, participants learn to change the size of their abnormal reflexes (either increasing or decreasing them as needed), triggering widespread beneficial plasticity that improves movement (Thompson, Chen, and Wolpaw, J Neurosci, 2009; Chen et al., Ann. N. Y. Acad. Sci., 2010). Present models of the neural mechanisms of H-reflex conditioning describe this beneficial plasticity as operating hierarchically. When participants learn to modify their H-reflex size, it generates plasticity in the sensorimotor cortex, which subsequently guides and maintains plasticity in the spinal cord (reviewed in Norton and Wolpaw, COBS, 2018). Thus, we hypothesize that guiding this critical first stage of plasticity in the sensorimotor cortex should improve the speed and efficacy of the entire H-reflex conditioning protocol. To investigate this, we have developed a sequential H-reflex conditioning protocol. In this protocol, participants are first trained to use a sensorimotor rhythm (SMR)-based BCI to control the amplitude of activity in their sensorimotor cortex (Wolpaw et al., Clin Neurophysiol, 1991). Then, they complete H-reflex operant conditioning enhanced with additional feedback on the amplitude of their SMRs. To date, we have identified seven participants with measurable flexor carpi radialis H-reflexes to complete a study of our enhanced H-reflex conditioning protocol. Of these seven participants, five have completed SMR-based BCI training (~10 sessions); four of these participants learned to use the BCI with better than 70% accuracy, and three significantly improved their accuracy with the BCI after training (Mann-Whitney U test; $p < 0.05$). In addition, we have completed the

development of a new version of the Evoked Potential Operant Conditioning System (EPOCS) that includes SMR-based BCI feedback. Healthy participants are now ready to complete the enhanced H-reflex conditioning protocol as soon as human research resumes. Pending positive experimental results with healthy participants, this enhanced H-reflex conditioning protocol will be investigated in Veterans with upper extremity motor impairments due to stroke.

Title: Neural activation of brainstem modulated by shoulder abduction loads during prepared arm lifting

Authors: *Y. ZHAO[1,5], K. WRIGHT[1,2], J. P. DEWALD[1,2,3,4], J. YAO[1,2,3];
[1]Physical Therapy and Human Movement Sci., [2]Northwestern Univ. Interdepartmental Neurosci., [3]Biomed. Engin., [4]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [5]Bioengineering Col., Chongqing Univ., Chongqing, China

Abstract: Motor preparation is task-specific. If the brainstem is involved in motor preparation of upper extremity movements, it is possible to modulate the brainstem's activity during the preparation phase by altering the motor task effort level at proximal joints. To demonstrate this, we used the startle responses to probe the brainstem's activity during shoulder abduction (SABD) against various loads (15 to 55% of a subject's maximal voluntary SABD load). We hypothesize that increasing shoulder load magnitude will result in an enhanced brainstem activity, as demonstrated by greater startle responses.
Four able-bodied subjects with right-hand dominance, no known hearing or movement deficits (2 females, 2males, aged 32± 10.6 years) were recruited to perform prepared shoulder abduction against five load levels (15%, 25%, 35%, 45%, and 55% of maximal voluntary SABD load) respectively. Each loading condition was performed in one block. The order of blocks was random. Each trial started with a 'ready' sound indicating subjects to prepare for a shoulder abduction effort after 5-6s. In 90% of all trials, a second sound either at 80dB (~65% trials as the 'go' condition) or at 115dB (~35% trials as the 'startle' condition) was presented randomly at 1.5-2s following the first "ready" sound, indicating subjects to perform the required task as quickly as possible. EMG data were recorded from the right biceps, triceps, intermediate deltoid, and sternocleidomastoid muscles. The root mean square (RMS) ratio of EMG data between the biceps and intermediate deltoid was calculated to quantify the responses evoked by different

sounds with various loadings. The results showed that the EMG ratio between biceps and intermediate deltoid increased as the loading was getting heavier under both the 'startle' and 'go' conditions. The startle-induced EMG ratio increased faster than induced by the ‘go’ sound resulting in a strong and positive linear relationship (R^2=0.9188). As startle responses reflect the activation level of the reticular formation, our results indicate that shoulder load magnitude can modulate the neural activation of the brainstem during a prepared arm lifting task.

Title: Transspinal stimulation downregulates flexor locomotor networks during stepping in humans

Authors: *M. ZAAYA[1], T. PULVERENTI[1], M. ISLAM[1], **M. KNIKOU**[1,2];
[1]Dept. of Physical Therapy, CUNY Col. of Staten Island, Staten Island, NY; [2]PhD Program in Biol. and Collaborative Neurosci. Program, City Univ. of New York Grad. Ctr., New York City, NY

Abstract: Non-invasive transspinal stimulation is a promising approach to augment movement-based rehabilitation following neurological injury. However, the knowledge regarding the effects of transspinal stimulation on different spinal networks during locomotion remains limited. We looked into the effects of transspinal stimulation on tibialis anterior (TA) flexion reflex during stepping in healthy individuals. The TA flexion reflex was evoked with a 30 ms pulse-train delivered to the medial arch of the right foot. This reflex was conditioned by a single pulse transspinal stimulation delivered at a conditioning-test (C-T) interval either after (~20 ms) or at the same time (0 ms) with the last pulse of the pulse train. Stimulation was delivered randomly at different phases of the step cycle, which was divided into 16 equal bins, based on the foot switch threshold signal. In this study we observed that short-latency TA flexion reflex was depressed throughout the step cycle at both sub- and supra-threshold transspinal intensities. Non-invasive transspinal stimulation over the thoracolumbar region of the spinal cord in healthy subjects during stepping depressed flexion reflexes which are considered part of the spinal locomotor networks. Thus, transspinal stimulation could be potentially used to decrease the excitability of the flexion reflex that is usually exaggerated following a central nervous system disorder.

Title: Startling Acoustic Stimulus Increases Activity in Flexors but Not Extensors During Lifting: A Preliminary Study

Authors: ***K. WRIGHT**[1,2], Y. ZHAO[1,5], J. P. DEWALD[1,2,3,4], J. YAO[1,2,3,4];
[1]Physical Therapy & Human Movement Sci., [2]Northwestern Univ. Interdepartmental Neurosci., [3]Biomed. Engin., [4]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL;
[5]Bioengineering Col., Chongqing Univ., Chongqing, China

Abstract: Startling acoustic stimulus (SAS) has been shown to elicit a quick release of a prepared movement via the reticulospinal tract (RST), making the SAS a useful tool to investigate the RST-innervated muscles in various movements. Previous work in primates has demonstrated that the RST favors flexor muscles over extensor muscles. In humans, earlier findings under pathological conditions evidenced the higher innervation of RST to flexors versus extensors. For instance, stroke survivors usually have strong upper extremity flexor muscle recovery, while the extensor muscles remain weak. However, we still lack evidence to support that RST favors the activation of flexors muscles in an intact human nervous system. To

determine this, our study investigates the effect of the startle response on elbow flexor and extensor muscles during the generation of various shoulder abductions (SABD) loads.
We recruited four able-bodied participants with right-hand dominance, no known hearing or movement deficits to perform SABD over five different loads (i.e., 15, 25, 35, 45, 55% of a subject's maximum voluntary force in the SABD direction). Each loading condition was assigned to a trial block, and the condition order was randomized. At the beginning of each trial, the subjects heard a 'ready' sound to prepare them for a self-initiated SABD after 5-6 s. In 90% of the trials, a second sound was delivered randomly at 1.5-2 s after the 'ready' sound. When hearing the 2nd sound, the subjects were requested to lift the arm as quickly as possible. 65% of the 2nd sounds were at 80dB (the 'go' sound), and 35% at 115dB (the 'startle' sound). EMGs were recorded from the right sternocleidomastoid, biceps (BIC), triceps (TRI), and intermediate deltoid (IDL). Muscle co-activation patterns were quantified to reflect the level of brainstem activity, which was calculated as the ratio of BIC or TRI activity to IDL activity.
Our results showed that EMG ratios of the BIC and TRI increased as a linear function of shoulder load. Furthermore, the BIC ratios were consistently greater than the TRI ratios. The slope of BIC data for the 'startle' condition was greater than the slope for the 'go' condition. However, the 'startle' and 'go' induced EMG ratios for the TRI were almost identical, suggesting the TRI was not reacting to the SAS. These preliminary findings imply that elbow flexors are preferentially activated by RST in an intact human nervous system and confirms earlier findings in the monkey as well as in individuals with hemiparetic stroke.

Title: Neurophysiology of cognitive load during physical performance

Authors: *W. STAIANO[1,2], E. J. GIBBINS[3], F. J. ROMERO GARCIA[2], M. ROMAGNOLI[2]; [1]REWIRE Fitness / Univ. of Valencia, Valencia, Spain; [2]Univ. of Valencia, Valencia, Spain; [3]Loughborough Univ., Loughborough, United Kingdom

Abstract: INTRODUCTION: The interaction of workload and fatigue in physical and mental domains has recently aroused interest although no specific procedure and measures are available. Moreover, the detrimental effects of mental fatigue has been recently studied and research is still in progress to fully understand the neurophysiological mechanisms occurring in the brain. In the present study we aimed to evaluate the relationship between workload and fatigue during traditional physical training (CON) vs. combined aerobic exercise and demanding cognitive tasks (EXP) to assess their effects on behavioural, physiological and cortical measures. **METHODS:** Twenty healthy and fit participants were tested in a randomized cross over order to compare the

acute psychological, physiological and neurophysiological effects of CON and EXP conditions . After a familiarization, each participant was asked to cycle for 1 hour in 2 different occasions at 75% percent of their maximal capacity. During EXP participants were asked to engage in highly demanding cognitive task, while they were cycling. Before and after the cycling trial, they were completing a psychomotor vigilant test (PVT). Pre, during and after cycling test Brunel Mood Scale, NASA Task Load Index, Rating of Perceived Exertion, heart rate, blood lactate, electromyography (EMG) and electroencephalographic recordings were used to evaluate workload and fatigue. **RESULTS:** There were no significant differences between EXP and CON conditions for of HR, blood lactate and EMG during cycling. HR ($P = 0.001$), blood lactate ($P = 0.003$) and EMG ($P = 0.001$) increased significantly over time in both conditions. The NASA TLX revealed significant differences between EXP and CON during cycling in Mental Demands ($P = 0.001$), Temporal Demands ($P = 0.02$), Performance ($P = 0.032$), and Effort ($P = 0.012$). Rating of perceived exertion was significant higher in the EXP condition ($P = 0.001$) during cycling. The Alpha/Beta ratio ($P = 0.022$) and Beta power/(theta power + alpha power) ratio, ($P = 0.031$) were higher during the EXP condition during cycling. Subjective feelings of fatigue increased significantly in EXP after the cycling ($P = 0.001$) compared to CON while vigour significantly decreased. Alpha/Beta ratio during the PVT increased significantly after EXP condition ($P = 0.001$). Average reaction time during the PVT increased significantly after EXP ($P = 0.021$). **DISCUSSION:** The increase of workload, adding cognitive tasks to exercise, required more mental effort than traditional physical training, as assessed by behavioural and electrophysiological measures of fatigue while no difference were detected in physiological variables.

Title: Characterizing REST/NRSF expression in motor neurons after peripheral nerve injury

Authors: *A. K. YASZEMSKI[1], N. MADIGAN[3], A. J. WINDEBANK[4], L. NESTI[2];
[2]Surgery, [1]Uniformed Services Univ., Bethesda, MD; [3]Neurol., Mayo Clin., Rochester, MN;
[4]Dept. of Neurol., Mayo Clin., Zumbro Falls, MN

Abstract: Introduction: Peripheral nerve injuries (PNIs) present complex challenges for repair as they typically include long-gap nerve injuries with surrounding trauma to the muscle and vasculature. Re-innervation of muscle tissue after injury is necessary for functional recovery, but motor neurons may not regenerate sufficiently to provide for complete recovery which can result in permanent loss of function. A deficiency in neurotrophic factors (NTFs) or the nuclear

programming of regenerative-associated genes can limit the capacity of axonal regeneration after PNI. Increased expression of the Repressor Element-1 Silencing Transcription factor (REST) may play a central role in transcriptional repression of the regenerating neuronal phenotype. Changes in REST expression have been shown in sensory neurons in models of neuropathic pain, but little is known about whether there is altered REST expression after injury in motor neurons. We are developing a novel approach to peripheral nerve regeneration by targeting the motor neuron nucleus to enhance the natural proximal to distal degeneration pattern. We have established a rodent model of lesion of the facial motor nerve to characterize potential alterations in REST expression specifically in motor neurons. **We hypothesize that a similarly induced upregulation of REST expression exists in motor neurons and will result in transcriptional repression of NTFs and other regenerative-associated genes.** Assessing whether REST activity after injury occurs in motor neurons may identify potential therapeutic targets for functional recovery after PNI.
Methods: Male Sprage-Dawely rats, 8-9 weeks old at the time of surgery were grouped into facial nerve transection or sham injury groups at 6-hour and 48-hour timepoints (n=12/group). The facial nerve transection injury involved a complete transection at the nerve trunk exiting the stylomastoid foramen, sham surgery received a skin incision wit the nerve trunk exposed but left intact. Protein and gene expression levels were assessed via immunohistochemistry and RT-PCR, respectively. Injury and sham groups were compared as well as the ipsilateral and contralateral sides in each animal as an internal control.
Results: There is significant upregulation of REST protein expression in injured animals compared to sham and naïve groups at both time points. No significant changes were present in mRNA expression in either timepoints, however samples are still in process.
Discussion: Facial nerve transection injury is an effective model for assessing functional mechanisms in PNI and injury-induced expression of REST exists at acute timepoints after facial nerve transection.

Title: Supraspinal Mechanisms of Fatigue and Fatigability

Authors: *A. CASAMENTO MORAN[1], R. NICKL[2], M. SINGHALA[2], T. GEORGE[2], V. CHIB[2], J. BROWN[2], P. CELNIK[2], G. CANTARERO[2];
[1]Johns Hopkins Hosp., Baltimore, MD; [2]Johns Hopkins, Baltimore, MD

Abstract: Fatigue is the subjective sensation of weariness, increased sense of effort, or exhaustion and is one of the most common and debilitating symptoms in neurological illnesses such as multiple sclerosis. Despite its epidemiological importance, there is a limited understanding of the neurophysiological mechanisms of fatigue driven by two major shortcomings in the current literature. First, most studies investigate the factors that impair cognitive or motor function (e.g. reduced force capacity, also known as fatigability) without addressing fatigue itself (the percept of weariness, etc.) - even though evidence shows fatigue is often unrelated to fatigability. Second, despite our extensive understanding of spinal and peripheral (i.e. neuromuscular junction and muscle) mechanisms of fatigue, we have a limited knowledge of its supraspinal mechanisms. Here we aim to disambiguate the supraspinal changes related to fatigue versus fatigability by characterizing the changes in primary motor cortex (M1) and somatosensory cortex (S1) at the single- and multi-unit activity (SUA/MUA) level and how they relate to *both* increased perception of fatigue and altered neuromuscular function. *We* ***hypothesize*** *that S1 activity will correlate with changes in the participant's percept of fatigue whereas M1 activity will correlate with increases in EMG activation and coactivation (i.e. fatigability).* To do this we will concurrently measure percepts of fatigue, neuromuscular activity via electromyography (EMG), and SUA/MUA of M1 and S1 before, during, and after a fatiguing task in a human spinal cord injury (SCI) participant implanted with microelectrode arrays (MEAs) in his sensorimotor cortex. Importantly, these MEAs were implanted in bilateral areas of M1 and S1 that control/project to areas of our participants upper limbs where he retains some motor abilities and sensory perception. The fatiguing task will require the participant to press against a force transducer, using his wrist extensor, and exert 60% of his maximum voluntary contraction (MVC) for 4 seconds. Critically, the task will be repeated until the participant is fatigued but before neuromuscular failure is induced. These results will allow us to better understand the supraspinal neurophysiological mechanisms of fatigue at the neuronal level for the first time in a human and disentangle it from peripheral mechanisms of fatigue. This knowledge will be fundamental for identifying biomarkers of fatigue and will aid in the development of effective treatments for this prevalent and debilitating symptom.

Title: High frequency ultrasound for the visualization of vagotopy in a pig model

Authors: *M. KASOLE[1], A. SKUBAL[1], M. L. SETTELL[1], B. E. KNUDSEN[1], N. A. PELOT[2], J. TREVATHAN[1], E. N. NICOLAI[3], C. HUANG[3,4], C. ZHOU[4], W. M. GRILL[2], S. CHEN[3], K.

A. LUDWIG[1];
[1]Univ. of Wisconsin-Madison, Madison, WI; [2]Duke Univ., Durham, NC; [3]Mayo Clin., Rochester, MN; [4]Sichuan Univ., Chengdu, China

Abstract: Vagus nerve stimulation (VNS) is an FDA approved treatment for epilepsy and depression and is currently being evaluated for treatment of numerous other disorders. Intraoperative placement of the clinical vagus nerve stimulating cuff is based on anatomical landmarks, with very little patient specificity in terms of vagal anatomy such as fascicular organization. As currently administered, VNS is associated with limited therapeutic effects and many intolerable side effects, such as dyspnea and cough, from off-target activation of motor fibers. These motor fibers extend into the superior and recurrent laryngeal branches of the vagus nerve, which innervate key muscles of the throat implicated in many of these therapy-limiting side effects.Previous histological studies in a pig model, similar in size and organization to that of humans, have shown bimodal organization between sensory and motor fascicles within the vagus nerve, otherwise known as vagotopy. Clinical outcomes could be improved by individualizing cuff placement using this organization. Intraoperative ultrasound imaging of vagotopy may lead to avoiding off target effects and improve efficacy. Ultrasound is traditionally used non-invasively at the surface of the skin to image peripheral nerves. However, non-invasive ultrasound does not offer the resolution required to visualize fascicular organization. In this study, we take advantage of the access provided during the surgical implant of the cuff by placing the ultrasound transducer within the surgical pocket of a pig model to increase resolution.High frequency ultrasound was found to accurately depict the bimodal organization of the pig vagus nerve intra-operatively, as confirmed via post-mortem histology. This bimodal organization was observed in the nodose ganglion with the grouping of motor fibers opposite a large fascicle containing pseudo-unipolar cell bodies. The pseudo-unipolar cell region indicated the origination of fascicle groupings containing sensory fibers. These groupings could be followed down the length of the vagus nerve to aid in informing cuff placement. Additionally, the superior and recurrent laryngeal nerves were identified to aid in characterizing the surgical window.Visualization of vagus nerve fascicular organization, or vagotopy, using ultrasound offers a minimally invasive approach during clinical procedure. This approach could be used to optimizeelectrode cuff placement in order to avoid unwanted activation of surrounding nerves and nerve fibers implicated in off-target effects and improve patient outcomes.

Title: Sex differences in vasti synergistic control patterns for neuromuscular endurance

Authors: *Z. WANG[1], A. JOHNSON[2], L. GRIFFIN[1];
[1]Dept. of Kinesiology and Hlth. Educ., [2]Dept. of Surgery and Perioperative Care, The Univ. of Texas at Austin, AUSTIN, TX

Abstract: There are sex differences in synergistic control patterns among the upper, middle, and lower subdivisions of trapezius during shoulder elevation. However, this have yet to be investigated in quadriceps subdivisions, especially between vastus medialis oblique (VMO) and vastus lateralis (VL). Different muscle synergistic patterns may project different degrees of neuromuscular fatigue on upstream central nervous system (CNS). The purpose of this study is to investigate sex differences in VMO-VL synergistic control patterns and their relationship with endurance time of sustained fatiguing tasks. Ten healthy females and ten healthy males were instructed to perform sustained isometric leg-extension until task failure at an intensity of 20% maximal voluntary contraction (MVC). Surface EMG of the VMO and VL was recorded. The endurance time was calculated as the time from the start of contraction until the force dropped by 5% below the target force. The VMO-VL synergistic control patterns were evaluated by averaging relative normalized EMG root mean square (RMS) ratios within each quarter of endurance time, i.e., (RMS_{VMO} / MVC RMS_{VMO}) / (RMS_{VL} / MVC RMS_{VL}) × 100%. Independent-samples t tests showed that the endurance time of females was significantly longer than that of males (F vs. M, 305. 7 ± 96.8 s vs. 204.8 ± 53.8 s, $p < 0.05$). A repeated-measures two-way ANOVA with sex as the between-group factor and fatigue phase as within-group factors revealed that the VMO/VL RMS ratios of males were significantly higher than those of females across all four fatigue phases (F vs. M, 73.1 ± 8.7 % vs. 103.4 ± 8.7 %, $p < 0.05$) and were close to 100%, whereas the VMO/VL RMS ratios of females were significantly lower than 100% (one-sample t test, $p < 0.05$). Pearson correlation analyses revealed that there was a significantly negative correlation between VMO/VL RMS ratios and the endurance time in females ($r = - 0.570$, $p < 0.05$) but not in males. This may be because higher VMO/VL RMS ratios require greater common drive from CNS to both VMO and VL and may incur greater fatigability in CNS and lead to shorter endurance in males. It may help to prevent the overuse of patellofemoral joints whose disorders are much more prevalent in females.

Title: Electro-cortical stimulation increases Gad1 transcription of ventral spinal cord GABAergic interneurons but does not change Gabbr1 expression of soleus motoneuron

Authors: *Y. WANG[1], B. HERRON[2], Y. CHEN[1], X. CHEN[1], J. CARP[1], A. VATO[1], T. FAKE[1], J. WOLPAW[1];
[1]Albany Stratton VA Med. Ctr., Albany, NY; [2]Albany Stratton VA Med. Ctr. & Wadsworth Ctr. of NYS DOH, Albany, NY

Abstract: Weak electrocortical stimulation (ECS) of rat sensorimotor cortex (SMC) over several weeks increases soleus H-reflex (HR) size; the increase persists for months. This increase correlates with GABA receptor decrease and GAD_{67}^{+} terminal increase on soleus motoneurons (SOL MN), showing that ECS affects spinal cord GABAergic function (Chen et al. 2007; Wang et al. 2012). We are studying the transcriptional mechanisms of these effects by determining *Gad1* and *Gabbr1* mRNA levels by single molecule in situ hybridization in GAD_{67}^{+} interneurons in spinal cord ventral horn ($Gad1^{+}$-INs) and SOL MN respectively. Rats are implanted with SOL EMG electrodes and a posterior tibial nerve stimulation cuff in the right leg and ECS electrodes over left hindlimb SMC. ECS (25-Hz train of 0.1-ms biphasic pulses for 1 s every 10 s) was delivered 24 hr/d X 30 days; it produced a small SOL motor evoked potential and no visible response. The SOL HR was recorded throughout; it increased to 243(±61 SE) % of initial value. At the end of ECS, ECS rats and naïve control (NC) rats are injected with cholera toxin subunit B (CTB) in SOL muscles and perfused 3 days later. L4-S1 lumbar cord is sectioned and hybridized with RNAscope™ probes targeting *Gad1* and *Gabbr1*. Images for $Gad1^{+}$-INs in ventral horn and CTB-labeled SOL MN are prepared; somatic *Gad1* and *Gabbr1* puncta are quantified; area fractions are calculated for cell images in a double-blind manner. Intergroup differences are assessed by one-way ANOVA. $Gad1^{+}$-INs are widespread in the spinal cord, including lamina VII (LVII) where most inhibitory pre-motor neurons are. In results to date, $Gad1^{+}$ puncta in LVII are significantly increased in the ECS group; they average 117±6/cell in NC rats vs 168±6 in right and left sides of ECS rats ($p<0.001$ vs NC). mRNA density/100 μm^2 somatic area was also increased; it averaged 39±2 for NC rats and 47±2 (left) and 45±2 (right) for ECS rats ($p<0.001$ (left) and $p< 0.01$ (right) vs NC). In SOL MNs, *Gabbr*1 mRNA puncta were similar between groups averaging 74±6 in NC rats and 80±5 in ECS rats ($p=0.3$ vs NC); mRNA densities were also similar, averaging 103±4 (left) & 104±3 (right) % of NC ($p=0.2$ and 0.3 vs NC, respectively). Combined with previous studies (Refs above), these initial results suggest two novel insights. (1) ECS significantly increases *Gad*1 mRNA in ventral spinal cord GABAergic interneurons, consistent with previous findings of increased GAD_{67}^{+} immunoreactivity; this implies a pre-translational mechanism. (2) The GABA receptor decrease in SOL MNs found previously is not associated with a decrease in *Gabbr*1 mRNA in SOL MNs; this implies a post-translational mechanism.

Title: Axon initial segment distance is a determinant of motoneuron excitability

Authors: *T. M. ROTTERMAN[1], D. I. CARRASCO[4,5], S. N. HOUSLEY[2], P. NARDELLI[2], T. C. COPE[3];

Abstract: The axon initial segment (AIS) is emerging as a contributor in regulating neuronal excitability and action potential initiation. Manipulating the somatic proximity and/or length of the AIS segment impacts neuronal excitability by varying threshold for action potential initiation. This study was motivated, in part, by continued interest in determining the biophysical and anatomical contributors to intrinsic motoneuron excitability which is essential for understanding rank ordering in recruitment of motoneurons within a motor pool, i.e. motoneurons (MNs) innervating the same muscle. A variety of parameters have been implicated in determining MN excitability such as input conductance, subthreshold voltage-sensitive currents, and channel properties underlying spike generation, however a definitive explanation for the diversity in MN excitability, and ultimately recruitment, remains incomplete. Furthermore, the possible role of the AIS as a contributing factor in addition to these biophysical parameters has not been studied for individual MNs. In our studies, we began by utilizing immunohistochemistry to identify and compare the AIS length and distance to soma between two retrogradely labeled motor pools known to differ in their relative recruitability; the medial gastrocnemius (MG, approximately 80%F/20%S-type) and the soleus (SOL, majority S-type) motor pools. The MG motor pool is known to have a much wider range in excitability as defined by rheobase which spans 20-30-fold, while the SOL motor pool is known to have a much narrower and lower rheobase on average compared to the MG MNs. We found that the MG MN population has, on average, a longer distance in AIS proximity compared to the SOL pool. We did not find any difference in AIS length between the two pools. However, these anatomical experiments did not directly measure excitability of individual MNs. In order to accomplish this, we recorded and intracellularly filled MG MNs *in vivo* in combination with anatomical measurements of the AIS. Using this combinatorial approach, we found evidence consistent with the idea that a more distal AIS associates with lower MN excitability. In fact, when compared to several other anatomical and biophysical measures obtained from the intracellularly filled MNs, AIS distance was the dominant determinant of intrinsic excitability.

Title: H-reflex up- versus down-conditioning effects on NMDA receptor 1, protein kinase C, and potassium-chloride cotransporter activation in soleus motoneurons of spinal cord-injured rats

Authors: *J. S. CARP[1], Y. WANG[1], Y. CHEN[1], X. Y. CHEN[1], B. HERRON[1,2], A. VATO[1], J. R. WOLPAW[1];
[1]Natl. Ctr. For Adaptive Neurotechnologies, Stratton VA Med. Center, Dept. of Veterans Affairs, Albany, NY; [2]Wadsworth Ctr., New York State Dept. of Hlth., Albany, NY

Abstract: H-reflex (HR) operant conditioning can increase (HRup mode) or decrease (HRdown mode) the soleus HR (Curr Opin Behav Sci 20:138-144, 2018 for review). Appropriate HR conditioning can improve locomotion in rats or people with incomplete spinal cord injury (SCI) (J Neurosci 26:12537-12543, 2006 & 33:2365-2375, 2013). Up- and down-conditioning are not mirror images; they appear to have different mechanisms. We are studying in SCI rats the effects of up- or down-conditioning on soleus motoneuron (SOL MN) NMDA receptor 1 (NR1), protein kinase Cα phosphorylation (p-PKC), and potassium-chloride cotransporter (KCC2).
Under anesthesia, 15 SD rats received a right T9 lateral column lesion. Ten of them were implanted in right leg with SOL EMG electrodes and a posterior tibial nerve stimulating cuff. After 30 days, the implanted SCI rats underwent HR down-conditioning (n=5, SCI-down) or up-conditioning (n=5, SCI-up) for 60 days; the other 5 SCI rats were maintained without implantation or conditioning (SCI-control) for 60 days. At the end of the protocol, all SCI rats and 5 body weight-matched naïve control rats (NC rats) received CTB-Alexa Fluor 647 injection in the right SOL muscle and were perfused 3 days later. Lumbar 4-5 spinal cords were isolated and cut for anti-NR1, anti-p-PKC, and anti-KCC2 immunofluorescence labeling. SOL MN 3-D image stacks were prepared, coded, and quantified double-blindly. SOL MN IR data were expressed in % of NC mean values; intergroup differences were assessed by one-way ANOVA. In SCI-control rats, NR1-, p-PKC-, and KCC2-IR intensity on SOL MNs averaged 94±2(SE)%, 98±4%, and 94±3% of NC ($p>0.05$ vs NC for all). In SCI-down rats, final SOL HR size was 62±11% of its initial value, NR1-IR was 93±2% ($p<0.01$ vs NC, $p=0.3$ vs SCI-control), p-PKC-IR was 94±2% ($p=0.02$ vs NC; $p=0.4$ vs SCI-control), and KCC2-IR was 91±4 % ($p=0.3$ vs NC; $p=0.7$ vs SCI-control). In SCI-up rats, final SOL HR size was 241±34% of initial ($p<0.01$), NR1-IR and p-PKC-IR on SOL MNs increased to 149±6% and 146±4%, respectively (both $p<0.0001$ vs either NC or SCI-control), while KCC2-IR decreased to 73±2% ($p<0.001$ vs either NC or

SCI-control).
In SCI rats, HRdown conditioning did not appear to affect SOL MN NR1, PKC phosphorylation, or KCC2; in contrast, HRup conditioning was associated with increased NR1 and PKC phosphorylation and reduced KCC2. These results provide further insight into the differing mechanisms of HRup and HRdown conditioning, and may be relevant to their potential therapeutic applications.

