Title: Temporal medio-lateral patterning of neurogenesis in the thalamus: new developmental insights from MacBrainResource, a macaque brain resource

Authors: *T. SPADORY, A. DUQUE, L. D. SELEMON;
Neurosci., Yale Univ. Sch. Med., New Haven, CT

Abstract: Maternal injections of ^{3}H-thymidine during gestation in the non-human primate have been used to determine the time of neurogenesis for various brain areas. Seminal analyses of two caudal thalamic nuclei revealed overlapping periods of neurogenesis in the lateral geniculate nucleus (E36-E43) and the pulvinar (E36-E45) (Rakic, 1977; Ogren and Rakic 1981). Here we examine neurogenesis in the rostral thalamus with focus on two higher order relay nuclei, the mediodorsal (MD) and the anterior (ANT) that have been implicated in the pathology of schizophrenia. The search function of MacBrainResource (macbrainresource.org) identified archived cases (N=12) of ^{3}H-thymidine-labeled slides (Collection 1) with maternal injection dates ranging from embryonic day 25 (E25)-E50 and postnatal sacrifice dates. Slides containing the rostral thalamus were scanned on an Aperio ScanScope at 20X magnification. Digital files (svs) of these scans were transferred to a MicroBrightField system, and Stereo Investigator software was used to map ^{3}H-thymidine labeled neurons within a contour that encompassed the entire rostral thalamus. In Adobe Illustrator, brain mappings (tif files) were superimposed onto closely corresponding sections from the online BrainMaps macaque atlas to facilitate analysis of the nuclear distribution of the label. Our novel analytic approach, i.e. mapping the entire rostral thalamus, uncovered topographic patterning in the temporal progression of neurogenesis in the thalamus. At E30, ^{3}H-thymidine labeled neurons were located in a compact medial band; by E38, labeling was more laterally and diffusely distributed, and at E40-E43 thalamic labeling predominated ventrolaterally. Peak neurogenesis in the MD spans E30-E43 and in the ANT occurs during a similar time frame (E31-E43). Because the time of neurogenesis represents a period of heightened neurodevelopmental susceptibility to prenatal insult, determining when neurons in the MD and ANT are born may provide insight into the etiology of neurodevelopmental pathologies such as schizophrenia. Moreover, discovery of a previously undetected temporal mediolateral patterning of neurogenesis in the thalamus advances our understanding of the sequentially staggered generation of thalamic nuclei.

Title: Effects of astakine and serotonin on adult neurogenesis

Authors: *S. C. BALDWIN, J. L. BENTON, B. S. BELTZ;
Dept. of Neurosci., Wellesley Col., Wellesley, MA

Abstract: Neurogenesis, the generation and integration of neurons into brain circuits, occurs throughout the lives of numerous organisms, ranging from mammals to crustaceans. Unlike mammals, the first-generation precursor cells in crayfish, which are housed in a neurogenic niche, are not self-renewing but rather are replenished by the immune system. Previous studies have shown that hemocytes (blood cells) are attracted to the niche and can differentiate into neurons. To better understand the link between the immune and the nervous systems, the influences of the neurotransmitter serotonin and the cytokine astakine on neurogenesis were tested. 1) Increased levels of 5-HT result in an attraction of hemocytes to the neurogenic niche, and also stimulates the expression of astakine in hemocytes. 2) Astakine then encourages the release of semi-granular cells, a particular type of hemocyte thought to be responsible for renewing the niche precursor cells. 3) Adoptive transfer experiments have shown that labeled hemocytes transferred from donor to recipient crayfish are found in recipient neurogenic niches and generate offspring that express appropriate neurotransmitters. 4) Further, exposure of recipient crayfish to increased serotonin levels increases the incorporation of donor hemocytes into recipient niches. With this knowledge, we designed an experiment to test whether serotonin and astakine serve as links between the immune and nervous systems. In adoptive transfer experiments, hemocyte donors are treated with astakine to provide maximal numbers of labeled hemocytes for transfer to recipient crayfish, and recipients are treated with serotonin. We hypothesize that these treatments will result in higher hemocyte counts in donor crayfish and more cells in the neurogenic niche compared to controls.

Title: Developmental exercise effects on adulthood brain and behavior

Authors: *K. H. GEHM, E. C. PEREZ, L. LEASURE;
Univ. of Houston, Houston, TX

Abstract: Sedentary behavior is an increasing concern in Western nations, particularly for children and adolescents. Aerobic exercise has many positive effects on brain plasticity, and research on early life positive stimulation (environmental enrichment) demonstrates lifelong brain benefits. But whether early life exercise benefits carry over into adulthood remains largely unexplored. Exercise conditions the stress circuitry without harmful psychological stress. The hippocampus, part of the stress circuitry, is a site of neurogenesis, a form of structural plasticity that is increased with exercise. In the hippocampal dentate gyrus (DG), there is a pool of quiescent (BLBP+) stem cells capable of dividing in response to a stimulus such as stress or exercise. This project assessed long-term effects of adolescent exercise: 1) whether it buffers the behavioral and cellular effects of chronic stress in adulthood, 2) whether a history of exercise increases neurogenesis after reintroduction of exercise in adulthood. Beginning at 5 weeks of age, male and female Long Evans rats voluntarily ran for 2hr daily, 5d/week for 6 weeks. Females were matched to male running distance. All rats then rested for 6 weeks, and then half underwent 10 consecutive days of chronic restraint stress (2hr/day). Rats were then tested in the open field and elevated plus maze, and then sacrificed 24hr post-stress for quantification of proliferating quiescent stem cells (Ki67+/BLBP+). Another group of rats exercised for 3 weeks (5d/week) after the rest period and were sacrificed immediately after the last exercise session for quantification of newly generated neurons (DCX+ cells). Chronic restraint stress increased anxiety-like and depressive-like behavior in males only. Males with a history of exercise escaped more quickly (although not significantly) from the restraint tube. Interestingly, in both sexes, brain size was increased by a history of exercise. Cellular quantification of BLBP+/Ki67+ cells in the DG demonstrated that stressed males had fewer proliferating stem cells compared to non-stressed males, regardless of exercise history. Again, females did not show any change. Quantification of DCX+ cells after the reintroduction of exercise in adulthood is ongoing. We conclude that adolescent exercise may impact stress-related behaviors, but not cellular changes in adulthood in response to chronic stress. Increased escape behavior suggests that coping strategies may be altered by exercise history in males. Additionally, given brain size increase, research on other structural elements of the brain that may be enhanced by a history of exercise is needed.

Title: D-cysteine is an endogenous regulator of neural progenitor cell homeostasis in the mammalian brain

Authors: *E. R. SEMENZA, M. M. HARRAZ, M. M. GADALLA, S. H. SNYDER, R. ROYCHAUDHURI;
The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The D-stereoisomers of amino acids are increasingly recognized as important signaling molecules in the mammalian central nervous system. However, the D-stereoisomer of the amino acid with the fastest *in vitro* spontaneous racemization rate, cysteine, has not been examined. Using high-performance liquid chromatography and a stereoisomer-specific luciferase assay, we establish the presence of endogenous D-cysteine in the mammalian brain. We identify serine racemase, which generates the NMDA receptor co-agonist D-serine, as a candidate biosynthetic enzyme for D-cysteine. Levels of D-cysteine are enriched over twentyfold in the embryonic mouse brain compared to the adult. Treatment with 1 mM D-cysteine reduces the proliferation of cultured mouse embryonic neural progenitor cells (NPCs) by approximately 50% as assessed by Ki-67 expression and 5-ethynyl-2'-deoxyuridine incorporation. This effect is not shared with D-serine or L-cysteine. The antiproliferative effect of D-cysteine is associated with a dose-dependent inhibition of Akt and corresponding activation of the transcription factor FoxO3a, which is negatively regulated by Akt. Accordingly, D-cysteine treatment enhances the expression of FoxO3a target genes including the cyclin-dependent kinase inhibitors $p21^{Cip1}$ and $p27^{Kip1}$, which mediate cell cycle exit, and the pluripotency factor Sox2, which is essential for the maintenance of NPC identity. Collectively, these phenotypes resemble the quiescent state adopted during the late embryonic stage by the subset of NPCs that persist throughout life as adult neural stem cells and suggest that D-cysteine may function to prevent premature exhaustion of the NPC pool. Finally, we perform an unbiased screen for D-cysteine-binding proteins in NPCs by immunoprecipitation with a D-cysteine-specific antibody followed by mass spectrometry. This approach identifies myristoylated alanine-rich C-kinase substrate (MARCKS) and its relative MARCKSL1 as putative D-cysteine-binding proteins. Together, these results establish the existence of mammalian D-cysteine and implicate it as an endogenous regulator of neural progenitor homeostasis in the developing brain.

Title: The transcription factor CLAMP is required for neurogenesis inDrosophila melanogaster.

Authors: *M. A. TSIARLI[1,2], A. M. CONARD[1], L. XU[1], E. NGUYEN[1], E. N. LARSCHAN[1]; [1]Dept. of Mol. Biology, Cell. Biol. and Biochem., Brown Univ., Providence, RI; [2]Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Neural stem cell (NSC) differentiation is controlled by cell-intrinsic and external signals from the stem cell niche including niche surface glia (SG). However, the mechanisms by which transcription factors drive NSC differentiation within the niche remain largely unknown. Here, we show that the transcription factor, Chromatin-linked adaptor for MSL proteins (CLAMP) is required for NSC differentiation. CLAMP promotes transcription of genes involved in stemness, proliferation, and glial development and represses transcription of genes involved in neurogenesis and niche survival. Consistent with transcriptional changes, CLAMP promotes NSC proliferation and SG production. Furthermore, glial-specific knock-down of *clamp* causes similar phenotypes to *clamp* null mutants. CLAMP motifs are present at many target genes including the glial-determining gene, *glial cells missing*, and *Notch*, a key regulator of neurogenesis. Collectively, our results suggest that CLAMP regulates a transcriptional program which drives NSC proliferation and differentiation *via* cell-intrinsic and niche-dependent mechanisms that involve niche glia.

Title: Prenatal Maternal T Cell Activation with Staphylococcal Enterotoxins Induces Postnatal Behavioral and Microglial Alternations in Mouse Offspring

Authors: *M. NISSENBAUM[1], R. GLASS[1], N. FOX[1], S. STEIGMAN[1], D. PRADO DE MAIO[2], L. COVEY[2], J. E. PINTAR[3], H. ZHANG[4], A. KUSNECOV[1]; [1]Psychology, [2]Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ; [3]Dept Neurosci & Cell Biol, Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; [4]Neurosci. and Cell Biol., Robert Wood Johnson Med. School, Rutgers Univ., Piscataway, NJ

Abstract: Maternal immune activation (MIA) during pregnancy has been shown to perturb normal neurobehavioral development. Recently, we found that maternal responses to Staphylococcal enterotoxins A (SEA) and B (SEB), induce deviations in normal offspring behavior. These toxins induce pronounced T cell proliferative and cytokine responses. To determine if genetic background influences the postnatal consequences of T cell activation, we used two strains of pregnant female mice (C57BL/6 and BALB/c). Pregnant mice (N=4-6/treatment) from each strain received saline, SEA or SEB (200 μg/Kg) on embryonic day 12.5 (E12.5). By 2hr, enterotoxin treatment induced increased maternal IL-2, IL-4, IL-6 and IFNγ levels, but no changes in IL-17A. Moreover, in additional studies in C57BL/6 pregnant females challenged with SEA or Saline (N=4/treatment) at E12.5, SEA-selective T cell expansion and cellular expression of IL-2 and IFNγ were increased by 48hr, suggesting that T cell responses to SEs are active over several days of embryonic development. Further experiments involving postnatal behavioral assessments of male and female juvenile offspring from SEA/SEB challenged mothers revealed strain-dependent differences in social behavior, in that BALB mice showed an increase, while C57BL/6 mice showed a decrease in social investigation. Both strains showed delayed spatial learning (using the Morris water maze). SEA treatment of pregnant C57BL/6 mice on E12.5 impaired acquisition of the water-based radial arm maze in male and female offspring. To determine if these behavioral effects were associated with changes in postnatal microglial density and morphology, pregnant C57 wildtype mothers mated with cx3cr1$^{gfp/gfp}$ males were given SEA or Saline on E10.5, E12.5 or E14.5. Quantitation of microglia across postnatal days P7-P30 were initiated in the hippocampus and prefrontal cortex. For P30 offspring of E10.5 injected mothers, SEA offspring (N=9), when compared to Saline offspring (N=9), had more microglia ($p<0.05$) in the CA1, CA3 and dentate gyrus (DG) of the hippocampus, and the prelimbic and infralimbic areas of the prefrontal cortex. At P15, SEA offspring (N=7) were significantly elevated only in the DG, compared to saline offspring (N=6). Offspring from E12.5 SEA-injected mothers did not show significant changes in microglia numbers. These data suggest that the gestational timing of SEA challenge can cause a postnatal deviation in the population dynamics of microglia in a brain region-specific manner. This might affect synaptic development and other characteristics of neuronal function. Analyses are ongoing to assess microglial morphological parameters.

Title: Effects of early life opioid exposure on brain development and its later life consequences.

Authors: *A. HURST, H. HARDER, L. HANUS, C. SEARLES, A. Z. MURPHY;
Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Individuals exposed to opioid drugs *in utero* tend to have deficits in long-term learning and memory. Cognitive disorders have been previously shown to have cellular manifestations in the dentate gyrus of the hippocampus. Gestational morphine exposure may cause alterations in dentate gyrus development resulting in long term cognitive disorders. With the recent increase in infants born with an opioid use disorder, information on how gestational opioid exposure affects brain development is essential. To model the effects of gestational morphine on hippocampal development, we used an early life morphine exposure paradigm. Experimental male and female rat pups on the first day of life (P0) were given 2 subcutaneous injections of morphine (2 mg/kg) spaced 6 hours apart. Since the rat dentate gyrus forms postnatally, morphine injections on P0 should expose the pups to morphine at the onset of dentate gyrus formation. Male and female rats were sacrificed at P7, P14, or adulthood (P 60-100) and the dentate gyrus was assessed immunohistochemically for neuroblast proliferation and microglial colonization using antibodies targeting PCNA, doublecortin, and Ibal. Differences were detected in the number of proliferating cells and microglia numbers in morphine exposed rats, suggesting a cellular developmental delay. To determine the impact of early life morphine on microglia activation, adult rats received an injection of lipopolysaccharide (LPS) (250 ug/kg; i.p.). Brains were collected 6 hours post-LPS and histologically analyzed for number and morphology of proliferating cells, microglia, and presence of young neurons in the dentate gyrus. Animals exposed to morphine neonatally show differentially reactive microglia, alterations in the number of proliferating cells, and differences in young neuron maturation when compared with controls. Information from this study can be used to infer the consequences of *in utero* morphine exposure in humans.

Title: Exercise and metformin to enhance neurogenesis and memory in dietary obesity

Authors: *O. GHOSH-SWABY[1], A. C. REICHELT[3], T. J. BUSSEY[4], L. M. SAKSIDA[2];
[1]Schulich Sch. of Med. and Dent., [2]Western Univ., London, ON, Canada; [3]Adelaide Med. Sch., The Univ. of Adelaide, Adelaide, Australia; [4]Robarts Res. Inst., London, ON, Canada

Abstract: Excessive consumption of high fat and high sugar (HFHS) foods can cause weight gain and obesity, reduce adult hippocampal neurogenesis, and impair learning and memory. We examined whether two interventions known to boost hippocampal neurogenesis, aerobic exercise, or the diabetes drug metformin, can reverse HFHS diet-induced cognitive impairment in male and female mice. To study the impact of exercise, mice were fed either an HFHS diet (n=32) or a control diet (n=32) for 28 days and randomly assigned to either running wheel access (n=16/diet group) for 3 hours, 5 days a week, or no access (n=16/diet group). To study the effects of metformin, mice were fed either an HFHS diet (n=40) or a control diet (n=40) and administered metformin (200mg/kg, i.p.; n=20/diet group) or saline (n=20/diet group) for 28 days. Memory was then tested on a spontaneous location recognition (SLR) task, shown to be sensitive both to the consumption of a high sugar diet and changes in hippocampal neurogenesis. During a sample phase, mice explored an arena containing identical landmarks in 3 locations arranged in a triangular formation. After 3 hours, memory was tested by assessing the extent that mice can discriminate and remember the locations presented during sample. Cognitive load was varied across 3 conditions under which the similarity of the to-be-remembered locations was manipulated parametrically: dissimilar (ds-SLR), similar (s-SLR), or extra similar (xs-SLR). Following SLR, brain sections were immunohistologically examined using doublecortin as a marker of neuroproliferation (DCX+ cells). A two-way ANOVA was used to analyze each measure of interest by sex. HFHS diet led to impairments in memory under s-SLR & xs-SLR conditions. In contrast, control-fed mice spent more time exploring the novel location during ds-SLR and s-SLR conditions. Mice that exercised exhibited enhanced memory and novelty exploration during xs-SLR. Both exercise and metformin reversed cognitive decline in HFHS-fed mice tested on ds-SLR and s-SLR. Interestingly, both exercise and metformin enhanced performance in xs-SLR in female mice fed an HFHS diet. However, the relationship between exercise- and metformin-induced increases in neurogenesis, and cognitive improvement, was not straightforward. Physiologically, exercise and metformin reduced HFHS diet-induced weight gain and adiposity. Our results indicate that exercise and metformin can reverse diet-induced cognitive impairment in a hippocampal-dependent task, but the neural mechanism by which metformin improved memory may not be associated directly with increased neuroproliferation.

Title: Understanding cell types in the developing human brain

Authors: *A. BHADURI, C. SANDOVAL ESPINOSA, M. OTERO, U. EZE, A. KRIEGSTEIN;
Univ. of California San Francisco, San Francisco, CA

Abstract: The human cortex is organized into distinct functional areas with unique physical structure, connectivity, and function relevant to human cognition and perception. How these cortical areas emerge, and when they are specified, have long been of interest as the timing and mechanism of arealization has important implications in the etiology of neurodevelopmental disease, modeling of cortical structures, and comparison of developmental cell types across species. To characterize the emergence of human cortical arealization, we performed single-cell sequencing on 14 individuals across 6 emerging cortical regions. These data validated previous observations that early specification exists in establishing frontal and occipital identities, and additionally highlight the role for presence or absence of occipital gene signatures in regulating radial glia and early neuronal spatial identities. We also observed a large number of differentially expressed genes within radial glia, noting that the area-specific gene signatures for each cortical region are substantially remodeled across differentiation and maturation events. Comparisons of this dataset to adult datasets across cortical regions highlighted some similarities, though substantial changes appear to exist between area-specific gene signatures during developmental periods and adult time points. To validate the patterns we observed in our profiling data, we used an adaptation of sequential fluorescent in situ hybridization (FISH) methods in conjunction with automated probing and high content imaging to produce a snapshot spatial atlas across cortical regions. This approach validated the strong frontal to occipital exclusion patterns in our data and identified new clusters based upon the FISH signal. This dataset provides a valuable resource for understanding the identity and development of distinct human cortical regions.

Title: Terminal selector genes link neuronal fate with wiring specificity in the Drosophila visual system

Authors: *M. OZEL[1], C. SKOK GIBBS[2], I. HOLGUERA[1], R. BONNEAU[2], C. DESPLAN[1];
[1]New York Univ., New York, NY; [2]Flatiron Inst., New York, NY

Abstract: Cascades of transcription factors (TF) in neural stem cells are responsible for generating the enormous diversity of cells types in nervous systems, from flies to humans.