Title: Cross-frequency dependencies in sensorimotor processes after monetary feedback

Authors: *A. A. VIVINO[1], D. BUTLER[1], P. WHITTAKER[1], S. AVIYENTE[2], E. M. BERNAT[1];
[1]Psychology, Univ. of Maryland, College Park, MD; [2]Dept. of Electrical and Computer Engin., Michigan State Univ., East Lansing, MI

Abstract: EEG/ERP research on reward feedback processing has reported important relationships between monetary gains/losses and oscillatory activity occurring within the delta (1-4Hz), theta (3-7Hz), and high beta (20-30Hz) frequency bands. However, there is a paucity of information about alpha (8-12Hz) and low-beta (13-20Hz) oscillatory activities during basic reward feedback processing. Previous research using performance feedback-locked epochs describes a desynchronization in sensorimotor alpha (SMα) and sensorimotor low-beta (SMb) power after accurate button presses (Luft, Takase & Bhattacharya, 2014). Literature on alpha and low-beta rhythms in motor mirror neurons suggests that the motor cortex is activated by observing rewarding stimuli and suppressed by observing punishment (Brown et al., 2013; Gros, Panasiti & Chakrabarti, 2015), but has not always found significant results in both frequency bands. Therefore, our study sought to determine how monetary feedback modulates SMα and SMb, and to assess their relationships to more widely-studied measures from gambling feedback tasks (i.e. delta, theta, and high beta). 145 participants completed a gambling task (Gehring & Willoughby, 2002) as EEG data were recorded. Centroparietal delta, midline medial frontal theta, bilateral SMα, bilateral SMb, and medial frontal high-beta amplitudes were band-pass filtered and each assessed for loss-gain differences with principal components analyses (see Watts et al. 2018). Delta (t=4.75, p<.001, Cohen's d=.39) and high-beta (t=4.14, p<.001, d=.34) power were both greater after gains than losses. Theta power was greater after losses than gains (t=-10.56, p<.001, d=-.88). SMα (t=-3.86, p<.001, d=-.32) and SMb power (t=-2.72, p<.01, d=-.23) were both attenuated after gains relative to losses. Neither delta nor theta nor high-beta loss-gain differences were significantly associated with one another (rs<.08, ps>.05), so all were used

to predict SMα and then SMb loss-gain differences in separate multiple regressions. Delta (β=.17, t=2.05, p<.05) and theta (β=.21, t=2.53, p=.01) power significantly predicted SMα power, but high-beta power did not (p=.61). Theta (β=.21, t=1.19, p<.01) and high beta power (β=.26, t=3.31, p=.001) predicted SMb power, but delta power did not (p=.24). These results replicate effects in delta, theta, and high-beta, and implicate the sensorimotor cortex in processing both gain and losses: loss-gain effects in SMα and SMb are similar in latency and direction and both depend on medial frontal theta, but are each associated with different gain-related signals.

Title: Single nucleus RNA-sequencing defines unexpected diversity of cholinergic neuron types in the adult mouse spinal cord

Authors: *M. R. ALKASLASI, Z. E. PICCUS, S. HAREENDRAN, H. SILBERBERG, L. CHEN, Y. ZHANG, T. J. PETROS, C. E. LE PICHON;
NIH, Bethesda, MD

Abstract: In vertebrates, motor control relies on cholinergic neurons in the spinal cord that have been extensively studied over the past hundred years, yet the full heterogeneity of these neurons and their different functional roles in the adult remain to be defined. Here, we developed a targeted single nuclear RNA sequencing approach and used it to identify an array of cholinergic interneurons, visceral and skeletal motor neurons. Our data expose markers for distinguishing these classes of cholinergic neurons and their extremely rich diversity. Specifically, visceral motor neurons, which provide autonomic control, could be divided into more than a dozen transcriptomic classes with anatomically restricted localization along the spinal cord. The complexity of the skeletal motor neurons was also reflected in our analysis with alpha, beta, and gamma subtypes clearly distinguished. In combination, our data provide a comprehensive transcriptomic description of this important population of neurons that control many aspects of physiology and movement and encompass the cellular substrates for debilitating degenerative disorders.

Abstract: To avoid falling, consequential to unexpected balance loss i.e., perturbation, require people to readjust their footing rapidly and effectively (i.e., recovery stepping response). For this study, we describe lower limb muscle activation and differences between ankle and knee muscle recruitment due to unexpected perturbations during walking as measured by surface electromyography (sEMG). We aimed to explore sEMG frequency content changes before and after unannounced perturbations. Twenty young adults (27.00±2.79 years, 10 females) were exposed to unannounced surface horizontal translation perturbations while walking on a treadmill in a virtual reality environment. Perturbations were applied randomly under 2 conditions (e.g., single vs. dual task), in different gait phases in 4 directions (i.e., anterior/posterior/ right/left). sEMG signals from both lower extremities were recorded from the tibialis anterior (TA), gastrocnemius lateralis (GC), vastus lateralis (VL) and biceps femoris (BF) muscles. sEMG total spectral power for all signal frequencies and for specific bands (40-150 Hz - Low, 150-250 Hz - Medium, 250-400 Hz - High) were compared between 4 seconds baseline walking prior to perturbation and four seconds after 457 unannounced perturbations. We found that compared to baseline in the early phase post perturbation, the total spectral power of lower-extremity muscles, for all frequencies, increased significantly ($p<0.001$). The highest spectral power increase was found for 40-150 Hz and the lowest for 250-400 Hz, which is consistent with the literature. Additionally, we found that TA had significant change in frequency bands: Medium > High > Low ($p<0.001$). The higher frequency elevation response lasted for the first second after perturbation followed by gradual return to baseline total spectral power subsiding after 3 seconds. Interestingly, VL demonstrated a different response (i.e., Low > Medium > High, $p<0.001$). Our finding suggests that recruitment of muscle fiber sub-types (i.e., slow and fast twitch muscle fibers) is modulated in real time to fit functional goal requirements i.e., rapid change of footing response/recovery stepping response.

Title: Firing rate trajectories of human motor units during isometric ramp contractions

Authors: ***A. M. ZERO**, E. KIRK, K. HALI, C. RICE;
Univ. of Western Ontario, London, ON, Canada

Abstract: During small increments of voluntary force in isometric contractions motor units (MU) exhibit initial firing rate acceleration followed by saturation demonstrating non-linear responses. Saturation of firing rates during increasing force may represent a decreased sensitivity to further input, with persistent inward currents (PICs) acting as a mechanism responsible for firing rate acceleration. However, there is evidence that PIC characteristics differ in relation to motoneuron size, such that smaller motoneurons (i.e. lower-threshold MUs) have a relatively greater normalized PIC response than larger motoneurons as well as having longer activation duration. In humans, evidence is limited as to whether later recruited (i.e. higher-threshold) MU firing rate saturation occurs and follows a trajectory like low-threshold units. Five participants were provided force targets of 10, 25 and 50% maximum voluntary contraction (MVC) for visual feedback in order to produce smooth 10s dorsiflexion ramp contractions to each level. During these contractions single MUs were recorded in the tibialis anterior using tungsten microelectrodes. To characterize firing rate trajectory, each MU sample was fit by firing rate as a function of force by both an exponential (i.e. saturated) and linear function, based on prior analysis methods (Fuglevand et al, 2015). This approach statistically compared the sum of squared errors (SSE) between models to determine if the exponential trajectory better fit the data than the linear trajectory. From recruitment thresholds ranging from 0.02 - 41% MVC, 261 MUs were collected ranging from 19-323 spikes per MU train. Linear regression provided a better fit for 94% of MUs, whereas the remaining MUs (6%) were fit better with an exponential (saturated) firing rate trajectory. As MU recruitment threshold (RT) increased the occurrence of firing rate saturation decreased. Greater rates of torque development (RTD) also resulted in a decline in saturation occurrence. As higher RT or RTD increased firing rates and variability, the SSE for both the linear and exponential trajectory also were increased. The likely lesser synaptic drive during low force levels when the lowest-threshold MUs are firing may not overcome the decreased sensitivity presented by the PIC leading to firing rate saturation. Conversely, the combination of greater synaptic drive and variability during higher intensity contractions

(increased RT and RTD), with presumed lesser PIC activity and activation of larger motoneurons leads to a linear increase in firing rates but with more rate variability. Supported by NSERC

Title: Multiscale Entropy of Lower Limb EMG During Walking Tasks in People with Parkinson's Disease: An Indicator of Altered Sensory-Motor Control

Authors: A. AMRAPALA[1], ***C. WATSON**[2], A. PANTALL[3];
[1]Chulalongkorn Univ., Bangkok, Thailand; [2]Newcastle Univ., Newcastle, United Kingdom;
[3]Translational Clin. Res. Unit, Newcastle, United Kingdom

Abstract: Background: Falls are a major health concern for older adults (OA) particularly in individuals with neurodegenerative diseases. Dual-task walking (DTW) presents an additional falls risk. Greater understanding of motor control of gait is essential for reducing falls. The purpose of this study was to investigate motor control through analysis of complexity of surface EMG signals. Complexity of EMG may indicate the richness of interactions within neural networks. The aims were to identify the effect of ageing and Parkinson's disease (PD) on complexity and how complexity is affected by walking tasks. Gender, muscle and symmetry were also examined. Based on the loss of complexity hypothesis and findings of current studies, it was hypothesized that people with PD have less complexity than healthy young adults (YA) and OA, and this complexity would further decrease during DTW due to cognitive-motor interference. Conversely, complexity was anticipated to increase during audio-cued walking (ACW) which decreases gait variability. Methods: A subsample of 15 individuals from a larger study group were randomly selected: 5 healthy YA, 5 healthy OA and 5 people with PD. Demographic and neuropsychological data were collected. Surface electrodes recorded EMG bilaterally from tibialis anterior (TA) and soleus (SO) using wireless EMG sampling at 1000 Hz. EMG was recorded during normal walking (NW), DTW and ACW. A 30 second block of EMG was analyzed for each muscle for each walking task. Surrogate analysis tested nonlinearity of EMG time-series. Optimal parameter calculation was undertaken yielding m = 2 and r = 0.25 (Lake et al. 2002). Multi scale entropy was determined and complexity index (CI) calculated across scales 4 to 40 (25-250 Hz) (Busa & van Emmerik, 2016) with lower complexity representing more regular movement. Statistical significance testing was carried out using the Kruskal-Wallis test. Results: People with PD had a lower CI across muscles compared to OA, although greater than YA. No walking task effect was observed. Females had a significantly higher CI compared to males. The CI was greater in the left side compared to the right side. Discussion: The lower CI in PD compared to age-matched controls supports our hypothesis. However, ageing was associated with greater CI. Older adults recruiting additional motor areas

resulting in more complex neuronal motor control (Vitorio et al. 2018) may partially explain this. The simplicity of the cognitive memory task in DT may account for CI similarity between conditions. The asymmetry may be linked to limb dominance or the clockwise walking track. The greater complexity in females is intriguing and needs further investigation

Title: Does intrinsic motoneuron excitability contribute to torque generating capacity at various joint angles?

Authors: *G. E. PEARCEY, J. A. BEAUCHAMP, O. U. KHURRAM, C. J. HECKMAN; Northwestern Univ., Chicago, IL

Abstract: All motor behaviours involve complex interactions between excitatory, inhibitory and neuromodulatory commands. We can readily measure motoneuron firing patterns from the muscle fibers they innervate, collectively known as motor units (MUs), due to their one-to-one spike ratio. Neuromodulatory commands set the intrinsic excitability of the motoneuron through dendritic persistent inward currents (PICs), which contribute to the amplification of motor commands. PICs decrease when the antagonist muscle is stretched in the decerebrate cat, and we have recently shown that estimates of PICs are also reduced with vibratory input to antagonist tendons in humans. Here, we examined whether changes in joint angle altered estimates of PICs and whether these changes were associated with the changes observed in maximum voluntary torque at the various joint angles. MU firing patterns of the tibialis anterior (TA), soleus (SOL) and medial gastrocnemius (MG) were discriminated using high-density surface electromyography array electrodes and a convolutive blind source separation algorithm. We estimated PICs using the paired MU analysis technique, which quantifies discharge rate hysteresis (ΔF) by comparing the onset and offset of a high-threshold MU with respect to the firing rate of a low-threshold MU, providing an estimate of intrinsic excitability of the MU. Participants performed isometric plantarflexion and dorsiflexion triangular ramp contractions to a peak of 30% of maximal voluntary contraction, and 10 s ascending and descending phases. In a random order, the ankle joint was set in a 1) neutral (90°), 2) dorsiflexion (70°), and plantarflexion (110°) position. Preliminary analysis suggests that putting the ankle into dorsiflexion reduces TA estimates of PICs and maximum dorsiflexion torque. On the contrary,

putting the ankle into plantarflexion reduces SOL and MG estimates of PICs and maximum plantarflexion torque. This suggests that sensory feedback from the antagonist muscle plays a role in the decrements in torque generating capacity at various joint positions by altering intrinsic excitability of motoneurons.

Title: Effect of single and double pulse TMS on the relationship between MEP amplitude and cortical silent period

Authors: *K. LOCKWOOD[1,2], N. PINKES[2], S. JACOBS-SKOLIK[1,2], M. FURMANEK[2], M. YAROSSI[1,2], E. TUNIK[2];

Abstract: Transcranial magnetic stimulation (TMS) can be used, as a "virtual lesion", to transiently disrupt function of a target brain area in order to test its role in a given task. When a long period of disrupted activity is desired, a second TMS pulse may be given at a latency of less than 100ms from the first pulse. Despite the popularity of this approach, rarely is the effectiveness of a virtual lesion in disrupting information reported. The cortical silent period (CSP), the silencing of EMG activity following a stimulation of the motor cortex during active contraction, can be used as a proxy to assess the length of disrupted cortical activity. In this study we examined the duration of disruption caused by single and double pulse TMS to M1 by measuring associated cortical silent periods. Ten young healthy right handed individuals participated in the study following institutionally approved informed consent. EMG was recorded in the right first dorsal interosseous muscle. Single pulse TMS, and double pulse TMS (50 ms inter-stimulus interval), were delivered to the left motor cortex at 110% of an individual's resting motor threshold, while the participant held a voluntary contraction equivalent to 25% of their maximum finger flexion force. CSP duration and MEP amplitude were labeled during post-processing. We compared the amplitudes of MEPs and durations of CSPs produced in the single pulse and double pulse TMS conditions. Greater MEP amplitude of the second pulse in the double pulse condition was associated with greater prolongation of the CSP, with respect to the single pulse condition ($r = 0.8414$, $p < 0.01$). These results have implications for the use of

virtual lesions for analysis of cortical involvement in behavior, and for understanding of inhibitory circuits in the motor cortex.

Title: The emergence of a collective sensory threshold in the response of ant colonies to temperature perturbations

Authors: *A. GAL, D. KRONAUER;
The Rockefeller Univ., New York, NY

Abstract: The sensory threshold is one of the most fundamental and well-studied computational primitives organisms perform, both as a standalone computation, and as a component of more complex tasks. In social organisms such as ant colonies, which perform computational tasks at the group level, the collective sensory threshold is an emergent property that depends on the responses of individuals in the group and on the interactions between them. Here we study this emergence in the clonal raider ant (*Ooceraea biroi*), a model system that provides convenient and precise control over the properties of the colony. We use automated individual tracking to show that an ant colony indeed responds collectively to step changes in temperature by initiating a coordinated and synchronized movement (Figure). We further show that this collective response is characterized by a threshold, and that this threshold is sensitive to the size of the colony. This implies that interactions play an important role in the response dynamics of the colony, and that the collective threshold is indeed an emergent property distinct from the sensory threshold of the individual ants. We then use a mathematical model to study how collective threshold can emerge in an interacting group of agents and show that an asymmetrical and change resisting interaction between the ants is required to replicate the experimental observation. Inspired by the history of computational neuroscience, we argue that studying simple responses to well controlled stimuli can advance our understanding of how sophisticated cognitive-like function emerge in complex social groups.
Figure: (**A**) A snapshot from a raw experimental video. (**B**) *Baseline state*. Before the onset of the perturbation most ants reside in the nest, with few scout ants wondering around the arena. (**C**) *Excitement*. Following the onset of the perturbation, the ants first respond by increasing their activity level around the nest. (**D**) *Moving out*. After a delay, the ants suddenly begin to leave the nest to a well-defined direction. (**E**) *Full emigration*. The colony forms a organised emigration column.

Title: Co-transmitting inhibitory interneurons drive olfactory behaviors through convergent and divergent pathways

Authors: *A. M. LYONS-WARREN[1], E. HANSON[2], M. KOCHUKOV[2], B. ARENKIEL[2];
[1]Pediatrics, [2]Mol. and Human Genet., Baylor Col. of Med., Houston, TX

Abstract: Sensory processing abnormalities are a common feature of neurodevelopmental disorders. Co-transmission is an important but not fully understood mechanism that contributes to sensory processing. One example of co-transmitting cells are superficial short axon cells (sSAC) in the olfactory bulb which release both GABA and dopamine. The aim of this study was to elucidate the role of co-transmission from sSAC in olfactory processing. First, we implemented whole cell electrophysiological recordings and immunohistochemistry to identify the dopaminergic and GABAergic targets of sSAC. We found that external tufted cells (ETC) receive both GABAergic and dopaminergic input from sSAC as part of a dopamine modulated feedback loop with projection neurons called Mitral cells. More specifically, in 76% of recordings we observed monosynaptic, GABAergic signals from sSAC onto ETC. Further, ETC that receive GABAergic input express dopamine receptor type 1 (D1) and exhibit decreased responses in the presence of a pharmacological D1 blocker. In contrast, less than 8% of Mitral cells, and no D1 expressing granule cells, received GABAergic input from sSAC. Next, we recorded monosynaptic, glutamatergic currents from labeled sSAC while stimulating Mitral cells. Finally, we found dopamine receptor type 2 (D2) labeling was restricted to olfactory sensory neurons, and that Mitral cells express dopamine receptor type 3 (D3). Thus, we conclude that GABA and dopamine from sSAC converge on ETC as part of a feedback loop but divergent pathways exist in which GABA and dopamine provide independent signals. Having identified

the GABAergic and dopaminergic targets of sSAC, we next measured odor discrimination via novelty response tasks and odor detection, and found that sSAC are necessary for both odor detection and discrimination. Interestingly, we found these behaviors are mediated via distinct pathways, in which loss of both GABA and dopamine impairs odor detection, but loss of either GABA or dopamine signaling alone disrupts odor discrimination. In conclusion, we have revealed a critical role for sSAC in odor detection and discrimination, and have begun to elucidate the circuit mechanisms underlying those functions. Namely, we identified a convergent pathway in which ETC receive GABAergic and dopaminergic signaling from sSAC as part of a dopamine modulated feedback loop with Mitral cells, as well as divergent dopaminergic targets that do not receive GABAergic input from sSAC including olfactory sensory neurons, granule cells, and Mitral cells. Together, these results improve our understanding of circuit mechanisms underlying sensory processing disorders.

Title: An ethological model of visual distance estimation in the mouse

Authors: *P. R. L. PARKER, E. T. T. ABE, N. T. BEATIE, E. S. P. LEONARD, D. MARTINS, S. SHARP, D. WYRICK, L. MAZZUCATO, C. M. NIELL;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: Distance estimation is a core function of visual systems across animal species, and is critical for behaviors ranging from navigation to prey capture. There are multiple strategies to obtain depth information, including pictorial cues, binocular stereopsis, and motion parallax. The latter of these requires integrating visual and self-motion signals, but its neural circuit mechanisms are not understood. Mouse visual cortex is strongly modulated by self-motion, including head movement and vestibular signals. Could these signals be integrated with visual input to compute depth? We sought to determine if mice judge distance using self-motion, which would permit the use of genetic tools to measure and manipulate neural activity during behavior. We adapted a gerbil/rat distance estimation task to mice, in which animals jump across a variable gap in order to obtain a reward. Mice are recorded with high-speed cameras from the top and side, and videos are tracked using DeepLabCut. We found that mice accurately jump to distant platforms across gaps up to 30 cm, and performance is similar under monocular vision,

demonstrating that binocular cues such as stereopsis are not necessary. Landing platform size is varied to prevent the use of retinal image size as a cue, and performance is equivalent across platforms. Analysis of behavior before jumping showed that mice perform a variety of head movements that could be used to generate motion parallax cues. The presence, frequency, and amplitude of movements vary with experimental condition and are correlated with performance on the task. Simultaneous recording of eye movements with miniature head-mounted cameras showed that gaze is maintained toward the platform throughout large-amplitude head movements. Finally, optogenetic suppression of primary visual cortex impairs performance on the task, suggesting a critical role in the neural computations underlying estimation of depth from motion. Together, these findings establish an ethological paradigm for the investigation of cortical sensory computations utilizing self-motion in mice.

[4]Sociedad Iberoamericana de Neurociencia Aplicada, A.C.
Behavior is the part of the functioning of an organism dedicated to acting with the outside world. Historically, behavior studies have focused mainly on vertebrates but research on invertebrate behavior has been increasing because the potential for research of those models. Nowadays when talking about mollusk behavior, cephalopods are the first group that stands out, however, there is a lack of research with the endemic species from México, particularly with *Octopus maya.* This species of octopus has shown to adapt well to laboratory conditions since breeding in captivity has been successfully achieved through several generations, giving it a great advantage as a research model. This allows reducing the number of variables that cannot be controlled, inherent in the use of captured specimens like other research groups do. However, to be able to work properly with a species in the laboratory it is necessary to know in detail its behavioral repertoire, that is why the main goal of this study was to make a detailed description of some behaviors that *O. maya* can display in controlled laboratory conditions, specifically the related to locomotion and stress. *O. maya* presents four behaviors related to locomotion: Crawling, jet propulsion, hovering and escalation; and three behavior related to stress during and after a tank cleaning procedure: Isolation, Ink ejection, and protection. Our results show that *O. maya* raised in captivity can display behaviors comparable to other species of octopus and support that it is an organism that can be proposed as a study model. Also, knowing the behavioral repertoire of this species allows greater control in subsequent investigations related to behavior and provide a great tool to constantly monitor the health status of organisms and its use for research, being a precedent for future behavioral research in this species related to neuroscience and cognition.

Title: Modulation of vestibular-sensitive neurons in deep mesecephalic nucleus to locomotion in walking monkeys

Authors: *R. WEI, E. GUGIG, O. STANLEY, K. CULLEN;
Johns Hopkins Univ., Baltimore, MD

Abstract: Locomotion is crucial for even the most basic needs. Successfully maintaining balance during locomotion requires incorporating self-motion cues such as vestibular information. The deep mesencephalic nucleus (DpMe) is a large the midbrain reticular area which plays a key role in integrating and processing sensory, attention, and limbic inputs. Its diverse connections include spinal, cortical, basal ganglia, and limbic inputs as well as outputs to thalamic nuclei and reticulospinal areas. DpMe cells have been shown to respond to passive vestibular (rotational) stimuli, which suggests that this region plays an important role in vestibulo-motor control. However, DpMe responses to locomotion have not yet been characterized. Here we analyzed single-unit extracellular activities from the DpMe in rhesus monkeys during passive vestibular stimulation (translations and rotation) and locomotion. Head-mounted 3Dgyroscopes/3Daccelerometers were used to record the head motion. High-speed cameras were used for motion recording synchronously. DeepLabCut were used to extract the animals' 3D posture for gait analysis. We identified that DpMe cells demonstrated a significant increase in activity during head-fixed treadmill walking, head-fixed and head-free ground walking when compared to resting activities. Notably, DpMe cells demonstrated phase-dependent modulation during walking, even in the absence of vestibular stimulation. Modulation patterns varied between DpMe cells- some cells demonstrated peak activity during swing phase, and others during stance. Taken together these results suggest that DpMe neurons play a critical role in processing multi-sensory input during the complex sensorimotor activities generated in everyday life, such as walking. In addition, our findings also advance our knowledge of the neural circuits that coordinate gait and balance and thus have important implications for the development of novel treatments and interventions.

Switzerland; [3]Chem., Univ. of Zurich, Zurich, Switzerland; [4]Bioengineering, Univ. of Texas at Dallas, Dallas, TX

Abstract: Non-invasive, receptor-specific, focal modulation of different brain circuits in a controlled, reliablemanner can lead to breakthroughs in future treatments of brain disorders. To achieve this, wesystemically deliver engineered ultrasound-controllable therapeutic drug carriers. We thenrepeatedly apply a two-component focused ultrasound pulse sequence at a region of interestinside the brain; the first sequence concentrates the drug carriers with millimeter precision byorders of magnitude. The second sequence uncages the carrier's cargo locally to achieve hightarget specificity and low off-target effects. Upon release from the carriers, the drug locally crossesthe intact BBB. As a proof of concept, we test this method in the rat brain where we inhibitinformation flow from vibrissae sensory cortex (vS1) to vibrissae motor cortex (vM1). We load theultrasound-controlled drug carriers with muscimol (a GABAA receptor agonist) which readilycrosses the BBB, we sonicate in vS1 and record whisker evoked neural activity with a penetratingmulti-electrode array from vM1. We prove that the drug delivery is confined to a small area byrecording visually evoked activity from primary visual cortex (V1), a cortical circuit which is notdirectly involved with the information flow between vS1 and vM1. The method uses orders ofmagnitude lower amount of drug than is otherwise required by systemic injection and very lowultrasound powers (20-fold below FDA limits for diagnostic ultrasound imaging). We show thatBBB remains intact using MRI-contrast agents and, sensitive fluorescent dye extravasation,immunohistochemistry and passive cavitation detection.

Title: Sequence processing in the auditory forebrain of the zebra finch (Taeniopygia guttata) and the budgerigar (Melopsittacus undulatus)

Authors: *A. FISHBEIN[1], K. LU[2], W. LIU[3], W. IDSARDI[1], J. FRITZ[4], S. SHAMMA[1], R. DOOLING[1];
[1]Univ. of Maryland Col. Park, College Park, MD; [2]Emory Univ., Atlanta, GA; [3]Rutgers Univ., New Brunswick, NJ; [4]Natl. Sci. Fndn., Alexandria, VA

Abstract: Human speech and birdsong both rely on central processing of acoustic sequences for vocal communication. Several lines of work show that humans surpass other primates in processing auditory sequences, raising the question of what neural mechanisms evolved that could explain such species differences. Interestingly, recent behavioral experiments in birds have shown that budgerigars, a parrot species, exceed zebra finches, a songbird species, in perceiving differences in auditory sequences. Comparative neurophysiological studies in these avian species can thus help illuminate differential mechanisms of sequence processing in the central nervous system. Here, we measured neural responses to sequence changes by inserting a 24-channel linear array (Plexon U-Probe) into the caudomedial nidopallium (NCM) of adult zebra finches and adult budgerigars. Neurons in the secondary areas of the auditory forebrain of birds are known to habituate in spike rate to repeated stimuli and dishabituate to novel stimuli. Awake, head-fixed birds were passively exposed to sequences composed of synthetic song elements differing in fundamental frequency (FF) and in conditions differing in the duration of each element (40, 80, 120, and 200 ms). Birds heard 20 repetitions of a sequence, followed by blocks of 20 repetitions of the same elements in a reordered sequence. We measured the change in spike rate after each change in sequence, using dishabituation as an index for sequence sensitivity. Additionally, we investigated what properties of the sequences the neurons may be encoding and conducted behavioral experiments using the same synthetic song sequences.We present the results of >100 neurons for each condition in the zebra finch (n = 27, 13 male, 14 female) and preliminary results from >40 neurons for each condition in the budgerigar (n = 6, 4 male, 2 female). We found significant sensitivity to sequence changes in both species but stronger dishabituation in budgerigar neurons than zebra finch neurons for the shortest elements (40 ms). Additionally, we provide evidence that budgerigar neurons more strongly encode changes in FF in terms of element position than do zebra finch neurons. Preliminary behavioral results (3 zebra finches, 2 budgerigars) show weak sequence sensitivity for these stimuli in both species, but a trend towards better performance in budgerigars than zebra finches for the shortest stimuli. These results suggest that neurons in NCM of the zebra finch and budgerigar differ in temporal sensitivity to sequence information, though future work is necessary to relate physiological responses to behavior.

Title: Reorganization of the neural substrate for tutor song memory after exposure to a novel song model

Authors: *P. ARYA[1], S. PETKOVA[2], P. P. KULKARNI[4], N. H. KOLODNY[3], *S. M. H. GOBES[1];
[1]Neurosci., Wellesley Col., Wellesley, MA; [2]Neurosci., [3]Chem., Wellesley Col., Wellelsey, MA; [4]Ctr. for Translational Neuroimaging, Northeastern Univ., Boston, MA

Abstract: Imitating the behavior of adults is critical for the development of some complex social behaviors, such as speaking in humans and singing in birds. Zebra finches (*Taeniopygia guttata)* normally learn to sing from their father but if they are exposed to a novel song model during the sensitive period, are able to imitate the song from their second tutor. The lateral magnocellular nucleus of the anterior nidopallium (LMAN), responds to the song from the first tutor in juvenile zebra finches, but adult LMAN neurons respond to second-tutor song. On the other hand, the caudomedial nidopallium (NCM) of adult zebra finches is activated in response to auditory playbacks of both tutors, and activity is related to the strength of song learning. However, how neural selectivity for the tutor song changes while learning a second song remains unknown. We investigated changes in neural activity during acquisition of two songs using blood-oxygenation level dependent (BOLD) functional magnetic resonance imaging (fMRI). Both fMR imaging and behavioral analysis were performed before (55 dph) and after (90 dph) exposure to the second tutor. We found that experience with a novel, tutor during the sensitive period for learning changes the BOLD response in both the auditory midbrain (mesencephalicus lateralis dorsalis [MLd]) and higher auditory regions (Field L, NCM, caudomedial mesopallium [CMM], caudolateral nidopallium [NCL]). Young birds (55 dph) exhibited a higher BOLD response to the novel second tutor song (TUT2) as compared to the learned first tutor song (TUT1) in the entire auditory cortex. After learning (90 dph), TUT2 song selectivity was visible in MLd while TUT1 song selectivity emerged in the left NCM. When comparing good and poor learners (based on the similarity with the second tutor's song), learning-related changes were apparent in the NCL. Even before learning the second song, a higher BOLD response in the entire auditory cortex distinguished good from poor learners. After learning the second song, only in good learners, the previously diffuse BOLD activity in the auditory cortex became localized to the NCL. Interestingly, the more the birds had learned from second tutor, the higher the BOLD response was in the NCL. Thus, we found neural response to song in several auditory regions is altered as a result of learning two songs. The modification of activity found in the NCL of good

learners is reminiscent of neural activity involved in language acquisition in human prefrontal cortex. Executive control from the prefrontal cortex could be a key mechanism directing attention necessary for successful multiple-model imitation in both birds and humans.

Title: Evolutionary Forces in the Bengalese Finch Song: Parallels and Implications for Study of Human Language Evolution

Authors: *M. FARIAS-VIRGENS[1], T. DEACON[2], K. OKANOYA[3], S. WHITE[1], E. HUERTA-SANCHEZ[4];
[1]Univ. of California at Los Angeles, Los Angeles, CA; [2]Univ. of California at Berkeley, Berkeley, CA; [3]Riken-BRI and Univ. of Tokyo, Tokyo, Japan; [4]Brown Univ., Providence, RI

Abstract: The ability of learning how to produce sounds, in addition to associating innate sounds with external events or objects, enables speech and language acquisition in humans. Despite being quite rare or rudimentary among mammals, vocal production learning is very prominent in three bird groups: songbirds, parrots, and hummingbirds. In this work, we identify genes and biological pathways of importance for functional aspects of vocal production learning in the Bengalese finch (*Lonchura striata domestica*), a domesticated songbird commonly found in pet shops, but also a popular animal model in the study of learned vocal behaviors. The Bengalese finch has a remarkably complex song, in which transitions between vocal units are not fixed, introducing variability in song sequencing. This vocal complexity evolved during its domestication from the white-backed munia (*Lonchura striata*), a wild songbird easily found throughout East Asia. We use whole-genome sequencing data and analytical tools from population genomics to assess the contributions of selection processes (such as female choice for more complex songs) and demographic events (such as the major population bottleneck during

domestication) in shaping the Bengalese finch's genetic variation. Using genome-wide Fst scans, we identify several differentiated genomic regions between domesticated and wild songbirds, with the sex chromosome Z showing the greater proportion of highly differentiated genes. We also find that, as many domesticated animals, Bengalese finches are overall less genetically diverse than their wild ancestors, as shown by reduced average heterozygosity per sampled individual. However, genome-wide Tajimas'D scans show that genetic diversity in munias deviates less from expected across the genome, while diversity deviates more from the expected in Bengalese finches, with long stretches of the genome showing either considerable loss or gain of variability. Interestingly, domesticated and wild songbirds differ in multiple components of the dopamine system, a biopathway fundamental to vocal learning. Our results serve to guide further comparative efforts toward identifying convergent patterns of evolutionary change leading to vocal learning in our own species.

Title: Inhibition of miR-128 rescues deficits in learned vocal communication by normalizing microglia

Authors: ***C. M. AAMODT**[1], Z. E. HEMMINGER[2], R. WOLLMAN[2], S. A. WHITE[1];
[1]Integrative Biol. & Physiol., [2]Chem. & Biochem., UCLA, Los Angeles, CA

Abstract: Novel approaches for identifying autism drug targets are urgently needed to develop therapeutics for patients with severe communication deficits. Autism risk genes are enriched in microRNA-128 targets, and miR-128 is also aberrantly upregulated in postmortem tissue from autism patients. Given its relevance to the disorder, miR-128 may be a broadly relevant target for therapeutic development.
The zebra finch songbird is a widely used animal model for speech and language. Previously our lab generated an activity-dependent gene expression network in the adult songbird striatopallidal song nucleus Area X to identify master regulators of learned vocal behavior. Using this dataset we discovered that the two host genes for miR-128 are among the top genes correlated to singing. We hypothesized that focal reduction of miR-128 in Area X after critical period closure would restore the capacity for improving song.
Zebra finches were raised in isolation (isolates) to generate developmental communication deficits, then bilaterally injected in Area X with a miR-128 siRNA sponge or scramble control

sequence. After recovery they were returned to a social learning environment for four weeks. We found that inhibition of miR-128 was sufficient to rescue deficits in learned vocal sequence organization relative to scramble controls.
To determine the cellular and molecular effects of miR-128 inhibition we used MERFISH to characterize the spatial location of 173 transcripts of interest in three sets of sibling-matched zebra finches: siRNA- treated isolates, untreated isolates, and typically reared animals. Strikingly, we identified a unique microglial cell type in untreated isolates that was not present in siRNA-treated isolates or typically reared siblings. These results dovetail with work in autism patients indicating that microglial activation directly correlates with severity of communication deficits. Inhibition of miR-128 may therefore be a viable therapeutic strategy for enhancing the efficacy of speech therapy in patients with severe autism.

Title: Repeats of vocalizations with unique temporal progression, accompanied by HVC activity representing past and future events, initiate the zebra finch song.

Authors: *D. RAO, S. CHITNIS, R. RAJAN;
Biol., Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: The naturally learned song of the zebra finch is a widely established model to study complex motor sequences. While the song sequence is stereotyped, song bouts begin with repeats of the same syllable called Introductory Notes (INs) that vary considerably in their number across bouts. Further, INs are associated with temporal and acoustic progression, where intervals between successive INs become shorter and less variable, and acoustic properties change for successive INs as they approach the song. (Rajan and Doupe, 2013). Also, the progression is independent of real-time sensory feedback from the external periphery, suggesting internal processes in the brain drive these changes towards song initiation (Rao et. al 2019). What drives INs to song and how complex motor sequences like song are initiated remains poorly understood. Here, we address the question of how repeats of INs transition to song by using a combination of behavioral analysis (19 birds), electrophysiological recordings of

interneurons in premotor nucleus HVC during singing (13 neurons, 2 birds), and computational modeling of the HVC network. First, we show that temporal progression is not a property of syllable repetition, but a property unique to INs before the song. In addition to previous work showing distinct HVC interneuron activity for the last IN (Rajan and Doupe, 2013), we show that individual interneurons show activity selective for the first and middle INs, middle and last INs, or last INs. Thus, for a given repeat position during INs, we find that the activity across HVC interneurons may be: 1. similar for first and middle INs, predicting the next syllable is an IN, 2. similar for middle and last INs, predicting the previous syllable was an IN, or 3. distinct for the last IN, predicting the next syllable is the start of the song. Finally, we explore how such responses in HVC may be generated using a computational model of a network of neurons within HVC. Taken together, our results show that the variable INs speed up to the song as activity in HVC changes across neurons representing past and future events. This suggests that the zebra finch HVC also represents variable elements in song by representing information about past and future syllable, much like what has been shown in songbirds with more complex vocal sequences.

Title: Songbird basal ganglia neurons respond differentially to stimuli of varying goal behavior-similarity

Authors: *L. E. EISENMAN, S. W. BOTTJER;
USC, Los Angeles, CA

Abstract: Procedural learning is necessary for the acquisition of vital skills such as speech. Vocal learning in songbirds is a powerful model for procedural learning because basal ganglia circuitry is highly similar between mammals and songbirds, and localized circuits in songbirds are solely dedicated to functions related to vocal learning and behavior. In both humans and songbirds, juveniles first memorize vocal sounds of a social tutor (the goal behavior) and then produce variable utterances during a phase of sensorimotor integration. To improve performance, these utterances must be evaluated against an internal representation of the goal behavior. Although cortico-basal ganglia circuitry has long been implicated in procedural learning, the mechanisms underlying the evaluation of comparisons between self-generated behavior and goal behaviors remain unclear. Previous research in the Bottjer lab has found that many neurons located in the cortical region LMAN-shell alter their firing rate only during playback of the

learned tutor song in juvenile birds. These "tutor-tuned" neurons provide the requisite internal representation of the goal tutor song. LMAN-shell neurons project to Area X-shell, a region of basal ganglia that is necessary for song learning. However, it is unknown how X-shell circuitry contributes to the evaluation of song performance. To determine the role of X-shell in the evaluation of song performance, I am recording neurons from both X-core (a sensorimotor region) and X-shell in anesthetized juvenile male zebra finches during early stages of vocal practice while presenting the following song stimuli: tutor song, self-generated songs that are either similar (OWN-SIM) or dissimilar (OWN-DSIM) to tutor song, and conspecific adult and age-matched conspecific control songs. Since LMAN-shell projects to X-shell, I hypothesized that tutor-tuned neurons were also present in X-shell. Unexpectedly, I found a small population of neurons that responded only to self-generated song that is similar to tutor song. In addition, neurons in X-shell responded more selectively, on average, to OWN-SIM stimuli compared to tutor song, OWN-DSIM, and conspecific juvenile stimuli. This suggests that neurons in X-shell can distinguish between tutor-similar self-generated song and actual tutor song and between "good" and "poor" matches to the tutor song. These neurons may be used as a "benchmark" of most recent, best performances. Understanding how cortico-basal ganglia circuitry evaluates comparisons between self-generated motor output and goal behaviors is critical to uncovering the fundamental building blocks of procedural learning across taxa.

Title: Experience dependent behavioral flexibility during social interaction

Authors: *R. S. CLEIN[1], M. WARREN[2], D. SANGIAMO[1], J. P. NEUNUEBEL[2];
[2]Psychological and Brain Sci., [1]Univ. of Delaware, Newark, DE

Abstract: Animals living in groups frequently interact with conspecifics and use social feedback to modify their behavior. While social status strongly influences how individuals modify their behavior in groups, other factors may also impact group dynamics. In particular, the role that an animal's current behavioral state plays in future interactions with other group members is less clear. To explore this question, we recorded unrestricted social interactions for 5 hours in mixed-sex groups (n = 11; two males and two females in each group) of adult mice (13-21 weeks old; B6.CAST-Cdh23Ahl+/Kjn) and automatically extracted distinct behaviors using a machine-based learning system (Kabra et al., 2013). For every recording, we computed an aggression score based on the number of aggressive behaviors performed by each male, with scores ranging

from 0.02 to 0.97. The overall level of a male's aggression did not affect the number or duration of male-female interactions (Mann-Whitney, all p values > 0.05). However, we found that a male's aggressive state profoundly influenced subsequent male-female interactions. Surprisingly, animals in a submissive state interacted with a female more frequently, for shorter durations, and sooner after the aggressive encounter than animals in an aggressive state (Mann Whitney, all p values < 0.04). In contrast, the number, duration, and temporal delay of interactions with a female were similar between males after non-social or non-aggressive behaviors (Mann-Whitney, all p's > 0.05). When looking at the movement patterns across different post-aggression behavioral sequences, the kinematics were strikingly different between males in submissive and aggressive states (Mann-Whitney, $p < 0.05$). The movement patterns of males with higher or lower aggression levels were similar (Mann-Whitney, $p > 0.05$), suggesting that a male's role in aggressive behavior strongly influenced subsequent male-female interactions. Additionally, movement patterns were highly predictive of a male's aggressive state and subsequent social engagement (Z-test, $p < 0.01$). Our results demonstrate that mice rapidly update their behavior in response to changes in aggressive social contexts, indicating that an animal's behavioral state influences overall group dynamics.

Title: Measuring voluntary behaviors in gerbil families

Authors: C. MITELUT, R. E. PETERSON, M. H. GAMER, L. DIEZ, *D. H. SANES;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Social interactions facilitate learning across a broad range of species, particularly during development, yet research has historically focused on short-term, laboratory-designed tests between adult dyads. However, outside of vocal learning in juvenile male songbirds (e.g. Slagsvold & Wiebe 2011), the impact of social learning, especially sex as a biological variable, remains uncertain. Importantly, historical studies have not characterized uninterrupted behaviours during developmental periods while each member of a family behaves freely in a homecage setting.To address this we established a habitat in which gerbil family cohorts (2 adults and 2-4 pups) could be monitored from birth to weaning (P1-P30). Audio and video recordings were obtained continuously to characterize the social behavioural repertoire of individual gerbils. We combined open source markerless pose estimation methods (Mathis et al 2018) with improvements to identify individual animals throughout day/night cycles and across weeks (Mitelut et al, Cosyne, in submission) (Fig A). Reviewing a single 24 hour recording, we found that we could track the circadian cycles of behaviour (Fig B). We also found that

interactions between animals varied with some animals preferring interaction with specific individuals. Lastly, we show the presence of social interaction biases where some animals are more likely than others to initiate movement. Our findings show that spontaneous behaviour can be tracked for highly social animals over periods of weeks pointing the way to future studies focusing on the neuroethology of social behaviours.

Title: Daily Administration of the Gonadotropin-Releasing Hormone Agonist Leuprolide Acetate Throughout Adolescence Delays the Development of Reproductive Physiology and Behavior in Male Rats.

Authors: *F. A. GUARRACI[1], L. K. DAVIS[2], E. L. HENNEMAN[2], E. TORO[2], S. E. ODELL[2], N. LE[2], J. M. NAVARRO[2], H. S. VALDIVIA[2], I. WILLIAMS[2], M. CREDEUR[2], A. C. GORE[3]; [1]Psychology, [2]Southwestern Univ., Georgetown, TX; [3]The Univ. of Texas, at Austin, AUSTIN, TX

Abstract: The present study was designed to examine the long-term effects of suppressing pubertal onset with leuprolide acetate, a gonadotropin releasing hormone (GnRH) agonist. Starting on postnatal day (PD) 25, male Long-Evans rats were injected daily with either leuprolide acetate (25 µg/kg dissolved in 0.9% sterile physiological saline; n=13) or sterile physiological saline (1.0 ml/kg 0.9% NaCl; n=14) for a total of 25 days. Males were monitored daily for signs of puberty (i.e., preputial separation). On the last day of leuprolide treatment (PD 50), half of each treatment group was injected with 10.0 µg of estradiol benzoate (EB) daily for three consecutive days (PD 50-52) and 1.0 mg of progesterone (P) on the 4th day (PD 53), whereas the other half of each treatment group received oil injections. Four hours after P injections, all subjects were given the opportunity to interact with a gonadally intact male and a sexually receptive female rat (i.e., a partner-preference test with and without physical contact). Copulatory behavior and sexual motivation were measured. Hormone injections and mating tests were repeated weekly for a total of 3 consecutive weeks. Leuprolide delayed puberty as well as the development of copulatory behavior and the expression of sexual motivation. By the last test, the leuprolide-treated subjects showed signs of catching up, however, some continued to be delayed. Estrogen and progesterone may have mildly feminized male physiology and behavior, but did not interact with leuprolide treatment. These findings can inform the delay of puberty in adolescents questioning their gender identity.

Title: Contributions of androgen action within the vomeronasal organ for sexual differentiation of the brain and behaviour

Authors: *Y. H. MARTIN[1], S. SALIA[1], S. CROSS[2], A. SWIFT-GALLANT[1];
[1]Dept. of Psychology, [2]Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: The vomeronasal organ (VNO) situated in the nasal cavity is largely responsible for pheromone processing and plays a critical role in mediating socio-sexual behaviors in mice. Testosterone masculinizes and defeminizes the brain and socio-sexual behavior during early development by acting directly on androgen receptors (AR) or indirectly via estrogen receptors (ER), following aromatization to estradiol. We asked whether androgens can act via the VNO in early development to affect the display of socio-sexual behaviors in adulthood. In Experiment 1, we administered a microinjection of testosterone locally to the VNO on the day of birth (PND1) in C57BL/6 male and female mice. In Experiment 2, we asked whether testosterone acts directly on AR or indirectly via ER by injecting the VNO directly with a vehicle, estradiol or the non-aromatizable androgen, dihydrotestosterone (DHT) on PND1. Socio-sexual behaviors of experimental mice were measured in two separate tests, once in response to an estrus-induced female and another in response to a castrated male mouse swabbed with the urine of sexually experienced male. In Experiment 1, we found that a single microinjection of testosterone on PND1 was sufficient to increase male territorial aggression but did not affect the behavior of female mice. In Experiment 2, our preliminary results suggest that both estradiol and DHT differentially affect behavior in male and female mice. Males exposed to DHT demonstrated increased anogenital investigation and territorial aggression to a male intruder, whereas both males and females exposed to estradiol demonstrated an increase in investigation and self-grooming in response to a female intruder. The results suggest that testosterone may be acting both directly on AR and indirectly through ER in critical periods in development within the VNO to affect adult socio-sexual behavior. Further analyses will assess whether androgen action via the VNO affects the sexual differentiation of downstream neural targets.

Title: Kisspeptin induces a conditioned place preference and sexual receptivity in female rats

Authors: *J. E. HERNÁNDEZ[1], R. G. PAREDES[1,2], M. BEDOS[2];
[1]Inst. de Neurobiología, Querétaro, Mexico; [2]Escuela Nacional de Estudios Superiores, Unidad Juriquilla, Querétaro, Mexico

Abstract: ABSTRACT

Kisspeptin induces a conditioned place preference and sexualreceptivity in female rats

J. Hernandez[1], R. Paredes[1,2], M. Bedos[2].1 Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, Mexico2 Escuela Nacional de Estudios Superiores, Unidad Juriquilla, Querétaro, Mexico

Paced mating induces a positive affective reward state as revealed by the conditioned place preference (CPP) paradigm. Using this methodology, our group showed that opioids are involved in the activation of the reward system associated with sexual behavior. Kisspeptin (Kiss), a potent regulator of the hypothalamic-pituitary-gonad axis, is also involved in other processes outside the hypothalamus, namely, the integration of sensory signals such as olfactory signals in rodents and the processing of the sexual and emotional information in humans. Interestingly, Kiss and its receptor (GPR54) are expressed in different brain regions known for their participation in the processing of reward and motivation of reinforcing behaviors. Therefore, in the present study we evaluated if Kiss induces a reward state and its role in the sexual behavior. We used sexually naïve Wistar female rats in all experiments. First, the paced mating behavior of 9 rats was evaluated in a Latin square design in 30min-sessions with sexually experienced males. All females received a s.c. injection of estradiol benzoate (E2, 2.5 µg/rat) 48h before the tests and either Progesterone (P4) 4h before the tests (s.c., 500µg/rat, E2+P4), Kiss 1h before the tests (i.p., 14nmol/rat, E2+Kiss), P4 and Kiss (E2+P4+Kiss) or vehicle (E2), depending on the session. The following parameters were recorded: lordosis intensity and quotient, exits from the male chamber and the time that the female took to return to the male chamber after a copulatory event. We didn't find any significative difference between groups except for the E2 group, which showed an increase in the number of exits from the male chamber and a decrease in the lordosis quotient and intensity. Secondly, we evaluated the effect of Kiss with the CPP paradigm. Rats were assigned to the following groups: 7 and 14 nmol of Kiss and Controls that were conditioned with saline (n=10 each). In the CPP test we found a significant increase in the time spent in the reinforced chamber between pretest and test after the administration of 7 or 14 nmol of Kiss (P=0.0012 and P=0.0049, respectively). Our findings provide evidence that Kiss administrated with E2 induces a similar receptivity and response to males during paced mating as with the classic E2+P4 treatment. Moreover, females injected with Kiss developed a clear CPP, demonstrating its reinforcing properties.

Title: Role of the medial Preoptic Area in tailoring maternal behavior to match offspring needs

Authors: K. PIZARRO-COLON, K. COPELAS, ***M. PEREIRA**;
Univ. of Massachusetts Amherst, Amherst, MA

Abstract: Maternal behavior that is sensitive to the needs of the young is essential for the healthy development and wellbeing of all mammals. Our prior research suggests that the medial Preoptic Area (mPOA), a critical node of the circuitry regulating maternal behavior, plays a significant role in coupling appropriate caregiving with the needs of the young. Maternal sensitivity refers to this maternal ability to link sensory cues with the underlying needs of the young and to respond appropriately (i.e., promptly and contingently) to meet those needs. The present study investigated the role of the mPOA in maternal sensitivity. To this aim, we used Gi-coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to selectively inhibit the mPOA of mother rats during maternal interaction with pups with varying needs. In order to examine the role of the mPOA in maternal sensitivity (versus maternal behavior), we used multiparous mother rats, as their caregiving behavior is more resilient to mPOA functional inactivation, and a within-subject design to examine the behavioral effect of chemogenetic inhibition of the mPOA. As expected, vehicle-treated mothers interacting with demanding pups adjusted their caregiving behavior to match their increased needs. However, chemogenetic inhibition of the mPOA following treatment with the DREADD agonist clozapine-N-oxide in these same mothers disrupted maternal sensitivity, as reflected by a similar expression of maternal behavior regardless of the offspring's needs. Additional studies combining RetroBeads retrograde tracing with immunostaining for the activity marker cFos detected differential patterns of responsive mPOA neurons projecting to the infralimbic cortex and the ventral tegmental area following maternal interaction with offspring with varying needs. Together, results from this study demonstrate that the mPOA orchestrates appropriate maternal caregiving with the needs of the pups.

Title: Nucleus accumbens serotonin 1A receptor expression is critical for normal postpartum social motivation

Authors: *E. M. VITALE[1], T. A. MEINHARDT[2], E. G. FORD[3], J. S. LONSTEIN[4];
[1]Pharmacol. and Toxicology, Univ. of Kansas, Lawrence, KS; [2]Psychology, [4]Neurosci.,
[3]Michigan State Univ., East Lansing, MI

Abstract: Mammalian mothers show a unique suite of behaviors beginning around the time of parturition that are necessary for rearing the young. This transition to motherhood requires changes in many neurochemicals, including classic neurotransmitters such as serotonin. Our lab recently found reproductive state-related changes in the expression of a number of serotonin receptor subtypes in the female rat forebrain and midbrain. The most robust of these changes was a 3-fold increase in the expression of 5-HT1A receptor mRNA in the nucleus accumbens shell (NAcSh) on the day of parturition compared to before mating or during mid-pregnancy. We also found that repeated variable stress during pregnancy prevented this parturitional increase in NAcSh 5-HT1A expression, as well as reduced maternal care and increased depression-like behaviors. The current experiment directly tested whether high 5-HT1A receptor expression in the NAcSh is necessary for the normal display of postpartum maternal caregiving and affective behaviors. Long-term knock down of 5-HT1A was established by infusing an adeno-associated virus promoting shRNA against 5-HT1A mRNA into the NAcSh during early pregnancy. In some ways similar to what we found after pregnancy stress, 5-HT1A knock down in the NAcSh resulted in higher frequencies of off-nest behaviors, delayed retrieval of displaced pups back to the nest, and increased anxiety-like behavior. These results further indicate that the periparturitional rise that we found in NAcSh 5-HT1A receptors is critical for postpartum caregiving and affective behaviors, and provide a potential mechanism via the brain's reward system through which pharmacological treatments that target the central serotonin system (e.g., SSRIs) may alleviate postpartum affective disorders.

Title: Differential impacts of early life stress paradigms on maternal care

Authors: *A. VALENTINE, L. GRANATA, H. BRENHOUSE;
Northeastern Univ., Boston, MA

Abstract: Animal models can elucidate the interactions between early life environment and brain development, with maternal care being a critical aspect of both. Poor quality and limited quantity of maternal behaviors carry a negative impact on emerging brain networks in rat pups. Maternal exposure to stress has been found to increase the unpredictability or fragmentation of maternal care, magnifying pup exposure to stress. Researchers report paradigms of early life

stress (ELS) initiate poor maternal care, but limited studies uncover the differential effects of the two most common ELS models: maternal separation (MS) and limited bedding (LB). Thus, we unobtrusively recorded MS, LB, and control litters (n = 10-12 dams/group) on postnatal day 8-9 for 30 minutes every 4 hours over 24 hours. We manually scored maternal behavior at three of the time points (1430, 2330, 0830) and categorized behaviors: nursing (none, passive, or arched back), nest (on or off), licking and grooming (none, licking and grooming, or self-grooming). Dams in the LB condition exhibited increased passive nursing and time on nest compared to other groups at 1430pm and 0830am. MS dams showed increased duration of arched back nursing at 1430pm compared to other conditions, possibly due to separations ending at 1400pm. Patterns of behavior were explored via transition matrices (see Figure), demonstrating small variances in predictability of maternal care amongst each paradigm and time point. Taken together, our results suggest that slight alterations in maternal care exist amidst ELS models; MS dams compensate for separation from their pups with more active nursing, and LB litters show increased quantity but poorer quality of maternal behaviors. However, fragmentation was not a characteristic of either ELS paradigm, possibly due to inadequate length of sampling periods. Next steps include analyzing additional time points to further reveal nuanced effects of models. Our results suggest researchers should consider how their ELS paradigm of choice differentially impacts maternal care and its implications on neurodevelopment.

Title: Sex differences in the transcriptional networks underlying playfulness suggest a distinct function for play in males compared to females

Authors: *A. E. MARQUARDT[1], J. W. VANRYZIN[2], S. A. AMENT[3], M. M. MCCARTHY[2]; [1]Program in Neurosci., [2]Dept. of Pharmacol., [3]Inst. for Genome Sci. and Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Social play, or rough-and-tumble play, is a dynamic behavior expressed by most juvenile mammals. While its function is debated, a prevailing hypothesis suggests play serves to sculpt and refine neural circuitry enabling expression of appropriate adult behavior. Importantly, in most species, males play more than females, a sex difference driven by the medial amygdala (MeA). To investigate whether the transcriptional signatures underlying play also differ by sex, we performed RNA-sequencing of MeA samples from high- and low-playing juvenile rats of both sexes. Using Weighted Gene Co-expression Network Analysis (WGCNA), we identified 22 co-expression modules, or networks of genes highly correlated in expression across samples. Of the 12 modules (for $p<0.05$) associated with play, almost all (11/12; ~92%) are sex-specific in expression, correlating with expression of play in one sex only. These data suggest there is a distinct transcriptomic profile associated with playfulness in the MeA of males compared to females, a noteworthy finding given the MeA regulates many sex-typical adult social behaviors. We propose that this is no coincidence: play-associated gene networks in the MeA are sex-specific because play modulates circuitry driving different adult behaviors depending on sex. To investigate this, we are currently exploring whether preventing play has distinct functional consequences on various adult behaviors in males and females. We created perforated Plexiglass cage dividers to separate animals during the juvenile period and thus prevent play, while still allowing for various other social interactions to occur. Preliminary data support our hypothesis, indicating a sex-specific effect of preventing juvenile play on adult copulatory behavior, social preference, and sex preference in males but not females. Surprisingly, we have observed no effects of this manipulation in females. Future experiments will also examine the effects of modulating expression of our identified sex-specific gene modules on juvenile playfulness and later-life behavior using a viral approach. Together, these analyses will provide novel insight into the ultimate function of play and how and why this may differ by sex.

Title: Assessing the oxytocin system as a target for pharmacotherapy of alcohol use disorder using socially housed prairie voles (Microtus ochrogaster).

Authors: *S. POTRETZKE, A. E. RYABININ;
Dept. of Behavioral Neurosci., Oregon Hlth. and Sci. Univ., Portland, OR

Abstract: The prevalence and devastating impact of alcohol use disorder (AUD) necessitate the development of efficacious treatments. Oxytocin (oxt), a hormone with crucial roles in a variety of social behaviors, has drawn interest as a promising pharmacotherapy for AUD with its implicated role in mediating the processes associated with drug use and its social effects which may serve to bolster abstinence. Oxt has been shown to be effective in decreasing alcohol craving in humans and consumption in rodents, including results from our own laboratory with repeated (intraperitoneal, i.p.) treatments in both prairie voles and mice. Of crucial importance in designing therapies are the complex interactions of alcohol-related behaviors with the social environment, demonstrating the need for incorporating social paradigms in alcohol consumption studies. Our laboratory utilizes the "Herdsman" cage system which incorporates RFID tracking and precision balances to allow for individualized measurements of both consumption and behavior in a truly social setting. In this investigation we tested whether intranasal (i.n.) oxt can decrease alcohol consumption in prairie voles (*Microtus ochrogaster*) - a socially monogamous rodent species with demonstrated translational validity to humans through common mechanisms regulating social behaviors. Adult male and female same-sex cagemates were socially housed and underwent a continuous access two-bottle choice (5% alcohol, water) procedure for 5 days to establish baseline measures of consumption. Oxt (5mg/kg or 10mg/kg, i.n.) or saline was then administered and various measures of consumption and behavior were collected. Oxt decreased alcohol consumption and preference during the first hour following treatment. Our ongoing experiments examine the effects of a small molecule oxt receptor agonist, LIT-001, which displays a more favorable pharmacokinetic profile. These studies will also characterize the behavioral mechanisms to establish whether oxt's effects on alcohol consumption are direct or mediated by increased social interaction. Together, these results will explicate oxt's role in mediating the reward processes associated with drug use and social behavior and serve to clarify whether oxt is a promising target for pharmacotherapy for AUD.

Title: Genetic disruption of the oxytocin receptor affects social interactions in a neutral arena test

Authors: *C. P. VADALA, E. A. AULINO, H. K. CALDWELL;
Kent State Univ., Kent, OH

Abstract: The neuropeptide oxytocin (Oxt) is well known for its neuromodulatory effects on social behaviors. These effects are mediated predominantly by Oxt signaling through the Oxt receptor (Oxtr), and disruption of Oxtr signaling results in impaired expression of social behaviors. For example, transgenic mice with lifelong genetic deletion of the Oxtr, i.e. Oxtr —/— mice, display increased inter-male aggression in a resident-intruder test. However, whether or not this heightened aggression phenotype extends to other social contexts remains unknown. Thus, in this experiment a neutral arena test, which lacks the "home cage advantage" of a resident-intruder test, was utilized. We hypothesized that male Oxtr —/— mice would exhibit heightened aggressive behavior compared to Oxtr wildtype (+/+) mice in this novel/neutral context. To test this hypothesis, adult male Oxtr +/+ or Oxtr —/— mice were placed into a clean cage with an adult stimulus male and the behavior of the experimental animal recorded for five minutes and later scored; this test was repeated across three days. Behaviors scored included nonsocial, prosocial, and aggressive behaviors. On Day 1, Oxtr —/— mice spent significantly more time being nonsocial and engaged in less anogenital contact than Oxtr +/+ mice. On Day 2 and Day 3, no genotypic differences in behavior were observed. These results indicate that disrupted Oxtr signaling impacts the early stages of social interactions in a context-specific manner. This work is relevant as it suggests that Oxtr signaling may be particularly important in territorial displays of aggression, and perhaps to a lesser extent in other types of inter-male interactions. More work must be done to determine the ways in which the Oxt system influences male-typical behaviors.

Abstract: Prosocial animals actively engage in affiliative contacts among conspecifics, and exhibit stress responses upon isolation. The neural mechanisms required for sensing and seeking for social contacts, however, have yet to be elucidated. Here we report that the amylin-calcitonin receptor (Calcr) signaling in the medial preoptic are (MPOA), which is recently found to be essential for parental care, also mediates social contacts among adult female mice. Calcr expressing MPOA neurons were activated by affiliative social reunion, but not by defensive huddling against an environmental threat, suggesting two separate circuits for affiliative vs. self-defensive social contacts. On the other hand, social isolation activates neurons in the medial part of central amygdala (CeM). Targeted knockdown of Calcr gene in the MPOA attenuated contact seeking behaviors during social isolation and reunion. MPOA expression of brain-gut neuropeptide Amylin, the ligand of Calcr, were depleted by physical isolation, and restored by social reunion. Disruption of amylin-Calcr signaling by using an antagonist of Calcr attenuated contact behaviors. These data present a novel and conserved neuromolecular basis of mammalian affiliative behaviors.