However, the gene-regulatory mechanisms that establish and maintain these cell fates in postmitotic neurons and instruct their specific morphology, connectivity and physiology remain unclear. The *Drosophila* optic lobes provide an excellent model system to address these questions with around 200 morphologically distinct neuronal types whose connectome has been almost completely characterized. In order to understand the cell-type specific transcriptional programs employed at different stages of neuronal differentiation, we have generated a very large single-cell RNA sequencing atlas spanning all stages of optic lobe development (Ozel, Simon et al. 2020, *Nature*). We found that unique combinations of 113 TFs, which are strongly enriched in homeobox proteins, are sufficient to define each of the 175 optic lobe neuronal types in our dataset (median: 8 TFs per cell type) throughout development as well as in adults. We hypothesized that these TFs represent terminal selectors that are activated in each neuron immediately after their birth and function as top-level regulators of their cell-type specific gene expression throughout their life. Accordingly, we show that modification of these TF 'codes' with knock-down and ectopic expression experiments in postmitotic neurons is sufficient to induce complete *in vivo* transdifferentiation between neuronal types. We identified a bistable loop formed by the mutually repressing TFs Mef2 and Aop in closely related transmedullary neurons. This ensures that transformations between them are all or none, with no intermediate phenotypes. We also performed computational network inference analysis using the *Inferelator* pipeline to understand the downstream effectors of these terminal selectors. This revealed that terminal selectors interact with other TFs that are transiently activated in response to extrinsic signals at specific time points to activate the cell-type specific cell-surface molecules and other effectors that instruct distinct morphological features and the synaptic partners of each neuron. Our results provide a unified framework of how specific fates are maintained in postmitotic neurons, and reveal the regulatory mechanisms that ensure the robustness of these cell fate choices. They open up new avenues to understand synaptic specificity through gene regulatory networks.

Title: Cell type specific characterization of the epigenomic landscape during CNS neuronal development and maturation

Authors: *K. MÄTLIK[1], E.-E. GOVEK[1], M. R. PAUL[1], E. KORB[2], C. D. ALLIS[1], M. E. HATTEN[1];
[1]The Rockefeller Univ., New York, NY; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Developing neurons undergo a complex series of dynamic, morphological changes to become highly specialized, polarized cells that relay information within brain circuitry. These transitions are accompanied by changes in chromatin conformation and gene expression. However, the epigenetic mechanisms that control neuronal differentiation and maturation are largely unknown. Using mouse cerebellar granule cells (GCs) as a model, we studied changes in epigenetic modifications during key stages of neurodevelopment: neuronal progenitor proliferation (postnatal day 7, P7), postmitotic neuron migration (P12) and synaptogenesis (P21). Importantly, observed epigenetic changes were correlated with changes in gene expression to assess their potential impact on the transcriptome. For each stage of development, we investigated specific histone modifications and bivalency using a combination of chromatin immunoprecipitation with sequencing (ChIPseq) assays for H3K4me3, H3K9me3, H3K27me3, H3K36me3 and H3K27ac, and imaging of a fluorescent H3K4me3 and H3K27me3 bivalency probe in GCs in ex vivo cerebellar slices. Chromatin accessibility was further assessed using an Assay for Transposase-Accessible Chromatin using sequencing (ATACseq). Accompanying changes in gene expression were evaluated using RNA sequencing. We found that specific changes in the distribution of histone modifications and their combinations are associated with gene expression changes that accompany cell cycle exit and neuronal maturation. In addition, we identified developmentally regulated histone bivalency at genes involved in GC proliferation and synaptogenesis. Visualization of bivalent chromatin domains using the fluorescent bivalency probe in GCs in *ex vivo* cerebellar slices revealed developmental stage specific differences between progenitors and differentiated GCs. Furthermore, by studying the distribution of histone modifications associated with cell identity, as well as enrichment of transcription factor motifs at developmentally regulated enhancers, we identified novel transcription factors predicted to be required at different stages of GC development. In conclusion, we present a comprehensive characterization of the epigenomic landscape and identification of novel mechanisms that regulate neuronal development in a specific, developing CNS neuron type *in vivo*.

Abstract: The hypothalamus is critically important for regulating many autonomic, metabolic, and behavioral traits, yet a comprehensive understanding of neuronal subtypes and their development in the human brain is lacking. Here, we characterized the prenatal human hypothalamus by sequencing the transcriptomes of 56,278 single-cells from 12 individuals, spanning gestational weeks 4 through 25. Clustering these cells revealed a temporal trajectory from proliferative stem cell populations in first trimester samples to maturing excitatory and inhibitory neurons and glia in the second trimester. Sub-clustering of 11,349 post-mitotic neurons revealed 42 neuronal subtypes. Gene regulatory network modeling predicted transcription factors (TFs) that may be responsible for neuronal development and lineage differentiation within distinct hypothalamic nuclei. A merged analysis with paired samples from the cortex and ganglionic eminences (GE) revealed two distinct neurogenesis pathways emanating from a common progenitor pool, one unique to cortex and another shared between GE and hypothalamus. This study greatly expands the number of genes that potentially play a role in hypothalamus development, which will allow researchers to consider additional gene candidates in neurodevelopmental or neuroendocrine disorders. Indeed, we found significant association between GWAS candidate genes for circadian regulation (morningness) and schizophrenia, both previously linked to hypothalamus function, to specific neuronal subtypes expressing these target genes during development. Together, these results provide the first comprehensive transcriptomic view of human hypothalamus development at cellular resolution.

Title: Novel genetic features of human and mouse Purkinje cell differentiation defined by comparative transcriptomics.

Authors: *D. E. BUCHHOLZ[1], T. S. CARROLL[1], A. KOCABAS[1], X. ZHU[1], H. BEHESTI[1], P. L. FAUST[2], L. STALBOW[1], Y. FANG[1], M. E. HATTEN[1];
[1]The Rockefeller Univ., New York, NY; [2]Columbia Univ. Irving Med. Ctr., New York, NY

Abstract: Comparative transcriptomics between differentiating human pluripotent stem cells (hPSC) and developing mouse neurons offers a powerful approach to compare genetic and epigenetic pathways in human and mouse neurons. To analyze human Purkinje cell (PC) differentiation, we optimized a protocol to generate hPSC-PCs that formed synapses when cultured with mouse cerebellar glia and granule cells and fired large calcium currents, measured with the genetically encoded calcium indicator jRGECO1a. To directly compare global gene expression of hPSC-PCs with developing mouse PCs, we used translating ribosomal affinity purification (TRAP). As a first step, we used *Tg(Pcp2-L10a-Egfp)* TRAP mice to profile actively transcribed genes in developing postnatal mouse PCs, and used metagene projection to identify the most salient patterns of PC gene expression over time. We then created a transgenic *Pcp2-L10a-Egfp* TRAP hESC line to profile gene expression in differentiating hPSC-PCs, finding that the key gene expression pathways of differentiated hPSC-PCs most closely matched those of late juvenile, mouse PCs (P21). Comparative bioinformatics identified classical PC gene signatures as well as novel mitochondrial and autophagy gene pathways during the differentiation of both mouse and human PCs. In addition, we identified genes expressed in hPSC-PCs but not mouse PCs and confirmed protein expression of a novel human PC gene, CD40LG, expressed in both hPSC-PCs and native human cerebellar tissue. This study therefore provides the first direct comparison of hPSC-PC and mouse PC gene expression and a robust method for generating differentiated hPSC-PCs with human-specific gene expression for modeling developmental and degenerative cerebellar disorders.

Title: The long-noncoding RNA Pantr2 affects radial glia differentiation timing through regulation of Nfix and Rgcc expression

Authors: *J. J. AUGUSTIN, L. A. GOFF;
Johns Hopkins Univ., Baltimore, MD

Abstract: Long-noncoding RNAs (lncRNAs) are defined as an RNA transcripts of length 200nt or longer with no protein coding potential. While functions for individual lncRNA transcripts remain largely unresolved, recent evidence has revealed critical roles for specific lncRNAs in both development and disease. The largest diversity of lncRNA expression in any somatic tissue is found within the mammalian central nervous system. As such, lncRNA biology has become a focus of neurodevelopment and neurodegenerative studies. Here, we characterize the mouse lncRNA Pantr2 and describe its function in the regulation of radial glia differentiation and neurogenic potential through interactions with the RNA binding protein Elavl1/HuR. Previous work has demonstrated that ablation of Pantr2 results in microcephaly and cortical mislamination in our knockout mouse model. This phenotype arises, in part, from a significant reduction in intermediate progenitor cells in the absence of Pantr2. Here we conduct an ATAC-seq study and identify regions of significant chromatin accessibility changes in Pantr2 knockout cortical neurospheres. We specifically identify an upstream regulatory element of the gene Rgcc with significant differential accessibility which contains a binding motif for the transcription factor Nfix. Single cell RNA sequencing analysis indicates that Pantr2 knockout-derived cortical neurospheres express both Nfix and Rgcc at significantly increased levels compared to wildtype controls, implicating these genes as downstream effectors of Pantr2 activity. We further test this association by demonstrating the ability for the Pantr2 transcription to function ectopically in Neuro2a (N2a) cells. N2a cells over-expressing Pantr2 exhibit significantly lower levels of both Nfix and Rgcc upon stimulation to differentiate. Moreover, a reduction in the percentage of differentiating Pantr2 overxpression N2a cells were observed in G2/ M phase of the cell cycle indicating a potential cell cycle block at M phase. Ex vivo analysis indicates ectopic expression of Nfix is sufficient to induce Rgcc expression in N2a cells and that expression of these two genes slows the progression of M phase. A block in M phase is consistent with the observed differentiation defect in the cortex of developing Pantr2 deficient mice. To confirm these results in vivo, in utero electroporation was used to demonstrate that ectopic expression of Nfix and/or Rgcc phenocopy the Pantr2 KO mice. Our results indicate that both Nfix and Rgcc are sensitive to Pantr2 RNA expression levels and that changes in the expression of these two genes recapitulates the Pantr2 KO phenotype.

Title: The first neurons of the human brain: towards a policy for extending the 14-day limit

Authors: *I. BYSTRON[1], A. ERLER[2];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]CUHK Ctr. for Bioethics, The Chinese Univ. of Hong Kong, Hong Kong, China

Abstract: *Devastating brain disorders affect more than one billion people worldwide. In spite of recent large-scale initiatives in neuroscience there are very few effective cures for neurological and neuropsychiatric disorders. A variety of studies have already highlighted differences between human brain development and that of other mammals.*
Using high-resolution volume rendering of 3D confocal data sets from a Zeiss LSM 710 microscope we have examined the initial stages of neurogenesis in the forming neural tube and emerging trigeminal, otic, pituitary placodes and olfactory placodes. Human embryos from Carnegie stages (CS) 10-12 (29-31 days post-conception) were obtained from the Human Developmental Biology Resource UK. The rostral end of the neural tube, which becomes the future telencephalon, closes at CS 11. We found bipolar TU-20-positive neurons scattering through the several regions of the early cephalic epithelium adjacent to the forming neural tube. Such cells, not seen in other mammalian species, delaminate from the epithelium to coalesce within the forming mesenchyme. Our discovery of the the first neurons migrating into the optic cup from diencephalon at CS11 and the first neurons of the human presumptive cortex at CS12, raises important questions on the origin and role of these unique neuronal populations in human brain development. That can be clarified only by research on tissue currently unavailable to the scientific community because of the difficulties of getting tissue obtained by termination of pregnancy during the formation of the neural tube at CS 8-11, and the limitations of the "14-day rule" on human embryo research in vitro. For a number of reasons, including being able to trace the origin of the first neurons in the human brain, a new policy is needed for the use of human embryos created through in vitro fertilisation. Such a policy should seek to maximize best use of donated embryos, which currently get discarded even before the formation of the neural plate, leading to unnecessary waste of precious tissue. The 14-day limit on embryo research should be re-examined considering the latest knowledge of the scientific and medical opportunity costs entailed by such a restriction.
As an alternative to the 14-day rule, we propose extending the limit to CS11. Such an extension based on wide public consultation, is essential if we are to understand how the structure that makes us human begins to form.

Title: Determining the Metabolic Requirements of Electrically Active Rodent Primary Neurons in Long-Term Culture

Authors: *C. K. H. MAK[1], K. MCCORMACK[1], A. C. EAVES[1,2], S. A. LOUIS[1], E. KNOCK[1]; [1]STEMCELL Technologies Inc, Vancouver, BC, Canada; [2]Terry Fox Lab., Vancouver, BC, Canada

Abstract: Neurons have a high metabolic demand with the brain accounting for 20% of total body energy consumption. Most neuronal cell culture media contain energetic substrates in excess to ensure this demand is met. We investigated whether media with physiologic (e.g. BrainPhys™) or supraphysiologic (e.g. Neurobasal™) glucose levels supported the metabolic requirements and sustained activity of primary neurons in high-density cultures. E18 rat cortices were dissociated into single-cell suspensions and plated in NeuroCult™ Neuronal Plating Medium supplemented with NeuroCult™ SM1 Neuronal Supplement (SM1) in 96-well microelectrode array (MEA) plates. After 5 days of incubation, cultures were transitioned to BrainPhys™ (BP) with SM1 by performing half-medium changes every 2 - 3 days for up to 8 weeks. Increasing levels of glucose were added to BP, ranging from 2.5 to 25 mM final concentration. Cells were also cultured in high-glucose media (Neurobasal™ [NB] and Neurobasal™ Plus [NBPlus]) following the supplier's protocols. Before each half-medium change, media were collected for glucose measurements using a YSI Biochemistry Analyzer. Spontaneous neuronal activity was recorded three times weekly using the Axion Biosystems MEA system. Neuronal activity was first detected in BP-cultured neurons around day 9, with mean firing rate (MFR) recorded at 3.1 ± 0.3 Hz (mean ± SEM, n = 3). The activity of neurons in NB remained low throughout culture, with < 1.3 Hz of MFR recorded over time. For NBPlus-cultured neurons, activity was not detected until day 14 at 1.6 ± 0.3 Hz and increased to 8.6 ± 2.3 Hz on day 18, but dropped significantly to 2.1 ± 0.9 Hz on day 24 (mean ± SEM). MFR was maintained below 2.7 Hz thereafter and decreased to 0.8 ± 0.3 Hz on day 54 (mean ± SEM). The same "peak and drop" activity pattern was also observed in BP when MFR dropped to 0.05 ± 0.02 Hz (mean ± SEM) around day 14. Glucose measurements of media on day 14 showed that glucose was depleted in BP but not in NB and NBPlus. With 12.5 mM glucose added to BP, MFR was measured at 3.8 ± 1.5 Hz on day 14, 3.1 ± 0.4 Hz on day 28 (mean ± SEM), and maintained at this level until the end of culture, with 3.3 ± 0.9 Hz recorded on day 54 (mean ± SEM). Notably, both NB and NBPlus had higher levels of glucose throughout culture but both displayed lower activity than BP after week 4. Glucose supplementation in BP at a higher (but not hyperglycemic) level was the only condition that could support neuronal activity in long-term culture. These data demonstrate that BrainPhys™ is not only optimized for energetic substrates but its performance can be further enhanced by supplementation with glucose to meet higher metabolic demands of electrically active neurons in vitro.

Title: Hypoxia-inducible factor 1 alpha promotes peripheral nerve myelination

Authors: *T. ARAKI, Y. UJIIE-KOBAYASHI, S. WAKATSUKI;
Dept PNS Res., Natl. Inst. Neurosci, NCNP, Tokyo, Japan

Abstract: Schwann cells (SCs) generate myelin sheath in the peripheral nervous system (PNS), and their differentiation plays an important role in PNS myelination. Mature SCs are formed via a stepwise differentiation during development from neural crest cell-derived SC precursors to immature SCs and pro-myelinating SCs, followed by myelinating/non-myelinating SCs. Characteristic expression of genes, including several transcriptional factors, have been described in each developmental stage. However, underlying mechanisms of SC differentiation remain unclear. Recent studies have shown that hypoxia-inducible factor-1 alpha (HIF-1α) plays a role in myelination in the central nervous system. Here, we investigated the role of HIF-1α in PNS myelination. We found that HIF-1α can be stabilized in nuclei of SCs cultured under hypoxia (1% O_2). Culturing in hypoxia or overexpression of HIF-1α bearing mutation to be resistant to proteasomal degradation resulted in upregulation of myelin related gene expressions in SCs. By immunohistochemistry, HIF-1α was localized in S100β-positive SCs in murine sciatic nerve during development. HIF-1α expression in protein level was higher during development than in adulthood in mice, while HIF-1α mRNA expression was almost constant. Moreover, HIF-1α stabilizing drug that inhibits prolyl hydroxylation was able to upregulate myelin protein expression and promoted myelination in culture. Transient hypoxic incubation also facilitated in vitro myelination. These finding suggest that HIF-1α induces SCs differentiation and promotes PNS myelination during development.

Abstract: Interlaminar astrocytes (ILAs) are a cortical astrocyte subtype that have a soma in layer I and long interlaminar processes that run perpendicular to the pia into deeper cortical layers. We previously performed a comparative study of ILAs in 46 species of therian mammals. We described *rudimentary ILAs* with short GFAP$^+$ processes confined to layer I, and *typical ILAs* with long GFAP$^+$ processes exiting layer I and extending into deeper cortical layers. We found that ILAs are present in all mammals, and what makes them special in primates is their highest number and highest morphological complexity.ILAs have been described in postnatal animals, but exactly when they appear during development has not been determined. We studied ILA developmental origin and differentiation of ILAs in prenatal and postnatal cortex by analyzing GFAP$^+$ and S100b$^+$ ILAs in fixed postmortem brains of mouse, rhesus macaque, chimpanzee and human. We found that ILAs are present in the prenatal brain and increase in number and morphological complexity throughout development. We compared the expression of specific markers in ILAs across development in mouse and macaque and found some similarities in protein expression by mouse rudimentary ILAs and macaque typical ILAs, but noted key differences that may indicate distinct functions across species. These data provide new information on ILA astrogenesis and function in the developing cerebral cortex.

Title: Gene expression of the glutamate transporters GLAST in glial cells of larvae, postalarvae, and adults of the Pacific sea biscuit Dendraster excentricus

Authors: *T. N. OLIVARES-BAÑUELOS[1], G. OSUNA-CORTEZ[1], F. CORREA-SANDOVAL[1], L. ENRIQUEZ-PAREDES[2], A. ORTEGA[3];
[1]Inst. de Investigaciones Oceanológicas, [2]Facultad de Ciencias Marinas, Univ. Autónoma de Baja California, Ensenada, Mexico; [3]Cinvestav-IPN, Mexico City, Mexico

Abstract: Echinoderms are a phylum within marine invertebrates characterized by having a pentaradial secondary symmetry. Marine invertebrates are strategic study models for biological sciences, helping to understand the functioning of the nervous system for the diagnosis and treatment of neurological disorders. Similarities have been found between invertebrates and vertebrates in their nervous system, which is made up of two main types of cells: neurons and

glia, whose nerve cells have similarities in biochemistry and functionality. Although the presence of glial cells in echinoderms has already been demonstrated, it is not yet known at what point in larval development these cells begin to develop. Considering this, the present work aims to analyze larval and adult tissue of the Mexican Pacific sea biscuit *Dendraster excentricus* to know the expression of GLAST transporters at each stage of larval and postlarval development. These information let us know in which stage these organisms have functional glial cells. *Dendraster excentricus* sea biscuit is a common echinoderm on the shores of the Pacific Ocean. Adult organisms of *D. excentricus* were collected from the Punta Banda estuary in Baja California, Mexico. Larvae cultures were carried out and larvae with four, six or eight-arms, competent and metamorphosed larvae, were collected. Quantitative PCR was carried by triplicate with each of the developmental stages, as well as with adults, to measure GLAST gene expression; ribosomal 18S housekeeping gene expression was measured too as internal control. Results showed statistically significant differences in GLAST expression between sea biscuit development stages and adults. The higher relative expression of GLAST was observed in adult samples, followed by the expression in both metamorphosed and six-arms larvae. Low expression of GLAST was detected in larvae with four- and eight-arms, besides in competent larvae. Based on these results, it seems that glia cells in the sea biscuit *Dendraster excentricus* are present from the six-armed stage. As was reported for other echinoderms, the nervous systems of adult organisms of *D. excentricus* present functional glial cells. Knowing the development and functional characteristics of a simpler nervous system is important to implement techniques that lead to the identification and development of new treatments for neurodegenerative diseases.