Title: Involvement of the nucleus accumbens oxytocin system in the regulation of social play behavior of male and female juvenile rats

Authors: *S. M. BOWDEN[1], J. D. A. LEE[1], R. BREDEWOLD[1], A. H. VEENEMA[2]; [1]Psychology, [2]Psychology and Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Juvenile social play is a highly rewarding behavior displayed by many mammalian species. Deficits in social play behavior are a hallmark symptom of children with Autism Spectrum Disorder (ASD). Although the oxytocin (OXT) system is being considered as a potential therapeutic to restore social functioning in ASD, little is known about the involvement of the OXT system in regulating social play. Here we show that infusion of the selective OXT receptor (OXTR) antagonist des-Gly-NH_2,d$(CH_2)_5$[Tyr(Me^2),Thr^4]OVT into the nucleus accumbens (NAc) of juvenile rats significantly decreased social play in both sexes, with males requiring a higher dose of the OXTR antagonist (100ng/ 0.5 µl) than females (10ng/ 0.5 µl). As a first step to understand the underlying mechanisms, we determined whether OXTR-expressing

neurons in the NAc were sex-specifically recruited in response to social play. Using in situ hybridization, we show that the proportion of activated *oxtr*-positive neurons (*oxtr+fos/oxtr* [%]) in the NAc was significantly lower in male and female rats exposed to social play compared to those not exposed to social play. Together, these findings suggest that the OXT system in the NAc facilitates social play in both sexes through inhibition of Oxtr-expressing NAc neurons. To further examine sex differences in the regulation of social play by the NAc-OXT system, we are currently focusing on the ventral pallidum (VP) as a potential downstream target of the NAc-OXT system. Using the retrograde tracer Cholera toxin B, we are determining whether activation of the NAc^{OXTR} to VP pathway is altered in response to social play, and if so, whether this occurs in a sex-specific manner. Overall, these experiments will provide insights into the neural circuitry by which OXT regulates juvenile social play behavior in sex-specific ways, with potential relevance to social play deficits seen in ASD, a disorder with higher prevalence in males.

Title: Dopamine receptors and social preference in young zebrafish

Authors: P. CRONELL, S. SHAMS, ***L. WESTBERG**;
Pharmacol., Univ. of Gothenburg, Gothenburg, Sweden

Abstract: The family of neurodevelopmental disorders commonly known as autism is characterized by social deficits, and severely affects the life of 1% of the global population. There are no established pharmacological treatment options available. To identify pharmacological tools for reversing social deficits we use the model organism zebrafish (*Danio rerio*), which is a highly social vertebrate relying on visual rather than chemosensory information in their social interactions. Zebrafish reproduce in large numbers and show robust social interaction already at 3-weeks of age, which enables more efficient and higher-throughput testing of sociability compared to other species. This study aims to investigate to what extent dopamine receptors are involved in social preference behavior in young zebrafish. Dopamine plays a prominent role in social reward and has been suggested to be relevant for the social deficits seen in individuals with autism. In this study, we investigate if agonists and antagonists for dopamine D1 and D2 receptors may alter social preference behaviour in three-week-old zebrafish. The behavioural experiments were performed in testing arenas flanked by social (fish stimuli) and non-social compartments (empty). Test fish were treated with different concentrations of

agonists and antagonists for dopamine receptor D1 (agonist, SKF-38393: 0, 1, 2.5, 7.5, and 15 uM; antagonist, SCH-23390: 0, 3, and 30 uM) and D2 (agonist, quinpirole: 0.5, 1, 2.5, 5 and 10 uM; antagonist, haloperidol: 0, 5, 10, 15 uM) for 60 minutes. Time and location of the fish in the arenas were scored and a social preference index was calculated. Generally, fish treated with dopamine receptor antagonists preferred the social stimulus side less than vehicle-treated fish. Moreover, higher concentrations of both agonists and antagonists decreased the distance travelled compared to the vehicle group. In addition, there was no apparent correlation between distance moved and social preference index. Our results suggest that dopamine receptors may regulate, independently of one another, social preference and locomotion in developing zebrafish.

Title: Domestic Cats with Latent Toxoplasma gondii Infection Show Higher Levels of Affiliative Behavior

Authors: *M. ALYETAMA;
Univ. of Nebraska At Omaha.

Abstract: Toxoplasma gondii alters risk-averse, exploratory and locomotory behaviors in rats to enhance their capture by felids, the only host where T. gondii can reproduce sexually. Among felids, the population size of domestic cats makes it likely that they are the largest environmental contributor of infectious T. gondii oocysts. Hence, parasite distribution could be markedly affected if T. gondii also manipulates cat behavior. We developed a humane, least-invasive paradigm to evaluate this issue in naturally infected pet cats. We asked pet-cat owners to present their cat with either a predator or control scent, and video-recorded their behaviors. We analyzed a subset of cat behaviors that were, based on studies in lab-infected rodents, predicted to be altered by parasite exposure. Time-budget and movement analyses indicate that unlike lab-infected rats, cats who were seropositive for prior T. gondii exposure and seronegative cats showed similar amounts of exploratory/locomotory, calm and fear behaviors, and responded similarly to predator and non-predator scents. However, seropositive cats displayed increased affiliative behavior. These results imply that naturally occurring T. gondii exposure of a definitive host leads to more subtle behavioral modification than that seen in lab-infected intermediate hosts, and, in this experimental paradigm, that prior infection either leads to a persistent increase in affiliative behavior or that felines with increased affiliative behavior are at greater risk of T. gondii infection.

Title: Intranasal oxytocin increases hippocampal immature neuron density and social approach following delay

Authors: *P. MONARI[1], Z. HERRO[2], C. MARLER[2];
[1]Psychology, Univ. of Wisconsin Madison, Madison, WI; [2]Psychology, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Intranasal oxytocin increases hippocampal immature neuron density and social approach following delaySocial avoidance is a common symptom underlying several psychiatric illnesses and neurodevelopmental disorders, and intranasal oxytocin is of potential therapeutic value to mitigating social avoidance due to its ability to promote affiliative behaviors. Moreover, oxytocin is known to regulate adult neurogenesis, which in turn is likely involved in anxiety regulation and social behavior. To examine how chronic intranasal oxytocin influences adult neurogenesis and social approach, we administered intranasal oxytocin to unpaired male and female California mice for seven days, and subsequently assessed their approach to a simulated unfamiliar intruder using an aggressive vocal playback test (No-Delay cohort). A separate cohort of males and females was also administered a seven-day series of intranasal infusions but received the approach test three weeks later (Delay cohort). In both cohorts we assessed the number of doublecortin positive cells in the dorsal and ventral hippocampus as well as the volume of the dentate gyrus. Intranasal oxytocin did not impact the amount of time males or females in the No-Delay cohort spent near the playback stimulus and did not increase the doublecortin-positive cell density in either the dorsal or ventral hippocampus for either sex. However, intranasal oxytocin increased the amount of time both males and females in the Delay cohort spent near the playback stimulus, and also increased the doublecortin-positive cell density in both the dorsal and ventral hippocampus of both sexes. Our results suggest that in California mice extended intranasal oxytocin treatment regulates social approach, but only after an extended delay. Additionally, this change in behavior is associated with a change in immature neuron density in the hippocampus, suggesting that adult neurogenesis may play a role in the oxytocin-mediated regulation of social approach.

Title: Mechanisms Associated with Placental Inflammation and Serotonin Production in Response to Maternal High Fat Diet

Authors: *C. HUYNH, A. CEASRINE;
Duke Univ., Durham, NC

Abstract: Maternal obesity is a rapidly increasing epidemic in the United States. Maternal high fat diet (mHFD) increases the risk for neuropsychiatric disorder development, such as anxiety and depression, in offspring potentially by promoting a fetal environment of chronic inflammation. With these observations in mind, we aim to analyze neurological mechanisms that contribute to offspring behavior changes in response to mHFD. One neurotransmitter that plays critical biological roles in behavior is serotonin. Serotonin levels can be negatively impacted by inflammation, and diminished levels of serotonin contribute to anxiety-like or depressive-like phenotypes in mice. Importantly, the placenta, a prime interface between the maternal inflammatory state (induced by maternal HFD) and the developing brain, is the source of fetal forebrain serotonin (synthesized from maternally-derived tryptophan). We hypothesize that mHFD-associated inflammation is communicated to the fetus through the placenta and decreases serotonin bioavailability. Preliminary immunohistochemistry data from our lab indicated male-specific inflammation in fetal mHFD placenta. Moreover, male mHFD offspring had significantly less serotonin in placenta, fetal forebrain, and adult prefrontal cortex (PFC). Interestingly, preliminary data demonstrate sex-specific behavior changes in male and female mHFD offspring. Both male and female neonatal mHFD offspring show diminished ultrasonic vocalizations, while adult male offspring show anhedonia (decreased sucrose preference) and juvenile female offspring show decreased social behavior. These data raise questions on sex differences in mechanisms contributing to fetal inflammation and serotonin bioavailability. My aim was to identify changes in inflammation-related and serotonin-related gene expression in mHFD placental macrophages, and assess whether increasing serotonin bioavailability during embryonic development would be sufficient to alleviate behavioral changes in male mHFD offspring. My data suggest that toll-like receptor signaling, particularly through Tlr4, may be contributing to increased inflammatory response in both male and female mHFD placenta. Further, preliminary experiments suggest that maternal tryptophan enrichment (hypothesized to increase embryonic serotonin bioavailability) rescues some male-specific behavior changes. Together, these findings point toward a mechanism through which mHFD-induced placental inflammation influences male and female behavior outcomes, likely through serotonin deficiency in males and through a distinct, yet still unknown, mechanism in females.

Title: Overexpression of interleukin-12 in the frontal cortex mediates impulsivity and protects against subsequent immune challenge

Authors: *K. M. HRELJA, T. J. HYNES, K. ONG, C. A. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: One behavioural change that has been noted following traumatic brain injury (TBI) is an increase in impulsive behaviour. In addition to affecting daily functioning, this puts individuals who have suffered TBI at risk of developing numerous psychiatric disorders. Following TBI, inflammatory responses are initiated resulting in increased levels of pro-inflammatory cytokines and diffuse white matter pathology, which are the neuropathological hallmarks of TBI. It is thought that these changes may underlie the behavioural effects of TBI. One cytokine of particular interest is interleukin-12 (IL-12), which is known to be increased following TBI and is correlated with increases in impulsive behaviour. In the current experiment, 32 male Long Evans rats were used to assess whether the overexpression of IL-12 alone is sufficient to cause behavioural changes detectable using the 5-choice serial reaction time task (5-CSRTT). In short, animals were trained to stability on the cognitive task, which requires them to make a nose poke response in an illuminated aperture. Upon reaching stable performance on the final training stage, rodents underwent stereotaxic surgery where they received bilateral viral infusions of AAV5-IL12-MYC (n=16) or control (GFP; n=16) into the orbitofrontal cortex. After recovery from surgery, rodents resumed daily 5-CSRTT sessions and differences in behaviour pre- and post- viral infusion were measured over the course of one month. After this time, animals were given two injections of lipopolysaccharide (LPS), one week apart, to act as an additional immune challenge. Following sacrifice, viral expression was confirmed and brain tissue was analyzed for TBI-related pathology. Contrary to our initial hypotheses, we found that overexpression of IL-12 reduced impulsive responding on the 5-CSRTT relative to controls, as evidenced by a decrease in premature responding. This is similar to what is seen after exposure to an acute stressor, and may suggest a biphasic effect of IL-12 on cognition. We also found that excess IL-12 offered some protection from LPS-induced sickness, which is consistent with the tolerance effects commonly observed following repeated immune stimulation. This project will lend insight not only into the molecular basis of TBI, but will also shed light on the behavioural effects of IL-12 itself. Furthermore, if successful, it will also indicate which neural correlates future treatments for the behavioural symptoms of TBI can target, as there are currently no existing treatments for these.

Title: Gut microbiome depletion in early development and adulthood alters sociosexual behaviors in male mice

Authors: ***S. SALIA**, Y. MARTIN, L. JACKMAN, F. F. BURKE, L. A. MYLES, F. BAMBICO, A. SWIFT-GALLANT;
Psychology, Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Gut microbes influence the brain and behavior via a bidirectional communication between the gut and brain. Gut depletion has shown a sex-dependent effect on behavior, such as anxiety-related behavior in germ-free and antibiotic-treated rodent models. The current study assessed whether gut depletion during early development or adulthood affects sex-typical sociosexual behaviors in male and female C57bl/6 mice. We used broad-spectrum antibiotics (AB) in drinking water to deplete the microbiota in either early development (embryonic day 16 to postnatal day 21) or adulthood (day 60 to 80) while the control group received normal drinking water. We measured preference for male and female soiled bedding in an olfactory preference test, and we quantified territorial aggression on the resident intruder paradigm, where mice were exposed to a castrated male mouse swabbed with the urine of a sexually experienced male in their home cage. Sexual behaviors were measured in response to an estrus-induced stimulus female introduced to their home cage. The olfactory preference test revealed that adult AB-treated males had a significantly decreased preference for female bedding, whereas the early treatment group did not differ from control males. Both early and adult AB-treated males showed a significant decrease in male aggression compared to control males. Male treatment groups did not differ in sexual behavior in response to an estrus-induced female. Female experimental mice displayed female-typical sociosexual behavior regardless of treatment condition. Our findings suggest sociosexual behaviors are permanently altered by antibiotic treatment in early development as well as adulthood in male mice. Given the androgen dependence of these behaviors future work will assess the gut microbiome's interaction with the endocrine system. Authors have no conflicts to declare.

Title: Environmental enrichment diminishes aggression and alters brain-derived neurotrophic factor gene expression in group-housed male mice

Authors: M. ALDHSHAN, *T. M. MIZUNO;
Dept. of Physiol. and Pathophysiology, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Mice are the most commonly used experimental animal in biological research and are typically group-housed. Although group housing is important for the welfare of social animals, it can increase within-cage aggression, one of the most serious welfare as well as scientific concerns in animal experiment. Environmental enrichment (EE) is an animal housing technique that aims to improve the welfare of the animal by providing complex sensory, motor and social stimulations that facilitate the expression of species-typical behaviors. EE is associated with improved cognitive function that is linked to increased neurogenesis and enhanced expression of brain-derived neurotrophic factor (BDNF). BDNF is a major neurotrophin in the central nervous system and participates in the regulation of aggression. It is encoded by multiple splice variants that exhibit brain-region specific expression and have distinct functions. It has been shown that mice housed under enriched conditions are less aggressive compared to mice housed under standard laboratory conditions, but the exact mechanism remains unknown. These findings led to the hypothesis that EE reduces aggressive behavior by altering the expression of *Bdnf* mRNA in a variant- and brain region-specific manner. To address this hypothesis, 3-4-week-old male C57BL/6 mice were randomly group housed (5/cage) under standard or EE conditions for 6-8 weeks. EE mice were housed in large cages supplemented with a house, running wheels, igloos, wood logs, a tube maze and nesting materials. Control mice were housed in a regular cage and were only provided with nesting materials. Aggressive interactions within each cage were evaluated by direct visual observations for 1 h 5 days a week throughout the experiment. Biting, chasing and fighting were considered as aggressive behavior. Mice were euthanized, and brain tissues were collected for gene expression analysis at the end of the experiment. The incidence of aggression was significantly reduced in EE mice (17.1%) compared to control mice (51.4%, $P < 0.005$ by chi-squared test, n = 35/group). Levels of *Bdnf* mRNA variant 1 in the prefrontal cortex (PFC) and the hypothalamus were significantly reduced in EE mice compared to control mice ($P < 0.01$ and $P < 0.05$, respectively, by Student's *t*-test, n = 8-9/group), while *Bdnf* mRNA variant 1 levels were significantly increased in the amygdala of EE mice ($P < 0.05$ by Student's *t*-test, n = 6-9/group). EE did not significantly alter levels of *Bdnf* mRNA variants 2c, 4 and 6 in the PFC and the hypothalamus. These findings support the possibility that EE diminishes intermale aggression by altering *Bdnf* mRNA expression in a variant- and brain region-specific manner.

Title: The glucagon-like peptide-1 receptor agonist, exendin-4, reduces aggressive behaviors in male mice

Authors: *J. VESTLUND, E. JERLHAG;
Dept. of Pharmacol., Inst. of Neurosci. and Physiology, The Sahlgrenska Acad. at the Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Abstract Aggression is a complex social behavior regulated by various hormones, peptides and neurotransmitters. Available pharmacotherapies for aggressive behaviors have moderate efficacy and substantial side effects. Thus, new pharmacological targets to treat these pathologies are warranted. Recent advances showed that the orexigenic gut-brain peptide ghrelin enhances various social behaviors, including aggressive behaviors in male mice. Glucagon-like peptide-1 (GLP-1) is another gut-brain peptide, which in contrast to ghrelin suppresses food intake. Recent studies in male mice show that a GLP-1 receptor (GLP-1R) agonist, exendin-4 (Ex4), reduces social behaviors such as sexual interaction behaviors. We therefore aimed to establish the effects of activation of the GLP-1R on aggressive behaviors in male mice, and to determine possible downstream mechanism participating in this behavioral outcome. We therefore investigated the effect of acute or repeated systemic injections of Ex4 on aggressive behaviors in male mice exposed to the resident intruder paradigm. We further evaluated the levels of monoamines in brain regions as well as corticosterone and testosterone levels in plasma in these mice. Compared to vehicle repeated, but not acute, Ex4 injections reduced attack behaviors in male mice. The mice treated repeatedly with Ex4 enhanced their prosocial behaviors, whereas Ex4 displayed no effect on non-social behaviors. Further, the serotonin and noradrenaline levels in nucleus accumbens were lower in Ex4 treated mice from the resident intruder test compared to those treated with vehicle. However, there were no differences in the plasma levels of testosterone or corticosterone between the treatment groups. Collectively, this indicates that the effect of clinically available GLP-1R agonists on aggression-related pathologies should be evaluated in a clinical population.

Title: Spatially-distinct neurons in the posterior amygdala generate male sexual and aggressive behaviors.

Authors: *T. YAMAGUCHI[1], D. LIN[2];
[1]New York Univ., New York, NY; [2]Neurosci. Inst., New York Univ. Sch. of Med., New York, NY

Abstract: The main pillars of social behaviors involve (1) mating, where males identify sexually-receptive females through olfactory and auditory communication, and (2) aggression, where males fight conspecific male competitors in territory guarding. Decades of study have shown that the hypothalamus governs social behaviors. The medial preoptic nucleus (MPN) works as the main integrative structure for male sexual behaviors, while the ventrolateral part of ventromedial hypothalamus (VMHvl) controls inter-male aggression. However, it remains ambiguous what area directs excitatory control of the hypothalamic activity and generates the initiation signal for social behaviors. The limbic area, including the amygdala, is a strong candidate area for relaying external information into the hypothalamus and controlling its activity. Through neural tracing, neural activity recording and functional manipulations, we found that PA sends "top-down" regulation signals into hypothalamic areas and determines the timing of behavior initiation. Combining retrograde neural tracer and genetic tools, we found direct projections from PA estrogen receptor alpha (Esr1) expressing cells, into MPN and VMHvl. Importantly, PA^{Esr1+} projection cells into MPN and VMHvl are spatially distinct populations and provide excitatory inputs. Using pathway-specific fiber photometry, we found that $PA^{Esr1+MPN}$ projectors were strongly activated during female investigation and sexual behaviors, while $PA^{Esr1+VMHvl}$ cells showed dominant responses during male investigation and inter-male aggression. Pharmacogenetic inhibition of $PA^{Esr1+MPN}$ cells abolished sexual behaviors while inactivation of $PA^{Esr1+VMHvl}$ cells decreased inter-male aggression. Pharmacogenetic activation of $PA^{Esr1+MPN}$ and $PA^{Esr1+VMHvl}$ neurons promoted sexual and aggressive behaviors, respectively. On a conceptual level, this study provides a wiring diagram for understanding how social behaviors are initiated at the circuit level.

Title: Regulation of value-based decision making by estrogenic hormones

Authors: *C. E. GOLDEN[1], A. MAH[1], L. CHEN[2], Y. LI[3], C. CONSTANTINOPLE[1];
[2]Ctr. for Neural Sci., [1]New York Univ., New York, NY; [3]Peking Univ., Beijing, China

Abstract: Individuals decide between alternatives based on their perceived subjective value. In humans, this value-based decision-making behavior varies by sex and across the menstrual cycle. However, it is not understood how endogenous sex hormones influence the neural dynamics that underlie decision-making. Estradiol, the principle estrogenic hormone that fluctuates across the reproductive cycle, is a compelling candidate because it is known to activate dopaminergic signaling in the nucleus accumbens, a key center for reward processing in the brain. We are exploring the effects of estradiol on value-based decision-making behavior in female rats as it naturally fluctuates in expression across their reproductive cycle (estrus cycle). To track the estrus cycle, we generated an automated classifier that determines estrus stage from vaginal cytology, which we have validated with enzyme-linked immunosorbent assays of estradiol expression. We have trained rats to perform a novel task wherein they must decide between waiting for an unspecified amount of time for a reward that is being offered or moving on to the next trial. The magnitude of reward being offered varies from trial to trial, and the local reward statistics vary over blocks of trials. In male rats, the decision to wait for the reward that is being offered depends on the magnitude of the rewards that they recently received (i.e., the local reward context). In female rats, the extent to which local reward context influences their willingness to wait for rewards varies across the estrus cycle. We have also found that dopaminergic signaling aligned to value-based decision-making epochs varies over the estrus cycle. A greater understanding of how sex hormones influence brain function could be revealing of the underlying etiology of neuropsychiatric disorders that present differently across the sexes in their incidence, progression, and severity.

Title: Long-term oral administration of a novel estrogen receptor beta agonist enhances memory consolidation and alleviates vasomotor symptoms in a mouse model of menopause

Authors: *A. FLEISCHER[1], J. C. SCHALK[2], E. A. WETZEL[3], A. M. HANSON[4], D. S. SEM[4], W. A. DONALDSON[3], K. M. FRICK[1];
[1]Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Dept. of Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE; [3]Dept. of Chem., Marquette Univ., Milwaukee, WI; [4]Dept. Pharmaceut. Sciences, Ctr. for Structure-Based Drug Design and Develop., Concordia Univ. Wisconsin, Mequon, WI

Abstract: Rationale: Menopause is associated with hot flashes, cognitive decline, anxiety, and depression. Estrogen-based therapies reduce these symptoms, but also increase risks of cancer and other health issues due to the activation of the alpha (ERα), but not beta (ERβ), estrogen receptor isoform. Thus, ERβ-selective therapies are promising options to mitigate negative menopausal symptoms without the complications associated with ERα activation. **Objective:** Our goal here was to determine whether long-term treatment with EGX358, a novel highly selective ERβ agonist, could reduce negative symptoms in a mouse model of menopause. **Methods:** Nine week-old female, ovariectomized C57BL/6 mice (n=10/group) were orally gavaged daily for 10 weeks with vehicle (10% DMSO), the highly potent estrogen 17β-estradiol (E_2; 0.2 mg/kg), the ERβ agonist diarylpropionitrile (DPN; 0.05 mg/kg), or EGX358 (0.5 mg/kg). Hot flash-like symptoms were first measured following 14-18 days of treatment by thermal imaging of tail skin temperature (T_{Skin}) after injection of vehicle or senktide, an NK-3 tachykinin receptor agonist that induces heat dissipation from the tail. Long-term treatment effects on hot flash-like symptoms were also determined by measuring T_{Skin} on the final day of behavioral observations, day 63 of treatment. Between days 22-29 days of treatment, anxiety-like behavior was assessed in the open field (OF) and elevated plus maze (EPM), and depression-like behavior was assessed in the tail suspension (TST) and forced swim tests (FST). Finally, between days 40-51 of treatment object recognition and spatial memory were assessed in the object recognition (OR) and object placement (OP) tasks, respectively. **Results:** E_2, DPN, and EGX358 reduced senktide-mediated increases in T_{Skin} and enhanced OP and OR memory relative to vehicle controls. Additionally, 63 days of E_2 treatment reduced T_{Skin} compared to vehicle. Although E_2 increased time in the center of the OF, no other treatment affected behavior in the OF, EPM, TST, or FST compared to vehicle. **Conclusions:** Long-term treatment with the highly selective novel ERβ agonist EGX358 reduced hot flash-like symptoms and improved spatial and object recognition memory consolidation in ovariectomized mice. As such, ERβ activation may be a promising avenue for reducing menopause-related hot flashes and memory dysfunction.

Title: Extracellular matrix metalloproteinase-9 (MMP-9) is required for estradiol enhancement of hippocampal memory consolidation

Authors: *K. S. GROSS, C. M. LINCOLN, M. M. ANDERSON, G. E. GEIGER, K. M. FRICK;
Psychology, Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: The potent estrogen 17β-estradiol (E_2) is a powerful modulator of hippocampal plasticity and memory. Research on molecular mechanisms of hippocampal E_2 signaling has uncovered multiple intracellular pathways that contribute to these effects, but few have questioned the role that extracellular signaling processes may play in E_2-induced plasticity. The extracellular matrix (ECM) is increasingly recognized as a critical synaptic component, and ECM modifying enzymes like matrix metalloproteinase-9 (MMP-9) are required for hippocampal learning and memory. Little is established about the extent to which E_2 regulates MMP-9 in the hippocampus, and the influence this interaction may have on hippocampal memory is unknown. Therefore, we sought to determine whether E_2 increases MMP-9 activity in the hippocampus to promote memory consolidation on object placement and recognition tasks. Female C57BL/6 mice were ovariectomized and cannulated in the dorsal hippocampus (DH) and dorsal third ventricle (ICV). Immediately following object training, mice were infused with vehicle or a non-memory impairing dose of an MMP-9 inhibitor into the DH and vehicle or E_2 into the ICV. Object placement or object recognition memory was then tested 24 or 48 hours later, respectively. We found that MMP-9 inhibition blocked the memory enhancing effects of E_2, suggesting that ECM modification may be a critical factor in estrogenic regulation of memory. Continuing work is examining how E_2 treatment influences MMP-9 expression and activity in the dorsal hippocampus.

Title: Cannabis co-opts the ghrelin signaling system to direct feeding behavior.

Authors: ***J. BRUTMAN**[1], E. WHEELER[1], J. DE HOWITT[1], S. GILL[1], S. WATSON[1], S. YU[1], C. DIAZ[1], P. CHOI[1], C. MOHR[1], C.-S. WU[2], Y. SUN[2], D. ROSSI[1], J. DAVIS[1]; [1]Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA; [2]Dept. of Nutr. and Food Sci., Texas A&M Univ., College Station, TX

Abstract: Background: The legalization of cannabis in the United States derived from its medical purposes. In this context, it is well established that *cannabis sativa* exposure promotes appetite, however, the mechanisms that contribute to this response are unresolved. Ghrelin is an appetite stimulatory hormone that promotes diverse aspects of feeding behavior. This study evaluated if ghrelin signaling contributed to the appetite promoting effects of inhaled cannabis. **Methods:** We used a novel vapor delivery system to measure the appetite-stimulatory and reinforcing effects of cannabis in rodents. Specifically, adult male Long Evans rats and mice were passively exposed to a behaviorally relevant dose whole cannabis plant matter (7-10% THC, 0.5% CBD, NIDA). Commercially available ELISA assays were used to measure cannabis induced changes in the appetite promoting hormone ghrelin. In separate studies, L-cysteine and JMV2959 were used to determine if ghrelin secretion or ghrelin-1a receptor (GHSR-1a) signaling contributed to cannabis induced feeding. In addition, we used *in vivo* optical imaging to visualize calcium dynamics in arcuate nucleus (ARC) neurons and slice electrophysiology to record spontaneous inhibitory synaptic events (sIPSCs) within hunger promoting agouti-related peptide (AgRP) neurons following cannabinoid-1 receptor (CB1R) agonism. Finally, we examined cannabis induced feeding following genetic ablation of GHSR-1a within AgRP neurons (AgRP-Cre; GHSR-1a$^{f/f}$). **Results:** Vapor cannabis exposure increased meal frequency, stimulated operant responding for sucrose, and promoted gastric ghrelin secretion. Pharmacologic blockade of gastric ghrelin secretion or central GHSR-1a activity attenuated this response. *In vivo* imaging studies revealed that expectation of palatable food led to increased calcium influx in ARC neurons and that cannabis augmented this process. Mechanistic studies confirmed that activation of the CB1R reduced sIPSCs onto AgRP hunger neurons. Further, genetic ablation of GHSR-1a in AgRP neurons attenuated cannabis induced feeding. **Conclusions:** In summary, vapor cannabis exposure augments anticipatory and consummatory

aspects of feeding behavior. The appetite stimulatory effects of cannabis vapor are regulated by ghrelin and cannabinoid receptor signaling within hypothalamic neurons that promote hunger. These data highlight the ability of cannabis to co-opt endogenous biological signaling pathways that regulate energy balance to support the appetite stimulating effects of inhaled cannabis.

Title: Neuropeptide mapping of the cockroach circadian system at the single cell level

Authors: *S. NEUPERT, I. SCHIRMER, J. SCHENDZIELORZ, A. WERCKENTHIN, M. STENGL;
Univ. of Kassel, Kassel, Germany

Abstract: Transplantation studies located the circadian clock of the Madera cockroach Rhyparobia maderae to the accessory medulla (AME), ventromedially to the medulla of the brain´s optic lobes. The AME receives photic entrainment from compound eye photoreceptors and orchestrates circadian rhythms in physiology and behavior synchronized to the external 24h light-dark cycles. About 240 neurons innervate the AME which are abundant of partly co-localized neuropeptides. The structural diversity and spatial localization of neuropeptides reflect their influence in an extensive variety of physiological processes controlled by the clock. The best studied neuropeptide of the insect circadian clock is pigment-dispersing factor (PDF) that orchestrates rest-activity cycles. However, the identity and functions of most other neuropeptides of the circadian clock are not known. As prerequisite to a functional analysis of neuropeptides in the cockroach circadian clockwork we started to identify the neuropeptidome of the AME of the Madera cockroach. We performed a transcriptome analysis of the central nervous system to assemble and identify 37 neuropeptide and protein hormone precursors of R. maderae brains. Peptidomics yielded a complete coverage for many of the neuropeptide propeptides. In total, we were able to identify more than 169 mature neuropeptides in the cockroach brain, using Q Exactive Orbitrap and MALDI-TOF mass spectrometry. By applying direct tissue profiling, we identified more than 140 mature neuropeptides in the AME. In a next step we started to identify

neuropeptides from individual neurons of the AME. Employing immunocytochemistry and backfilling with subsequent single cell analysis by mass spectrometry (SCMS) we obtained precise evidence of co-localization of neuropeptides from different neuropeptide genes at the single cell level. The results of our study provide novel and necessary input for subsequent experiments revealing the functional role of neuropeptides in the insect´s circadian clock network.

Title: Pubertal immune challenge suppresses the hypothalamic-pituitary-gonadal axis in male and female mice

Authors: *K. B. SMITH[1], E. MURRAY[1], R. CHANDRASEGARAM[2], J. LIANG[1], J.-F. MALLET[1], C. MATAR[1], J. D. BLAUSTEIN[3], N. ISMAIL[1];
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Cardiff Univ., Cardiff, United Kingdom; [3]Univ. of Massachusetts, Amherst, MA

Abstract: Kisspeptin is a neuropeptide responsible for propagating the hypothalamic-pituitary-gonadal (HPG) axis and initiating puberty. Pubertal exposure to an immune challenge causes enduring sexual behavior dysfunction in males and females, but the mechanism underlying this stress-induced sexual dysfunction remains unknown. Previous findings show that stress exposure can downregulate the HPG axis in adult females. However, it is unclear whether stress induced HPG axis suppression is limited to adult females or also extends to males and to pubertal animal models. The current study was designed to investigate the sex-specific consequences of a pubertal immune challenge on specific components of the HPG axis. Forty 6-week old pubertal male and female mice were treated with saline or with lipopolysaccharide (LPS), a bacterial endotoxin. Expression of hypothalamic kisspeptin ligand (Kiss1) and kisspeptin receptor as well as serum concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), and growth hormone were examined. Pubertal LPS-treatment decreased hypothalamic Kiss1 expression in both males and females, however, only males showed decreases in circulating LH and FSH. These results show that pubertal immune challenge suppresses the HPG axis by inhibiting Kiss1 production and decreasing serum gonadotropin concentrations in pubertal males, but points to a different mechanism in pubertal females.

Title: Zearalenone modifies the function of GnRH neurons in prepubertal female mice

Authors: *V. CSILLAG[1,2], F. BÁLINT[2], Z. LIPOSITS[2,4], I. FARKAS[3];
[1]Tamas Roska Doctoral Sch. of Sci. and Technol., Peter Pazmany Catholic Univ., Budapest, Hungary; [2]Lab. of Endocrine Neurobio., [3]Lab. of Reproductive Neurobio., Inst. of Exptl. Med., Budapest, Hungary; [4]Dept. of Neurosci., Peter Pazmany Catholic University, Fac. of Information Technol. and Bionics, Budapest, Hungary

Abstract: Reproduction is controlled by the hypothalamo-pituitary-gonadal (HPG) axis. Environmental endocrine disruptors (EEDs) can accelerate the onset of puberty and cause infertility in adults. Zearalenone (ZEA) is a potent estrogenic metabolite produced by some Fusarium and Gibberella species which can infect grains. A previous study has revealed that this mycotoxin advances puberty onset in young female rats by the premature activation of HPG axis, very likely by increasing the hypothalamic kisspeptin-GPR54 signaling to GnRH neurons (Yang et al 2016.). However, the direct effect of ZEA on GnRH neurons has not been examined yet. In order to elucidate its action in the regulation of reproduction at the level of GnRH neurons, *in vitro* electrophysiological experiments were carried out on GnRH-GFP neurons in acute brain slices from prepubertal (23-29 days) female mice. Whole-cell patch-clamp measurements demonstrated increased frequency (to 138.0±10.78% compared to the control values) of the spontaneous postsynaptic currents (sPSCs) after application of 2nM ZEA. ZEA also activates estrogen receptor beta (ERβ) in GnRH neurons and increases the frequency (to 140.6±13.02% compared to the control) of miniature postsynaptic currents (mPSCs). The ZEA-triggered increase in the frequency of mPSCs was prevented by using the nonselective ER receptor blocker, Faslodex or the specific ERβ receptor antagonist, PHTPP.The study provided clear electrophysiological evidence that ZEA is capable of increasing the frequency of both spontaneous and miniature PSCs of GnRH neurons with the involvement of ERβ in the process. Therefore, the direct targeting of GnRH neurons by this mycotoxin is conceivable.

Title: Reproductive parameters of female rats treated with Topiramate during childhood

Authors: *J. O. BILIBIO[1], L. I. BORGES[1], S. FORCATO[1], D. G. DA SILVA[1], M. P. FRANCO[2], G. S. CERAVOLO[1], D. C. GERARDIN[1];
[1]Physiological Sci. Dept., Univ. Estadual de Londrina, Londrina, Brazil; [2]Physiol. Dept., Univ. Federal de São Paulo, São Paulo, Brazil

Abstract: The Developmental Origins of Health and Disease suggest that the exposition to certain factors during critical stages of development, such as childhood and puberty, may influence features on adult individuals. Topiramate (TOP) is an antiepileptic drug approved by the Food and Drug Administration (FDA) for treatment of epilepsy during childhood, one of those critical stages. Female adult Sprague-Dawley rats treated with TOP (100 mg/kg/day) for 28 days displayed a significant reduction in the ovaries mass as well as embryos weight (Khouri, 2005). The aim of the present study was to discover if the treatment with TOP during childhood is capable of affecting the female reproductive system. Female Wistar rats (n=7-13) were treated with TOP (41 mg/kg/day) (TOP groups) or water (CTR groups) by gavage during childhood (from postnatal day (PND) 16 to PND 28) and subsequently evaluated either immediately after the end of treatment (PND 29) – Group 1, and during adult life (PND 90-110) – Group 2. The parameters analyzed on both groups were body weight, reproductive organs' weights, anogenital distance, and histomorfometric analysis of the uterus, whereas the puberty installation (day of vaginal opening and of first estrus occurrence) and estrous cycle evaluation were analyzed only on Group 2. Data were compared by analysis of covariance (ANCOVA), Student's *t* test or Mann-Whitney U. Our results show that the treatment with TOP during childhood caused an increase in the perimetrium thickness of the adult rats' uterus (CTR2: 12.45 μm (11.47 – 13.55); TOP2: 13.70 μm (11.62 – 16.15)*; $p<0.05$, Mann-Whitney U), while the young rats uterus showed no differences. The occurrence of this alteration solely on the adult rats suggests TOP may have induced epigenetic alterations which lead to changes only observed later in life. Further studies are necessary to elucidate the mechanisms behind the changes observed.

Title: Ubiquitin-dependent control of the hypothalamic-pituitary-gonadal axis constituents

Authors: *A. J. GEORGE[1], Y. C. HOFFIZ[1], C. B. WARE[1], B. DONG[2], N. FANG[2], E. HRABOVSZKY[3], A. M. MABB[1];
[1]Neurosci. Inst., [2]Chem., Georgia State Univ., Atlanta, GA; [3]Inst. of Exptl. Med., Budapest, Hungary

Abstract: Ubiquitin E3 ligases are enzymes that catalyze the ubiquitination of protein substrates, which can result in their removal. Recessive mutations in the E3 ligase *RNF216/TRIAD3* cause Gordon Holmes syndrome (GHS), with pathologies of hypogonadotropic hypogonadism, cognitive impairment, dysarthria, cerebellar ataxia, and dementia. Individuals diagnosed with GHS have dysfunction at multiple levels of the hypothalamic-pituitary-gonadal (HPG) axis. This includes deficiencies in the release of pituitary gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), with the diminished secretion of the gonadal hormones, estradiol and testosterone in males and females. The role of *RNF216/TRIAD3* in the HPG axis and its selective vulnerability in the hypothalamus, specifically gonadotropin-releasing hormone (GnRH) neurons, is unknown. Previously, we found that RNF216/TRIAD3 co-localizes with clathrin-coated pits at endocytic zones in neurons, a region where receptor-mediated endocytosis takes place. Here, we found that both knockdown and overexpression of the *RNF216/TRIAD3* isoform, Triad3A, in cortical neurons disrupts the trafficking of the ubiquitous transferrin receptor, suggesting RNF216/TRIAD3 may broadly control receptor trafficking. To test the role of RNF216/TRIAD3 function in regulating surface receptor expression within the HPG axis, we knocked out *Rnf216/Triad3* via CRISPR-Cas9 in a GnRH immortalized cell line (GT1-7), and measured membrane expression of key HPG axis receptors, GPR54 and GnRHR. We next used the cytosolic Ca^{2+} sensor R-GECO1 to determine if Rnf216/Triad3 KO GT1-7 cells had altered baseline activity. We found that KO cells had a reduction in both frequency and amplitude of Ca^{2+} transients that were coupled to a reduction in GnRH. To determine if these alterations led to changes within the intact HPG axis, we generated a *Rnf216/Triad3* knockout mouse. While female mice were fertile and had normal gonadal weights, they surprisingly exhibited a reduction in the proestrus phase without alterations in baseline FSH and LH levels. Male mice had dramatically reduced testicular weights, a marked reduction in fertility, and a significant increase in FSH. We further found that the density of GnRH neurons was not significantly different in male and female KO mice compared to controls; however, the morphology of these cells was altered in both male and female KO mice. Taken together, our work illuminates how disruptions in *RNF216/TRIAD3* lead to early-onset changes in the HPG axis in males and females and informs translational research for neurological disorders involving HPG axis disruption.

Title: Kisspeptin/neurokinin b/dynorphin (KNDy) neurons exhibit reduced progesterone sensitivity and dynorphin expression in a mouse model of polycystic ovarian syndrome

Authors: *A. M. MOORE, L. M. COOLEN, M. N. LEHMAN;
Biol. Sciences, Brain Hlth. Res. Inst., Kent State Univ., Kent, OH

Abstract: Polycystic ovarian syndrome (PCOS) is the most common cause of infertility in women of reproductive age worldwide. PCOS patients exhibit an increase in luteinizing hormone (LH) pulse frequency due to impaired central steroid hormone feedback to gonadotropin-releasing hormone (GnRH) neurons, the final output cell in a larger neuronal network controlling fertility. Neurons in the arcuate nucleus (ARC) that co-express kisspeptin, neurokinin B and dynorphin, known as KNDy cells, are postulated to mediate steroid hormone feedback and are strongly implicated as the GnRH/LH pulse generator. We sought to test the hypothesis that reduced steroid hormone sensitivity in KNDy cells may lead to impaired negative feedback in PCOS. To achieve this, we used a mouse model of PCOS generated using prenatal androgen (PNA) treatment that exhibits the reproductive and neuroendocrine symptoms of the syndrome. RNAscope Hiplex (ACD) fluorescent *in situ* hybridization was performed on coronal slide-mounted brain sections from PNA female (n=6) and prenatal vehicle-treated (PNV) male (n=5) and female (n=4) adult mice to simultaneously visualize and quantify gene expression of receptors for androgens, estrogen and progesterone (AR, ESR1, PGR), KNDy neuropeptides (KISS1, TAC2, PDYN), receptors for neurokinin B and dynorphin (TAC3R, OPRK1) and markers of the major neurotransmitters glutamate (SLC17A6, vGluT2) and GABA (SLC32A1, vGaT). RNA transcripts and DAPI labeling of cell nuclei was imaged using confocal microscopy and the average number of RNA transcripts for each gene within cells containing KISS1 (representative of KNDy cells) or VGaT were automatically quantified using Cellprofiler software. Compared to PNV female mice, the number of AR RNA transcripts in KISS1 and VGaT cells were elevated in PNA mice ($p<0.05$) to levels comparable with PNV males, indicating increased testosterone action at these cells. Conversely, in the same KISS1 and VGaT cells, the number of PR transcripts were reduced in PNA female mice compared to PNV females ($p<0.05$), consistent with reduced progesterone sensitivity. KISS1 cells in PNA mice with changes in steroid hormone sensitivity additionally exhibited a reduction in the number of DYN transcripts and a conversely elevated number of OPRK1 transcripts compared to male ($p<0.05$)

and female ($p<0.05$) controls. These data suggest that high testosterone levels in PCOS patients disrupt central progesterone feedback at ARC GABA and KNDY cells and suggest a mechanism by which testosterone reduces progesterone inhibition of dynorphin in KNDy neurons, leading to an increase in GnRH neuron activity and high LH pulse frequency in PCOS.

Title: Neural correlates of mating system diversity: Oxytocin and vasopressin receptor distributions in monogamous and nonmonogamous Eulemur

Authors: *A. SHARMA[1], N. M. GREBE[1], S. M. FREEMAN[2], M. C. PALUMBO[3], H. B. PATISAUL[4], K. L. BALES[5], C. M. DREA[1];

Abstract: Contemporary theory on the role of oxytocin and vasopressin in mammalian social bonds has been shaped by seminal vole (*Microtus)* research that revealed interspecific variation in neuroendocrine circuitry by mating system. This paradigm has since been extended to explain social bondedness in humans. Nevertheless, there exist substantial challenges to the interpretation and translation of findings in rodents to humans and other mammalian groups. Research on strepsirrhine primates is particularly well-suited to fill this gap, as the *Eulemur* genus contains both socially monogamous (MO) and non-monogamous (NM) species, making it the sole primate analog to voles. This clade thus offers a rare opportunity for comparative nonapeptide research that holds increased evolutionary relevance to humans. Relying on natural mortality in these critically endangered species, we performed oxytocin and arginine vasopressin 1a receptor (OXTR; AVPR1a) autoradiography using competitive binding on 12 *Eulemur* brains (4 MO; 8 NM) from seven closely related species. We first characterized OXTR and AVPR1a distributions in this genus, and then examined variation in receptor distribution as a function of mating system. We found some OXTR and AVPR1a binding patterns reminiscent of olfactory-

guided rodents and others congruent with more visually oriented haplorhines, consistent with strepsirrhines occupying an ‘intermediary’ evolutionary niche between these two groups. As there were no significant sex differences in binding profiles, we combined males and females in each species. Although we found differential receptor expression by mating system in a few nuclei, most areas previously identified as part of a "pair-bonding circuit" in monogamous voles and primates were not similarly distinguished in monogamous *Eulemur*. While illuminating neurobiological bases underlying species diversity, mapping nonapeptide receptors in these nontraditional primates questions existing assumptions about conserved neuroendocrine function and informs proposed evolutionary explanations about the biological bases of monogamy.

Title: Ghrelin receptor signalling is not required for glucocorticoid-induced obesity in female mice.

Authors: ***Z. SILVER**[1], S. ABBOTT-TATE[2], L. HYLAND[1], F. SHERRATT[1], B. WOODSIDE[1], A. ABIZAID[1];
[1]Neurosci., [2]Hlth. Sci., Carleton Univ., Ottawa, ON, Canada

Abstract: Chronically elevated glucocorticoids (GC) increase food intake, weight gain and adiposity, which can lead to metabolic imbalance. Like GC, chronically elevated ghrelin levels also result in increased food intake, weight gain and adiposity. These data suggest that the effects of chronic GC could be mediated by ghrelin. The purpose of this study was to determine if the ghrelin receptor (GHSR) was required for the metabolic and behavioural effects of increased corticosterone (CORT). To do this, female WT and GHSR KO mice were treated with either CORT in a 1% ethanol (EtOH) solution or 1% EtOH alone in their drinking water for five weeks. Daily measures included food and water intake as well as estrous cycle testing. Behavioural testing was done after four weeks of CORT treatment to determine changes in coping behaviors due to chronic CORT. Metabolic data includes weight gain, glucose tolerance, adiposity, and various hormone levels (ghrelin, LEAP-2, leptin etc.) to establish endocrine profiles. Behaviour testing included the forced swim test, social interaction test, open field test, and sucrose preference test. Results showed that CORT treatment resulted in increased food intake, weight gain and adiposity, with no differences observed between GHSR KO and WT mice. CORT treatment also impaired glucose clearance independent of genotype. Both GHSR KO and WT CORT-treated mice experienced disruptions of the reproductive system in the form of

suppression of regular cycling. Behaviourally, CORT treatment resulted in increased locomotion and time in the perimeter of the open field arena in WT CORT-treated mice, and increased time in the center of the arena in GHSR KO-CORT treated mice, potentially reflecting changes in coping behaviors in GHSR KO CORT-treated mice compared to WT CORT-treated mice. CORT treatment also resulted in decreased sucrose preference independent of genotype. Overall, these data demonstrate that the metabolic effects of CORT are largely independent of GHSR signalling in female mice.

Title: Effects of ovariectomy on body weight, metabolic hormones and neuroreceptors in rats

Authors: *K. BURCH, K. CURTIS, K. MCCRACKEN, R. DAVIS, D. BUCK;
Oklahoma State University-Center For Hlth. Scienc, Tulsa, OK

Abstract: Obesity effects over 40% of American adults, and particularly concerning is the greater incidence of obesity in women, especially after menopause. This specific area of health issues has not been greatly studied. We model post-menopausal weight gain in ovariectomized (OVX) rats and recently reported that post-OVX weight gain is accompanied by changes in neuroimmune signaling in central nervous system (CNS) regions that respond to metabolic hormones including leptin, ghrelin and insulin. In this study, 90 day old female Sprague-Dawley rats were divided into groups of OVX (n=24) or sham OVX (aka control, n=24). Rats were housed individually in plexiglass cages on a 12:12 dark:light cycle and given ad libitum access to standard laboratory chow and water throughout the experiment. After acclimation to the colony room, rats were bilaterally OVX or sham OVX and body weights were recorded daily for 5 days postoperatively. One subgroup of rats (OVX: n=8, sham: n=8), was sacrificed on day 5. Remaining subgroups of rats were weighed weekly thereafter and sacrificed at 33 (OVX: n=8, sham: n=8) or 54 (OVX: n=8, sham: n=8) days post-operatively. At termination, body weight was determined and brains and plasma were collected. Brain punches were obtained from the arcuate nucleus (ARC), dorsal vagal complex (DVC), and paraventricular nucleus (PVN) and then homogenized. ELISA kits were used to measure leptin, ghrelin and insulin receptor expression in these brain regions, in addition to circulating insulin, ghrelin and leptin levels. Body weight increased rapidly and progressively in OVX rats but not in sham OVX rats. Plasma leptin levels increased over time, especially in OVX rats, while plasma ghrelin and insulin levels

were increased more transiently. Insulin, ghrelin and leptin receptor levels in the ARC did not differ between OVX and sham OVX rats after an initial increase in leptin receptor levels. In the DVC, insulin receptor levels decreased over time in OVX rats and were significantly less than those in sham OVX rats by day 54; however, neither ghrelin or leptin receptor levels differed. In the PVN, all receptor levels were reduced in OVX rats by day 54, with the leptin receptor levels also less at day 33. These results do not demonstrate a clear relationship among body weight gain, circulating hormone levels, and hormone receptors in OVX rats. Nonetheless, an inverse relationship between circulating leptin and leptin receptor levels that occur with body weight gain in OVX rats was evident in the PVN. Moreover, the PVN showed the largest change in hormone receptor levels, suggesting it is an area of interest to understand hormone effects in the CNS and their role in body weight gain.

Title: Evidence for hippocampal contributions to neuroendocrine regulation

Authors: ***A. B. COLE**[1], S. M. THOMPSON[2];
[1]Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: The neuroendocrine stress response broadly and rapidly alters a number of physiologic processes in order to respond to an acute threat. Because of the powerful and wide-ranging effects of glucocorticoids, the hypothalamic-pituitary-adrenal (HPA) axis exerts strict control over glucocorticoid production to avoid the deleterious effects seen when levels become either too high, too low, or follow an abnormal time course. Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis is one of the most consistent biological findings in patients with major depression. The hippocampus has long been implicated as a critical regulator of the HPA axis, although the mechanisms and circuits are not known. The primary neuronal effector cells for the production of glucocorticoids are corticotropin-releasing factor positive (CRF+) neurons in the paraventricular nucleus of the hypothalamus (PVN). Lesions of the hippocampus or its projections to the PVN have been shown to result in an increase in HPA axis activation. The major output of the hippocampus is excitatory, whereas the physiology seems to indicate an inhibitory contribution to PVN function. One possible explanation is that intermediary brain regions are important in this regulation by switching the hippocampal output from excitatory to

inhibitory. The GABAergic inhibitory cells of the bed nucleus of the stria terminalis (BNST) are a likely candidate. In order to test this hypothesis, we used a combination of electrophysiology and optogenetics to isolate hippocampal contributions to PVN regulation. Cre-dependent expression of fluorophores allowed for cell-type specific patch-clamp recordings of GAD2+ inhibitory neurons in the BNST and CRF+ neurons in the PVN. Anatomical tracing in male and female mouse brain indicates that there are substantial axonal terminals projecting from the ventral hippocampus and subiculum to both the BNST and PVN. Optical stimulation of these hippocampal terminals resulted in both excitatory and inhibitory evoked responses in these two brain regions. In GAD2+ BNST cells, the vast majority ofa majority of cells (7/8) displayed monosynaptic excitation, followed by as well as delayed inhibition. In CRF+ PVN cells, although monosynaptic excitation was occasionally observed, cells displaying only inhibitory responses predominated (4/5). These results are consistent with a model in which hippocampal output drives disynaptic inhibition of CRF+ PVN cells via GABAergic cells in the BNST, thereby providing a circuit for hippocampal dependent negative feedback of the HPA axis. Future work will test the neuroendocrine and behavioral consequences of modulating these synapses *in vivo*.

Title: Alcoholism: cortisol and the course of neuroendocrine healing

Authors: *T. BERESFORD[1], P. J. RONAN[2];
[1]DEPT OF VETERANS AFFAIRS, AURORA, CO; [2]Psychiatry and Basic Biomed. Sci., VA Research/USD Sanford Sch. of Med., Sioux Falls, SD

Abstract: Background: A lifetime alcohol dependence (AD) diagnosis applies to 20%-50% of patients in public and university general hospitals. Subtle early brain healing processes may involve changes in the neuro-endocrine stress system that can affect both cognition and decisions about treatment options. Method: To test whether neuro-endocrine healing occurs in frequent, heavy drinkers, this study 1) compared AD test subjects (n=16) with light drinking control subjects (n=15) at baseline and then 2) assessed the test subjects prospectively at three, and six months of supervised, disulfiram assisted abstinence. The subjects provided diurnal salivary cortisol samples on waking, waking +30 minutes, noon and 4 PM for each of the follow-up time points. Significance required alpha = 0.05. Results: Baseline test group cortisol means were significantly higher than control levels ($p < 0.04$ to <0.003) with a notable absence of the morning cortisol response. The Three Month average diurnal curve suggested an exaggerated

morning response ($p< 0.038$), while the Six Month average curve approximated the baseline control values ($p>0.05$). Conclusions: These data indicate that neuro-endocrine healing may take up to six months to reach its full potential. This suggests the possibility that 1) neuro-endocrine effects may impair complex cognition and decision making early in the healing course and 2) neuro-endocrine healing late in the course may account for the often unrealistic sense of well-being that occasions alcohol relapse. Focused treatment may serve to expedite healing and add to the likelihood of sustained remission.

Title: Dna methylation of estrogen receptor alpha and its role in specifying sex differences in cell phenotype within the arcuate nucleus

Authors: L. R. CORTES[1], C. D. CISTERNAS[2], D. MASON[1], I. N. K. V. CABAHUG[1], A. CASTILLO-RUIZ[1], N. G. FORGER[1];
[1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Inst. de Investigacion Medica Mercedes y Martin Ferreyra, Cordoba, Argentina

Abstract: Most mammals display sex-specific behaviors, such as mating, aggression and parental care, that are controlled by sexually dimorphic groups of neurons defined by their gene expression (*i.e.*, neurochemical phenotype). Within the arcuate nucleus of the hypothalamus (ARC), for example, females have more neurons that express estrogen receptor alpha (ERα;) and kisspeptin than do males. Little is known regarding how these sex differences develop, but our research suggests that epigenetic mechanisms play a role. We previously showed that expression of the epigenetic enzymes that place and remove DNA methyl marks is highest during the first week of life in the hypothalamus, and differs by sex (Cisternas et al., 2020). In this study, we manipulated DNA methylation or de-methylation during the perinatal critical period for sexual differentiation and examined its effects on sex differences in the ARC several weeks later. In the first study, a global DNA methylation inhibitor (zebularine) or 10% DMSO in saline (vehicle) was injected into the ventricles of male and female pups (n = 9-13 per group) on the first two days of life; animals were sacrificed at weaning and ERα; and kisspeptin labeling examined. Neonatal zebularine treatment abolished the sex difference in ERα; in the ARC by decreasing labeling in females to male-like levels. Kisspeptin labeling was also reduced in females after zebularine treatment, but a sex difference remained. To test the role of de-methylation in specification of ERα; cell type, we used intracerebroventricular injections of targeting or non-

targeting siRNA to knock-down expression of *Tet2* and *Tet3* in neonates (n = 6-9 per group). At weaning, ERα; labeling in the ARC of males was feminized (i.e., increased) to female-like levels. Thus, both DNA methylation and demethylation early in life shape sex differences in cell type in the hypothalamus. We are currently using pyrosequencing to map DNA methylation levels in the *Esr1* promoter region in male and female mice on the day of birth (when there are no sex differences in ERα; labeling) and during the juvenile period (after sex difference have appeared). Our findings shed light on the molecular mechanism(s) that establish sex differences in neurochemical phenotype in the brain.

Title: "Four core genotypes" rats: comparing XX and XY rats with the same type of gonads to detect sex chromosome effects that cause sex differences in physiology and disease

Authors: *A. P. ARNOLD[1], X. CHEN[1], M. GRYZBOWSKI[3], L. LAZCARES[3], A. TAKIZAWA[3], L. VERGNES[2], C. B. WIESE[4], H. SKALETSKY[5], D. C. PAGE[5], K. REUE[2], M. R. DWINELL[3], A. M. GEURTS[3];
[1]Integrative Biol. & Physiol., [2]Human Genet., Univ. of California Los Angeles, Los Angeles, CA; [3]Physiol., Med. Col. of Wisconsin, Milwaukee, WI; [4]Human Genet., UCLA, Los Angeles, CA; [5]Howard Hughes Med. Inst., Whitehead Inst., Cambridge, MA

Abstract: The mouse Four Core Genotypes (FCG) model has successfully allowed comparison of XX and XY mice with the same type of gonads, to determine if sex differences in mouse traits are caused by cell-autonomous effects of X and Y genes ("sex chromosome effects", SCEs). For example, among 30 brain regions shown by MRI to have different volumes in FCG mice, almost 45% showed differences caused SCEs (XX vs. XY), whereas others showed differences caused by gonadal hormones (Corre et al., 2016, PMID 25445841). We sought to produce an FCG-like model in rats, because many sex differences are studied in rat brain and behavior (and other traits), but measuring SCEs has not been possible in rats. A major issue is that rats have 10 or more *Sry* genes, with unknown functions beyond testis determination. We knocked out the testis-determining function on the Y chromosome using CRISPR, to produce XY^{Δ} gonadal female rats that breed easily, producing and XY^{Δ} and XX rats, both with functional ovaries, in the same litters. These rats are compared to measure the differential effects of XX vs. XY sex

chromosomes (SCEs) in rats with ovaries. Secondly, we integrated a BAC transgene (*Sry*-tg) encoding *Sry4A*, *Sry3C*, and *Sry1*, onto an autosome to cause testis development in XX rats lacking any other Y genes, showing for the first time that these 3 *Sry* genes are sufficient as a group to cause testis differentiation. XY(*Sry*-tg+) males, mated to WT XX females, produce XX(*Sry*-tg+) and XY(*Sry*-tg+) rats with testes, allowing comparison of XX and XY rats with testes. XX(*Sry*-tg+) rats have testes lacking sperm, as expected from studies in other mammals. XX and XY rats have similar anogenital distance in the first postnatal week if they have the same type of gonad, suggesting XX and XY levels of testosterone prenatally are comparable within each gonadal sex. Body weight at 7 weeks was higher in rats with testes than ovaries, as previously reported, but there was also greater body weight in XY than XX rats, an SCE. Adult XX and XY rats differed in fat storage in gonadal fat pads, but fat accumulation in subcutaneous fat pads was different in rats with ovaries vs. testes. Thus, we have created a novel rat model that allows easy breeding of XX and XY rats with the same type of gonads, which can be compared to investigate SCEs that cause sex differences in any rat phenotype.

Abstract: Chronic stress is an influential risk factor for major depressive disorder (MDD) and chronic-stress based animal models have established that repeated stress exposure results in depressive-like behaviors. Corticolimbic brain regions such as the anterior cingulate cortex

(ACC), amygdala (AMY), nucleus accumbens (NAc) and hippocampus (HPC) have identified behavioral, cellular and molecular deficits following chronic stress exposure. In this study, magnetic resonance imaging (MRI) was used to assess brain region specific structural alterations associated with mice exposed to 2 and 5 weeks of chronic restraint stress (CRS). These structural changes were linked to behavioral and synaptic alterations. Brains were then scanned using ex-vivo MRI and synaptic changes in key brain regions showing volumetric changes were assessed using immunohistochemistry and puncta analysis for PSD95 (postsynaptic density protein 95) and VGLUT1 (vesicular glutamate transporter 1). We confirmed that CRS mice display anhedonia- and anxiety-like behaviors. Macrostructural changes in total brain volume showed that CRS mice exhibited reduced brain volume proportional to changes in depressive-like behavior ($r= -0.490$; $p=0.002$). A region-specific *a priori* analysis focusing on structural changes in key corticolimbic brain regions, identified a significant decrease in volume of the ACC in mice exposed to 2 and 5 weeks of CRS ($p<0.05$). This decrease in volume negatively correlated with depressive-like behavior ($r=-0.50$; $p=0.002$). Although no structural changes of the AMY, NAc and HPC were identified as a result of CRS, there was a significant negative correlation between volume of the AMY, and NAc with depressive-like behavior. Structural covariance network (SCN) analysis identified a progressive decrease in degree of the ACC and increase in the AMY following 2 and 5 weeks of CRS exposure. Microstructural changes in synaptic puncta density of PSD95 and VGLUT1 was not significantly altered in the ACC following CRS. However, ACC volume positively correlated with PSD95 puncta density ($r=0.35$, $p<0.05$), and negatively correlated with depressive-like behavior ($r=-0.36$, $p<0.05$). Analysis of the AMY identified significant increases in VGLUT1 puncta density that significantly correlated with depressive-like behavior ($r=0.404$, $p<0.05$) but not amygdala volume. Our results demonstrate that chronic stress effects on ACC volume and synaptic density are linked to the expression of depressive-like deficits. Our findings highlight key structural and morphological alterations in the ACC relevant to stress-related illness including mood and anxiety disorders.