Title: Exploring the combinatorial functions of proneural genes Neurog1 and Neurog2 in neocortical stem cell maintenance

Authors: *A.-M. OPROESCU[1,2], S. HAN[1,3], D. ZINYK[1], C. SCHUURMANS[1,3];
[1]Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada; [2]Lab. Med. and Pathobiology, [3]Biochem., Univ. of Toronto, Toronto, ON, Canada

Abstract: Proneural genes encode basic-helix-loop-helix transcription factors that promote neural stem cell (NSC) differentiation in the developing nervous system. In the embryonic

neocortex, proneural genes *Neurog1* and *Neurog2* are redundantly required to specify a glutamatergic neuronal identity. Paradoxically, our lab previously found that *Neurog1* tampers the pace of early-stage neurogenesis when co-expressed with *Neurog2*. In the present work, we observe precocious depletion of NSCs in *Neurog1*$^{-/-}$;*Neurog2*$^{-/-}$ but not in *Neurog1*$^{-/-}$ or *Neurog2*$^{-/-}$ single mutant control cortices. Therefore, the aim of this study is to test the hypothesis that *Neurog1* and *Neurog2* operate together to maintain the neocortical NSC pool. We utilize a novel split-Cre system to examine only those NSCs that co-express *Neurog1* and *Neurog2*, generating two new knock-in lines, *Neurog1CCre*^{KI} and *N2NCre*^{KI}, in which the C- and N-terminal regions of Cre are knocked-in to *Neurog1* and *Neurog2* loci, respectively. When both genes are co-expressed, functional full-length Cre is re-constituted. By crossing *Neurog1CCre*^{KI};*N2NCre*^{KI} mice with a *Rosa-ZsGreen* reporter line, we performed long-term lineage tracing of double-positive NSCs throughout embryonic corticogenesis and into the postnatal period. *Neurog1-Neurog2* co-expressing cells give rise to neurons throughout the deep and superficial layers of the cortical plate, and to cells that populate the entire neocortex and thalamus in postnatal day 150 brains. To assess the functional requirement for *Neurog1-Neurog2* cells in NSC pool maintenance, *Neurog1CCre*^{KI};*N2NCre*^{KI} mice are now being crossed to *Rosa-DTA* mice in which cell death is achieved by the expression of Diphtheria toxin fragment A only in double-positive NSCs. With these studies, we aim to determine whether *Neurog1-Neurog2* co-expressing cells have a unique role in maintaining the neocortical NSC pool.

Title: Sox2 reveals a stem cell potential in the human fetal subplate

Authors: *J. KOPIC, T. MISKIC, A. JUNAKOVIC, I. KOSTOVIC, Z. KRSNIK;
CIBR, Sch. of Medicine, Univ. of Zagreb, Zagreb, Croatia

Abstract: Human neocortical organization is established by orchestrated spatio-temporal histogenetic and neurogenetic processes regulated by differential gene expression. During fetal corticogenesis, critical step happens in the proliferative ventricular (VZ) and subventricular

(SVZ) zone, where neurons are born from stem cells and other progenitors. SOX2 is a transcription factor responsible for upholding the identity of neural stem cells, therefore represents a key player during corticogenesis. The aim of our study was to identify stem cells and cells with proliferative capacity in the human non-proliferative, synaptic subplate during midgestation, by utilizing double labelling immunofluorescence on postmortem human fetal material. Interestingly enough, our results show shifts in the SOX2 expression pattern from proliferative zones at midgestation. Furthermore, during the late mid-fetal period, SOX2 was sparsely distributed throughout the subplate, whose neurodevelopmental role remains elusive.

Title: Atp and calcium oscillations in huntington's disease: targeting neural stem cells

Authors: *T. GLASER[1], Y. D. TENG[2], R. KAGEYAMA[3], H. ULRICH[4];
[1]Univ. De São Paulo, Sao Paulo, Brazil; [2]Harvard Med. Sch., Boston, MA; [3]Kyoto Univ., Kyoto, Japan; [4]Chem. Inst., Univ. de Sao Paulo, Sao Paulo, Brazil

Abstract: Background: Purinergic receptors have been attributed with developmental functions including gastrulation and neural differentiation. Upon activation, P2 purinergic receptors trigger intracellular calcium transients controlling cellular processes. Huntington’s disease (HD) is a genetic neurodegenerative disease caused by the loss of GABAergic neurons (GABANs) from the basal ganglia and the symptoms onset start around the third decade of life spam. Thus recent studies propose that the disease actually starts much earlier, and HD is a neurodevelopmental disease. For clarifying this correlation, we induced GABAN differentiation of neural stem cells derived from a HD patient and recorded the intracellular calcium oscillations during the process of differentiation and compared to ATP-promoted response and cell death rates. Methods and results: First of all, P2Y2 receptor stimulation along differentiation of mouse embryonic stem cells increases the efficacy of GABANs differentiation (27±5 vs 42±2.2, n=3) by boosting the frequency of spike-like calcium oscillations. Using a technique that couples the imaging of alterations in cytosolic calcium concentration by Fluo4-AM (calcium imaging) and Ascl-1 or Neurogenin 2 by luciferase activity (stable transfected cells with Ascl-1 or Ngn2 promoter-protein fusion to luciferase reporter construct), we observed the effectiveness improvement was due to prolonged expression of Ascl-1. In view of that, we investigated HD-NPC and control NPC differentiation patterns. HD-NPCs differentiated from patient iPS cells did not reveal any

spike-like oscillations, while they showed increased cell death / apoptosis rates when compared to the healthy donor (30±8.3 vs 8.6±4.1, n=3), despite of caspase3/7 activation. Moreover, HD NPCs challenged with ATP showed higher amplitude of cytosolic calcium transients if compared to the healthy donor (4.2±0.4 n=51 vs 2.4±0.06 n=35). Blockade of intracellular calcium mobilization by P2Y2 receptors using thapsigargin could not prevent cell death. Thus, NPC differentiation status was changed, by decreasing the pool of undifferentiated NPCs when calcium oscillations were blocked, indicated by nestin expression detected by flow cytometry (90.7±1.1vs 48.4±10.4, n=3). Conclusion: Altogether these data suggest that P2Y2 receptor activation or inhibition modulates spontaneous calcium oscillations during neural differentiation and consequently changes the expression pattern of Ascl-1, thus controlling the cell fate decision to GABAergic neurons. This process is altered in HD patients' cells, compromising the pool of NPCs during early nervous system development.

Title: Is non-canonical Notch independent Hes-1 expression responsible for maintenance of adult neural stem cell of embryonic origin in the SVZ?

Authors: V. MEERA, P. A. RIYA, S. SURYA, B. BASU, S. PARVATHY, S. LALITHA, *J. JAMES;
Neuro Stem Cell Biol., Rajiv Gandhi Ctr. For Biotech., Trivandrum, India

Abstract: It is known that the quiescent neural stem cells in the adult sub ventricular zone (SVZ) are maintained through notch signaling. There are also reports in adult rodent cortex that show activation of Notch-1 receptor only in the activated neural stem cells and not in the quiescent state. Previous reports from our lab have show that Notch receptor independent Hes-1 (NIHes-1) expression is responsible of maintaining the embryonic neural stem cells in the developing embryonic neocortex *(Dhanesh et.al., Cerebral Cortex, (8)27, 2017, 3943–3961)*. Reading the above two reports together we hypothesized that NIHes-1 could be responsible for maintenance of the quiescent neural stem cell in adult SVZ.To prove this we generated a plasmid construct that expressed GFP upon activation of NIHes-1. This plasmid construct was electroporated into adult mouse SVZ. Further, to show the quiescent nature of the neural stem cells we injected BrdU into E14 pregnant mouse. The pups that were delivered we allowed to grow for 2-3 months. The quiescent neural stem cells in the SVZ was identified by the fragmentation if BrdU. The neural stem cells with minimum fragmentation were considered as quiescent since they had undergone minimum number of cell division. Whereas, cells that have highly fragmented BrdU

was considered as actively proliferating cell. All animal experiments were approved by the Institutional Animal Ethics Committee (IAEC) of Rajiv Gandhi Center for Biotechnology and carried out as per CPCSEA guidelines. Our results showed the existence of both notch dependent (NDHes-1) and NIHes-1 expression in adult SVZ. Out of this a majority of quiescent neural stem cells with unfragmented BrdU in the SVZ also showed GFP expression (NIHes-1 expression). Further interpretation of the data showed the embryonic origin of the quiescent neural stem cells in adult SVZ. These observations showed that the quiescent neural stem cells in the adult SVZ is of embryonic origin and is maintained through NIHes-1 expression.

Abstract: Quiescence is a cellular state characterised by reversible cell-cycle arrest and diminished biosynthetic activity that protects against environmental insults, replicative exhaustion and proliferation-induced mutations. Entry into and exit from this state controls development, maintenance and repair of tissues, plus in the adult central nervous system, generation of new neurons and thus cognition and mood. Cancer stem cells too can undergo quiescence, which confers them resistance to current therapies. Despite clinical relevance, quiescence lacks understanding and is defined functionally given lack of molecular markers. Inhibition of the Target of Rapamycin pathway is a common denominator of quiescence across species and cell types. This pathway integrates diverse signals towards control of metabolism and cytoskeleton, and lowered pathway activity in quiescence ensures decrease of the most resource-intensive cellular process of protein synthesis. Here, we combine *Drosophila* genetics and a mammalian model to show that altered nucleocytoplasmic partitioning and nuclear bias of a fraction of polyadenylated RNAs are novel evolutionarily conserved mechanisms of quiescence regulation. Moreover, we observe widespread decreased in intron retention in the transcripts that accumulate in the nucleus upon quiescence induction. Altogether, we propose that alterations to mRNA export and differential subcellular partitioning of transcripts are novel and underappreciated mechanisms to inhibit protein translation in quiescent cells, whilst likely priming them for quick reactivation in response to appropriate cues.

Title: Age-related neural pathologies and cognitive impairments of NRMT1 knockout mice are preceded by expansion of the neural stem cell population

Authors: *J. CATLIN, L. N. MARZIALI, B. REIN, Z. YAN, M. L. FELTRI, C. E. SCHANER TOOLEY;
Univ. At Buffalo, Buffalo, NY

Abstract: Neural stem cell-based therapies show great promise for treatment of ischemic stroke and neurodegenerative diseases. While spontaneous neurogenesis occurs post-injury, this process is transient and inadequate for repair of significant damage. Identifying targets for therapeutic intervention that could increase and prolong endogenous neural stem cell (NSC) response could significantly diminish or reverse accumulated damage. Here we identify the N-terminal methyltransferase NRMT1 as a novel regulator of NSC proliferation and differentiation. N-terminal methylation by NRMT1 regulates protein/DNA interactions and plays a role in many cellular processes, including DNA damage repair, mitosis, proliferation, transcriptional regulation, and protein stability. Our previous generation of a constitutive NRMT1 knockout ($NRMT1^{-/-}$) mouse demonstrated that its loss results in sensitivity to DNA damaging agents, severe developmental abnormalities, and premature aging phenotypes. As accumulation of DNA damage and appearance of premature aging phenotypes often precede or accompany neurodegeneration, we began to more specifically examine how NRMT1 loss affects neural pathology and cognitive behaviors. We find that $NRMT1^{-/-}$ mice have postnatal enlargement of the lateral ventricles, significant reduction of striatal and corpus callosum volume, age-dependent hippocampal neurodegeneration, and short- and long-term memory impairments. Interestingly, these morphological and behavioral abnormalities are preceded by a significant increase in Sox2 positive (Sox2+) NSCs and Doublecortin positive (Dcx+) neuroblasts, indicating that early misregulation of the NSC pool may be altering postnatal neurogenesis and impeding replacement of aged or damaged neurons in $NRMT1^{-/-}$ mice. This is the first work showing a role for NRMT1 in neural development, neurodegeneration, and NSC regulation.

Title: Modulation of mesenchymal stromal cells secretory activity from Wistar rats exposed to neural tissue segments

Authors: *I. SANTOS[1], M. B. DA SILVA[2], R. DE MELO REIS[1], V. RIBEIRO-RESENDE[1];
[1]Federal Univ. of Rio De Janeiro, Rio de Janeiro, Brazil; [2]Immunopharmacology, Oswaldo Cruz Institute- Fiocruz, Rio de Janeiro, Brazil

Abstract: Bone marrow-derived mesenchymal stromal stem cells (BM-MSC) exert regenerative potential due to their paracrine activity and the modulation of the microenvironment of injured tissues. Activity occurs due to the capacity of these stem cells to release soluble factors with trophic activity. Studies have revealed the potential of the BM-MSC to promote regeneration of Peripheral Nervous System (PNS), but gaps are present regarding the behaviour of MSCs in the injured tissue microenvironment. In this study, we investigated the role of BM-MSC trophic activity through indirect co-culture with different neural tissue explants. BM-MSCs were obtained from bone marrow of male Wistar rats and characterized by their morphology immunolabeling (CD90). The indirect co-culture of BM-MSC was performed under different conditions based on the following explants: skin, sciatic nerve, cerebral cortex and spinal cord, during 48 hours. BM-MSCs co-culture conditioned medium was analyzed by Enzyme-Linked Immunosorbent Assay (ELISA). The viability and proliferation of BM-MSCs were evaluated by LIVE/DEAD assay and by selective markers. BM-MSCs in indirect co-culture showed no difference in cell viability, but the morphology of cells in co-culture with cerebral cortex and spinal cord fragments were altered. BM-MSCs culture density increased when exposed to fragments of both spinal cord or sciatic nerve when compared to fragments of cerebral cortex. Cell proliferation of BM-MSCs, evaluated by immunocytochemistry, showed no significant difference between conditions. Conditioned medium was evaluated for the presence of VEGF (Vascular Endothelial Growth Factor) and showed a small increase of VEGF levels when BM-MSCs were co-cultured with Central Nervous System (CNS) tissues. Moreover, we observed alterations in cytoarchitecture of BM-MSCs co-cultured with cerebral cortex fragments, by actin filaments stain. In conclusion, BM-MSCs exposed to CNS tissue fragments altered their morphology as well as VEGF expression, indicating that the interaction with these tissues may be modulating the behaviour of MSCs.

Title: Single-cell RNA-sequencing reveals discrete steps in the transformation of developmental precursors to adult neural stem cells

Authors: *A. M. BOND, D. JIMENEZ-CYRUS, G.-L. MING, H. SONG;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: The dentate gyrus region of the hippocampus is one of only two regions in the adult mammalian brain where substantial levels of neurogenesis occur throughout adulthood.

Quiescent adult neural stem cells in the subgranular zone of the dentate gyrus occasionally become reactivated in adulthood to generate new neurons which integrate into the existing network and contribute an added layer of plasticity to the hippocampus. Previously, our lab showed that embryonic neural stem cells which contribute to developmental cytogenesis in the dentate gyrus transition into quiescent adult neural stem cells, suggesting that a common lineage of neural stem cells contributes to developmental and adult neurogenesis. However, the molecular mechanisms regulating this developmental transition remain completely unknown. Here we used single-cell RNA-sequencing of $Hopx^{+}$ dentate gyrus progenitors across multiple stages of early postnatal development in mice to identify the molecular cascade associated with the transformation of developmental precursors to quiescent adult neural stem cells. We discover that early postnatal dentate gyrus neural stem cells exist in multiple heterogeneous states, and we identify a trajectory of cycling neural stem cells as they transition into a quiescent state. We also discover that dentate gyrus precursors gradually acquire an adult-like state after they exit cell cycle. This suggests that the developmental transition consists of two sequential steps: first precursors exit cell cycle to enter a quiescent state and then precursors acquire an adult-like state throughout a quiescence maturation period. We further identify transcription factor networks associated with each stage of the transition and biological processes that change over the course of the transition. Collectively, our work identifies molecular and cellular mechanisms associated with the transformation of developmental precursors to quiescent adult neural stem cells, and serves as a foundation for future studies investigating mechanisms that regulate formation of the adult neural stem pool.

Title: Understanding the Role of Eed Deletion in Medulloblastoma

Authors: *M. CHURIWAL, A. CLEVELAND, T. GERSHON;
Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Medulloblastoma is uniquely sensitive to DNA damage-inducing therapies with conventional treatment resulting in an 80% 5-year survival rate. By researching the apoptotic pathways that make treatment effective in some and how those pathways contribute to resistance in others, we can identify therapies that reduce the need for toxic radiation and chemotherapy. In cerebellar development, Sonic Hedgehog (SHH) signaling drives proliferation of cerebellar granule neuron progenitors (CGNPs), but hyperactivation leads to SHH-subgroup

medulloblastoma, making up 30% of medulloblastoma cases. In differentiated cerebellar neurons, where SHH signaling is low, the polycomb repressive complex 2 (PRC2) silences target genes by trimethylating H3K27 residues in regulatory regions. SHH signaling upregulates target genes by displacing the PRC2 and removing H3K27 trimethylation marks via the JMJD3/KDM6B demethylase complex.Based on its divergent roles in proliferating and differentiating cells, the PRC2 has varying effects in different tumors. We deleted Eed, a component of PRC2, in SHH medulloblastoma tumors in mice to see its effects on tumor development. While Eed deletion reduced proliferation and tumor size at postnatal day 12 (P12), the mice had poorer survival. This study aimed to elucidate how cell cycle dynamics are altered in Eed-deleted medulloblastomas by performing fluorescence-activated cell sorting (FACS).We bred Math1-Cre;SmoM2 mice, which develop tumors by constitutively expressing Smoothened allele (SmoM2) in a CGNP-specific manner (Math1+ population), with EedloxP/loxP mice. The resulting Math1-Cre; SmoM2;EedloxP/loxP (Eed cKO) mice developed tumors in which Eed was deleted. We then dissociated tumor tissue from 6 Eed cKO, 5 Eed het, and 5 control tumor mice at P12 as well as 3 Eed cKO, 4 Eed het, and 4 control tumor mice at P18. We subsequently stained for pRB, EdU, and FX cycle violet before performing FACS. We then measured the percentage of total cells in G0, G1, S, G2, and M; we also measured the percentage of cells that were in each of G1, S, G2, and M out of the total number of pRB-positive cells. Based on these quantifications, we found that at P12, there are more cells exiting the cell cycle, but of the ones that remain, they are cycling faster than in control tumors. By the time the mice reach P18, they are not significantly different from control tumors. Thus, we hypothesize Eed deletion slows tumor growth in early development, but the tumor later develops resistance to cause decreased survival. Our goal is to better understand how SHH signaling regulates target gene expression in order to identify novel therapeutics for SHH-driven medulloblastoma.