Abstract: There is growing evidence that suggests astroglia anomalies play a key role in the pathogenesis of mood disorders including major depressive disorder (MDD). Studies consistently report reduction of astroglia density and astroglial marker expression in the prefrontal cortex (PFC) of patients with MDD. Similar reductions have also been reported in mouse model of chronic stress. In rodents these reductions are also associated with alterations of neuronal morphology and atrophy. However, it is yet to be confirmed if chronic stress exposure also alters astroglia morphology and whether this is linked to the behavioral deficits associated with chronic stress. We used mice expressing GFP (green fluorescent protein) expressing mice under the GFAP (glial fibrillary acid protein) promotor were subjected to 7, 21 or 35 days of chronic restraint stress (CRS). Behavioral deficits induced by CRS were measured (coat state assessment, sucrose intake and PhenoTyper tests) at each time point and summarized as a Z-emotionality score. We used Sholl analysis to investigate changes PFC GFP- or GFAP-positive cells morphology following CRS. Specifically, we adapted the standard Sholl analysis to obtain a more comprehensive quantification of astrocyte complexity using a complexity index (CI). We confirmed that chronic stress increases in anxiety-like behavior at 7, 21 and 35 days of CRS and anhedonia-like behavior at 35 days. While standard Sholl analysis was not able to detect effects of CRS, the adapted analysis revealed a significant reduction in intersection number for distal radius steps following 21 and 35 days of CRS in both GFAP+ and GFP+ cells. GFP+ cells also showed an increase in proximal processes associated with stress. When considering overall morphology using the CI, we found that GFP+ cell morphology complexity was significantly reduced following 21 and 35 days of CRS. This CI of PFC GFP-cells significantly negatively correlated with anxiety-like ($r=-0.503$, $p<0.01$) but not anhedonia-like behavior ($r= 0.023$, $p>0.05$). Additionally, for both GFAP+ and GFP+ cells CI were trending towards a significant negative correlation with Z-Emotionality ($r=-0.330$, $p=0.065$; $r=-0.381$, $p=0.079$). Chronic stress exposure induces a progressive atrophy of cortical astroglia cells which may contribute to maladaptive neuroplastic changes associated with stress-induced behavioral deficits and stress-related disorders.

Title: Effect of social defeat on the activity of medial amygdala subnuclei

Authors: *A. C. RITGER[1], M. K. LOH[2], N. C. FERRARA[2], J. A. ROSENKRANZ[2];
[1]Neurosci., [2]Cell. and Mol. Pharmacol., Rosalind Franklin Univ., North Chicago, IL

Abstract: Depression is among the most prevalent psychiatric disorders, and social stressors are a common factor in depression. The medial amygdala (MeA) regulates social behaviors and responses to social cues. There is evidence for reduced MeA volume and connectivity in depression, suggesting that altered MeA activity may regulate social symptoms of depression. Repeated social defeat stress induces long term changes consistent with depression and results in increased MeA immediate early gene expression. However, despite its strong connection with social behavior, the role of the MeA in depression and sensitivity to social stress is understudied. The goal of this study was to determine the effect of social defeat on MeA activity in rats. We hypothesized that repeated social defeat would increase the spontaneous firing rate of neurons in the MeA. 40 adult male Sprague Dawley rats underwent five days of social defeat with a retired breeder Long Evans rat using the resident-intruder paradigm or control procedures. Control rats were placed in a transport cage for the same amount of time. Within 10 days of social defeat or control procedures, we performed *in vivo* extracellular single-unit electrophysiology in anesthetized rats and recorded the firing rate of spontaneously active neurons in the posterodorsal (MeApd) and posteroventral (MeApv) nuclei of the MeA. There was no significant difference in overall MeA firing rate between social defeat and control groups, however we found evidence of an interaction of MeA subnucleus and social defeat on firing rate, such that socially defeated rats had a higher firing rate in the MeApd and lower firing rate in the MeApv (Control-MeApd: 1.1 ± 0.4/16 neurons, Stress-MeApd 2.2 ± 0.5/24 neurons, Control-MeApv 1.2 ± 0.5/17 neurons, Stress-MeApv 0.7 ± 0.2/14 neurons, data expressed as mean ± SEM). There was also a trend towards a positive association of the number of times the rat was attacked per day and the average firing rate of the MeA ($R^2 = 0.33$, n = 8 rats), suggesting a dose-dependent effect of the intensity of the stress on MeA firing. These results may indicate that the MeA is sensitive to prolonged social stressors and that social defeat may differentially affect the activity of MeApd and MeApv subnuclei.

Title: Impact of stress and antidepressants on excitatory/inhibitory balance: Excitatory/inhibitory imbalance promotes stress susceptibility

Authors: *S. POTHULA, R.-J. LIU, A.-N. SLIBY, C. H. DUMAN, R. J. DILEONE, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Mounting evidence suggests an impaired excitatory/inhibitory (E/I) balance in major depressive disorder (MDD) with functional deficits in both glutamatergic and inhibitory transmission. Chronic psychosocial stressors are susceptibility factors for stress-induced behavioral and synaptic deficits in prefrontal cortex (PFC), a key region implicated in MDD. Further, antidepressants are known to reverse these deficits. However, the impact and underlying mechanisms of stress- and antidepressant-induced changes in glutamatergic and GABAergic systems, and whether E/I functional imbalance enhances susceptibility to stress still remains elusive. Here, we used patch clamp electrophysiology, biochemical and behavioral experiments using chronic unpredictable stress (CUS) paradigm to evaluate the functional impact of stress on glutamatergic and GABAergic transmission as well as effect of rapid antidepressants on expression of excitatory/inhibitory synaptic proteins in PFC. Our results demonstrate that CUS reduces both excitatory and inhibitory spontaneous postsynaptic currents in layer V pyramidal neurons which are reversed with the rapid antidepressant rapastinel. Also, we found that rapid antidepressants like ketamine and rapastinel increase both excitatory and inhibitory synaptic proteins in PFC, suggesting that antidepressants enhance plasticity in both excitatory and inhibitory systems. Further, we generated Sst-cre$^{GluN2Bfl/fl}$ mice by conditional deletion of NMDAR-GluN2B subunits specifically from Sst-interneurons, which mimics stress-induced reduction in GABAergic input to excitatory neurons, and evaluated if these mice are susceptible to stress. Our results confirm both a reduction in inhibitory input to layer V pyramidal neurons and behavioral deficits in Sst-cre$^{GluN2Bfl/fl}$, but not WT, mice after sub-chronic stressors, demonstrating that E/I imbalance promotes susceptibility to stress.

Title: Deconstructing the neural circuitry of stress susceptibility and resiliency in mice

Authors: *K. R. ANDERSON, D. DUMITRIU;
Psychiatry, Columbia Univ., New York, NY

Abstract: Depression ranks amongst the most disruptive disorders worldwide. Treatment after diagnosis can successful but prevention before depression onset holds an even greater potential to reduce suffering and treatment cost. Depression often arises following a stressful event but not all individuals are susceptible. Even in the presence of severe stressors, some display natural stress-resilience. Therefore, to inform prevention we must first understand of what mediates stress-susceptibility and resiliency.

It is well established that stress alters neural circuitry in susceptible rodents but it is unknown if neural circuity is different in susceptible or resilient rodents prior to stress. Our research aims to uncover and understand the individual variability in circuits of affect. We hypothesize that divergent stress-responses result from exacerbation of individual variability in functional and structural connectivity that exists prior to stress-exposure.

A commonly used depression model is chronic social defeat stress (CSDS). CSDS is an etologically relevant and highly validated paradigm to study depressive-like behavior in rodents. We developed an acute social defeat stress (ASDS) model as a tool to probe for preexisting differences in stress responses. Importantly, we expanded this paradigm to include females. ASDS produces behavioral responses that are predictors of later resilience or susceptibility in stress-naïve animals. To uncover if preexisting differences exist in the brains of susceptible and resilient animals, the immediate early gene cFos was analyzed following ASDS. Preliminary data uncovered divergent connectivity between the control, susceptible, and resilient mice: the basolateral amygdala (BLA) emerges as a critical node, while the prelimbic area (PL) to BLA emerges as a critical pathway selectively active in susceptible mice.

To further determine if depressive-like behavior in individuals that are susceptible to CSDS are due to preexisting differences in connectivity that can be seen in ASDS and that this susceptibility circuit becomes uniquely strengthened during stress-activation, we are utilizing the TRAP2/Ai14 mice. The acute response as the probe for preexisting differences will be visualized by trapped dTomato in neurons activated by an initial stress and the chronic response as the probe for long-term outcome will be visualized by cFos. These experiments will establish a framework for the investigation of preexisting variability in neural circuits leading to divergent stress responses.

At Mount Sinai, New York, NY

Abstract: Depression risk has long been known to be highly influenced by both genetic and environmental factors. More recently, it has been proposed that epigenetic mechanisms may also contribute, representing a third basis of risk. Paternal stress can induce long-lasting changes in germ cells potentially propagating heritable changes across generations. To date, no studies have investigated differences in transmission patterns between stress-resilient and susceptible animals. We tested the hypothesis that transcriptional alterations in sperm during chronic social defeat stress (CSDS) transmit increased susceptibility to stress phenotypes to the next generation. We demonstrate differences in offspring from stressed fathers that depend upon paternal category (resilient vs susceptible) and offspring sex. Importantly, artificial insemination reveals that sperm mediates some of the behavioral phenotypes seen in offspring. Using RNA-sequencing we report substantial and distinct changes in the transcriptomic profiles of sperm following CSDS in susceptible vs resilient fathers, with alterations in long non-coding RNAs (lncRNAs) predominating especially in susceptibility. Using co-expression network analysis, we identify key transcriptional modules and a susceptible-specific lncRNA hub gene, Gm27211. Together, these studies advance our understanding of transgenerational epigenetic transmission of behavioral experience.

Title: Targeted neuroepigenetic editing regulates stress in a sex-specific manner

Authors: ***A. S. SASE**[1], B. A. SANTHUMAYOR[1], S. I. LOMBROSO[1], K. S. CZARNECKI[1], M. N. DITTRICH[1], E. A. HELLER[2];

Abstract: Major depressive and posttraumatic stress disorder (MDD and PTSD) share stress as an etiological contributor. The vast majority of preclinical studies to elucidate gene regulatory underpinnings of these disorders are limited to male rodents. Yet, the human epidemiological and neurobiological studies report female-specific stress responsivity. Over the past several decades, it has become clear that gene expression changes conferred by epigenetic modifications underlie mood regulation and resilience to environmental stressors. This has led to a growing interest in the sex-specific molecular and epigenetic mechanisms underlying these diseases. Cyclin-dependent kinase 5 (Cdk5) is known to regulate such behaviors and the magnitude of these behaviors. Although there is much evidence on the function of the Cdk5 protein, very little is known about the sex-specific epigenetic regulation of *Cdk5* expression in stress-related disorders. Recently we discovered that targeted *Cdk5* histone acetylation is sufficient to reduce fear memory only in female, while *Cdk5* deacetylation decreased fear memory only in male mice. We hypothesized that histone modification(s) at the *Cdk5* promoter is sufficient to regulate its expression and influence sexually-dimorphic stress response in MDD and PTSD. We used chronic unpredictable mild stress (CUMS) to study stress response in mice, as it is a robust translational paradigm used successfully to elucidate molecular mechanisms of MDD and PTSD. Followed by multiple behavioral tests to measure anxiety, anhedonia, and depression-like behavior. We then analyzed *Cdk5* mRNA expression and histone modifications by chromatin immunoprecipitation at *Cdk5* promoter in male and female mice. Next, we used CRISPR mediated epigenetic editing at the *Cdk5* promoter paired with quantification of the stress response, expression of *Cdk5*, and enrichment of histone modifications at the *Cdk5* promoter. We found sex-specific stress responses to 14, 21 and 28 days of CUS. We also found that male, but not female, mice activated *Cdk5* expression in response to 14 days of CUS and that this

activation was specific to the nucleus accumbens. CRISPR mediated *Cdk5* activation was sufficient to induce stress response after 7 days in both male and female mice in the absence of stressors. This stress response persisted after 14 days of CRISPR mediated *Cdk5* activation. In conclusion, our work provides a model of stress evoked sex-specific chromatin remodeling at the C*dk5* promoter and reveals *Cdk5* transcriptional regulation's causal relevance to the stress response.

Title: Blood microRNAs as a biomarker for stress susceptibility or resiliency and treatment response in major depressive disorder

Authors: *Y. Y. VAN DER ZEE[1,2], O. ISSLER[1], C. K. LARDNER[1], D. M. WALKER[1], A. TORRES-BERRÍO[1], A. RAMAKRISHNAN[1], E. M. PARISE[1], A. M. CUNNINGHAM[1], B. RUTTEN[2], J. W. MURROUGH[1], E. J. NESTLER[1];
[1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Maastricht Univ., Maastricht, Netherlands

Abstract: Major depressive disorder (MDD) is an episodic form of mental illness that is characterized by mood disturbances, anhedonia, and alterations in cognitive function. There is an urgent need for objective biomarkers for diagnosing depression, assigning treatment, and assessment of treatment response. MicroRNAs (miRNAs) are small noncoding RNA molecules, which can be detected in body fluids and have emerged as potential biomarkers of disease conditions, including depression. These molecules act as potent epigenetic post-transcriptional regulators of gene expression. Interestingly, miRNAs can be detected in the circulation and evidence suggests correlation between specific circulating miRNAs levels and several disease states. The present study explored the potential use of miRNAs as biomarkers for MDD and for prediction and assessment of treatment response. We profiled the expression levels of approximately 600 circulating blood miRNAs from mice that was collected before and after exposure to chronic social defeat stress (CSDS), as well as after either repeated imipramine or single-dose ketamine treatment. We observed robust differences in blood miRNA signatures between resilient and susceptible mice after an incubation period but not immediately after exposure to stress. Furthermore, treatment with ketamine, but not imipramine, re-established

baseline miRNA expression levels in mice that responded to the drug, but not in non-responders. Analysis of candidate miRNAs in human blood samples validated a subset identified in mice as candidate biomarkers to aid depression diagnosis and predict ketamine treatment response. Lastly, we demonstrate that systemic manipulation of one of these validated miRNA targets is sufficient to reduce the depression-related phenotype in susceptible mice after stress, without an appreciable effect in resilient or control mice. Taken together, this study enhances our understanding of epigenetic changes in response to stress and identifies candidate miRNAs that warrant further investigation as biomarkers for depression treatment response.

Title: 5ht2a receptors are not required for the anti-anhedonic and electrophysiological actions of psilocybin in chronically stressed mice: implications for antidepressant treatment

Authors: N. HESSELGRAVE, T. TROPPOLI, A. B. WULFF, A. COLE, ***S. M. THOMPSON**;
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Major depression is a devastating psychiatric illness affecting millions of individuals worldwide. Current first-line pharmacologic treatments, the selective serotonin reuptake inhibitors, are only about 60% effective and take 4-6 weeks before clinical effects are reported. Fast-acting and more effective treatments are sorely needed. Recent studies have shown that psilocybin has rapid and enduring antidepressant effects in human depression. It is believed that the serotonin 2A (5HT-2A) receptor is required for this antidepressant action because they are known to mediate the mind-altering effects of psilocybin. However, the mechanism of action has not been tested. We tested the hypothesis that psilocybin has rapid-acting antidepressant effects in a stress-based mouse model of anhedonia and tested the role of 5HT-2ARs pharmacologically. Chronic multimodal stress in male mice caused anhedonic responses in the sucrose preference and female urine sniff tests. Anhedonic mice were pretreated with saline or ketanserin, a 5HT2A/C antagonist, 60 minutes prior to receiving psilocybin or saline (4 groups, 2 cohorts). Hedonic behavior was reassessed 24-48 hours after treatment. Preferences for sucrose and female urine recovered to prestress values in psilocybin treated mice, regardless of pretreatment, but not in vehicle controls. Additionally, electrophysiological measurements of the stress-

sensitive hippocampal TA-CA1 synapse after the final hedonic assessment revealed that psilocybin-treated mice had higher AMPA:NMDA ratio, indicative of greater synaptic strength, whether pretreated with ketanserin or saline. We ensured the efficacy of ketanserin by measuring head-twitches and psilocybin-induced decrease in hippocampal low-frequency oscillations, both of which were inhibited by ketanserin pretreatment. We have demonstrated that psilocybin has rapid-acting antidepressant-like effects in a stress-based mouse model of anhedonia, facilitating study of psilocybin's mechanism of antidepressant action. We conclude that the anti-anhedonic effects of psilocybin are independent of the 5HT-2A receptors, suggesting that altered perception may not be required for psilocybin's antidepressant effects. We further suggest that a 5-HT2AR-independent restoration of synaptic strength in cortico-mesolimbic reward circuits may contribute to its antidepressant action. The possibility of combining psychedelic compounds and a 5-HT2AR antagonist offers a potential means to increase their acceptance and clinical utility, although human studies are required.

Title: Implicating the Hippocampal Glycome in the Regulation of Emotional Behavior

Authors: *A. M. O'CONNOR[1], L. A. DOKAS[1], T. PARDO-GARCIA[2], E. K. HEBDA-BAUER[1], P. MARAS[1], K. E. PRATER[3], M. H. HAGENAUER[1], S. J. WATSON, Jr.[1], H. AKIL[1];
[1]MBNI, [2]Univ. of Michigan, Ann Arbor, MI; [3]Neurol., Univ. of Washington, Kirkland, WA

Abstract: The Heparan Sulfate Proteoglycan (HSPG) family is a major component of the glycome and key players in the brain extracellular matrix, mediating neuronal migration, synaptic maturation and the activity of multiple growth factors and morphogens. However, their roles in temperament and emotional reactivity remains unexplored. In this study we use a genetic rat model of temperamental tendencies to address the role of the glycome in emotionality. The genetically bred High Responder (bHR) and Low Responder (bLR) rat lines are models for externalizing and internalizing mood disorders, and provide an insight into how the environment

and genetic predisposition for emotionality can intersect. Recent meta-analysis showed that expression of HSPG genes differs between bHR and bLR hippocampus. In situ hybridization was used to assess the anatomical specificity of this expression difference for two HSPGs, Syndecan-4 (Sdc4) and Glypican-1 (Gpc1), and whether P1 FGF2, adolescent EE (P35-P60) and/or social defeat stress (P60-P64) impacted their expression. Bilateral heparinase-1,3 administered to the hippocampus of adult rats (P75) determined whether neural HSPGs directly influence behaviour, and cell culture was used to directly investigate how heparinase-1,3 impacts cellular signalling. All animals used in these studies were male, to match the social defeat stress animals.Endogenous Gpc1 and Sdc4 are differentially expressed in the hippocampus and NAcc of animals with genetic differences in emotionality. These HSPGs also respond differentially to environmental manipulations, suggesting that they may play a role in affective behaviors. Gpc1 is responsive to P1 FGF2, adolescent EE and social defeat stress while Sdc4 is responsive only to P1 FGF2, suggesting that the brain glycome should not be considered as a single, uniform structure. Dissolving hippocampal HSPGs in vivo exacerbates anxiety-like behavior in the more vulnerable bLR line, and in vitro dissolution of HSPG sidechains decreases cellular responsiveness to FGF2. Whether the increased anxiety in vivo is due to the decreased effectiveness of endogenous FGF2 remains to be determined.Our work shows that breeding for temperament alters the hippocampal glycome, likely leading to differences in growth factor and morphogen signaling efficacy in this brain region. We also show that the hippocampal glycome is responsive to environmental and chemical interventions. This is the first demonstration of HSPGs both regulating emotional behaviours. The HSPG system offers a promising therapeutic target to fine-tune growth factor and morphogen signaling in mood disorders and other neurological conditions.

Title: Basolateral amygdalar inactivation promotes resilience to chronic immobilization stress through microglial modulation in the prefrontal cortex

Authors: *S. J. TRIPATHI, S. CHAKRABORTY, B. S. SHANKARANARAYANA RAO; Dept. of Neurophysiology, Natl. Inst. of Mental Hlth. and Neuro Sci. (NIMHANS), Bengaluru, India

Abstract: Stress is a risk factor in the etiology of affective disorders and cognitive deficits. Both, stress-induced affective symptoms and cognitive deficits are associated with aberrant changes in microglial structure and function. Additionally, stress differentially modulates the functioning of prefrontal cortex (PFC) and basolateral amygdala (BLA). Chronic stress causes hyperactivation of BLA leading to enhanced functioning of the hypothalamic-pituitary-adrenal (HPA) axis. Contrastingly, PFC undergoes degeneration following stress, which leads to impaired negative feedback to the HPA axis. The BLA and PFC have intense reciprocal connections, which could modulate stress outcomes. Recently, we showed that the silencing of BLA promotes resilience to stress via modulation of corticosterone levels, glucocorticoid receptors, and volumes of PFC; however, effects of BLA silencing on stress-induced alterations in affective behaviors, cognitive performance, and associated changes in cortical microglia cells are relatively unknown. Thus, we hypothesized that BLA inactivation during chronic-immobilization-stress (CIS) might preclude affective symptoms, impaired social interaction, cognitive deficits, and associated microglial anomalies in the PFC. To address this, adult male Wistar rats were subjected to BLA inactivation by infusion of lidocaine during each session of CIS for 10 consecutive days. Then, rats were subjected to assessment of depressive-, anxiety-like behaviors, social interaction, and cognitive test. Thereafter, rats were sacrificed and Iba-1^{+} microglial cells were localized using immunohistochemistry. Microglial expression was stereologically quantified, and their processes were reconstructed in prelimbic and anterior cingulate subregions of PFC. We demonstrate that inactivation of BLA precludes CIS-induced depressive- and anxiety-like behaviors, impaired social interactions, and cognitive deficits. Interestingly, BLA inactivation-associated cognitive remission to depression and anxiety was accompanied by the prevention of microgliosis in the prelimbic and anterior cingulate cortex. Further, BLA inactivation was sufficient to preclude CIS-induced hyper-ramification of microglial cells in the PFC. Our results indicate that BLA inactivation might prevent heightened immune-mediated microglial response in the PFC, which in-turn could promote resilience to chronic stress. We propose that combating BLA hyperactivity during stress might be an effective therapeutic approach to limit microglial/immune-associated dysfunctions in the PFC.

Title: Cumulative effects of early life adversity on prefrontal cortex microglia morphology and perineuronal net integrity: A role for sex-dependent neuroimmune priming

Authors: *K. R. GILDAWIE[1], L. M. RYLL[1], R. ORSO[2], J. C. HEXTER[1], S. PETERZELL[1], A. A. VALENTINE[1], H. C. BRENHOUSE[1];

[1]Northeastern Univ., Boston, MA; [2]Pontifical Catholic Univ. of Rio Grande Do Su, Porto Alegre, Brazil

Abstract: Early life is rife with sensitive periods during which aberrant experience can have lasting effects on plasticity and behavioral development. Microglia, the main immunocompetent cells in the brain, play an important role in synaptic development and can become chronically sensitized following an initial insult, priming them for over-activation. Here, we aimed to determine whether early life adversity increases vulnerability to a secondary hit later in development in a sex-dependent manner. First, male and female rat pups underwent maternal separation (MS) for 4 hours per day from postnatal day (P) 2-20 (or control rearing) and were exposed to the endotoxin lipopolysaccharide (LPS) in juvenility or adolescence. We observed that both MS and LPS administration affected morphological characteristics of Iba1+ microglia in the prefrontal cortex (PFC) of juvenile males and females, with MS exposure leading to a greater increase in soma size following LPS in females. Evidence also suggests that microglia influence extracellular development and degradation. Formation of perineuronal nets (PNNs) - specialized extracellular structures that preferentially enwrap fast-spiking parvalbumin (PV)-expressing interneurons - is essential for proper neurodevelopment. It is unknown, however, whether multiple adverse experiences during sensitive developmental periods has lasting effects on PNN and PV expression and whether this differs by sex. In a separate cohort, pups were exposed to MS (or control rearing), followed by juvenile social isolation (SI) from P21-35 (or standard pair-housing). Anxiety-like behavior was measured in early adulthood using the elevated zero maze. In adulthood, MS paired with juvenile SI resulted in decreased structural integrity of PNNs surrounding PV cells and reduced PV cell count, in females only. This potentiated effect of SI on MS-exposed females altered the relationship between PV+ PNN intensity and anxiety-like behavior. To determine whether the observed sex-dependent effects may be influenced by neuroimmune priming during MS, we conducted qRT-PCR at P9 to quantify levels of gene expression of high mobility group box 1 (HMGB1), a damage-associated molecular pattern that is upregulated during sensitization to stress. We present evidence that multiple hits of adversity influence neuroimmune and neurostructural development in a sex-dependent manner that may impact later-life behavioral outcomes. Moreover, the current work helps lay the foundation for mechanistic investigation of sex-specific changes in plasticity, which will further our understanding of neuropsychiatric sequelae and potential preventative therapies.

Title: Microglial P2RY12 mediates stress-induced synapse loss in the prefrontal cortex and associated cognitive-behavioral deficits.

Authors: *J. L. BOLLINGER, D. T. DADOSKY, I. L. RAINER, S. C. WOODBURN, E. S. WOHLEB;
Pharmacol. & Systems Physiol., Univ. of Cincinnati Col. of Med., Cincinnati, OH

Abstract: Recent studies in our lab demonstrate that chronic unpredictable stress (CUS) drives microglia-mediated neuronal remodeling, which contributes to synapse loss in the prefrontal cortex (PFC) and associated cognitive and behavioral deficits. Despite this, it remains unclear what mechanisms regulate neuron-microglia interactions in chronic stress. Other work indicates that neuronal activity-dependent purinergic signaling directs microglial processes via the purinergic receptor, P2RY12, which is exclusively expressed by microglia in the brain. Thus, microglial P2RY12 may play an important role in regulating stress effects on synaptic structure and function in the PFC. To investigate this, we used genetic (*P2ry12-/-*) or pharmacological (clopidogrel, 50 mg/kg, i.p. daily) approaches to block P2RY12 signaling in the context of CUS. Various behavioral, cytometric, and molecular endpoints were analyzed. Our results showed that both P2RY12-deletion and treatment with clopidogrel prevented CUS-induced increases in forced swim test immobility and attenuated discrimination deficits in temporal object recognition. In separate studies, immunohistology and flow cytometry revealed that genetic ablation of P2RY12 or clopidogrel significantly reduced P2RY12 expression in frontal cortex microglia. Further analyses showed that P2RY12-deletion or treatment with clopidogrel altered other markers (CX3CR1 and CD115) on frontal cortex microglia, independent of CUS exposure. Confocal imaging in Thy1-GFP(M) mice showed that clopidogrel blocked CUS-induced increases in the number of neuronal inclusions per microglia and prevented dendritic spine loss in the medial PFC, suggesting that P2RY12 regulates microglia-mediated neuronal remodeling. Together, these findings indicate that microglial P2RY12 mediates stress-induced dendritic remodeling in the medial PFC and subsequent behavioral deficits.

Title: Molecular neurobiology of enrichment loss: multi-omics analysis reveals a role of microglia

Authors: *M. A. SMAIL[1], B. L. SMITH[2], R. SHUKLA[4], J. K. REIGLE[5], K. ALGANEM[4], J. P. HERMAN[3], R. E. MCCULLUMSMITH[4];

Abstract: Background: Psychological loss impacts nearly all of our lives, yet little is known about what happens in the brain during this experience. Loss occurs when one is deprived of something perceived as important, such as a valued relationship, home, or job, and its symptomology resembles atypical depression. Given the common occurrence of loss-precipitating events, there is an urgent need to uncover the mechanisms underlying loss and identify potential therapeutic targets. Our laboratory simulates loss in rats by removing environmental enrichment, producing unique behavioral and physiological phenotypes that resemble loss in humans. Here we probe the molecular neurobiology of enrichment loss with a multidimensional approach that spans big data techniques, brain regions, and sex. Methods: Male and female rats were divided into 3 groups: environmentally enriched (EE), enrichment removed (ER), and control (CON). EE and ER animals were housed in groups of 10 in large, multi-level cages with toys. ER animals were removed from enriched housing after 4 weeks and moved to single-housing. Two weeks after removal, brains were collected. Bilateral micropunches were taken of regions implicated in loss by c-fos expression, including the infralimbic prefrontal cortex, basolateral amygdala (BLA), and medial amygdala. These regions were run on parallel RNAseq, shotgun proteomics, and kinomics platforms. A series of bioinformatics analyses were then used to derive molecular signatures of loss that span RNA, protein, and kinase activity levels. Results: Immune signaling, MAPK activity, and cell-matrix communication were consistently dysregulated in the BLA of ER males. Many of the genes driving these pathways were predominantly expressed in microglia, and these results were supported across RNA, protein, and kinase levels. Given that the BLA is a positive mediator of stress, impaired microglial regulation of neurons in this region could permit increased anxiogenic signaling, contributing to ER phenotypes. We have also identified signaling hubs that represent intriguing candidates for ameliorating ER phenotypes. Further analyses will continue to expand these signatures of enrichment loss across brain regions and sex. Conclusion: Taken together, these results allow us to start to understand what is happening in a rat's brain during enrichment loss, offering insight into the mechanisms that could underlie psychological loss in humans. They also point to potential therapeutic targets that may offer relief to people experiencing loss and have broader applications in depression.

Title: Calcineurin Inhibition Attenuates Stress-Induced Neuroinflammation

Authors: *P. J. RONAN[1,2], T. MEHTA[1,2], T. P. BERESFORD[3];
[1]USD Sch. of Med., Sioux Falls, SD; [2]Sioux Falls VA Healthcare Syst., Sioux Falls, SD; [3]UNIV COLORADO SCHOOL OF MEDICINE/ DEPT OF VETERANS, AURORA, CO

Abstract: We have shown that immunosuppressants (ICV) that act through the inhibition of calcineurin (CLN) reduce alcohol intake in mice. Calcineurin is an abundant phosphatase in brain and plays a key role in the transcription of neuroinflammatory and stress signaling molecules. Ethanol use induces both neuroinflammatory responses as well as many stress-induced molecules associated with withdrawal effects such as corticotropin releasing factor (CRF). We have shown that stress-induced activation of CRF in the central nucleus of the amygdala (CeA) is attenuated by cyclosporine A (CsA). Stress also induces neuroinflammatory responses. Here we sought to determine the effects of CsA on stress-induced neuroinflammatory markers in brain. Rats (n=8) were given either CsA (30 mg/kg, I.P.) or vehicle, exposed to 30 minutes of restraint stress and returned to their home cage for 90 minutes. Brains were rapidly dissected and frozen in isopentane on dry ice. The CeA and PVN were microdissected from 300 um frozen sections and qRT-PCR was performed. Overall, Cyclosporine inhibited the expression of a wide range of neuroinflammatory markers in these regions including cytokines such as IL-2, IL-1β, IL-6, TNFα; markers of glial activation: CD45 and Iba-1; chemokine and chemoattractant molecules such as CCR2 and CCL2; as well as other inflammatory signaling molecules such as COX-2. Some of the largest effects were seen on IL-1 β and IL-6 expression in both CeA and PVN. While CsA inhibited the expression of CD45 and iba1 in the CeA, in the PVN these effects were striking. This suggests that stress rapidly induces glial activation in these regions which is inhibited by CsA. Together these data suggest that rapid, stress-induced neuroinflammatory signaling is attenuated by inhibition of CLN activity. This has implications for the treatment of multiple disorders in which stress is an etiological or maintenance factor such as PTSD and AUD.