Abstract: Background and Objective: The dentate gyrus of the hippocampus contains stem and progenitor cells that generate new neurons throughout the mammalian lifespan via neurogenesis. Our group and others have demonstrated that certain key members of the autophagy pathway are required for adult neurogenesis. This work specifically determines if and how Beclin1, a key member of the autophagy pathway involved in the initiation of the autophagosomes, dynamically maintains adult hippocampal neurogenesis
Methods: This project uses an inducible transgenic mouse model of Beclin1 deletion from adult nestin-expressing hippocampal neural stem cells and progeny to perform in vivo lineage tracing. Neurogenesis and cell cycle was measured using a variety of assays, including immunohistochemistry, flow cytometry, and neurosphere assay. Furthermore, 10x genomics single-cell RNA sequencing and machine learning were used to identify unique transcriptional changes associated with the removal of Beclin1-dependent autophagy.
Results: Beclin1-null neurogenic cells had a significant reduction in autophagic flux in vivo as measured using mCherry-EGFP-LC3 retroviral labeling. Two weeks after removal of Beclin1 the number of proliferating neural stem cells and progenitor cells was reduced, which led to a significant reduction in adult-generated NeuN-expressing neurons by one month. Single-cell RNA-sequencing of wildtype and Beclin1-null cells revealed the dynamic role of Beclin1 in driving the activation and proliferation of adult neural stem and progenitor cells by regulating cell cycle and differentiation.
Conclusions: Beclin1-mediated autophagy is essential for adult hippocampal neurogenesis with transcriptional profiling of Beclin1-null cells supporting Beclin1 as a regulator of proliferation that is essential for the coordination of the life-long addition of adult-generated dentate gyrus neurons.

Title: The role of DNA repair and replication in BRCA2-null medulloblastoma

Authors: *D. KEAHI[1], A. SMOGORZEWSKA[2], M. HATTEN[2];
[1]The Rockefeller Univ., ; [2]The Rockefeller Univ., New York, NY

Abstract: Medulloblastoma is the most common metastatic pediatric brain cancer and can arise from cerebellar granule cell progenitors. Granule cell progenitors undergo a period of high proliferation during cerebellar development. We hypothesize that this high level of proliferation

will necessitate robust DNA repair mechanisms to avoid an accumulation of mutations during this crucial period in development. Over seventy percent of children that have mutations in the tumor suppressor BRCA2 develop medulloblastomas before the age of five. Thus, we hypothesize that BRCA2 will be necessary to preserve genome stability in granule cell progenitors during postnatal cerebellar development and prevent medulloblastoma formation. The main aims of this study are to investigate how the loss of BRCA2 affects cerebellar development and induces mutations that lead to medulloblastoma. We have been able to observe tumor formation within two to three months of age in BRCA2-deficient mice have analyzed these tumors through RNA and whole-genome sequencing, identifying the overexpression of genes important in DNA repair and the protection of replication. We have developed primary cell culture of medulloblastoma cells as well as *ex vivo* slice culture of tumor tissue to validate the role of these genes in providing a selective advantage for these tumor cells. We have also adapted methods to study DNA replication fork behavior and chromosomal abnormalities for granule cell progenitors as well as primary medulloblastoma cells. We will be able to use tools developed in the field of DNA repair and replication to provide a novel characterization of how mutagenesis occurs in granule cell progenitors and leads to tumor formation in childhood brain cancer.

Title: Adult-born neurons modulate activity in developmentally-born neurons during learning

Authors: *A. ASH[1], E. REGELE-BLASCO[1], D. SEIB[1], E. CHAHLEY[1], J. S. SNYDER[2];
[2]Dept. of Psychology, [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Recent reports indicate that lateral inhibition plays a powerful role in selecting which dentate gyrus (DG) neurons are recruited during memory formation. This raises the question of whether developmentally-born and adult-born DG neurons have distinct roles for inhibition, particularly in vivo when neuronal ensembles are selected during memory encoding. To address this we combined chemogenetics and immunohistochemistry for BrdU+Fos to silence and measure activity in developmentally and adult-born neurons as rats learned a spatial water maze task. Specifically, retrovirus was injected into the DG of male rats at 6 weeks of age to express the inhibitory DREADD receptor, HM4Di, in neurons born in adulthood. The same rats were also injected with BrdU to label developmentally or adult-born neurons. At 10 weeks of age rats were injected with either the HM4Di agonist CNO or vehicle, then trained in the water maze. We found that silencing a subset of adult-born neurons (aged 4 weeks) increased activity levels in the

developmentally-born neuron population. However, silencing adult-born neurons did not affect activation in other adult-born neurons within the DG, suggesting limited interaction amongst the adult-born population. As well, we have examined activation of interneurons (PV+ and SST+) within each treatment group to determine if silencing neurons at different ages impacts downstream activity in inhibitory interneurons. Our recent findings implicate PV+ interneurons in the modulatory subcircuit between neuron populations within the DG.

Title: Modeling adult neurogenesis in vitro: morphometric and marker analysis of neural precursors from young and adult mouse hippocampus using the neurosphere assay

Authors: *O. VAFAEVA[1], P. NAMCHAIW[2], K. D. MURRAY[1], E. DIAZ[3], H.-J. CHENG[4]; [2]Ctr. for Neurosci., [1]Univ. of California, Davis, Davis, CA; [3]Dept Med. Pharmacol, UC Davis Sch. of Med., Davis, CA; [4]UC Davis, Davis, CA

Abstract: Adult neurogenesis in the dentate gyrus (DG) of the hippocampus is involved in many physiological functions such as learning and memory, as well as neurological disorders such as Alzheimer's disease and age-related cognitive decline. Most of the neurogenesis quantification and manipulation studies are done on rodents soon after they reach sexual maturity (around postnatal day 40), which is routinely used as an approximation of an adult-like stage of development. Such studies however do not provide much insight into long-term contribution of newly generated granule cells (GCs) to hippocampal function and disorders later in life, which underscores the need for more studies regarding neurogenesis in the adult brain across different ages. Additionally, hippocampal neurogenesis undergoes dynamic changes throughout life and is affected by numerous intrinsic and extrinsic factors that make studying this process in vivo challenging. Here, we show the neurosphere culture system that was developed to isolate neural progenitor cells from the subgranular zone of DG of adult mice (≥8 months) and to differentiate them to mature GCs *in vitro*. These studies would allow us to systematically examine the phenotypical and molecular properties of cells in transit. We were able to successfully isolate and establish multiple stable neurosphere cell lines from adult wild-type mice and compare them to neurosphere cell cultures derived from the young (≤3 months) animals. We found that the dynamics of neurosphere growth derived from the young and the adult animals were different. Neurospheres from the adult brain were consistently smaller in diameter than the ones from the young brain over the course of two weeks in culture. Differentiation of neural progenitors within neurospheres was studied in monolayer assay, where dissociated neurospheres were grown on an adherent substrate. Morphological and molecular marker analysis demonstrated that

neurospheres from young and adult brains generate mature hippocampal GCs in the cell culture environment within 21 days by the markers Prox1 and NeuN. Additionally, neural progenitors from neurospheres from both age groups are multipotent as immunocytochemical staining confirmed differentiation to astrocytes and neurons in monolayer assay. Overall, this approach for isolating and propagating neural progenitor cells from DG of the adult brain offers a novel *in vitro* model of adult neurogenesis and can serve as a platform for investigating important biological questions regarding the development and differentiation of hippocampal GCs generated throughout adult life.

Abstract: RESEARCH OBJECTIVE/RATIONALE: Jordan's Syndrome is a rare, neurodevelopmental intellectual disability (ID) caused by *de novo* missense mutations in protein phosphatase 2 regulatory subunit b'delta (*PPP2R5D)*. *PPP2R5D* encodes a regulatory subunit of protein phosphatase 2A (PP2A) and is involved in the proper development of and signaling between neurons. Advancements in neuronal disease modeling provide a starting point of investigation to elucidate the molecular underpinnings of *PPP2R5D*-related ID. The overall goal of this project is to evaluate four common variants of Jordan's Syndrome patient-derived fibroblasts that have been reprogrammed into iPSCs, differentiated into neural progenitor cells (NPCs), as well as differentiated to neurons to establish developmental alterations at the cellular and molecular levels. **METHODS/RESULTS:** The most common *PPP2R5D* variant—E198K—and its isogenic control were grown and cultured as induced pluripostent stem cells (iPSCs). RT-qPCR was performed to evaluate gene expression of *PPP2R5D* and western blotting was performed to semi-quantify protein expression. At the cellular level, immunocytochemistry was used to characterize morphology through differentiation from iPSC to neural stem and progenitor cells and mature neurons using antibodies targeting proteins

expressed in each cell type. Because PP2A is a negative regulator of AKT, we are also evaluating how downstream targets of the PI3K/AKT/mTOR signaling cascade is impacted by PPP2R5D variants. A comparison between multiple causative variants and their isogenic controls will determine how *PPP2R5D* influences cellular, molecular, and developmental function. **CONCLUSIONS:** The data obtained from this characterization of *PPP2R5D* variants and their isogenic controls in addition to identifying how downstream targets of PI3K/AKT/mTOR signaling cascade is impacted by these variants would be an important step toward development of biomarkers and could provide us with therapeutic targets for individuals diagnosed with this rare neurodevelopmental disorder.

Abstract: Copy number variations (CNVs) are often the cause of multiple neurodevelopmental diseases, among them there is Smith-Magenis syndrome (SMS; MIM 182290, incidence 1/15,000) which is linked to interstitial deletions in the 17p11.2 chromosome region spanning around 75 genes. Among them, RAI1 is considered the causative gene of the disease because its nucleotide mutations reproduce almost all SMS clinical features. SMS is a disorder characterized by dysmorphic craniofacial features, brachydactyly, hypotonia, developmental delay and sleep abnormalities. Most individuals present a moderate range of intellectual disability; however, the substantial deleterious behaviours leads to altered adaptive function and a lower perceived cognition. Autistic spectrum disorder has been reported in as many as 90% of SMS subjects. Little is known about RAI1 molecular function and its role in neural development. This gap of knowledge is likely due to limited availability of patient-derived cell models that recapitulate

disease and lack of information of the pathogenetic mechanisms underlying *RAI1* haploinsufficiency. METHODS: We obtained two fibroblast lines from two SMS patients, one carrying point mutation in *RAI1* gene (RAI1-S399P40fx), the other carrying the canonical SMS-CNV (RAI1 del). In order to avoid confounding effects due of the loss of several genes occurring in the CNV, and rather to identify which neurodevelopmental features are specifically altered by the loss of RAI1, Neural Stem Cells where generated upon RAI1-S399P40fx fibroblast reprogramming into induced Pluripotent Stem Cells (SMS-hiNSCs). RESULTS: Both fibroblast lines showed a loss of nuclear RAI1, altered cell proliferation and enhanced cell death. Gene expression analysis showed a series of dysregulated genes. We produced SMS-iPSCs and differentiated them into SMS- hiNSC in order to evaluate how the truncated form of RAI1 might influence the cell fate, the proliferation and differentiation pattern of these cells in vitro. The SMS-hiNSCs were transplanted into immunodeficient mice and differentiated in vitro: our results showed that hiNSC cells carrying RAI1 mutation showed a low ability to differentiate, compared to the control lines consistent with the SMS phenotype.

Abstract: Among the hundreds of In recent years, genetic variants associated to autism, studies have identified tens of autism susceptibility genes. Among them the chromodomain helicase DNA-binding 8 (*CHD8*) is is one of the most frequently mutated bona fide causative genes leading autism-associated gene. While the accompanying macrocephaly *CHD8* haploinsufficiency leads to autism accompanied by macrocephaly, implicatesying cortical development abnormalities in *CHD8* autism, however, itsthe function of the human *CHD8* in human brain development remains unexplored. Here we employecombinedd human cerebral organoids and single cell sequencingtranscriptomics to studydefine the effect of ASD-linked *CHD8* mutations in aon human cortical developmenting brain model. We found thatWe found

that while wild type cerebral organoids recapitulate well the sequence of events of human brain development, C*HD8* haploinsufficiency causes a major disruption of-mutant samples show abnormalneurodevelopmental trajectories. with In particular, we report that C*HD8*-mutantions lead to an accelerated generation of inhibitory neurons and a delayed production of excitatory neurons alongside the ensuing protraction of the and an accelerated generation of inhibitory neurons. The delayed generation of excitatory neuron, and consequent sustained proliferation phase. This imbalance, leads to a significant cerebral organoids enlargement of cerebral organoids aligned to, resembling the macrocephaly observed in patients with *CHD8* mutations. Furthermore,By adopting an isogenic design of employing patient- specific mutations and a mosaic cerebral organoids, we model we show a define genotype-phenotype relationships and uncover their that the abovementioned phenotypes are governed by cell-autonomous nature defects. Finally, our resultsdata assign different *CHD8*-associateddependent molecular defects to particular cell types, pointing to abnormal ribosomal biogenesis and alternative splicing as specifically affected in, respectively, suggesting that inthe radial glial and mature cells *CHD8* mutations are associated with abnormal ribosomal biogenesis while in neuronal compartments.s By identifying linking temporally restricted with cell-type specific effects of human CHD8 mutations, our study uncovers transient developmental slopes as reproducibìlereproducible endophenotypes for neurodevelopmental disease modelling.they are linked to alternative splicing defects. Al together, our study reveals that *CHD8* mutations lead to transient molecular defects in a cell type-specific manner, thus impacting the normal course of human cortical development.

Abstract: Human cytomegalovirus (HCMV) is a beta herpesvirus that upon infection during pregnancy can cause severe congenital birth defects including microcephaly, vision loss, and hearing loss. Currently, no approved treatment options exist for managing in utero infections. Our previous work has shown that HCMV infection in undifferentiated human induced pluripotent stem cell (iPSC) derived neural progenitor cells (NPCs) and iPSC derived cortical

organoids have changes in calcium signaling. Following infection using GFP-expressing HCMV, NPCs and organoids exhibited reduced baseline calcium levels and were unresponsive when evaluated 5 days post infection. To extend these studies, we have determined that it is feasible to conduct RNA sequencing on different NPC populations within an infected organoid labeled with GFP to understand how the infection impacts the transcriptome. These studies were again conducted using a GFP expressing HCMVTB40e strain. Which creates unique cell populations of varying viral load that can be sorted via FACs sorting and then sequenced. Our studies demonstrate that HCMV infection significantly impairs neural function and several developmental pathways. Interestingly, these developmental gene targets are significantly downregulated in all sorted populations within the infected organoid regardless of viral load. Many of these gene targets fall into the basic helix loop helix transcription factor family which performs crucial roles in neurodevelopment. Specifically, downregulation is observed in the NeuroD/Hes1 pathway which controls neural progenitor cell proliferation and differentiation. Additionally, from our RNA seq results we were able to identify, map, and quantify the expression of HCMV viral genes within our sorted infected organoid populations. In an attempt to understand what viral proteins and genes are responsible for the transcriptomic changes observed, we conducted additional experiments using a modified HCMV virus that allows us to control immediate early (IE) gene expression. These IE genes are demonstrated regulators of fibroblast gene expression, but little is known at this time about their involvement in NPC gene regulation. We found that on their own these genes were not responsible for developmental gene downregulation, so they must interact with other viral genes to cause these effects.

Title: From cohorts to organoids: Endocrine disruption in human neurodevelopmental models

Authors: *N. CAPORALE[1,2,3], C. CHERONI[1,2], G. TESTA[1,2,3];
[1]Dept. of Exptl. Oncology, IRCCS, Milan, Italy; [2]Dept. of Oncology and Hemato-oncology, Univ. of Milan, Milan, Italy; [3]Human Technopole, Milan, Italy

Abstract: Endocrine disrupting chemicals (EDC) are compounds interfering with the human hormonal system. A growing body of evidence correlates early life EDC exposure with human disorders, but the triggered molecular events remain unknown. As opposed to previous studies

focusing on single compounds, we interrogated the impact of the EDC mixture associated to neurodevelopmental adverse outcomes, in the Selma epidemiological study. We integrated the pregnancy cohort results with in vitro exploration of the molecular effects of EDC exposure in human cellular systems. We used two complementary models that transcriptionally resemble the early stages of brain development: i) human fetal primary neural stem cells, and ii) 3-dimensional cortical brain organoids differentiated from human pluripotent stem cells. These models underwent both acute and chronic exposure to several EDC mixture dilutions, including the environmental concentration. Transcriptomic analysis highlighted differentially expressed genes that are significantly enriched for gene ontology categories related to epigenetic regulation, cell proliferation and neuronal maturation. Moreover those results were confirmed by immunofluorescence assays on cortical brain organoids. We also showed how key genes related to different hormonal pathways are affected by EDC exposure and finally that among the EDC dysregulated genes there is significant enrichment for genes with genetic causative role for autism spectrum disorders. In conclusion we showed that real life relevant EDC mixture affect gene networks linked to neurodevelopmental disorders, a finding that should guide EDC policy regulators.

Title: Neuregulin-1 attenuates Plasmodium falciparum histidine rich protein II-induced inflammation and neuronal injury in brain organoids

Authors: *A. HARBUZARIU[1], A. NTI[1], K. HARP[1], J. CESPEDES[1], A. SHAW[2], S. ASBERRY[2], J. K. STILES[1];
[1]Morehouse Sch. of Med., Atlanta, GA; [2]Georgia Inst. of Technol., Atlanta, GA

Abstract: Brain disorders associated with exposure to *Plasmodium falciparum* (Pf) infection during fetal stages of life are responsible for significant morbidities, mortalities and disabilities globally. Exposure to malaria in pregnancy leads to significant rates of developmental sequelae in newborns but the factors mediating the brain injury during brain development are unclear. Previous *in vitro* studies showed that increased erythrocyte destruction during parasite multiplication release heme and histidine rich protein II (HRPII) into maternal/fetal circulation which disrupts the placental trophoblasts and exposes fetuses to the deleterious factors. Elevated plasma HRPII antigen, widely used as a marker of Pf infection for diagnosing malaria, correlate

with malaria severity and mortality. Previous attempts to assess HRPII-induced brain injury in 2D cell cultures and murine experimental cerebral malaria, did not adequately recapitulate the direct effects of hemolysis and HRPII on brain development, inflammation, and neuronal injury. However, the HRPII effects was attenuated by infusion of Neuregulin1 (NRG1), a neuroprotective factor. We used 3D brain cortical organoids to model the HRPII-induced brain neuronal damage associated with fetal exposure to Pf infection. We hypothesized that HRPII will induce brain inflammation and reduced neuronal viability that can be attenuated by NRG-1. We assessed the direct effects of HRPII on organoid growth, and brain injury (BDNF) marker expression. We tested the role of NRG-1 and its receptor ErbB4 in attenuating HRPII effects. For rigor and reproducibility, we utilized flow cytometry, immunohistochemistry, western blot and gene arrays to investigate neuronal apoptosis and brain organoid inflammation (CXCL10, Ang2 and Ang1) in response to exposure to HRPII during brain organoid development. Our results show that exposure of brain organoids to physiologically relevant concentrations of HRPII during malaria infection compromised their structural architecture and altered expression of cleaved caspase 3 as well as key astrocyte, neuron, and microglia marker genes. Pro-inflammatory factors including CXCL10 and its receptor CXCR3, as well as the ratio of Ang2:Ang1 were elevated. The HRPII effects were mediated by toll-like receptor signaling and were attenuated by NRG-1 via an ErbB4 mediated pathway. In conclusion, our brain organoid model has enabled us to investigate the role of HRPII in malaria-induced fetal brain damage and dysfunction as well as the attenuating effects of NRG1.