Title: Neuroinflammation in the Locus Coeruleus of Female Rats Enhances Anxiety-like Behaviors Induced by Social Stress

Authors: *S. J. BOUKNIGHT[1], B. S. POPE[2], G. MARTINEZ-MUNIZ[1], E. HARRINGTON[1], L. AUGENBLICK[1], S. K. WOOD[1];
[1]Univ. of South Carolina Sch. of Med., Columbia, SC; [2]Univ. of South Carolina, West Columbia, SC

Abstract: Stress-mediated anxiety is a prevalent psychosocial phenomenon that is associated with neuroinflammation. It is well known that women are more susceptible to developing anxiety-related disorders, thus may be more vulnerable to neuroinflammatory effects, as well. As a defining feature of neuroinflammation, cytokine overproduction occurs during stress and may regulate associated anxiety-like behavior. This study focused on the locus coeruleus (LC) due to its dense noradrenergic neuron population and significant role in behavioral and physiological responses to stress. We previously reported that microglia depletion in the LC reduces anxiety-like burying in females exposed to social stress in the form of witnessing a social defeat encounter between two males. To further support the role of microglia in anxiogenesis, this study seeks to examine how activation of microglia in the LC via the endotoxin lipopolysaccharide (LPS) affects witness stress-evoked burying behavior. Young adult female Sprague-Dawley rats with a bilateral LC cannula received a local injection of LPS (1µL; 0µg, 1µg, or 3µg) into each LC (n=6 per group) over a 60-second period. Forty-five minutes post-injection, rats were briefly handled and returned to their home cage to be subjected to "control stress" and video recorded for 15 minutes. Immediately following the control period, each rat was exposed to witness stress for 15 minutes (video recorded), then euthanized for blood and brain collection. All videos were analyzed by two researchers blinded to subject treatment with inter-rater reliability within 10 percent. ELISAs were used to analyze levels of plasma corticosterone (CORT) and plasma interleukin (IL)-1β in duplicate. Intra-LC LPS injection produced no effect during control stress. However, there was a dose dependent increase in LPS-induced burying, with rats that received 3µg of LPS displaying the most anxiety-like burying and the quickest burying latency after the start of witness stress. Additionally, rats that received 3µg of LPS exhibited significantly elevated levels of CORT and tended to have higher levels of IL-1β in the plasma, both likely resulting from the LPS-induced neuroinflammation that primed the release of norepinephrine and elicited a greater anxiety-like response. Taken together, these data suggest that neuroinflammation driven by microglial activation in the LC exacerbates the anxiety-like behavior induced by social stress in female rats.

Title: Effects of estrogen on host gut microbial population and their metabolites in rats with chronic restraint stress

Authors: *M. XU[1], H. SHI[2], K. KROLICK[2], J. ZHU[3];
[1]Miam, oxford, OH; [2]Miami Univ., Oxford, OH; [3]Ohio State Univ., Columbus, OH

Abstract: The brain-gut axis is a bidirectional communication system between the central nervous system and the gastrointestinal tract with diverse population of microorganisms, whose metabolites change constantly and feedback to the brain. Stress activating the hypothalamus-pituitary-adrenal (HPA) axis is known as an important factor for both mental and physical health. Both rodents and humans display sex-specific stress responses dependent on estrogen status. In this study, gut microbial population and their metabolites were characterized in rats with and without estrogen under control or stress conditions. Female Sprague Dawley rats received either sham operation thus having intact ovaries and normal estrogen levels (Sham) or ovariectomy (OVX) thus lack of endogenous estrogen. OVX rats received either oil (OVX+Oil) or estradiol (OVX+E2) replacement. Rats underwent either daily one-hour restraint stress or no-stress for 13 continuous days. Gut and trunk blood was collected on the last day. Plasma corticosterone (CORT) levels in tail blood were measured using ELISA. Stress significantly increased CORT levels of OVX+Oil rats during the entire stress period. In contrast, stress increased CORT levels of Sham and OVX+E2 rats at the beginning of the stress period, but such increase disappeared at the end of the stress period. Integrated 16S rDNA sequencing and LC-MS/MS based metabolic profiling were utilized to discover any significant differences in gut microbial genus and microbial metabolites. Beta diversity of microbial community was characterized by principal coordinates analysis (PCoA) that indicated the stress rats tended to form a cluster distinctly separated from the no-stress rats in both sham and OVX+E2 groups, but not OVX+Oil group. The microbial metabolic analysis revealed a similar attribute, with separation in major metabolic pathways between stress and no-stress rats of Sham rats and OVX+E2 rats, but not OVX+Oil rats. Therefore, when estrogen level was reduced as seen in OVX+Oil rats, the HPA axis stress response persisted, indicated by increased CORT levels throughout the stress period. However, a diminished stress response involving gut microbiota was observed, indicated by overlapping patterns of microbial community and similar microbial metabolite profiles between no-stress and stress OVX+Oil rats. Normal levels of estrogen seen in Sham and OVX+E2 groups relieved stress response involving the HPA axis but persisted the response involving gut microbiota. We conclude that estrogen may benefit brain-gut homeostasis, at least partially, via relieving prolonged stimulation of the HPA axis but maintaining microbial sensitivity to stress.

Title: The effect of gut dysbiosis and probiotics on stress-induced neuroinflammation in pubertal male and female CD1 mice

Authors: *P. ESPOSITO, M. KEARNS, K. SMITH, N. ISMAIL;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Puberty is a critical period of development marked by sexual maturation and central nervous system (CNS) remodeling and reorganizing. These physiological and neurological pubertal changes render the CNS particularly sensitive to stressors. The gut microbiome plays a critical role in the development of the immune system and neuro-immune signaling. Exposure to the bacterial endotoxin lipopolysaccharide (LPS) during puberty induces changes in microbial composition that can result in permanent deficits in brain functioning and immune regulation in adulthood. Probiotic supplementation has been shown to influence immunomodulation and have positive effects on immune responsivity. However, it is unknown whether probiotic supplementation could reverse the effects of microbial dysbiosis on LPS-induced neuroinflammation. Therefore, the objective of the current exploratory research project was to examine whether the adverse effects of pubertal microbial dysbiosis on LPS-induced immune response can be mitigated by probiotic supplementation in male and female mice. A total of 120 (72 male and 48 female) mice were used in this experiment. At 5 weeks of age, male and female CD1 mice received either broad-spectrum antibiotics or sterile water through gavage, twice a day, for seven days. During the same period, mice received either a probiotic supplement or placebo in their drinking water. At 6 weeks of age (pubertal sensitive period), mice received either an intraperitoneal injection (i.p.) of LPS or saline. Eight hours following the injection, mice were euthanized and brains were collected. The hypothalamus and pre-frontal cortex (PFC) were extracted using micropunches and processed with a real-time quantitative PCR (RT-qPCR) to examine central cytokine mRNA expression (i.e. IL-1β, TNF- α, and IL-6). It is expected that antibiotic treatment will increase LPS-induced central cytokine mRNA expression in the PFC and hypothalamus. Additionally, probiotic supplementation is expected to mitigate these effects. The results from this experiment will further our understanding of how pubertal gut dysbiosis influences neuro-immune signaling following LPS exposure, and whether probiotics can be used to mitigate these effects.

Title: Factors influencing microbiota, brain and behaviour

Authors: E. TOLSDORF, B. KWIECIEN-DELANEY, *J. A. FOSTER;
McMaster Univ., Hamilton, ON, Canada

Abstract: Microbiota-brain communication influences behaviour and brain function. Evidence from both rodent studies and clinical studies demonstrate an association between microbiota and anxiety. Genetic and environmental factors contribute to the composition and function of the gut microbiota, it is important to determine the influence of these factors on host systems in order to better determine how microbiome-brain signaling pathways impact behaviour. Common mouse strains show distinct phenotypes related to anxiety-like behaviour. Growing evidence shows that differences in anxiety-related behaviours in mice are associated with altered gut microbiomes. Previously, our lab examined the microbiome in healthy male and female mice (C57Bl/6, Balb/C, FVB, CD1) and identified bacterial taxa that were influenced by strain and sex. Further, 77 taxa were associated with anxiety-like behaviour, including 10 taxa that were associated with anxiety-like behaviour across all strains tested. The current study extended this work to consider housing conditions and source/supplier on microbiota composition. First, inbred male and female (C57BL/6, Balb/C, FVB) and outbred (CD1) mice were bred in house or pregnant dams were ordered from outside supplier and fecal microbiota composition analyzed at postnatal day 24 (P24) by amplifying 16S rRNA gene and sequencing using the Illumina MiSeq platform. Data was analyzed using DADA2, and additional analysis conducted using R software. Second, C57BL/6 and FVB mice were ordered from an outside suppler at P22 and housed with the same strain or in a mixed strain condition. Fecal microbiota composition was analyzed at P23, P27, P30, and P37. Notably, at P37, differential abundance of 18 taxa (ASVs) was observed between C57Bl/6 and FVB housed with the same strain, yet only 1 taxa distinguished C57Bl/6 and FVB mice housed in the mixed strain condition. Further, the identified housing-related taxa were distinct from the anxiety-like behaviour taxa previously identified.

Title: Peripheral reelin has fast-acting antidepressant-like effects evaluated in the repeated-corticosterone paradigm of chronic stress

Authors: *J. T. ALLEN[1], R. ROMAY-TALLON[2], J. JOHNSTON[1], M. A. MITCHELL[3], K. J. BRYMER[3], G. PINNA[2], L. E. KALYNCHUK[1], H. J. CARUNCHO[1];
[1]Univ. of Victoria, Victoria, BC, Canada; [2]The Psychiatric Institute, Univ. of Illinois at Chicago, Chicago, IL; [3]Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Chronic stress often precedes the onset of depression and can be modeled preclinically by subjecting rats to several weeks of daily corticosterone (CORT) injections. CORT-treated rats exhibit a depressive-like phenotype that is paralleled by decreases in hippocampal reelin, an extracellular matrix protein that regulates neuronal plasticity in the adult brain. We recently reported that intrahippocampal infusions of reelin had fast-acting antidepressant-like actions, rescuing CORT-induced despair-like behavior in the forced swim test (FST), neurogenesis, and imbalances in GABAergic and glutamatergic systems. In the present study, we aimed to evaluate whether peripheral intravenous administration of reelin would have a similar antidepressant-like effect. Rats received either daily vehicle or CORT injections for 21 days along with either vehicle or 3µg of reelin administered every 10 days over the CORT-injection period, or a single injection of reelin (either 3µg, 5µg, 7µg, or 9µg) on day 21. They were then subjected to the FST followed by post-mortem analyses of the number of reelin-, GABAAβ2/3-, and GluA1-positive cells. Peripheral reelin (repeated and singular infusions) rescued CORT-induced depressive-like behavior in the FST and decreases in reelin expression. As well, CORT-induced decreases in the number of GABAAβ2/3- and GluA1-positive cells were reversed by reelin. There were no apparent sex differences in response to reelin treatment. These novel findings show that peripheral reelin has antidepressant-like effects associated with the restoration of neurochemical deficits in the hippocampus. Although additional mechanistic and pharmacokinetic studies are necessary, our data open the possibility of developing reelin peptides with antidepressant activity.

Title: Cellular mechanisms of allostasis involving mitochondria alter extracellular vesicle cargo to coordinate enduring effects of stress

Authors: *N. R. KANYUCH[1], J. CHAN[2], C. MORGAN[3], C. MANNELLA[4], N. YADAVA[5], T. L. BALE[1];
[1]Univ. of Maryland Baltimore, Baltimore, MD; [2]Dept. of Neurosci., Icahn Sch. of Med. at Mount Sinai, Manhattan, NY; [3]Ctr. for Epigenetic Res. in Child Hlth. and Brain Develop., [4]Dept. of Physiol. and Ctr. for Biomed. Engin. and Technol., [5]Dept. of Anesthesiol. and Ctr. for Shock, Trauma and Anesthesiol. Res., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Lifetime experiences including stress, trauma, and infection are associated with lasting effects that alter reproductive and embryo developmental outcomes. However, the cellular mechanisms contributing to these lasting post-exposure effects are not clear. For males, somatic cell reprogramming that involves the reproductive tract and germ cell maturation is an especially intriguing model to examine allostatic mechanisms. Sperm within the epididymis receive maturation signals, including growth factors and extracellular vesicles, from epididymal epithelial cells (EECs). In mice, we have previously shown that the content of these signals is altered following a chronic period of stress and that these changes are causal in post-conception neurodevelopmental outcomes. However, how EECs store past stress experiences at the molecular level is unclear. The glucocorticoid receptor (GR) is a key regulator of the stress response and is a known cellular target for orchestration of allostasis. To examine the hypothesis that stress-dependent cellular programming involves GR, we used EEC targeted reduction of GR and male stress to look at the passage of signals to sperm and offspring phenotype. Reduction of EEC GR in fact prevented the passage of post-stress signals and normalized the offspring brain development and physiological phenotype. Transcriptomically, genes differentially expressed between wildtype and GR^{Het} EEC accounted for two clusters of co-regulated genes related to metabolic processes and mitochondrial transport, and chromatin-modifying processes as defined by functional annotation analysis. Using an EEC cell culture model of stress and Seahorse XFe technology to assess the GR capacity to program basal mitochondrial function, prior stress hormone treatment profoundly decreased basal respiration. Transmission electron microscopy demonstrating condensed mitochondria after stress hormone treatment further confirmed the enduring impact of stress on mitochondrial state. Together these studies demonstrate GR's role in programming vital functions including baseline energy demand and production to regulate a sustained change in the cell's *basal* state, or homeostatic set point, in response to stress. These studies demonstrate GR's vital importance at the intersection between epigenetic and metabolic consequences of stress and explain how paternal stress or trauma experience can produce important changes in offspring development long after the experience occurred.

Title: Cell-type specific labeling of epididymal extracellular vesicles with CD63-HA: listening in on the somatic to germ cell communication of life's lessons

Authors: *C. P. MORGAN[1], R. MARX-RATTNER[1], B. ALTAS[1], J. C. CHAN[2], M. KANE[3], T. L. BALE[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Perelman Sch. of Med., Philadelphia, PA; [3]Univ. of Maryland Sch. of Pharm., Baltimore, MD

Abstract: Extracellular vesicles (EVs) are a unique mode of intercellular communication capable of incredible specificity in transmitting signals involved in cellular function. One example of this is the essential role EVs secreted by epithelial cells lining the lumen of the reproductive tract play in the post-spermatogenic maturation of sperm. EVs released by epididymal epithelial cells (EECs) transport bioactive cargoes including small non-coding RNA (sncRNA), proteins and lipids that are required for sperm to develop essential properties, including the ability to swim and fuse with the ovum. We recently demonstrated that this fundamental process also plays a causal role in the somatic-to-germline transmission of information regarding paternal stress experience capable of altering fetal development in a preclinical mouse model. In this model, paternal preconception stress produces lasting histone and transcriptomic alterations in mouse EECs *in vivo*, with corresponding persistent changes in the miRNA, proteomic, and lipid composition of EVs secreted by immortalized DC2 EECs treated with corticosterone (cort) *in vitro*. Demonstrating causality, we showed that sperm incubated with EVs collected from these cort-treated DC2 EECs produce offspring with the same significant changes in neurodevelopment and adult stress reactivity observed in offspring of stressed males. While we would like to extend these results using EEC EVs collected *in vivo*, EV populations within the epididymal lumen originate from diverse cell types and are highly heterogeneous. To address this challenge, we have developed a transgenic construct that would allow for cell-type specific labeling of EVs via Cre-induced hemagglutinin (HA) tagging of the endogenous CD63 protein. CD63 is a tetraspanin protein enriched in EVs generated by diverse cell types in tissues throughout the body. Concurrent with our efforts to generate a transgenic mouse model, we are validating this construct in a stably transduced immortalized EEC cell line. We demonstrate that this transgene responds appropriately to Cre expression, resulting in HA-tagged EVs that do not differ from those produced by parallel cell lines naïve to Cre at the level of quantity produced, size distribution, and molecular composition. These studies present novel

and mechanistic insight into the somatic to germline transmission of environmental signals to maturing germ cells involved in altering fetal development. In addition, a CD63-HA transgenic mouse would be a valuable tool with applications in the study of EV function across biomedical fields.

Title: Early life adversity leads to enhanced fear-potentiated startle in female mice

Authors: *C. DEMAESTRI, K. G. BATH;
Columbia Univ., New York, NY

Abstract: Stress-related disorders such as generalized anxiety disorders, post-traumatic stress disorders, and panic disorders affect over a third of the population. Experiencing early life adversity (ELA) increases our lifetime risk of developing these disorders, and females show increased prevalence and severity of symptoms. Patients with stress-related disorders, and those who have experienced ELA, such as resource scarcity, exhibit increased fear-potentiated startle and increased acoustic startle responses with females having the potential for greater risk. Here, we test the impact of ELA on the evolutionarily conserved startle response and threat anticipation in a mouse model. Using the limited bedding model of ELA, we've found that, after tone-shock conditioning, mice who experience ELA exhibit enhanced startle to an intense white noise, both when presented in the presence and absence of the conditioned tone. This effect was only observed in females. Furthermore, we explored potential mechanistic changes in startle circuitry by testing for disturbances in corticotrophin releasing hormone expression patterns in the bed nucleus of the stria terminals and central amygdala. Disruption in the ability to accurately predict threat exclusively when it is present is critical for mental health and may lay the groundwork for sex-specific vulnerability to psychopathology. Understanding the mechanism by which disrupted threat-anticipation and enhanced startle occurs, and sex differences in risk following ELA, will be key in understanding behavioral disturbances in stress-related disorders and sex-specific vulnerabilities.

Title: Early life adversity reveals sex-specific outcomes in rebound feeding in adolescent mice

Authors: *M. CRITZ[1], C. DEMAESTRI[2], K. G. BATH[3];
[1]New York State Psychiatric Inst. - Columbia, New York City, NY; [2]Neurobio. and Behavior, Columbia Univ., New York, NY; [3]CLPS, Brown Univ., Providence, RI

Abstract: Early life adversity (ELA) increases the risk for psychiatric disorders later in life, including anxiety, depression, and eating disorders. Eating disorders disproportionately affect young women and lead to a host of negative consequences, including metabolic disorder, adult obesity, and [maybe include one more]. ELA during critical developmental windows can alter the functioning of systems associated with stress and feeding, which may underlie an increased risk of developing disordered feeding patterns in adolescence. Using a resource-based mouse model of ELA, we tested the effects of ELA on adolescent feeding behavior after a period of starvation. To assess for changes in stress- and feeding-related systems, we measured plasma levels of leptin and corticosterone and hypothalamic mRNA expression of leptin receptor. We found that experiencing ELA resulted in hyperphagic "binge-like" feeding behavior on high-fat food in males, while both control and ELA-reared females showed an overall increase in "binge-like" behavior. Behavioral patterns were accompanied by higher basal corticosterone levels in males and increased leptin levels across groups. These results indicate that ELA has sex-specific effects on behaviors that increase the risk for developing eating disorders in adolescence that may be mediated through changes in the development of stress and and feeding-related systems. Understanding of the sex-specific effects of ELA on feeding behavior in adolescence as well as the mechanisms underlying this relationship is essential for treatment and prevention of pathological disordered eating.

Title: Maternal Preconception Stress Produces Female Offspring-Specific Changes in Hypothalamic Extracellular Matrix Neurodevelopment

Authors: *K. MONTGOMERY, Y. CISSE, T. L. BALE;
Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Lifetime maternal exposure to chronic stress and trauma represents a significant risk factor for the development of neuropsychiatric disorders in their offspring; however, the exact mechanisms by which preconception experiences are transmitted to the next generation and influence neurodevelopment are not well understood. Our previous work established a novel mouse model of maternal preconception stress (MPS) where female, but not male, offspring of MPS dams have heightened stress reactivity in adulthood, a hallmark of many neuropsychiatric disorders. We hypothesized that MPS imparts sex-specific changes to the developing paraventricular nucleus of the hypothalamus (PVN), the master regulator of the hypothalamic-pituitary-adrenal (HPA) axis, that result in the observed elevated stress phenotype. To test this, we used our MPS model and performed PVN Sim-1 neuron-specific RNA sequencing in male and female postnatal day 21 offspring. Female offspring of MPS dams had over 2200 differentially expressed genes (DEGs) compared to female offspring from control dams. In contrast, male MPS offspring had only 63 DEGs compared to control males. Functional analysis of female DEGs revealed significant enrichment of genes involved in production and remodeling of the extracellular matrix. The brain's extracellular matrix undergoes considerable change during development, transitioning from a juvenile state to the adult state beginning in the second postnatal week. This transition coincides with the closure of plasticity windows in specific brain regions, though the majority of this work has been conducted solely in males and in non-hypothalamic brain areas. Dysregulation of either the developmental rate and/or composition of the extracellular matrix could impart lasting effects on the formation of PVN circuitry, including the organization of the HPA response, that persist into adulthood. We next determined that MPS enacts lasting effects on offspring PVN neurons by conducting RNA sequencing on adult MPS offspring. Female offspring again had the highest enrichment of DEGs related to the extracellular matrix. Taken together, these results suggest that MPS imparts enduring sex-specific changes to the formation and maintenance of neuronal extracellular matrix in the PVN. Ongoing studies will determine how dysregulation of extracellular matrix formation in MPS female offspring results from increased neuronal activity and accelerated developmental maturation rate. Results from these studies will provide insight into the significant contributions of maternal preconception experiences on female neurodevelopment and lifetime disease risk and resilience.

Title: Lipopolysaccharide induces local glucocorticoid production in the mouse brain during early development

Authors: *H. BAJAJ[1], M. X. LI[1], J. E. HAMDEN[2], M. SALEHZADEH[2], C. MA[1,2,3], K. K. SOMA[1,2,3];

Abstract: Glucocorticoids (GCs) are steroid hormones and critical modulators of nervous system development and function. Stressors activate the hypothalamic-pituitary-adrenal (HPA) axis and lead to the secretion of GCs from the adrenal glands into the blood. GCs are also locally produced in extra-adrenal organs, such as the brain. During early development (postnatal day (PND) 2 to 12), mice have very low circulating GC levels at baseline and small increases in response to stressors, this is termed the stress hyporesponsive period (SHRP). Local GC production in the brain may be of particular importance during the SHRP, to allow GC signaling in specific brain regions without general effects throughout the body. However, the effects of an immunological stressor during the SHRP on local GC levels within specific brain regions remain unknown. To study these effects, we assessed systemic and brain GC levels in neonatal (PND5) C57BL/6J mice 4 hours after administration of lipopolysaccharide (LPS) (50 µg/kg i.p.) or vehicle control (n=12/group). We examined blood and microdissected brain regions (prefrontal cortex, hippocampus, hypothalamus, and amygdala) using the Palkovits punch technique. Using a within-subject design, GCs (corticosterone and 11-dehydrocorticosterone) were measured via liquid chromatography tandem mass spectrometry (LC-MS/MS), and transcripts of key steroidogenic enzymes (*Hsd11b1*, *Hsd11b2*) were measured via RT-qPCR. LPS administration induced greater increases in corticosterone in every brain region but the prefrontal cortex, compared to blood. In contrast, for 11-dehydrocorticosterone, LPS treatment induced greater decreases in every region but the prefrontal cortex, compared to blood. Transcripts of key steroidogenic enzymes are present in all brain regions examined. Taken together, these results suggest that LPS rapidly stimulates local corticosterone production in the neonatal mouse brain and provide insight on the effects of bacterial infections on the developing nervous system.

Abstract: Previously, we have shown that prenatal stress causes changes in serotoninergic system function, with low ventral hippocampus serotonin release after behavioral forced swim tests in adulthood. In the current study, changes in serotonin transporter (SERT) in the ventral hippocampus of prenatally stressed rats after sucrose intake and after forced swim tests, was evaluated. Three months old, prenatally stressed male rats were used for the study. Sucrose intake was assessed, identifying anhedonic and non-anhedonic rats. Serotonin extracellular concentration were assessed by microdialysis, after sucrose intake test. Ventral Hippocampus were dissected and SERT evaluated by Western Blot. Other males were submitted to the forced swim test. Serotonin release was assessed, and at the end of the behavioral test, ventral hippocampi were dissected and SERT was evaluated in control and prenatally stressed, anhedonic and non-anhedonic rats. The results show an increase in SERT content in the ventral hippocampus of control rats after the forced swim test. In anhedonic and non-anhedonic rats, however, SERT did not change neither after sucrose teste, nor after the forced swim test. These data indicate that higher immobility in forced swim test in prenatally stressed males are related to lower serotonin release, but not to SERT content.

Title: Live imaging of brain network dynamics in an acute threat response by MEMRI: Effects of early life adversity on noradrenergic system anatomy

Authors: *T. W. USELMAN[1], R. E. JACOBS[2], E. L. BEARER[1,3];
[1]Dept. of Pathology, UNM Hlth. Sci. Ctr., Albuquerque, NM; [2]Zilkha Neurogenetic Institute, USC, Keck Sch. of Med., Los Angeles, CA; [3]Div. of Biol. and Biol. Engin., Caltech, Pasadena, CA

Abstract: Monoaminergic signaling in cortical-limbic circuits regulate both normal physiology and responses to stress. Indeed, monoaminergic reuptake transporters, located on the pre-synaptic terminals of distal projections, are common pharmacological targets for mental

disorders, like anxiety and depression. Early life adversity (ELA), which has an interaction with monoaminergic systems, increases vulnerability to mental disorders later in life. Despite this, we are yet to understand how ELA alters brain-wide patterns of neural activity. Here, we combine Manganese-enhanced MRI (MEMRI) with behavioral tracking and immunohistochemistry to investigate the effects of ELA on the modular neuroarchitecture and behavioral response to acute threat. ELA was administered from P2-P9 by depriving dams of adequate bedding. Mice (10 weeks, n=24) +/- ELA were subject to paired MEMRI and behavior longitudinally. Intraperitoneal injections of paramagnetic Mn(II) (0.3 mmol/kg) highlights brain activity in awake behaving mice. Behavior was recorded during Mn(II) uptake to assess avoidance and motility before, during and nine days after acute exposure to predator odor (TMT, 2,3,5-Trimethyl-3-thiazoine). Histochemical analysis was performed on serial brain sections from mice sacrificed and perfused at the conclusion of paired behavior-imaging experiments. MEMRI images were skull-stripped, spatially registered, and intensity normalized. To measure the degree of activity and relationships between brain regions we performed statistical parametric mapping (SPM), segmentation of 90 brain regions, cross-correlation analysis, and Louvain community detection. Predator stress increased avoidance behavior (percent of time in light) for both groups ($p<0.05$, Tukey-Adjusted), while only inter-subject variance was observed to be different between +/- ELA groups. Results suggest basal neural activity of ELA mice resembles that of acute fear in normally reared mice, with increased activity in the basal forebrain and hindbrain. Additionally, ELA disorganized network structure, increased modularity of basal brain networks and altered the dynamic response to acute threat. Staining for the norepinephrine transporter revealed lesser numbers of distal termini, suggesting alterations in neural activity could be due to an effect of ELA on the development of the noradrenergic system. Together our data find that ELA disrupts the arborization of noradrenergic projections, alters the coordination of basal neural activity and of neural activity in response to acute threat.

Title: Priming of chromatin by monomethyltransferase Setd7 overexpression in the VTA mimics early life stress

Authors: *J.-A. RODIER, A. S. CHEN, C. J. PEÑA;
Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: In humans, adverse childhood experiences increase the risk for psychiatric disorders such as depression. There is evidence that early life stress sensitizes individuals to future experience of stress. To study how epigenetic mechanisms might mediate maladaptive behavioral outcomes following early-life stress (ELS), and their impact on neurodevelopment, we use a stress model in mice. We recently found that in the ventral tegmental area (VTA), the proportions of chromatin modifications associated with a more open or permissive state increases. Here, we verified by Western blot that ELS in male mice increases monomethylation of histone 3 lysine 4 (H3K4me1), an epigenetic modification that has been associated with transcriptional priming in across biological kingdoms. Reanalysis of published RNA-seq data in VTA also revealed a trend for increased mRNA levels of *Setd7*, a mono-methyltransferase specific to H3K4 (t-test, p=0.1012, n=4, males only, trend). We hypothesize this open chromatin state, marked by H3K4me1, may enable more reactive transcription in response to additional stress across the lifespan. To causally test this hypothesis, we manipulated the epigenome *in vivo*: we developed custom viral vector tools to over-express the H3K4-specific monomethyltransferase *Setd7* during an ELS-specific time-sensitive period. We performed stereotaxic surgery to target viral over-expression of *Setd7* in the VTA, a deep brain structure, of male and female pups at 14 days old. We validated that our vector increases SETD7 protein (6.0-fold increase in SETD7 mice compared to endogenous levels in GFP-injected mice, $p<0.001$, n=12) and H3K4me1 (1.35-fold increase, $p = 0.0014$, n=6 GFP and n=11 for SETD7) in the VTA, similar to early-life stress. We then measured depression- and anxiety-like behavior, in both male and female mice, before and after adult chronic social defeat stress. We found an interaction between juvenile *Setd7* overexpression and experience of adult stress on social avoidance behavior. This provides causal evidence linking early life stress to epigenetic modifications in reward circuitry that directly mediate lifelong stress sensitivity.