Title: Urine sample-derived cerebral organoids suitable for studying neurodevelopment and neuroregeneration

Authors: ***J. HU**, V. LIN, Y.-C. WANG;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Purpose: Human cerebral organoids (COs) have yielded significant discoveries regarding developmental biology, disease mechanisms and pharmacological responses in the central nervous system. Here, we intend to establish cerebral organoids suitable for modeling brain development and neuroregeneration based on somatic cells that are isolated noninvasively. **Methods:** The development of such organoids began with the collection of urinary epithelial cells (UECs) from human urine samples, followed by reprograming them into induced

pluripotent stem cells (hUEC-iPSCs), which were further used for the generation of COs. To comprehensively characterize the cellular and molecular features of our COs, we examined samples at different developmental time points *in vitro*. To check their survival ability and the neuroregenerative potential, the COs were implanted into immunodeficient mouse brains and further examined.
Results: The hUEC-iPSC-developed COs exhibit normal development with neurogenesis and maturation of neuronal cells forming brain layers. These COs produce neurotropic and anti-inflammatory factors that are presumably critical for neurogenesis and neural repair. Several metalloproteases that may facilitate cell migration and microenvironment rearrangement are also present. After transplantation into the mouse cerebrum, vascularization quickly develops in the implanted COs, suggesting their viability and ability to interact with the environment.
Conclusions: Our work begins to reveal the promise of generating personalized COs from cells that are isolated from urine samples. With further adaptation, this human CO platform could form a unique and personalized model for the investigation of neural development and facilitate the innovation of novel therapies for treating neurological diseases.

Title: Efficient production of pure midbrain dopaminergic neurons from human iPS cells by lineage-promoting transcription factors

Authors: *S. POWELL[1], C. O'SHEA[1], I. PRYTKOVA[2], K. DOBRINDT[1], R. ELAHI[1], S.-M. HO[3], P. A. SLESINGER[4], S. AKBARIAN[5], K. BRENNAND[1];

Abstract: Dopaminergic neurons are critical to many motor, motivational, affective, and cognitive systems in the brain and are dysregulated in several disease processes. Derivation of dopaminergic neurons from human induced pluripotent stem cells (hiPSCs) enables isogenic, in vitro modeling of both typical neurodevelopment and disease biology. Current techniques for generating hiPSC-derived dopaminergic neurons yield heterogenous cell populations with variable purity, have inconsistent reproducibility across donor lines and labs, and require extended maturation to achieve functional maturity. We report the efficient production of relatively homogenous induced dopaminergic neurons (iDANs) from hiPSC with lineage-

promoting transcription factor reprogramming combined with chemical selection. Throughout the technique, iDANs (n=5 donors; 3 female, 2 male) showed a gradual development of neuronal morphology and expressed key marker genes at markedly higher levels than in hiPSC at two weeks in vitro (WIV2), with some genes showing further increases in expression at WIV5. By WIV3, iDANs consisted of cells that stained ~90% positive for *Tyrosine Hydroxylase* across five donors with at least two replicate staining experiments each. Immunocytochemistry followed by confocal microscopy confirmed pervasive expression of several additional marker genes. We observed a dramatic maturation-dependent increase in dopamine synthesis from WIV0 to WIV3 by ELISA. Electrophysiologic recordings of individual neurons from two donors (n=15-18 cells each) at WIV5 revealed that iDANs possessed hallmark functional properties of in vivo midbrain dopaminergic neurons, including a-type potassium currents, slow-rising after hyperpolarization potentials, tonic sub-threshold oscillatory activity, and spontaneous burst firing (~1 Hz). Finally, transcriptome analysis with RNA-seq of isogenic (n=2 donors; 1 female, 1 male) hiPSC, iDANs, and induced GABAergic and glutamatergic neurons found that iDANs widely express genes involved in midbrain dopaminergic neuron functional identity and specifically expressed genes identified from previous scRNA-seq studies. For these reasons, iDANs may serve as a vital source of relatively homogenous, functionally mature neurons that can be generated reproducibly across multiple donor lines for modeling normal and disordered biological processes.

Title: Human pluripotent stem cell modeling of the ATOH1 lineage reveals a heterochronic shift in transcriptional regulators in the developing human cerebellum

Authors: *H. BEHESTI, A. KOCABAS, D. E. BUCHHOLZ, T. CARROLL, M. E. HATTEN; Rockefeller Univ., New York, NY

Abstract: Brain development is regulated by conserved transcriptional programs across species, but little is known about divergent mechanisms that create species-specific characteristics. Among brain regions, the cerebellum is now recognized to contribute to human cognitive evolution having a broad range of non-motor cognitive functions in addition to motor control. Emerging studies highlight the complexity of human cerebellar histogenesis, compared with non-human primates and rodents, making it important to develop methods to generate human cerebellar neurons that closely resemble those in the developing human cerebellum. Here we

report a rapid and simple protocol for the directed derivation of the human ATOH1 lineage, the precursor of all excitatory cerebellar neurons, from human pluripotent stem cells (hPSC), and strategies to decrease culture variability; a common limitation in hPSC studies. By Translational Ribosome Affinity Purification (TRAP)-seq, the ATOH1 lineage most closely resembled human cerebellar tissue in the second trimester. Unexpectedly, TRAP-seq identified a heterochronic shift in the expression of RBFOX3 (NeuN) and NEUROD1, which are classically associated with differentiated neurons, within granule cell progenitors (GCPs) in the human external granule layer. This molecular divergence may provide the mechanism by which the GCP pool persists into year two post birth in humans, but only lasts for two weeks in mice. Our approach provides a scalable *in vitro* model of the human ATOH1 lineage that yields cerebellar granule cells within 48 days as well as a strategy for identifying uniquely human cellular and molecular characteristics.

Abstract: Cellulose based materials are being studied extensively for applications in the biomedical field due to its abundance, amenability and biocompatibility. We created novel, stable TEMPO cellulose materials utilizing the TEMPO/NaOCl/Oxone® ($KHSO_5$) with microwave irradiation method. We further tested these TEMPO cellulose materials as an extracellular matrix substratum to support *in vitro* neural stem cell (NSC) differentiation into neurons/oligodendrocytes (ODCs). Rat NSCs harvested at E14 (embryonic day 14) were propagated and differentiated on a TEMPO cellulose-coated culture surface in neuron-favoring conditions for 7 days. At day 7, immunocytochemical staining was performed to determine the percentage of cells positive for neuronal marker βIII tubulin and astrocytic marker GFAP (glial marker glial fibrillary acidic protein) relative to the total cell count. About 33% and 25% of NSCs differentiated into neurons and astrocytes on TEMPO cellulose substratum, respectively,

comparable to the traditional poly-D-lysine surface. Separate batches of NSCs were propagated for 10 days on the TEMPO cellulose surface under ODC-favoring culture conditions. By Day 10, about 70% and 30% of NSCs differentiated into Rip (receptor interacting protein)+ ODCs and GFAP+ astrocytes, respectively, similar to those on the precursor micron cellulose surface. These results indicate that TEMPO cellulose is a viable material supporting stem cell survival and differentiation *in vitro*.

Title: Exploration of human neural phenotypic diversity through mixed-donor cultures of stem cell-derived NGN2-accelerated progenitors

Authors: *M. F. WELLS[1], M. SALICK[2], J. MITCHELL[1], E. HILL[1], J. NEMESH[3], S. GHOSH[3], R. NEHME[3], O. PIETILAINEN[3], A. KAYKAS[2], S. MCCARROLL[4], K. EGGAN[1]; [1]Harvard Univ., Cambridge, MA; [2]InSitro, San Francisco, CA; [3]Broad Inst. of Harvard & MIT, Cambridge, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: Our species is characterized by an immense diversity in neurological and psychological traits that partially originates from differences in the behaviors of cells present during the earliest stages of brain development, including neural progenitor cells (NPCs). We currently know little about the role of genetic variation on the cellular and molecular mechanisms underlying NPC diversity given the rarity of manipulatable human brain tissue and inefficiencies with conventional stem cell-derived NPC induction methods. Here, we describe a novel *in vitro* culture system that captures the influence of genetic diversity on specific NPC phenotypes on a large scale. Stem cell-derived NGN2-accelerated Progenitor cells (SNaPs) are human dorsal telencephalic NPCs created through a highly reproducible 48-hour induction protocol. We pooled SNaPs generated from dozens of unique donors into a shared culture environment known as a "village-in-a-dish," which enabled high-throughput and unbiased cell line comparisons under conditions that minimize technical noise. We then processed our SNaP villages through new whole genome ("Census-seq") and scRNA-seq ("Dropulation") analytical pipelines to reveal dramatic differences across cell lines in proliferation dynamics and gene expression. We detected around 900 expression quantitative trait loci (eQTL), including a single

nucleotide polymorphism in the promoter of the antiviral *IFITM3* gene. To assess functional impact, we infected a SNaP village with the neurotropic Zika virus and discovered that this *IFITM3* SNP could explain one-third of the variation in viral susceptibility across cell lines. Our work uncovers the impact of genetic diversity on certain neurodevelopmental processes and establishes a blueprint for future endeavors seeking to do the same.

Abstract: Neovascularization for optimal survival of neural transplants Authors: Krzyspiak, J., Yan, J., Galinski, B., Lituma, P., Zukin, S., Castillo, P., Weiser, D., Khodakhah, K., Hebert, J. Dominick P. Purpura Dept. of Neuroscience, Albert Einstein College of Medicine, Bronx, NY 10461, USA
Disclosures: None.
The transplantation of neural stem cells holds promise for improving function in the damaged brain. After transplantation, however, transplant-derived cells can be greatly reduced in numbers. There is growing evidence that supporting cell types may be required to facilitate the success of a transplant in contrast to transplanting pure populations of cells. Specifically, there is evidence that neovascularization may be critical for transplant cell survival. As in the fetus where vascularization must match the physiological demands of each growing tissue, vascularization of neural cell transplants might also need to occur rapidly to promote neuron survival, differentiation, and function. Here we test the hypothesis that combining vascular and neuronal precursors improves engraftment by transplanting mixed embryonic neocortical cells into adult mice with neocortical strokes. Our studies with transplants of dissociated embryonic 12.5 forebrain cells into the young adult neocortex of unaffected and stroke-affected male and female mice show that transplants generate large grafts (up to 15 mm^3) containing upper and lower cortical neuron identities. The neurons are often arranged in pseudo-layers, which can project to appropriate host targets and become synaptically integrated. Grafts also formed donor-derived

vessels that anastomosed with host vessels to perfuse blood. To show that donor-derived vessels are integrating with the host circulation, we used an intravenous fluorescent dye to confirm fusion with host vessels. Graft size increased with the proportion of total vasculature that came from the donor, with the contribution of donor-derived vessels within the graft increasing as a function of distance from the graft-host border. Interestingly, graft size was also greater when cells were transplanted at stroke sites than when transplanted in uninjured neocortex, suggesting that stroke sites are especially conducive to donor-derived vascularization of the graft. We observe that within transplants on the stroke- affected side, blood vessels primarily develop from donor-derived cells, in contrast to the control side. Indeed, excluding vascular cells from the donor cell population strictly limited graft size. Thus, inclusion of vessel-forming vascular cells with NSCs is required for more efficient engraftment and ultimately tissue repair.

Ctr. of Heart, Brain, Hormone and Healthy Aging, The Univ. of Hong Kong, Pokfulam, Hong Kong; [5]GMH Inst. of Central Nervous Syst. Regeneration, Jinan Univ., Guangzhou, China; [6]City Univ. of Hong Kong Shenzhen Res. Inst., Shenzhen, China

Abstract: In central nervous system (CNS), the hostile extrinsic microenvironment and limited intrinsic regenerative capacity of adult neurons remained major obstacles for successful axon regeneration after injuries. By contrast, adult peripheral neurons are capable of regenerating their injured axons. However, the slow rate of regeneration (1-2mm/day) significantly limited the regain of motor functions as the regenerated axons fail to reinnervate their distal targets largely due to chronic denervation. Therefore, there is an urgent need to search for bioactive compounds which enable long-distance axon regeneration for clinical meaningful functional restoration. Wolfberry (*Lycium barbarum*) is a widely used traditional Chinese medicine known to exhibit a broad range of neuroprotective effects in various neurological disorders such as glaucoma and

spinal cord injury. In this study, we first demonstrated that *Lycium barbarum* polysaccharides (LBP, major bioactive constituent of wolfberry) promoted sensory and motor functional restoration after severe peripheral nerve injury (PNI). In CNS, intravitreal injections of LBP induced robust axonal regrowth 14 days after optic nerve crush (ONC) injuries. In an attempt to screen for bioactive small molecules that recapitulated the transcriptional change induced by LBP in peripheral neurons, we successfully identified two FDA-approved small molecules which promoted axon regeneration in both PNS and CNS. Similar to LBP, these two small molecules markedly enhanced the intrinsic growth capacity of axotomized dorsal root ganglion neurons *in vitro*. The distal extent of *in vivo* sensory axonal regrowth was also increased in mice treated with both small molecules 3 days after PNI. More importantly, we confirmed that both FDA-approved small molecules could facilitate long-distance axon regeneration after CNS injuries. While only limited axons can regenerate across the lesion in vehicle-treated mice, mice treated with both small molecules displayed remarkable axon regeneration 14 and 28 days after ONC. Some axons could even regenerate along the entire length of optic nerves and reached the optic chiasm 28 days after ONC in mice treated with these small molecules. In both time points, only 20% of RGCs were survived in vehicle-treated controls, which was dramatically increased in mice treated with both small molecules. Taken together, our study demonstrated the therapeutic potential of LBP and two FDA-approved small molecules in promoting axon regeneration after injuries. Further study is required for optimizing the dosage of these bioactive compounds in order to improve the clinical outcomes after nervous system injury.

Title: Overexpression of basic helix-loop-helix protein induces sustained long-distance axon regeneration and elicits neural activity at distal brain targets

Authors: ***C. H. E. MA**[1], N. P. B. AU[1], G. KUMAR[1], S. K. CHIU[2], D. H. GESCHWIND[3], G. COPPOLA[3];
[1]Neurosci., [2]Biomed. Sci., City Univ. of Hong Kong, Kowloon Tong, Hong Kong; [3]Psychiatry and Neurol., UCLA, Los Angeles, CA

Abstract: Peripheral nerve injury (PNI) primes the peripheral neurons to an active growing state via reactivation of a transcription program that recapitulate some of cellular processes for robust axonal outgrowth during developmental stage. These neurons are capable of regenerating their

injured axons at an extremely slow rate (i.e. 1-2mm/day) after PNI. However, patients with proximal PNI, such as brachial plexus injuries, usually have poor clinical outcome even after immediate surgical repair after injury. Since long-distance axon regeneration is required for these patients, the regenerated axons fail to form functional synapses at the motor end plates largely due to chronic denervation. In contrast, the neurons in central nervous system (CNS) have limited intrinsic regenerative capacity, and virtually no axons can regenerate across the lesion for target reinnervation after CNS injuries. This leads to permanent loss of motor functions in patients with CNS injuries such as spinal cord injury and optic neuropathy. There is an urgent need to develop new therapeutic strategy to promote axon regeneration and functional recovery after injuries to our nervous system. Previously, we identified basic helix-loop-helix (bHLH) protein as a key regulator for successful axon regeneration. Overexpression of bHLH induced robust axonal regrowth, and accelerated sensory and motor functional recovery after PNI. Here, we tested if overexpression of bHLH could also induce robust axon regeneration after CNS injuries. Two weeks before optic nerve crush injuries, adeno-associated virus (AAV) overexpressing bHLH (i.e. AAV-bHLH) was intravitreally injected to the injured eye for transduction of bHLH in retinal ganglion cells (RGCs). The extent of axonal regrowth and the survival of RGCs was assessed at days 14 and 28 post-injury, respectively. Strikingly, we observed a marked increase in axon regeneration with increased RGC survival in AAV-bHLH-treated mice 2 and 4 weeks after optic nerve crush injury, respectively. In particular, some of the regenerating axons could even reach optic chiasm in AAV-bHLH-treated mice 4 weeks after injury. By combining bHLH overexpression with *Pten* deletion, a gene manipulation known to promote CNS regeneration, we successfully detected reliable eye-evoked local field potentials in superior colliculus (SC) upon optical stimulation in injured RGCs 6 weeks after injury, suggesting that a considerable amount of regenerating axons could reinnervate to distal brain target at SC. Screening of small molecules identified bioactive compounds that induce transcription program recapitulating the growth-promoting effects by bHLH overexpression.

Title: Stromal cell-derived factor 1 is a macrophage-derived growth factor for non-α retinal ganglion cells

Authors: *Y. YIN[1,2], O. STRELKO[1,2], M. MA[1,2], L. I. BENOWITZ[1,2,3,4];
[1]Dept. of Neurosurgery, Children's Hospital, Harvard Med. Sch., Boston, MA; [2]F.M. Kirby Neurobio. Center, Boston Children's Hosp., Boston, MA; [3]Dept. of Ophthalmology, Harvard Med. Sch., Boston, MA; [4]Program in Neuroscience, Harvard Med. Sch., Boston, MA

Abstract: Although adult mammalian retinal ganglion cells (RGCs) lose the ability to regenerate injured axons, this loss can be partially reversed by factors expressed in cells of the innate immune system. Stromal cell-derived factor 1 (SDF1), one of the key factors mediating the effects of intraocular inflammation on optic nerve regeneration, is produced by infiltrative macrophages and acts synergistically with oncomodulin (Ocm), which is expressed by neutrophils and macrophages)[1]. Here we report that regeneration induced by SDF1 treatment arises from distinct populations of non-αRGCs. Using Kcng4-GFP mice (Kcng4-Cre:STOP$^{flx/flx}$ GFP) in which αRGCs express GFP, we found that, with SDF1 treatment (via AAV2-monomeric SDF1, AAV2-mSDF1), GFP^{+} axons (from αRGCs) were seen proximal to the injury site but failed to extend beyond this point. Thus, the regenerating axons do not arise from αRGCs. This result contrasts sharply with the effects of Pten inactivation, in which growing axons are GFP^{+} and thus from αRGCs[2]. When combined, treatment with AAV2-mSDF1 and AAV2-shPten induced high levels of regeneration, although most regenerating axons were GFP negative, and thus again not from αRGCs. By examining the survival of different RGC subtypes, we found that SDF1, either alone or combined with Pten inactivation, did not change the percentile of surviving αRGCs, ipRGCs and oo-dsRGCs among the total surviving RGC population after optic nerve injury. This is also different from another treatment (Sox11 overexpression) that stimulates non-αRGC regeneration but is toxic to αRGCs[3]. Our study demonstrates that the RGC subtypes that are stimulated to regenerate are treatment-specific. SDF1-induced regeneration is non-αRGC based, and when combined with Pten inactivation, which otherwise targets αRGCs, SDF-1 enhances strong regeneration from non-αRGCs. Thus, the regenerative RGC subtypes are not a simple addition of two pools of regenerating RGC subsets. These findings may help uncover important interactions among signaling mechanisms in RGCs. **References** 1. Y. Yin *et al.*, Annual Meeting, SfN, San Diego, CA, 2018. 2. X. Abstract: Injured central nervous system neurons display limited axon regeneration. There is a pressing need for new experimental models that can mimic human-specific features and for strategies that can enhance axon regeneration of mature human neurons. To address these issues, we developed an approach to investigate the dynamics of injured human cortical synaptic networks using donor-derived cells transplanted into the mouse brain, intravital structural and functional longitudinal imaging and laser microsurgery. Being able to follow the fate of individual fluorescent axons over time *in vivo*, we have been able to observe unequivocal human axon regeneration occurring as early as 6-hours post-injury, with axons reaching and growing past the lesion site at 3 weeks post-transplantation. Most immature human axons (~ 70%) were able to regenerate past the lesion site within 24-hours, while fewer regenerated as early as 6-hours post-lesion (~12% of all regenerating axons). In contrast to mouse cortical axons, regenerating human axons followed their original trajectories. The maximum regrowth observed was ~2 mm over 7 days. Importantly, the proportions of regenerating axons significantly decreased with maturity of grafted human cortical neurons at 3 months post-transplantation. In addition, mature non-regenerating human axons progressively retracted over 7 days *in vivo*. To investigate the role of neural activity in regulating intrinsic human axon regenerative capacity, we measured axonal calcium signals before and after injury in regenerating and non-regenerating human cortical neurons, using the activity-dependent sensor GCaMP6s and an activity-independent cell-filling reporter tdTomato. Mapping calcium responses to human axonal injury at single-cell-resolution *in vivo* revealed significantly higher pre-lesion activity levels of mature regenerating human axons compared to mature non-regenerating and immature human axons. Ongoing experiments are aimed at using non-invasive temporal interference stimulation technology to enhance regeneration fractions of mature human cortical axons. Overall, this experimental system recapitulates many important features of the physiological axon response to injury, including proximal axon fragmentation, the loss of regeneration potential with maturity, progressive die-back and retraction of mature human axons from the injury site, as well as sprouting and branching. Together, these data establish a new *in vivo* model and method to study human cortical axon regeneration *in vivo*.