Title: Extracellular vesicles as potentiators of stress signals to alter placental and fetal development

Authors: *H. C. ZIERDEN[1], K. E. MORRISON[2], B. M. NUGENT[3], T. L. BALE[4];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Psychology, West Virginia Univ.,

Abstract: Maternal stress is linked to a variety of adverse fetal and pregnancy outcomes. In our well-established mouse model of early prenatal stress (EPS), we observe impaired cognitive function, alterations in metabolic programming, and heightened stress sensitivity, especially in male offspring. We hypothesize that stress may contribute to fetal neurodevelopment via changes in extracellular vesicle (EV) signaling. EVs are cell-derived particles that participate in intercellular communication by transporting signaling factors between cells and tissues. We first addressed the role of stress in EV signaling by isolating circulating EVs from donor dams in control and EPS-exposed groups. We performed small RNA-seq to analyze the content of these EVs. Next, we injected labeled EVs into naïve dams, and used an *in vivo* imaging system (IVIS) to detect EV trafficking in maternal and fetal compartments. A separate cohort, also receiving EV injections, was used to detect transcriptomic changes in placental and fetal tissues. EVs were administered to a cohort of naïve dams, and offspring were monitored throughout adulthood for growth and hypothalamic-pituitary-adrenal (HPA) stress axis reactivity. To identify the role of EVs in male-specific consequences of EPS, EVs were isolated from control and EPS-exposed neonates, labelled, and injected into age-matched naïve neonates. A cohort of naïve neonates was sacrificed following EV injection to investigate the distribution of EVs throughout the body via IVIS. In a separate cohort, we monitored offspring throughout adulthood for growth and hypothalamic-pituitary-adrenal (HPA) stress axis reactivity. We observed that EVs from control and EPS-exposed neonates were differentially trafficked into the neonate brain in both EPS- and sex-specific ways. EVs derived from EPS-exposed males promoted long-term changes in male body weight and HPA stress axis sensitivity, while female EPS EVs had no long-term programmatic effects on naïve females. Together, these studies provide insight into the role EVs play in promoting stress signals in both maternal and fetal circulation, their interaction at the level of the placenta, and the impact of prenatal stress on important signaling dynamics between maternal and fetal compartments during gestation.

Title: Maternal Stress Increases Anxiety-Like Behavior of Rodent Infant Offspring.

Authors: *H. M. RIVERA, C. COLLINS, J. CAGE, J. GERSTENBERGER, A. HASKELL; Hartwick Col., Oneonta, NY

Abstract: Epidemiological studies and animal studies reveal that adverse events early-on in the life of the mother can have a long-term impact on the health of their children. While data exists on the effect of maternal stress on adult offspring, currently, there is a lack of information in juveniles. Because laboratory studies of mothers can isolate maternal stress as a factor, they are powerful tools in investigating these effects. The goal of the present study was to begin to examine the role of maternal stress on anxiety-like behavior during the infant developmental stage. Rat dams were assigned to one of two groups: the maternal stress group (n = 5, dams underwent variable psychological stress during the last 7 days of gestation) or the maternal control group (n = 4, dams underwent no stress). Dam and offspring body weights were measured at the infant stage (i.e. postnatal day 22). Anxiety-like behavior were determined in offspring with the elevated-plus maze behavioral assay (postnatal day 22). One female and one male offspring were used per day for offspring body weight and behavior analysis to prevent cohort effects. Group differences in dam body weights, offspring body weights, and offspring elevated-plus maze behavior were calculated with unpaired t-tests. During the infant stage, our results showed that stressed dams displayed a significant decrease in their body weights relative to non-stressed dams ($t(7) = 3.34$, $p = 0.01$). In contrast, offspring from stressed dams and non-stressed dams did not exhibit group differences in body weight ($t(16) = 0.13$, $p = 0.90$). When looking at offspring anxiety-like behavior in the elevated-plus maze, offspring from stressed dams displayed no group differences in the time spent on the closed arm relative to the non-stressed group ($t(16) = 0.74$, $p = 0.47$). However, offspring from stressed dams revealed a significantly lower amount of entries in the open arms relative to offspring from non-stressed dams ($t(16) = 2.49$, $p = 0.03$). Together, these findings indicate that maternal stress alone increases offspring anxiety-like behavior in infant offspring. These studies presented here confirm that we started developing an animal model of adverse maternal stress effects on infant development. Building on our unique experience with this animal model, our research group will continue to assess maternal stress across all stages of development.

Title: Sex-specific impact of perigestational opioid exposure on juvenile play behavior in rats

Authors: *H. J. HARDER, C. T. SEARLES, L. A. HANUS, M. G. GOMEZ, A. J. AUSTIN, A. Z. MURPHY;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Juvenile play is a natural and essential part of rodent social development and is often disrupted in animal models of neuropsychiatric or developmental disorders. It has been previously reported that acute exposure to opioids, including morphine, in juvenile rats has been shown to increase juvenile play in a nucleus accumbens mu-opioid receptor-dependent manner. However, the consequences of developmental exposure to opioids on juvenile play are unknown. Using a novel assay of perigestational opioid exposure that consists of pregestational, gestational, and postnatal exposure to morphine, we tested the hypothesis that chronic exposure to opioids during critical periods of development would disrupt juvenile play due to alterations in reward signaling. Juvenile play behavior was measured in control or perigestationally morphine exposed male and female rats at P25, P35, and P45. Classical features of juvenile play were measured, including social play, time not in contact, pins, and nape attacks. Preliminary data shows that morphine-exposed females participated in less social play, with a corresponding increase in time spent alone. Morphine-exposed females also initiated fewer pins and nape attacks. Together, this data suggests that females perigestationally exposed to morphine are less motivated to participate in social play, potentially due to an alteration in the reward circuitry due to developmental exposure to morphine. We are currently analyzing mu-opioid receptor expression throughout the reward circuit to elucidate a potential mechanism for this behavioral change.

Background. Prenatal ethanol exposure (PE) leads to a variety of psychological conditions. Individuals with Fetal Alcohol Spectrum Disorders (FASD) often show severe anxiety and fear, in which the serotonergic neurons located in the dorsal raphe nucleus (DRN) are implicated. But it is unclear how PE alters serotonergic neurotransmission in the DRN, leading to increased anxiety. A valid rodent model could help unravel the underlying neural mechanisms. The purpose of the present study was to establish a rat model to study anxiety-like behavior in rats with PE. **Materials and Methods.** Pregnant Sprague Dawley rats were gavaged twice/day with 0 or 3 g/kg/treatment ethanol (15% w/v) during gestational days 8-20, mimicking second-trimester heavy PE in humans. Their adult offspring underwent three different tests of anxiety-like behavior: elevated plus maze, elevated zero maze, and open field tests. Some male rats also underwent an acute restraint (2 hour) procedure before the open field test. All the tests were conducted in dimly-lit rooms after rats were habituated for 15 min. Animal behavior was tracked using the ANY-maze software. **Results.** In the elevated plus maze test, PE male rats spent less time on the open arms than controls. In the elevated zero maze test, PE led to a decrease in number of entries into the open quadrants in male rats as well as a decrease in time and distance travelled on the open quadrants in female rats, as different manifestations of increased anxiety-like behavior in PE rats. In the open field, PE female but not male rats spent less time in the center area than controls; the same results, however, were observed in PE males after acute restraint stress. **Conclusion.** The results from all three tests show that PE leads to an increase in anxiety-like behavior in both male and female rats. The increase appears more marked in PE females than in PE males. In addition, PE male rats show increased anxiety in response to acute stress.

Title: The estrous cycle modulates early life adversity effects on defensive behavior, activity levels and ventral hippocampal theta rhythm in female mice.

Authors: *B. J. LAHAM, S. MURTHY, M. CLAPPIER, M. HANANI, S. BOYER, E. GOULD;
Psychology & Neurosci., Princeton Univ., Princeton, NJ

Abstract: Early life adversity (ELA) predisposes people to develop neuropsychiatric conditions, including anxiety disorders and attention deficit hyperactivity disorder. Using maternal separation with early weaning, a mouse model of ELA, we previously found increased defensive behavior and activity levels in adult males but no significant effects on these behaviors in adult females (Murthy et al., 2019). These findings were unexpected because the link between ELA and neuropsychiatric disorders is even stronger in women than men. Estrogen has been shown to modulate some stress responses (Eid et al., 2020), so we sought to investigate whether naturally occurring fluctuations in ovarian steroids across the estrous cycle might interact with ELA-induced behavioral changes. When tested during the estrus phase of the estrous cycle, when levels of estrogen are relatively high, adult females previously subjected to ELA exhibited no change in behavior compared to control reared mice in estrus. By contrast, when tested during diestrus, adult ELA females showed a behavioral phenotype similar to adult ELA males: increased defensive behavior and increased activity levels compared to controls. Previous work done in male mice has shown that theta oscillations in the ventral hippocampus are causally linked to defensive behavior (Padilla-Coreano et al., 2019) and that ELA-induced increases in defensive behavior and activity levels are accompanied by increased theta power in this brain region (Murthy et al., 2019). Thus, we sought to explore whether ELA-induced changes in behavior during diestrus are associated with increased theta rhythm by carrying out wireless electrophysiological recordings in awake behaving female mice during diestrus and estrus. We found that during diestrus, but not estrus, ELA female mice exhibit significantly greater theta power in the ventral hippocampus compared to controls. We also found that, compared to controls, diestrus female mice subjected to ELA have smaller perineuronal nets surrounding parvalbumin-positive interneurons, a cell population known to contribute to rhythmic firing. Taken together, these findings show that ELA has similar effects on behavior and ventral hippocampal function in diestrus females as it does in males, but that higher levels of estrogen during estrus may transiently protect against these effects. The extent to which changes in perineuronal nets occur across the estrous cycle and contribute to fluctuations in ELA-induced increases in theta oscillations, defensive behavior and activity levels, remains to be determined.

Title: Therapeutic effects on working memory and anxiety of early physical exercise in CD-1 adult mice from gestational undernourished dams

Authors: *M. ORTIZ[1], N. A. MOY-LÓPEZ[1], M. F. PINTO-GONZÁLEZ[2], R. PEDRAZA-MEDINA[3], J. GUZMÁN-MUÑIZ[3];
[1]Univ. De Colima, Colima, Mexico; [2]Lab. of Neurosciences, Univ. of Colima, COLIMA, Mexico; [3]Univ. de Colima, Colima, Mexico

Abstract: Gestational undernutrition (GU) has severe long-term consequences on neuronal organization, which underly cognitive and emotional processes like working memory and anxiety, that alters the well-being and development of individuals. The aim of this work was to analyze the therapeutic effects on working memory and anxiety of early physical exercise in CD1 adult mice with undernourished mothers during gestation. For the underfed groups, female CD-1 mice received different percentages of a balanced diet (50%, 70% and 100%) during the three weeks gestation. At postnatal day 4 (PD4), pups were randomly distributed in different dams and separated on three groups: exercise group (EG), without movement group (WMG) and without exposition group (WEG). Exposure to physical exercise begins at PD15 and ends at P56, contemplating five days of adaptation. Rehearsals are from Monday to Friday for 1 hour, resting on weekends. Weaning was at PD21 and from then pups were given an ad lib diet. At PD60 subjects were evaluated with the Morris Water Maze (MWM) for four days, while at PD64 groups were tested in the open field (OF). Results showed significant differences in weight from PD18 until PD60 between EG and WEG groups ($p<0.0001$) without sex differences. By other hand on MWM, no significant differences were observed on any evaluation day, neither in latency nor in swimming velocity ($p>0.05$). In contrast, in the OF, significance was identified anxiety indicators, being WEG which had less mobility and speed ($p<0.01$), traveled less distance ($p<0.0001$) and spent more time in the periphery ($p<0.001$), compared to the other two groups, while EG showed higher scores. In conclusion, physical exercise in the early stages does not showed an effect on working memory, but in anxiety indicators in animals exposed to undernutrition during prenatal stages. Based on this, longer exposure to exercise could be considered for evaluation, also other behavioral tests could be used to understand the mechanisms that may be affected by GU, as well as its possible therapeutic alternatives.

Title: Different models of early life adversity differentially alter development of infant ultrasonic vocalizations, adolescent social behavior, and prefrontal cortex cytokine expression across development

Authors: *L. GRANATA[1], H. C. BRENHOUSE[2];
[2]Psychology, [1]Northeastern Univ., Boston, MA

Abstract: Early life adversity impacts the development of later-life social function. Vulnerability to specific psychiatric outcomes are influenced by the type of adversity and biological sex, necessitating the investigation of sex-specific effects of different forms of adversity. Social dysfunction, a shared symptom among several psychiatric conditions including depression and schizophrenia, is associated with aberrant development of the prefrontal cortex (PFC), a late-maturing region susceptible to early environmental insults. Neuroimmune mechanisms involving pro- and anti-inflammatory cytokines are integral to neuronal developmental processes contributing to synaptic plasticity. However, the underlying behavioral factors of different types of adversity that may be mediating later-life social deficits and neural dysfunction are still unclear. We used two rodent models of early life adversity—maternal separation (MS) (P2-P20) and limited bedding (LB) (P2-P14)—to determine the effects of altered maternal care on development in male and female offspring. In neonatal rats, ultrasonic vocalizations (USVs) are a species-typical care-eliciting behavior and communication tool. We modeled the developmental growth curves of USV types based on their sonographic structures on postnatal days (P) 5, 10, 15, and 21 and quantified the predictability of call type sequences using an entropy rate calculation. Then, adolescent (P35) rats underwent a dyadic social interaction test to determine the effects of rearing condition on social approach and play behaviors and whether these are mediated by juvenile USVs. In separate cohorts, adolescent (P35) and young adult (P60) mRNA expression of pro-inflammatory (IL-1β, IL-6, and TNF-α) and anti-inflammatory (IL-10) cytokines in the PFC were quantified via RT-qPCR to determine whether social aberrations were associated with persistent neuroimmune dysfunction. Results indicate that age-related changes in USV emissions and social behavior depend on rearing condition and sex. LB delayed the USV development exclusively in males, while MS accelerated the curve only in females. Social behavior was also impacted differentially in males and females depending on rearing condition. This indicates that dysfunctional mother-pup interactions as measured by adaptive USVs may mediate later-life social dysfunction and cytokine expression across development. These findings highlight specific aspects of the early life environment most critical for neural and behavioral development following adversity.

Abstract: DREADD mediated activation of Parvalbumin cells during early post natal development: effect on mood related behaviours
AUTHORS: TOSHALI BANERJEE, SONALI S SALVI, STHITAPRANJYA PATI, PRAACHI TIWARI, DARSHANA KAPRIVIDITA A. VAIDYA
Early life stresses (ELS) have been implicated in adult onset of psychiatric disorders such as anxiety, depression, schizophrenia, etc. The Early life window is crucial for the functional development of the nervous system. Experiences during this stage sets the tone for the functional integration of various neurotransmitter and neuromodulator systems (such as Serotonin, endocannabinoids, etc.). Several lines of evidence, across preclinical animal models and clinical post-mortem studies on subjects that have undergone ELS, indicate that an altered cortical Gq signalling, downstream of the Serotonin receptor $5HT_{2A}$ and other Gq coupled receptors such as mGlu2, drives the onset of anxiety like behaviours in adulthood. The same has been corroborated in pharmacological models such as Post-natal fluoxetine treatment and Chemogenetic upregulation of Gq signalling in forebrain excitatory neurons(Pati et al, 2020). While majority of the $5HT_{2A}$ receptors are present on principle excitatory neurons of the cortex, it is also expressed in the inhibitory Parvalbumin interneurons. Interestingly, perturbations in Parvalbumin interneurons signalling via $5HT_{2A}$ has been implicated in various disorders such as Schizophrenia. Hence, we were interested in exploring the effects of an early life perturbation of Gq signalling, exclusively in the Parvalbumin interneurons. In this study, we chemogenetically drive Gq signalling in Parvalbumin cells using hM3Dq-DREADD in the postnatal window P2-P14 and carry out a battery of behaviour experiments to study its effect on anxiety and despair like behaviours in adulthood. We do not observe a difference in development of reflex behaviours during post natal development. We observe a mild, task specific anxiolysis with broad postnatal increase in Gq signalling in Parvalbumin cells on measures such as Open field test and Elevated plus maze test. We do not see this effect in age matched genotype negative controls, hence validating our observation. We also assay for despair like behaviours and do not observe any significant difference. This study could indicate potential differences in cell type based regulation during development and opens up room for investigating circuit specificity for such cell type based regulation.

Title: The effects of lps-induced preterm labor on learning and memory in adult WAG / Rij rats

Authors: A. NURAYDIN, PhD, D. SAHIN, ***S. KARADENIZLI**, T. SAHIN, N. ATES; Physiol. Dept., Kocaeli Univ. Med. Sch., Kocaeli, Turkey

Abstract: The effects of lps-induced preterm labor on learning and memory in adult WAG / Rij ratsOBJECTIVE: The risk of preterm birth increases in mothers diagnosed with gram-negative bacterial infection during pregnancy. This situation constitutes important risk factors in the formation of important neurological disorders such as epilepsy, white matter damage in the brain and cerebral palsy in premature babies. Lipopolysaccharide (LPS) is a commonly used agent to create a preterm delivery model in rats. In our study, it was planned to investigate the effects of LPS induced preterm model on neurobehavioral performance, learning and memory in the adult WAG/Rij rats. The aim of this study is to evaluate the effects of preterm birth on learning and memory in a pathological genetic background such as absence seizure activity.METHODS AND METHODS: It was planned to be Group1(naive) n=8, Group2(SF) n=8, Group3(LPS) n=8.SF and/or Lipopolysaccharide(200µg/kg) were injected on the 15th and 16th day of pregnancy. At postnatal six month later, effects on locomotor activity, passive avoidance and morris-water-tank tests were investigated.RESULTS: When locomotor activity was evaluated, there was no significant change in total activity between the groups. In the passive avoidance test, the retention time in the LPS induced group was shortened compared to the naive and SF control groups($p<0.05$). In the Morris-water-tank test, in LPS induced group, there was a decrease in the correct squatting time according to the naive and SF control groups($p<0.05$).CONCLUSIONS: Idiopathic generalized epilepsy has a genetic basis, including absence epilepsy. WAG/Rij rats can be regarded as a valid genetic animal model of absence epilepsy with comorbidity of depression. Behavioral studies indicate that WAG/Rij rats exhibit depression-like symptomps. In WAG/Rij rats with genetically pathological background, premature birth induced by injection of LPS caused disruption in learning and memory tests in the adult period of the offspring. Further studies are needed to investigate the accompanying neurochemical and systemic changes in order to explain changes in learning and memory behavior.**Keywords:** Absence epilepsy, Passive avoidance, Water maze test

Abstract: The DLPFC as a neural correlate of resilience to major depressive disorder
Background. The risk factors familial risk and childhood maltreatment increase the risk for major depressive disorder (MDD). When both risks are present in an individual, they are considered to be at high risk for MDD. However, while some may develop MDD, some are resilient and maintain mental health. The brain morphometric correlates of this resilience are still unknown. To pinpoint this complex adaptation process on a brain morphometric level, interaction analysis of risk and diagnosis are needed.
Methods. We analyzed four groups of participants (N=804) with distinct risk (low-risk, i.e absence of CM and familial risk vs. high-risk, i.e. presence of both risks) and diagnosis (healthy vs. MDD) profiles in a 2x2 design, analyzing brain structural data (3T MRI) by means of voxel-based morphometry (VBM; CAT12 toolbox). Using (pre)frontal region of interest (ROI) analysis, we analyzed the interaction effect of risk and diagnosis.
Results. Resilient subjects (i.e. healthy, high risk participants) showed significantly higher volume in the left dorsolateral prefrontal cortex (DLFPC), compared to all other groups, (k=199, x/y/z= -34/48/12, T= 4.06, p=.047, family-wise error (FWE) corrected). We did not detect significant results for the bilateral superior frontal gyri, frontal poles, pars orbitalis of the inferior frontal gyri, and the right middle frontal gyrus ($p > .05$)
Conclusions. Higher volume in the left DLPFC might be an adaptive process in high risk subjects. The DLPFC is involved in emotional and cognitive processes, and higher volume in this area might aid such high-risk individuals in maintaining mental health. An increased volume in this region might therefore constitute a neural correlate of resilience to MDD in high risk.

Title: Long Term Effects of Early Life Morphine Exposure on Development, Affect and Cognition

Authors: *C. I. BANGO[1], S. ROBINSON[2];
[1]Williams Col., ; [2]Psychology, Williams Col., Williamstown, MA

Abstract: Both in-utero and postnatal opioid exposure can lead to neonatal opioid withdrawalsyndrome (NOWS). While the incidence of NOWS has dramatically increased in the last 15years, its potential long-term effects are not well understood. Our study sought to determine ifneonatal opioid exposure and withdrawal in a rodent model leads to changes in development,affect and cognitive performance in adolescence and adulthood. C57/BL6 mice were mated togenerate litters assigned to saline or morphine treatment. All pups in a given litter received thesame treatment. 57 animals were tested from 8 injected litters (3 saline-treated (N=28) and 5morphine-treated (N=29)). Male and female pups were injected bi-daily with morphine or saline(10mg/kg) from PND 1-14 (equivalent to the third trimester of a human pregnancy). Pups wererandomly assigned to different cohorts for behavioral analyses in neonatal (PND 13-15),adolescent (PND 42-44),and adult stages(PND 105-112). Morphine-treated animals showedreduced body weight relative to saline treatment independent of sex ($P < .005$). These weightdiscrepancies persisted to adolescence, $P = <.01$, but not into adulthood. In addition,morphine-treated pups showed deficits in the forelimb grasp ($P=<.01$) and surface righting tests($P=<.01$) on PND7. During adolescence, morphine-treated mice exhibited anxiety-like behaviorby spending less time in the center during the Open Field Test ($P= <.05$). A similar effect wasfound in adulthood, as morphine-treated mice spent more time in the corners ($p < 0.05$), andtrended towards more border time ($P=.08$). In the adult Novel Object Recognition Test,morphine-treated mice showed greater exploration time and novel object exploration time ($p <0.05$). However, there were no differences observed in the recognition index, suggesting thisdifference could be explained by a hyper-active phenotype in morphine-treated mice. Inconclusion, our study suggests that early opioid exposure leads to several anxiety-like behaviorsin adolescence and adulthood comparable to that of a hyperactive, chronic-stress phenotype. Inaddition, early opioid exposure delays the emergence of important developmental milestones.Lastly, early opioid exposure blunts weight gain during PND1-PND14, and this weightdiscrepancy persists into adolescence but recovers before adulthood. Future directions mayconsider how developmental delays and behavioral differences in morphine-treated animalsaffect other behaviors such as memory tasks, mating and maternal behavior, further explore sexdifferences, and study the neural correlates underlying these behavioral differences.

Title: Adaptive strategies of honey bee colonies to hurricane associated loss of resources: A case study with the Gentle Africanized Honey Bees (gAHB) in Puerto Rico

Authors: *S. L. CRUZ RODRIGUEZ[1], I. CLAUDIO- FORD[2], I. F. RODRIGUEZ[2], E. FLOREZ GÓMEZ[1], J. ALEMÁN RIOS[2], E. PEREZ CLAUDIO[2], E. CARABALLO SANCHEZ[2], I. COLLADO HERNANDEZ[2], R. MERGET[2], T. GIRAY[2], J. AGOSTO-RIVERA[2];

Abstract: In September 2017, Hurricane Maria hit Puerto Rico and was associated with the loss of approximately 80% of managed honey bee colonies mainly due to the winds and the posterior lack of floral resources. As part of an ongoing project, we monitored activity on a colony of Gentle Africanized bees (gAHB) with videos of the hive entrance, photos from all frames, and various sensors measuring internal parameters. This effort allowed us to capture the period before and after Hurricane Maria and provided a unique opportunity to gain insight into how surviving honey bee colonies responded to this climate event. We were also able to investigate whether sugar syrup and protein patties administration were sufficient to support survival, reproduction, and physiological control of the internal colony environment. Our findings indicate that despite the presence of high levels of honey from our syrup administration, and a small but stable amount of pollen stored, there was a dramatic decrease in brood shortly after the hurricane (October). Intriguingly analysis revealed that brood had already recovered from the October drop to levels comparable to those before the Hurricane, before protein patties supplementation, we observed a slight brood increase six days after the start of the pollen substitute. We interpret brood decrease as being caused by cannibalism since this behavior was generally observed in the apiary during this time period. Using our novel methodology to automatically detect pollen entry showed that by the 2nd month after the hurricane (November), pollen entry was recovered to pre-hurricane levels and coincided with the recovery of brood levels. We speculate that the lack of fresh pollen entry to the colony after the hurricane served as a signal to nurses to cannibalize young larvae.

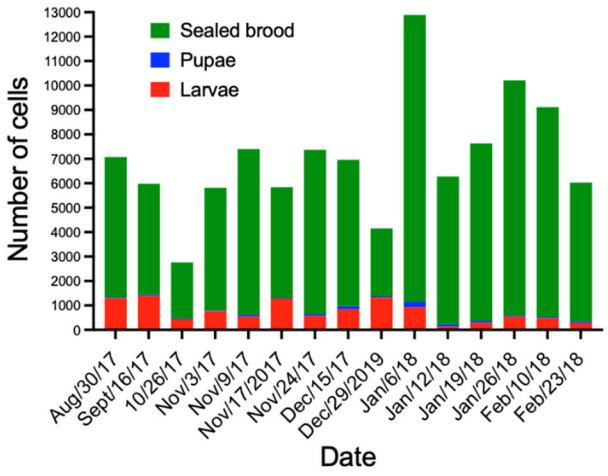

Figure 1. Number of cells of all frames of sealed brood and unsealed brood in each day the photos were taken.

Title: Racial disparities in stress or health? Modeling consequences of lifetime stress on maternal health and offspring development

Authors: *Y. M. CISSE[1], S. CARTER[2], T. JOVANOVIC[3], T. L. BALE[4];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Georgia State Univ., Atlanta, GA; [3]Wayne State Univ. Sch. of Med., Detroit, MI; [4]Univ. of Maryland Baltimore, Baltimore, MD

Abstract: Despite major advancements in maternal-fetal health, African-American women are three times more likely to die in childbirth or postpartum than their non-Hispanic white counterparts, independent of education, medical care, and income. Racial discrimination, a pervasive lifetime stressor unmitigated by socioeconomic status, precipitates a state of chronic stress and allostatic load. Lifetime discrimination experience (LDE) is indeed associated with blunted cortisol rhythms and stress responses, as well as an increased risk of chronic and inflammatory diseases in African-American women. Consistent with these data, we report that LDE is positively correlated with circulating cell-free mitochondrial DNA (ccf-mtDNA) in African-American women. Ccf-mtDNA reflects cellular stress, a common etiology of chronic and affective disorders, and serves as a novel peripheral biomarker of disease severity. Maternal lifetime stress is a strong predictor of adverse perinatal outcomes and offspring neuropsychiatric disease risk. However, little is known about the mechanisms by which pre-conception stress history affects offspring neurodevelopment. We developed a novel mouse model of maternal preconception stress (MPS), where female, but not male, offspring of MPS dams show elevated adult stress reactivity[BT1] . Female MPS offspring exposed to stress show an exaggerated stress response, suggesting an additive generational effect of preconception stress. To identify mechanisms by which MPS alters offspring development, we investigated sex-specific changes in the mid-gestation placental and fetal brain transcriptome. As the site of signaling and nutrient exchange, the placenta is a major determinant of fetal development. Placental adaptations modulate the ability of the placenta to support fetal growth in response to an adverse *in utero* environment. Male placentas of MPS dams had a robust transcriptional response, downregulating genes involved in immune function and upregulating genes involved in DNA damage response and repair, and mitochondrial translation. However, placentas of female MPS offspring exhibited minimal changes in gene expression. To investigate the neurodevelopmental consequences of MPS, we identified downregulation of genes involved in synaptic development and steroid hormone secretion in female MPS offspring brains relative to controls during a key window in hypothalamic development.

Title: Chronic corticosterone exposure blunts psilocybin anxiolysis in mice

Authors: *N. JONES[1], Z. ZAHID[2], S. GRADY[2], Z. SULTAN[2], Z. ZHENG[1], M. BANKS[2], C. WENTHUR[1];
[1]Pharm., [2]Neurosci., Univ. of Wisconsin, Madison, WI

Abstract: Research into psychedelics as psychiatric therapeutics has increased after demonstrating therapeutic efficacy in small scale clinical studies. For example, psilocybin, a 5-HT2AR agonist, has shown positive results when administered to individuals with major depressive disorder or end-of-life anxiety. Interestingly, despite these long-term anxiolytic effects, psilocybin is often acutely anxiogenic in humans, especially at elevated doses. Despite the potential relevance of these acute stress responses to the clinical effects of psilocybin, few studies have assessed the impact of drug-induced stress hormone release on the behavioral effects of psychedelics. In these studies, C57BL/6J mice were chronically exposed to either vehicle or corticosterone (80 ug/mL) in their drinking water, injected with IP psilocybin (3mg/kg), and assessed in the novelty suppressed feeding test, open field test, or sucrose preference test. As validation for the model, psilocybin acutely induced corticosterone-release ($p < 0.05$) compared to saline, but this psilocybin-induced release was significantly blunted in corticosterone-exposed mice ($p < 0.01$), such that there was no difference from saline. Additionally, corticosterone-treated mice spent significantly less time in the center of the open field apparatus ($p<0.01$) and had a lower sucrose preference ($p<0.001$) than vehicle-treated animals. In the novelty suppressed feeding test, psilocybin alone reduced the latency to feed ($p < 0.05$) compared to saline, but this effect was lost in the context of corticosterone pretreatment. In the open field test, an interaction between psilocybin and corticosterone exposure was identified ($p < 0.05$), with vehicle plus psilocybin increasing the time in center, but corticosterone plus psilocybin decreasing the time in center. In the sucrose preference test, corticosterone-exposure resulted in a significant induction of anhedonic effects for psilocybin ($p<0.05$). These results demonstrate that corticosterone pretreatment is associated with an acutely blunted corticosterone release following psilocybin administration and expression of a less anxiolytic and more anhedonic behavioral profile as compared to animals with an intact stress- hormone response to psilocybin.

Title: Sex-dependent long-term effects of adolescent stress on the posterior parietal cortex

Authors: M. FARIBORZI, S. B. PARK, A. OZGUR, ***G. LUR**;
Univ. of California, Irvine, Irvine, CA

Abstract: Adolescence is a time of intense cortical development and a period of heightened sensitivity to insult. To determine how sex affects the short- and long-term outcomes of adolescent stress, we subjected 30-day old male and female mice to repeated multiple concurrent stressors (RMS). In the posterior parietal cortex (PPC), RMS caused the elimination of excitatory synapses in deeper layers while inhibitory synapse density was predominantly diminished in superficial layers. These short-term effects coincided with reduced visuo-spatial working memory and were similar in both sexes. The loss of excitatory synapses and impaired working memory persisted in males past a 30-day recovery period. In contrast, we observed a remarkable recovery of excitatory transmission and behavioral performance in females. Inhibitory synapse density recovered in both sexes. We have also observed late onset anxiety- and depression-type behaviors in RMS exposed females that were largely absent in males. Overall, our results indicate that there are marked sex differences in the long-term effects of adolescent stress on cortical synapses and behavior.