Title: Targeting mitochondrial dynamics as a therapeutic intervention to promote axon regeneration

Authors: *P. ASTHANA, N. P. B. AU, R. CHAND, W. Y. TAM, C. H. E. MA; Neurosci., City Univ. of Hong Kong, Kowloon Tong, Hong Kong

Abstract: Axon regeneration is an energy-demanding process which involves active polymerization of actin and tubulin (building blocks of microtubule) at the barbed end of a growth cone for proper axon elongation. After a peripheral nerve injury (PNI), axonal transport of mitochondria markedly increases in the regenerating axons to fulfil the increased energy demand at distal axons. In contrast, the axonal mitochondrial transport was significantly impaired after spinal cord injury (SCI; a form of CNS injury), leading to limited extent of axonal regrowth in SCI. This suggests that active mitochondrial transport plays a pivotal role in successful axonal regrowth after injuries. In the current study, we first examined the mitochondrial transport in peripheral neurons overexpressing a human heat shock protein 27 (hHsp27), a known regeneration-associated gene to promote axonal regrowth after PNI. In hHsp27-overexpressing neurons, we observed an increased number of mitochondria at the most distal axons with increased mitochondrial size. Kymograph analysis revealed a marked increase in the velocity of axonal mitochondrial transport in these neurons compared with the wild-type controls in the same culture. Blockade of axonal mitochondrial transport using Ciliobrevin D completely abolished the growth-promoting effects of hHsp27 overexpression in cultured dorsal root ganglion (DRG) neurons. Next, we tested if a bioactive small molecule known to promote mitochondrial fusion could recapitulate the growth-promoting effects of hHsp27 overexpression via modulation of mitochondria dynamics. In line with our hypothesis, this small molecule markedly enhanced mitochondrial clustering at the distal axons of axotomized DRG neurons, and promoted mitochondrial fusion (as indicated by larger mitochondrial size) via up-regulation of mitochondrial fusion proteins Opa1 and Mfn2. Also, this small molecule markedly enhanced axonal mitochondrial transport in cultured DRG neurons via up-regulation of the molecular machineries for both anterograde and retrograde axonal transport. Remarkably, this small molecule markedly enhanced the intrinsic growth capacity from axotomized DRG neurons, and accelerated the *in vivo* axonal regrowth after PNI. Taken together, our study shed new light for the development of mitochondria-based therapy to orchestrate mitochondria dynamics which enable long-distance axon regeneration for target reinnervation and functional recovery after PNS injuries. Further study is required to examine if modulation of mitochondrial dynamics using this small molecule could also induce long-distance axon regeneration after CNS injuries.

Title: Pathogenic GRM7 mutations associated with neurodevelopmental disorders impair axon outgrowth and presynaptic terminal devleopment

Authors: *J. SONG, Y. SUH;
Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Metabotropic glutamate receptor 7 (mGlu7) is an inhibitory heterotrimeric G protein-coupled
receptor that modulates neurotransmitter release and synaptic plasticity at presynaptic terminals in the mammalian central nervous system. Recent studies have shown that rare mutations in glutamate receptors and synaptic scaffold proteins are associated with neurodevelopmental disorders (NDDs). However, the role of presynaptic mGlu7 in the pathogenesis of NDDs remains
largely unknown. Recent whole-exome sequencing studies in families with NDDs have revealed that several missense mutations (c.1865G>A:p.R622Q; c.461T>C:p.I154T; c.1972C>T:p.R658W and c.2024C>A:p.T675K) or a nonsense mutation (c.1757G>A:p.W586X) in the GRM7 gene may be linked to NDDs. In the present study, we investigated the mechanistic links between GRM7 point mutations and NDD pathology. We find that the pathogenic GRM7 I154T and R658W/T675K mutations lead to the degradation of the mGlu7 protein. In particular, the GRM7 R658W/T675K mutation results in a lack of surface mGlu7 expression in heterologous cells and cultured neurons isolated from male and female rat embryos. We demonstrate that the expression of mGlu7 variants or exposure to mGlu7 antagonists impairs axon outgrowth through the MAPK-cAMP-PKA signaling pathway during early neuronal development, which subsequently leads to a decrease in the number of presynaptic terminals in mature neurons. Treatment with an mGlu7 agonist restores the pathological phenotypes caused by mGlu7 I154T but not by mGlu7 R658W/T675K due to its lack of neuronal surface expression.
These findings provide evidence that stable neuronal surface expression of mGlu7 is essential for neural development and that mGlu7 is a promising therapeutic target for NDDs.

Title: Investigating the effects of temperature on the regulation of the expression of neuronal GFP in C. elegans

Authors: *B. G. GARCIA-GONZALEZ, S. J. AVANT, A. E. CARRASCO-PENA;
Dept. of Biol. Sci., St. Edward's Univ., Austin, TX

Abstract: Jeopardized genetic and environmental factors such as the disruption to the mTOR signaling pathway and prenatal stress are hypothesized to lead to the development of schizophrenia. Researchers Lee and colleagues observed decreased levels of DPYSL2 in the prefrontal cortex and hippocampus of rats exposed to prenatal stress. DPYSL2 is important for axonal outgrowth, cell differentiation, and promoting proper microtubule assembly in humans. The *C. elegans* homolog of DPYSL2, UNC-33, is also important for proper axonal formation and elongation. The purpose of this study is to monitor the effects of environmental stress, using the stressor of high temperatures, on the expression of GFP driven by the *unc-33* promoter. Preliminary studies from our laboratory have shown that neuronal GFP expression driven by the *unc-33* promoter is reduced at high temperatures. Herein we present results from a novel thermal tolerance curve investigating the gradual effect of increasing temperatures on GFP expression driven by the *unc-33* promoter. To this end, *C. elegans* hermaphrodites were incubated at various temperatures until they reached an L2/L3 stage. Using confocal microscopy, the head of *C. elegans* hermaphrodites was imaged to determine the GFP expression in the nerve ring and glial cells. The analysis of the quantification of thirty nematodes per condition shows that GFP expression in neurons decreases as temperature increases. While the neuronal expression is reduced due to this high temperature, glial expression is increased. This study provides insight into the role that high temperature has on regulating the expression of neuronal *unc-33*, one of the molecular players shown to be negatively impacted by prenatal stress in rats and by polymorphic variations in patients suffering from Schizophrenia.

Title: The role of extracellular matrix molecule hyaluronan in hippocampal neuron morphological development in vitro

Authors: *M. I. ABRAHAM, R. N. KARUNASINGHE, T. M. FOWKE, J. M. DEAN; Physiol., Univ. of Auckland, Auckland, New Zealand

Abstract: The brain's extracellular matrix provides key structural and functional support to neurons and glial cells. Hyaluronan is a glycosaminoglycan sugar, and a major component of the developing brain's extracellular matrix. Hyaluronan metabolism is regulated by the family of hyaluronan synthases (HAS1-3) and hyaluronidases (Hyal1-5, SPAM1, CEMIP, and TMEM2), which synthesise and degrade hyaluronan, respectively. Hyaluronan has a wide range of functions including both structural and functional, and in particular can activate signaling pathways important for non-neuronal cell growth. However, a specific role for hyaluronan in controlling neuronal development remains unclear. Herein, we examined the expression and function of hyaluronan, HASs, and Hyals in developing hippocampal neurons *in vitro*. Dissociated hippocampal neuron cultures (<5% glial cells) were generated from Sprague Dawley rat embryos (E18) and collected at 1-21 days *in vitro (DIV)*. Cultures were fixed for immunocytochemical localisation studies. Live-cell images were acquired with a Nanolive 3D Cell explorer, a holographic tomographic microscope that resolves lamellipodia, transient early developmental structures associated with cell motility and neurite outgrowth. Cultured cells exhibited robust mRNA (RT-qPCR) and protein (immunocytochemistry) expression of HAS2-3, Hyal1-3 (but not HAS1, Hyal4, 5, SPAM1, or CEMIP), and hyaluronan, from (DIV) 1 to 21 (n=4 independent cell cultures per time-point). Pharmacological HAS inhibition with 4-methylumbelliferone (4-MU), or Hyal inhibition with L-ascorbic acid 6-hexadecanoate (VCPAL), altered early neuron morphological development, and both treatment groups had significantly reduced lamellipodia number and area, and filopodia numbers at DIV2 compared to controls (n=10 cells for each treatment condition from 4 independent cell cultures). HAS inhibition also increased primary neurite number and average neurite length compared to controls, as well as an increase in axonal outgrowth from 24h in culture (n=10 cells for each treatment condition from 4 independent cell cultures). Conversely, Hyal inhibition reduced primary neurite number (DIV3) and average neurite length (DIV2 & 3). These data suggest that hippocampal neurons can endogenously metabolise hyaluronan, and that neuronally-regulated hyaluronan metabolism is important for the early stages of morphological development, including growth cones and neurite outgrowth.

Title: Caspase-3 prefers a non-canonical consensus sequence associated with cytoskeletal substrates during auditory brainstem development

Authors: *F. WEGHORST[1], Y. MIRZAKHANYAN[2], P. D. GERSHON[2], K. S. CRAMER[1];
[1]Neurobio. and Behavior, [2]Mol. Biol. and Biochem., UC Irvine, Irvine, CA

Abstract: The auditory brainstem contains extremely precise circuitry responsible for determining sound source location based on interaural differences in sound arrival time. We previously showed that the apoptotic protease caspase-3 is necessary for development of the auditory brainstem projection from chick *nucleus magnocellularis* (NM) to *nucleus laminaris* (NL). Inhibition of caspase-3 prior to the period of developmental cell death in auditory brainstem nuclei resulted in NM axon mistargeting. However, the mechanisms by which caspase-3 facilitates the formation of the NM-NL projection are not known. To this end, we characterized proteins cleaved by caspase-3 in the chick auditory brainstem. Embryos were treated with intraventricular injection of the caspase-3 inhibitor z-DEVD-fmk or vehicle solution on embryonic days 9 and 10. Brainstems were harvested and subjected to proteomic mass spectrometry. Peptidomes were filtered for peptides likely generated by *in vivo* caspase-3 activity based on two criteria: the peptide terminated in a caspase-like cleavage site (i.e. with a C-terminal aspartate or glutamate residue) and was present in vehicle-injected brainstems but absent in caspase-3-inhibited brainstems. Proteins with at least one such peptide were considered likely auditory brainstem caspase-3 (ABC3) substrates. We generated an IceLogo of the ABC3 consensus cleavage site and found that the resulting tetrapeptide sequence N-terminal of the scissile bond (DHRD) bore some similarity to that of the canonical caspase-3 consensus site (DEVD). However, the substitution of "EV" with "HR" suggested a systematic change in the usual substrate preference of caspase-3. We used functional annotation enrichment analysis to determine whether ABC3 substrates with "HR" cleavage sites were associated with a specific protein category disproportionately targeted by caspase-3 activity. Compared to the background of all ABC3 substrates, substrates with an H or R at the same position as the consensus sequence were enriched for the the GO term "structural constituent of cytoskeleton." The observed consensus sequence therefore reflects a shift toward cleavage of cytoskeletal proteins, which are essential for axon guidance and synapse formation, suggesting a specialized, non-apoptotic function for caspase-3 in auditory brainstem circuit formation.

Title: Microtubules as a determinant of DRG axon asymmetry and regenerative capacity

Authors: *A. COSTA[1], B. MURILLO[1], T. MISGELD[2], M. BRILL[2], M. SOUSA[1];
[1]Nerve Regeneration group, IBMC/i3S, Porto, Portugal; [2]Inst. of Neuronal Cell Biol., Technische Univ. München, Munich, Germany

Abstract: In dorsal root ganglion (DRG) neurons a single axon bifurcates into a peripheral and a central branch with different functions and properties. Whereas the peripheral DRG axon regenerates, the central DRG axon only gains regenerative capacity after lesion to the peripheral axon -conditioning lesion (CL) effect. We have previously shown that a CL induces a global increase in axonal transport that extends to DRG central axons, supporting their regeneration. To further understand the mechanisms underlying central-peripheral DRG asymmetry and the conditioning lesion effect, we analyzed the microtubule (MT) cytoskeleton of DRG axons. By live imaging of DRG explants from Thy1-EB3-GFP mice, we observed that MT dynamics is asymmetric in the DRG, with central axons displaying a more dynamic cytoskeleton. Importantly, peripheral axon injury, but not central axon injury, decreased MT dynamics in both peripheral and central axons, leading to a more stable MT cytoskeleton following injury. While the severing enzymes spastin and katanin control MT dynamics by destabilizing MTs, Tau binds to MTs increasing their stability and protecting them from the action these enzymes. We observed that in the DRG central branch the expression of katanin and spastin is dramatically increased, while the expression of Tau is higher in the DRG peripheral branch. Our results suggest that Tau in the DRG peripheral branch protects MTs from the action of severing enzymes and, consequently, increases the stability of this DRG branch. We next investigated if spastin is a specific regulator of DRG MT dynamics and axonal transport asymmetry, by crossing a spastin knock-out mice with either the Thy1-EB3-GFP mouse or Thy1-MitoRFP mouse. We observed that in the absence of spastin loss of asymmetry of MT dynamics occurs in DRG axons as well as disrupted mitochondria axonal transport, particularly in central axons. Finally, *in vivo*, the absence of spastin led to decreased regeneration of DRG peripheral axons following sciatic nerve crush and DRG central axons following a conditioning lesion. In summary, our results support that spastin is a specific regulator of MT dynamics in DRG neurons underlying their central-peripheral asymmetry, being an essential enzyme for optimal axon regeneration to occur.

Title: Neuron navigator 1 in early neural development

Authors: ***R. POWERS**[1], B. CALABRESE[1], E. DESAI[1], S. L. HALPAIN[2];
[1]UC San Diego, La Jolla, CA; [2]Neurobio., UC San Diego Section of Neurobio., La Jolla, CA

Abstract: Proper regulation of the cytoskeleton is essential for neurodevelopment. Cytoskeleton associated proteins integrate extra- and intracellular signals to influence actin and microtubule dynamics in the developing neuron. These cytoskeleton dynamics are necessary for later circuit integration and brain development, but many of the proteins involved and mechanisms have yet to be elucidated. Neuron Navigator 1 (Nav1) is a microtubule +TIP protein highly expressed during brain development. Nav1 is necessary for neuritogenesis, but the underlying mechanisms are relatively unknown. Using RNAi and knockout strategies in primary neurons and cell lines, we find that Nav1 is important for coordinating the cytoskeleton of the cell periphery for proper cell morphogenesis. This includes an unexpected role in regulating F-actin in the growth cone, as well as a novel role in regulating actin-membrane coupling. These data highlight the importance of Nav1 in cell morphogenesis, as well as reveal new roles of this +TIP protein in regulating actin and plasma membrane behavior.

Title: A functional role for a hypothetical Linear ubiquitin chain Determining Domain of the RNF216/TRIAD3A Ubiquitin Ligase

Authors: *D. W. YAKOUT[1], J. KADIRVELU[1], R. LIU[2], A. CHARLES[1], J. YIN[2], A. M. MABB[1];
[1]Neurosci. Inst., [2]Dept. of Chem., Georgia State Univ., Atlanta, GA

Abstract: Ubiquitination is a type of posttranslational modification (PTM) that involves the covalent attachment of Ubiquitin (Ub) to various substrates. This PTM controls several cellular processes, which include proteasome-dependent substrate degradation. Ub conjugation requires the activity of three enzymes: A Ub activating enzyme (E1), Ub conjugating enzyme (E2), and the Ub ligase (E3). RBR (RING-Between-RING) is an E3 ligase subfamily which includes HOIP (HOIL-1-Interacting Protein), which is a subunit of LUBAC (linear ubiquitin chain assembly complex). HOIP contains an LDD (Linear ubiquitin chain Determining Domain) that transfers the Ub chain to the N-terminus of its target substrate and is involved in the catalytic activity and specificity of linear ubiquitin chain assembly. Linear ubiquitination promotes inflammation and regulates cell death, but there is no evidence for its role in the nervous system. Here, we show that the RNF216 E3 ligase isoform TRIAD3A (the most abundant isoform in the brain) has an amino acid sequence that shares homology with the LDD of HOIP. Deletion of this sequence decreases TRIAD3A autoubiquitination. Moreover, deletion of this domain alters the localization of the protein in primary hippocampal neurons, reduces dendritic complexity and alters dendritic spine morphologies. Our findings suggest that the Triad3A hypothetical LDD might act independently of its RBR domain to regulate hippocampal neuron development via ubiquitination of unique substrates.

Title: Validation of neurite orientation dispersion and density imaging (NODDI) magnetic resonance imaging (MRI) for assessment of brain development in the neonatal rat

Authors: *P. B. WHITE[1], J. D. PRASAD[1], Y. VAN DE LOOIJ[2], S. SIZONENKO[2,3], S. RANASINGHE[1], L. BENNET[1], A. GUNN[1], J. M. DEAN[1];
[1]Dept. of Physiol., Univ. of Auckland, Auckland, New Zealand; [2]Dept. of Pediatrics and Gynecology, Univ. of Geneva, Geneva, Switzerland; [3]Ctr. for Biomed. Imaging, Lausanne Federal Polytechnic Sch., Lausanne, Switzerland

Abstract: Preterm birth increases a child's risk of brain injury and is associated with reduced cortical growth and poor neurodevelopmental outcomes. However, brain injury is seldom

diagnosed immediately. Diffusion tensor imaging (DTI) is a magnetic resonance imaging (MRI) model used clinically to identify preterm brain injury. Although, DTI parameters lack cellular specificity. Neurite Orientation Dispersion and Density Imaging (NODDI) is a type of diffusion MRI that aims to provide greater specificity than DTI for assessing the cellular components contributing to diffusivity changes. However, the histological correlates of NODDI parameters in the brain remain unclear, but are important for detecting the origin and evolution of preterm brain injury. Herein, we examined the histological correlates of NODDI parameters during normal brain development. Sprague Dawley (SD) rats were euthanized at postnatal day (PND) 1, 3, 7, 14, 21, and 35 (n=10, per age, male and female). Brain tissues were processed for Golgi-Cox staining (n=5 per age) or fixed for *ex-vivo* MRI analysis (n=5 per age, using an actively shielded 9.4T/31cm magnet). Data were fitted with the NODDI toolbox (Matlab) and spatially normalised DTI. MRI tissues were processed for immunohistochemistry (microtubule associated protein 2, glial fibrillary acidic protein), and cellular process density was calculated via the Spaceball method (radius =7.5µm, Stereoinvestigator software). Dendritic morphology was assessed in Golgi-Cox tissue via manual tracing (Neurolucida software), on a Zeiss Axio Imager M2 upright microscope. In both the motor (M1-M2) and somatosensory (S1HL-S2) cortices, the DTI parameter fractional anisotropy progressively decreased from PND1-PND7, while the NODDI parameter orientation dispersion index progressively increased from PND1-PND14. Both values plateaued thereafter. The DTI parameter mean diffusivity increased from PND1-PND3 and then decreased from PND3-PND7, while the NODDI parameter neurite density index decreased from PND1-PND3 and then increased from PND3-PND7. Histologically, there was a progressive increase in all dendritic complexity measures in the motor and somatosensory cortices from PND1-PND21. Correspondingly, dendritic density decreased at PND3. These data suggest that while MRI measurements may reflect changes in dendritic morphology and density with development, there may be other contributing factors to developmental cortical anisotropy. Nevertheless, NODDI may provide a novel technique for assessing cortical pathology in preterm-born infants.

Title: Mechanism of axonal TrkB signaling endosomes inducing long-distance dendritic growth in cortical neurons

Authors: G. MOYA-ALVARADO[1], W. C. MOBLEY[2], C. WU[3], E. PERLSON[4], ***F. C. BRONFMAN**[5];
[1]Dept. of Biol., John Hopkins Univ., Baltimore, MD; [2]Dept. of Neurosciences, Univ. of California San Diego Dept. of Neurosciences, La Jolla, CA; [3]Neurosciences MC0624, UCSD, La Jolla, CA; [4]Dept. of Physiol. and Pharmacol., Tel Aviv Univ., Tel Aviv, Israel; [5]Inst. of Biomed. Sci., Univ. Andres Bello, Santiago, Chile

Abstract: Brain-Derived Neurotrophic Factor (BDNF) is broadly expressed in many circuits of the central nervous system (CNS). It binds TrkB and p75 to trigger different signaling pathways, including ERK1/2 and PI3K-mTOR, to induce dendritic growth and synaptic plasticity. When binding to BDNF, TrkB and p75 are endocytosed to signaling endosomes to continue signaling inside the cell. Whether BDNF/TrkB-p75 signaling endosomes in axons are regulating long-distance signaling in cell bodies to modify neuronal morphology is unknown. Here, we studied the functional role of BDNF signaling endosomes in long-distance regulation of dendritic growth using compartmentalized cultures of rat and mouse cortical neurons derived from $p75^{exonIII}$ knock-out or $TrkBF^{616A}$ knock-in mice. By applying BDNF to distal axons, we showed the capacity of axonal BDNF to increase dendritic arborization in cell bodies. This process depended on TrkB activity, but not p75 expression. In axons, BDNF/TrkB co-localized with Rab5 endosomes and increased active Rab5. Also, dynein was required for BDNF long-distance signaling, consistent with sorting and transport of signaling endosomes. Using neurons derived from $TrkBF^{616A}$ knock-in mice and the 1NM-PP1 inhibitor, we were able to demonstrate that TrkB receptors activated in the axons by BDNF, were required in the neuronal cell body to increase TrkB activity and phosphorylation of CREB. Also, we were able to visualize endosomes containing activated TrkB. PI3K activity was not required in the axons for dynein dependent BDNF responses. However, dendritic arborization induced by axonal BDNF signaling required both nuclear CREB and PI3K activation in cell bodies. Consistently, axonal BDNF increased protein translation in cell bodies and CREB and PI3K and mTOR activity were required for this process. Altogether, these results show that BDNF/TrkB signaling endosomes generated in axons allows long-distance control of dendritic growth coordinating both transcription and protein translation. Our results suggest a role of BDNF-TrkB signaling endosomes wiring circuits in the CNS.

Title: Molecular and cellular functions of the PP2A serine/threonine phosphastase in dendritic diversification

Authors: *S. BHATTACHARJEE[1], E. N. LOTTES[1], S. NANDA[2], G. ASCOLI[2], D. N. COX[1]; [1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]George Mason Univ., Fairfax, VA

Abstract: Uncovering the molecular mechanisms that regulate dendritic diversification is essential to understanding the formation and modulation of functional neural circuitry. However, the molecular mechanisms by which this is achieved remain incompletely understood. Studies in *Drosophila* multidendritic (md) sensory neurons reveal that the Cut homeodomain transcription factor regulates cell-type specific dendritogenesis through cellular pathways that converge on cytoskeletal architecture. Neurogenomic and phenotypic analyses identified the highly conserved PP2A serine/threonine phosphatase complex as a downstream effector of Cut. The PP2A complex is composed of a catalytic subunit encoded by *microtubule star (mts),* a scaffolding subunit encoded by *PP2A-29B* and one of four alternate regulatory subunits encoded by *widerborst (wdb), twins, well-rounded (wrd)* and *CG4733.* Mutant analyses of *mts* and *PP2A-29B* reveal severe reductions in dendritic arborization with *wdb* functioning as the relevant regulatory subunit in Class IV (CIV) md sensory neurons. In contrast, mutations in *mts* and *PP2A-29B* leads to increased dendritic complexity via *de novo* filopodia formation in Class I (CI) md sensory neurons. Mechanistically, while Mts and PP2A-29B are also part of the STRIPAK complex with Cka as the regulatory subunit, our data indicate that the PP2A and STRIPAK complexes function in parallel to regulate dendritic architecture. Live imaging reveals that *mts* mutations leads to microtubule (MT) destabilization. In addition, dynamic EB1::GFP imaging of MTs reveals Mts is required to maintain dendritic MT polarity. In contrast to its effect on MTs, *mts* knockdown leads to F-actin reorganization with a proximal shift towards the soma. Loss of *mts* leads to significant reductions in dendritic localization of organelles including mitochondria and satellite Golgi outposts in CIV neurons, while in CI neurons, *mts* mutants show increased Golgi outpost trafficking along the dendritic arbor. Further, *mts* mutant neurons exhibit defects in neuronal polarity as revealed by Golgi outposts appearing in the proximal axon whereas in controls Golgi outposts are primarily restricted to the soma and at satellite locations on dendrites. Furthermore, in *mts* mutants selective markers of dendritic and axonal compartments are detected in the opposing compartments. At a regulatory level the β-tubulin subunit 85D represents a common PP2A target across these md neuron subtypes. Collectively, these studies provide novel insights into the functional roles of the PP2A phosphatase in promoting dendritic diversity.

Title: Mir-9 regulates the structure of spiny neurons in Area X of zebra finches

Authors: *H. JARRELL, Z. HUANG, Z. SHI, Y. DING, X. LI;
Neurosci., LSUHSC, New Orleans, LA

Abstract: Area X, the avian basal ganglia, plays important roles in song related sensory-motor learning and performance in zebra finches. We have recently shown that the expression of miRNA miR-9 is regulated in Area X during song development and overexpression of miR-9 in Area X of juveniles leads to impairments in vocal learning and vocal performance. We have also shown that miR-9 regulates FOXP2 (a gene associated with speech and language development) and many FOXP2 downstream genes that have been associated with neuronal structural plasticity. These observations prompted us to examine miR-9's role in modulating neuronal structure in Area X. We made a lentiviral vector that expresses miR-9 and a fluorescent marker mCherry, and stereotaxically injected the lentivirus into the Area X at 25-30 days old juveniles. We sacrificed the animals at 60 days and 100 days of age, imaged virally labeled neurons, traced neuronal dendritic structure, and quantitatively analyzed neuronal dendrite and spine structure. We report that miR-9 overexpression in juvenile Area X reduces dendrite length and complexity of spiny neurons. miR-9 overexpression also reduced spine density of these spiny neurons. In addition, miR-9 downregulates DARPP-32, a molecule for dopamine signaling. These impairments are long lasting and persist into adulthood. Together, these results provide strong evidence for miR-9's roles in regulating basal ganglia neuronal structure. As the basal ganglia is key to many neurological and psychiatric disorders, dysregulation of miR-9 may contribute to these disorders.

Title: Delayed development of input plasticity at lateral perforant path synapses onto adult-born dentate granule neurons.

Authors: *N. P. VYLETA[1], J. S. SNYDER[2];
[1]The Univ. of British Columbia, Vancouver, BC, Canada; [2]Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In the mammalian brain, the dentate gyrus of the hippocampus uniquely generates new neurons throughout the lifetime of the animal (adult neurogenesis). Adult-born granule cells undergo a period of maturation during which their membranes are more excitable and inputs from neurons in the medial enthorinal cortex (via medial perforant path) can more easily induce long-term potentiation of synaptic responses. This previously described "critical window" exists between approximately four- and six-weeks of cell age. Whether signaling from the other major cortical input to the dentate gyrus—the lateral enthorinal cortex via the lateral perforant path—undergoes the same timecourse of maturation remains unknown. We measured synaptic responses to stimulation of lateral perforant path axons at adult-born granule cells between three- and thirty-weeks old. Surprisingly, we find that long-term potentiation of synaptic responses matures over an extended timecourse, with a peak at around 15-weeks of cell age. Cells between 4- and 6- weeks of age are more likely to experience long-term depression of lateral perforant path inputs than are older cells. We find that facilitation of transmitter release increases over a similar timecourse as long-term potentiation. Furthermore, the magnitude of long-term potentiation could be predicted by either the starting level of facilitation or by the reduction of facilitation (increase in release probability) after induction of the potentiation. Therefore, these data suggest that an increase in presynaptic release probability at lateral perforant path synapses is the major mechanism of long-term potentiation, and that this plasticity is more prominent at inputs onto older neurons.

Title: Excitatory to Inhibitory Transition in GABAergic Currents Guides Circuit Formation of Cortical Interneurons

Authors: *K. ZAVALIN, A. HASSAN, C. FU, E. DELPIRE, A. LAGRANGE;
Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Rationale: Excitatory GABA is a crucial developmental cue that guides perinatal neuronal migration, synaptogenesis, and circuit formation. However, maturing neurons typically switch to hyperpolarizing responses through onset of KCC2 expression. We investigated how indefinitely-prolonged excitatory GABA responses in cortical interneurons (INs) adversely affect cortical circuit development using an IN-specific KCC2 knockout (KO).
Methods: We created the KO by crossing the IN-specific Dlx5:cre-IRES-eGFP and the $KCC2^{flox}$ lines. We measured seizure susceptibility by latency to onset of flurothyl-induced GTC seizure. We recorded sIPSCs using whole-cell voltage clamp in layer 5 (L5) pyramidal neurons in acute brain slices. We used immunohistochemistry and epifluorescence/confocal imaging to visualize expression of KCC2 and $GABA_A$ receptor subunits α1-5, and IN distribution by Dlx5-driven

reporters and somatostatin (SST)/parvalbumin (PV) antibodies. Experiments focused on P12-14 barrel field.
Results: KO mice exhibit abnormal neurological development, including: spontaneous seizures, a 45% faster onset of flurothyl-induced seizures, reduced body weight, and late postnatal mortality, but normal gross and histological anatomy of organs, including feeding structures and the brain. We observed the earliest cortical KCC2 expression in L5 INs, as early as E16-18 in wild-type mice. We expected these cells to be the most affected by loss of KCC2, and indeed found a 30% increase in density of INs specific to L5. However, we observed that the INs and inhibitory synapses of KO appear normal in many aspects: distribution of immature Dlx5+ INs, frequency of L5 principal cell sIPSCs, and $GABA_A$ receptor subunit expression.
We postulated that the effects of KCC2 loss might be specific to IN subtypes, which in L5 consist mainly of SST and PV INs with distinctly different circuit functions and developmental sequences. We found opposing changes in densities of these subtypes: a 12% increase in L5 density of SST INs in KO, but a decrease in PV IN density in L2-4 and L6.
Conclusions: Cortical INs are vital in regulating neuronal excitability and circuit function, and improper GABAergic excitation of INs underlies genetic and acquired epilepsies. Our data show that loss of KCC2 in developing INs causes failure to thrive and promotes seizures, which may be a result of altered IN distribution. To determine the underlying causes, we are now investigating (1) the early distribution of INs in the KO that precedes the changes in SST/PV distribution, and (2) whether GABAergic responses are anachronously excitatory in maturing INs in KO.

Title: Vasp ubiquitination regulates actin dynamics and neuronal morphogenesis

Authors: *L. E. MCCORMICK, S. L. GUPTON;
Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: In neurons, filopodia are critical for neuritogenesis, axon guidance, and dendritic spine formation. Defects in these processes can result in improper synaptic connectivity, neurodevelopmental disorders, and psychiatric syndromes. The actin polymerase VASP localizes to the filopodial tip complex and influences actin dynamics. Previously, the Gupton lab showed

VASP transiently co-localizes with the E3 ubiquitin ligase TRIM9 at the filopodial tip. TRIM9 was required for the reversible, non-degradative ubiquitination of VASP and this modification was associated with decreases in growth cone filopodia number and stability. Although the dynamic actin cytoskeleton and VASP are also appreciated to play important roles in the postsynapse, it is not known how VASP activity is regulated in dendritic filopodia and the maturing dendritic spine. Here we show VASP, TRIM9 and ubiquitinated VASP (VASP-Ub) localize to the PSD following differential centrifugation, suggesting a role for VASP-Ub in dendritic spines. Cultured murine cortical neurons overexpressing VASP or VASP-KR (a non-ubiquitinatable construct) exhibit no significant changes in dendritic filopodia number. Although the guidance cue netrin promotes synaptogenesis, neurons overexpressing VASP or VASP KR demonstrated a decrease in dendritic filopodia number following netrin treatment. To understand this puzzling result, we are currently utilizing live cell imaging to quantify the lifetime of these filopodia. Ongoing work is also examining *Trim9* deletion, as well as VASP and VASP-KR overexpression, on dendritic spine number, maturity, and synaptic plasticity. Future work will explore the mechanistic impact of ubiquitination on actin-VASP interactions through in vitro biochemical reconstitution assays.

Title: Kit Ligand Influences Cerebellar Molecular Layer Interneuron Migration and Synapse Formation

Authors: T. ZAMAN[1], Q. ALSABIA[1], A. STAFFORD[1], B. W. LUIKART[2], ***M. R. WILLIAMS**[1];
[1]Pediatrics & Human Develop., Michigan State Univ., Grand Rapids, MI; [2]Mol. and Systems Biol., Geisel Sch. of Med. at Dartmouth Col., Hanover, NH

Abstract: Mutation of the receptor tyrosine kinase Kit is associated with rare cases of intellectual disability and with autism spectrum disorder, suggesting that Kit is important for brain development. Kit Ligand (KL) promotes the development of Kit expressing cells in the body periphery; KL may also act in the brain to influence Kit+ neuron development. In human and rodent brains, KL and Kit are differentially expressed in synaptically coupled neurons. This complementary expression is consistent with a role for KL/Kit in circuit formation, but this model has not been tested. In both human and mouse brains, Kit expression is highest in cerebellar molecular layer interneurons (MLIs), while cerebellar KL is restricted to Purkinje cells

(PCs). In development, MLIs migrate to and synapse upon PCs. This MLI maturation happens largely postnatally in the mouse and is experimentally accessible. We therefore sought to test the hypothesis that target-derived (PC) KL attracts Kit+ cells (MLIs) to migrate and form synapses. This was accomplished through in vivo manipulations of KL, followed by analyses of MLI migration and of MLI:PC synapses. Leveraging a mouse expressing eGFP under the Kit promoter, we could observe the normal migration and morphology of Kit expressing MLIs. By conditional knockout, we found that PC KL was *not necessary* for normal MLI migration. However, by ectopic expression of KL, we found that KL *was sufficient* to attract and arrest MLI migration. We therefore investigated, instead of acting in an all or none fashion, whether KL influenced the local strength or specificity of MLI:PC synapses. By viral transduction, we sparsely overexpressed or knocked out KL, from PCs. By patch clamp electrophysiology, we found that increasing or decreasing PC KL caused a corresponding change in GABAergic input from MLIs. This suggests that PC KL levels may act as a rheostat controlling MLI synapse strength and/or number. This role was not relegated to neurons natively expressing KL; ectopic expression of KL in cerebellar Golgi cells induced MLIs to sprout axon collaterals to invest KL+ Golgi cells. Having established that modulating KL levels in a postsynaptic cell is sufficient to change input from Kit+ MLIs, we are now investigating whether presynaptic Kit is required for normal synapse formation. Our long-term goal for this project is to elucidate the molecular biology through which KL/Kit signaling elicits synapse formation, not only to inform normal development, but to understand neurodevelopmental disorders in which Kit is implicated, and to investigate whether the synaptogenic potential of Kit signaling may be leveraged therapeutically.

Title: Compartmentalized 3D neuronal cultures enhance neuronal maturation and improve access to circuits for measurements and manipulation

Authors: *A. M. TAYLOR, T. NAGENDRAN;
Xona Microfluidics, Inc., Research Triangle Park, NC

Abstract: 3D cultures aim to recapitulate the complex microenvironment found *in vivo* and to bridge the gap between traditional 2D cell culture approaches and *in vivo* animal models. Because of the complexity of the brain, there is a need to develop reliable 3D networks that also provide access to cellular compartments for measurements and manipulations.

Compartmentalized chips made of cyclic olefin copolymer (COC) provide a consistent and reliable platform to compartmentalize neurons and create assessable co-culture model systems. Among different matrices for culturing neurons in 3D, the Matrigel® matrix provides a promising environment for growing neurons, because of its richness in structural proteins found in the brain, such as laminin and collagen. Dissociated neurons from E18 rat combined cortex-hippocampus tissue were grown within the Matrigel® matrix in two compartment COC chips for 12 days *in-vitro* (DIV). Confocal z-stack images of fluorescently labeled neurons within the chamber demonstrate healthy neuron growth and development in 3D pattern. Neurons in 3D cultures that were retrograde labeled with GFP G-deleted rabies virus show increase in dendritic spines compared to 2D controls. In summary, we successfully modeled 3D neuron cultures within compartmentalized chips. These 3D cultures show an increase in dendritic spine formation and suggest a possibility to promote neuronal maturation. Further our results suggest that establishing 3D neuron cultures within these compartmentalized microfluidic devices provides a novel method to visualize the somatodendritic compartments while specifically performing targeted drug manipulations to axons extending into the axonal compartment in 2D. This method helps to develop highly organized *in vitro* assays to mimic and treat brain disorders.

Title: Pannexin 1 regulates cortical neuron dendritic protrusion dynamics and dendritic spine density

Authors: ***J. C. SANCHEZ-ARIAS**, E. VAN DER SLAGT, R. N. CANDLISH, L. SWAYNE; Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Dendritic spines develop from highly dynamic, filopodia-like protrusions arising from the dendritic shaft; here we present recent data from our lab demonstrating that the ATP-release channel protein pannexin 1 (PANX1) regulates mouse cortical neuron dendritic protrusion dynamics and dendritic spine density. Cultured cortical neurons lacking PANX1 exhibited increased dendritic spine density and formed larger cortical neuron networks. PANX1 was enriched in cerebral cortex synapses and its expression levels were downregulated during the critical period for synapse formation in the mouse sensory cortex. Panx1 knockout (KO) mice exhibited increased cortical neuron dendritic spine density in situ (layer 5 sensory cortex pyramidal neurons) and in vitro, establishing, in part, the mechanism underlying PANX1 regulation of neuronal networks. To determine whether changes in stability of developing dendritic protrusions contributed to the increased spine density observed in Panx1 KO cortical neurons, we next developed new methods to measure dendritic protrusion dynamics at 10 days-in-vitro (DIV10). To improve the detection of dendritic protrusions, we transfected neurons with a fluorescent membrane tag (mCherry-CD9-10). This approach resulted in a ~34% increase in the detection of dendritic protrusions when compared to a cytoplasmic fluorescent label (EGFP). Additionally, we confirmed that Panx1 KO led to higher density of dendritic protrusions, while transient expression of PANX1-EGFP in wildtype and Panx1 KO neurons resulted in a significant decrease in dendritic protrusion density. Moreover, using live cell microscopy, we acquired z-stack images of dendritic segments over a period of 10-minutes (1 frame every 5 seconds). We found that dendritic protrusions in Panx1 KO neurons are more stable, while transient expression of PANX1-EGFP significantly increased the overall movement and turnover of dendritic protrusions. Altogether, these new findings confirm and expand our understanding of PANX1 regulation of neuronal development and suggest that PANX1 regulation of dendritic spines is mediated, in part, by modulating dendritic protrusion dynamics in neurons. This work has been published in eNeuro at https://www.eneuro.org/content/6/3/ENEURO.0503-18.2019 and https://doi.org/10.1523/ENEURO.0079-20.2020.

Title: Sez6 family proteins are novel complement inhibitors expressed by neurons.

Authors: W. QIU[1], S. LUO[1], S. MA[1], P. SAMINATHAN[1], H. LI[1], J. GUNNERSEN[3], H. A. GELBARD[4], ***J. W. HAMMOND**[2];

[2]Neurol., [1]Univ. of Rochester, Rochester, NY; [3]Univ. of Melbourne, Melbourne, Australia; [4]Neurol., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: The Sez6 family consists of Sez6, Sez6L, and Sez6L2. Its members are expressed throughout the brain and have been shown to influence synapse numbers and dendritic morphology. They are also linked to various neurological and psychiatric disorders. All Sez6 family members contain 2-3 CUB domains and 5 complement control protein (CCP) domains, suggesting that they may be involved in complement regulation. We show that all Sez6 family members inhibit C3 deposition by the classical and alterative pathways with varying degrees of efficacy. For the classical pathway, Sez6 is a strong inhibitor, Sez6L2 is a moderate inhibitor, and Sez6L is a weak inhibitor. Using Sez6L2 as the representative family member, we show that it specifically deactivates C3 convertases by accelerating the decay or dissociation of the C3 convertase components. Sez6L2 also deactivates C3 convertases of the alternative pathway by serving as a cofactor for Factor I to facilitate the cleavage of C3b. However, Sez6L2 has no cofactor activity toward C4b. In summary, the Sez6 family are novel complement regulators that inhibit C3 convertases.

Sch. of Med., Shanghai, China; [4]Boys Town Natl. Res. Hosp, Omaha, NE

Abstract: In the developing auditory system, spontaneous activity generated in the cochleae propagates into the central nervous system to promote circuit formation. Effects of peripheral firing patterns on spontaneous activity in the central auditory system are not well understood. Here, we describe wide-spread bilateral coupling of spontaneous activity that coincides with the period of transient efferent modulation of inner hair cells from the brainstem medial olivocochlear system. Knocking out α9/α10 nicotinic acetylcholine receptors, a requisite part of the efferent pathway, abolishes these bilateral correlations. Pharmacological and chemogenetic experiments confirm that the efferent system is necessary and sufficient to produce bilateral coupling. Moreover, auditory sensitivity at hearing onset is reduced in the absence of pre-hearing

efferent modulation. Together, our results demonstrate how afferent and efferent pathways collectively shape spontaneous activity patterns and reveal the essential role of efferents in linking otherwise independent streams of bilateral spontaneous activity during the prehearing period.

Title: Folding and lamination of the human neocortex depend on the sodium potassium pump alpha 3 (ATP1A3) subunit

Authors: ***R. S. SMITH**[1], C. A. WALSH[2];
[1]Genet. and Genomics, Boston Childrens Hosp. / Harvard Med. Sch., Boston, MA; [2]Genet. and Genomics, Boston Children's Hosp., Boston, MA

Abstract: ABSTRACT
Osmotic equilibrium and membrane potential in animal cells depend on concentration gradients of sodium (Na^+) and potassium (K^+) ions across the plasma membrane, a function that is catalyzed by the Na,K-ATPase alpha subunit. In vertebrates, four paralogous genes, *ATP1A1-4*, encode distinct alpha subunit isoforms ($a_{1\text{-}}a_4$), three of which (a_1, a_2, a_3) are expressed in the brain, and two (a_1, a_3) predominantly in neurons. The a_3 isoform, encoded by *ATP1A3*, is critical to neuronal physiology, and a growing spectrum of neurological diseases are associated with *ATP1A3* pathogenic variants, with ages of onset ranging from early childhood to adulthood. Here, we describe *ATP1A3* variants encoding dysfunctional a_3 subunits in children affected by polymicrogyria, a developmental malformation of the cerebral cortex characterized by abnormal folding and laminar organization. To gain cell-biological insights into the spatiotemporal dynamics of prenatal *ATP1A3* expression, we established a transcriptional atlas of *ATP1A3* expression during cortical development using mRNA *in situ* hybridization and transcriptomic profiling of ~125,000 individual cells with single-cell RNA sequencing (Drop-Seq) from various areas of the midgestational human neocortex. We find that fetal expression of *ATP1A3* is restricted to a subset of excitatory neurons carrying transcriptional signatures of neuronal activity and maturation characteristic of the developing subplate. Furthermore, by performing Drop-Seq on ~52,000 nuclei from four different areas of an infant human neocortex, we show that *ATP1A3* expression persists throughout early postnatal development, not only within excitatory neurons across all cortical layers, but also and more predominantly in inhibitory neurons, with specific enrichment in fast-spiking basket cells. In addition, we show that *ATP1A3* expression, both in fetal and postnatal neurons, tends to be higher in frontal cortical areas than in occipital areas, in a pattern consistent with the rostro-caudal maturation gradient of the human neocortex. Finally, we discover distinct co-expression patterns linking catalytic α subunit

isoforms (*ATP1A1,2,3*) and auxiliary isoforms (*ATP1B1,2,3*), suggesting the ATPase pump may form non-redundant, cell-type specific α-β combinations. Together, the importance of the developmental phenotypes and dynamic expression patterns of *ATP1A3* point to a key role for *a3* in the development and function of human cortex.

Title: Early postnatal TrkB activity protects receptive field refinement in superior colliculus of dark reared adults by maintaining GABA levels rather than by maintaining $GABA_A$ receptor, NMDA receptor, gephyrin, PSD-95 or chloride pump protein levels.

Authors: *P. S. JUVALE[1], D. B. MUDD[2], N. S. RAMESH[2], S. L. PALLAS[1];
[1]Dept. of Biol., Univ. of Massachusetts Amherst, Amherst, MA; [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Sensory experience during a critical period is typically thought to be crucial for development of neural circuits. However, our previous work on critical period plasticity in the visual pathway showed that Syrian hamsters do not require visual experience and that spontaneous activity is sufficient for visual receptive fields (RFs) in superior colliculus (SC) to refine. Instead, early (P33-P40) visual experience is necessary to stabilize RF size in adulthood via a BDNF-TrkB dependent mechanism. Without this early TrkB activation, RFs of dark-reared (DR) hamsters begin to enlarge around P60, due at least in part to a reduction in lateral inhibition from local GABAergic interneurons. Our pharmacological assays also suggested reduced $GABA_A$ receptor function in visually deprived animals. Visual perception assays revealed that RF re-enlargement significantly reduces the visual processing abilities of DR hamsters, but treatment with a TrkB agonist during the critical period rescued normal visual ability. In this study, we sought to identify the possible postsynaptic changes that could underlie RF re-enlargement in SC of DR adults and explain how reduced TrkB activation affects visual function. Using western blotting, we tested whether light exposure during the early critical period stabilizes adult RF size by affecting the composition or anchoring of $GABA_A$ receptors ($GABA_AR$). We predicted that dark rearing would interfere with the maturation of $GABA_AR$ subunit composition, resulting in a higher α2/α1 (immature/mature) subunit ratio. We also considered that the α5/α1 (extrasynaptic/synaptic) $GABA_A$ receptor subunit ratio in DR hamsters might be higher than normal, resulting in reduced synaptic inhibition. We then studied gephyrin and PSD-95 because reduced synaptic accumulation of these scaffold proteins could reduce the

stability of synaptic $GABA_A$ and glutamate receptors (NMDAR and AMPARs). Alternatively, dark rearing could reintroduce a juvenile chloride pump (lower NKCC1/KCC2 ratio), reducing the overall inhibitory effect of GABA. Lastly, we tested whether dark rearing results in an immature NMDAR composition (higher NR2B/2A ratio), slowing the decay kinetics of NMDARs in previously formed synapses in SC, thus expanding the correlation window. We found no significant differences in levels of these proteins in SC between DR and normal animals. Our results rule out several alternative explanations for the loss of $GABA_A$ receptor function identified by our earlier work, and support reduction in presynaptic GABA rather than postsynaptic alterations as the primary explanation for the loss of RF stability in DR animals.

Title: Developmental roles of Pcdh1a in neural circuit assembly

Authors: *S. LIGHT, J. JONTES;
The Ohio State Univ., Columbus, OH

Abstract: Vertebrate neural development is a dynamic process that is shaped by complex spatial and temporal interactions between cells. These interactions influence the trajectory of development to determine the final structure of the brain, which in turn underlies its functional capacity. Protocadherins (pcdhs) are homophilic cell adhesion molecules that are critical effectors during development. Additionally, pcdhs are both causative and risk genes for various neurodevelopmental disorders including autism spectrum disorder, schizophrenia, and epilepsy. In this project, we investigated the effect of the loss of Pcdh1a on neural development and brain organization at the local circuit level. To accomplish this, we performed whole brain *in vivo* calcium imaging of spontaneous neuronal activity in wild type and *pcdh1a* mutant zebrafish larvae over the course of the first developmental week. This time window represents a critical period of circuit assembly and structural maturation. We analyzed these data with graph theory to evaluate the network development using the principle that neurons that fire together are physically connected. This approach allowed us to quantitatively compare wild type and mutant networks over time. We observed that *pcdh1a* mutants display increases in several complex network measures like clustering, transitivity, and assortativity, and decreases in modularity. These specific alterations suggest that *pcdh1a* mutants have an altered developmental trajectory and pattern of connectivity than wild type controls, although they do not show any overt morphological defects. This could be the result of increased neurogenesis as well as dysregulation of synaptogenesis at the local circuit level. We are currently investigating the

cellular roles of Pcdh1a that may contribute to the altered network phenotypes we observed. Ultimately, we theorize that pcdhs influence brain architecture by locally regulating and coordinating developmental processes. Our long-term goals are to determine the molecular and cellular mechanisms of pcdhs in order to better understand how they guide brain development and how their loss of function leads to disease.

Title: Enhancing adult neuroplasticity by epigenetic regulation of PV cells

Authors: *M. LAVERTU JOLIN[1,2], B. CHATTOPADHYAYA[1], A. VLAD VARLAN[2], K. GAUVIN[2], D. ROBERTSON[1], H. AFFIA[1], G. ANDELFINGER[1,2], G. PINEYRO[1,2], G. DI CRISTO[1];
[1]Ctr. de recherche du CHU Sainte-Justine, Montreal, QC, Canada; [2]Univ. de Montréal, Montreal, QC, Canada

Abstract: A traumatic event can form an indelible fear memory trace and behavioral therapy for post-traumatic stress disorder (PTSD) is limited by the restricted adult brain plasticity level. Parvalbumin-expressing GABAergic interneurons (PV) are characterized by their highly complex axon, contacting hundreds of neurons. In adults, their somas are surrounded by a matrix-like structure, the perineuronal nets (PNN). Decreasing PV inhibition or digesting the PNN are sufficient to foster adult brain plasticity. However, the molecular mechanisms that regulate PNN are not well understood. To enhance adult brain plasticity and increase fear extinction retention, we studied PNN formation around PV somata. Activity-regulated and synaptic plasticity-associated genes are controlled by the chromatin acetylation level. We generated conditional *PV_Cre;Hdac2$^{lox/lox}$* mouse line (cKO) and found that adult mice show enhanced fear memory extinction retention, along with reduced PNN around PV cells in prefrontal cortex (PFC) and basolateral amygdala, but not in somatosensory cortex. Drop-Seq analysis, followed by RNAScope *in situ* hybridization, in the PFC yielded the *acan* gene, which encodes for the aggrecan protein, as a PNN component specifically expressed by PV cells. We confirmed the reduced aggrecan agglomeration around PV cells in the cKO PFC which was then rescued by Cre-dependent viral overexpression of *Hdac2*. Further, we show that a single injection of a novel Hdac2 inhibitor, before extinction training, is sufficient to increase fear extinction retention in WT adult mice, and concomitantly reduce *acan* expression and destabilize PNN in PFC. Altogether, our work supports a model in which PV cells and PNN play a pivotal role in brain plasticity and suggests that modulation of either Hdac2, or the *acan* gene, along with therapy could improve PTSD treatment.

Title: Role of p75 neurotrophin receptor in cortical parvalbumin-positive GABAergic interneurons and cognitive flexibility

Authors: *P. CHEHRAZI[1,2], B. CHATTOPADHYAYA[1], M. CARREÑO-MUÑOZ[1], M. LAVERTU JOLIN[1], G. DI CRISTO[1,2];
[1]CHU Sainte Jusinte, Montreal, QC, Canada; [2]Neurosci., Univ. de Montreal, Montreal, QC, Canada

Abstract: Parvalbumin (PV)-positive GABAergic interneurons constitute the majority of inter-neurons in the cortex and play a key role in the function and synchronization of cortical networks. Alterations in PV-interneuron connectivity, especially in the medial prefrontal cortex (mPFC), have been found in different psychiatric disorders. We have previously shown that the expression of the p75 neurotrophin receptor (p75NTR) regulates the time course of PV cell synapse maturation in a cell-autonomous fashion. Here, we show that p75NTR removal in postnatal PV cells affects the connectivity and physiology of PV interneurons and mPFC function in PvCre dependent conditional knockout (cKO) mice. We first analyze the effect of p75NTR removal on the efferent and afferent connectivity of PV cells. We quantified putative perisomatic synapses formed by PV cells, identified by the juxtaposition of PV and gephyrin, a post synaptic scaffolding protein of GABAergic synapses. Both the density of PV+gephyrin+ puncta and the percentage of perisomatic PV puncta showing juxtaposed gephyrin were significantly increased in mPFC but not in visual cortex of cKO mice. Analysis of putative glutamatergic synapse density on PV cell somata is ongoing. An important indication of PV cell maturation is the appearance of specialized extracellular matrix structures called perineural nets (PNNs) around the soma and primary dendrites of mature cortical PV cells. p75 cKO mouse show a significant increase in the number of PV cells encircled by PNN, as revealed by WFA staining, in mPFC but not visual cortex. These mice also show deficits in attentional set-shifting task, a measure of attention and cognitive flexibility in mPFC, and in extinction of fear memories, both of which rely on mPFC function. Moreover, extracellular recordings in the cKOs show that p75 removal induces an increase in ɣ activity, an oscillation dependent on PV cells, in the mPFC of anesthetized mice. Taken together, our data suggests that p75NTR expression in postnatal PV cells play a role in their connectivity specifically in mPFC function.

Abstract: The mature brain connectome emerges during development via the extension and pruning of connections. Glial cells have been identified as key players in the phagocytic elimination of neuronal synapses. However, our understanding of pruning has been hampered by a lack of knowledge about the neuronal *eat-me* signals and associated transduction systems involved. Here we identified Xk-related protein 8 (Xkr8), a phospholipid scramblase, as a key factor for the pruning of axons in the developing mammalian brain. We found that phosphatidylserine scrambling is upregulated during synaptic pruning and preferentially found exposed on synaptic structures to promote microglia-synapse interactions. Mice lacking Xkr8 showed excess excitatory synapses, increased corticospinal projections and global brain hyperconnectivity. These data identify phospholipid scrambling by Xkr8 as a central process in the labelling and discrimination of developing neuronal projections for pruning in the mammalian brain.

Title: Maturation of cFOS expression during development follows information flow through the hippocampal formation circuitry

Authors: *M. POMPEIANO, M. T. COLONNESE;
The George Washington Univ. Sch. of Med., Washington, DC

Abstract: The hippocampal formation codes for spatial memory and navigation. In mammals, sensory information from cortical areas reaches the layer 2/3 of entorhinal cortex (Ent L2/3) and then flows to the dentate gyrus granule cell layer (DGC), Ammon's horn pyramidal cell layer (CA3 and CA1) before returning to Ent L5 which distributes information to cortical areas. In development, these functions seem to start around eye opening, when environment exploration starts (Speed and Dobrunz 2009), but the specific order of maturation is unclear. Here we used cFOS immunofluorescence (a marker of activation) to assess whether the mature hippocampal cFOS expression pattern is reached simultaneously among regions, or whether maturation occurs gradually following the direction of activity through the circuitry or other principles (for example, following the "rhinal to dentate" neurogenetic gradient). We compared cFos expression in mouse pups at postnatal day (P) 4, 9, 13 and 17 with adults (n=4 for all ages). All animals were kept awake for 1-2 hours, then immediately anesthetized and perfused with fixative. The brains were frozen and cut at a cryostat in 40μm thick sections. Adult mice showed cFOS in Ent (all layers), DGC, CA1 and CA3. We observed initial cFOS expression in Ent L2 and DGC on P4, and Ent L3, CA3 and CA1 expression on P9. In DGC, the initial staining was present only at the border with the molecular layer, where cells mature earlier than in DGC proper (as measured by decreasing doublecortin expression; Allen Institute for Brain Science 2008). The staining became distributed throughout the DGC only after P17. An adult-like level of staining was present in DGC on P9, in CA3 at P13, and CA1 after P17. Initial cFOS was seen in Ent L5 on P9-P13 and it was not adult-like even at P17. Thus cFOS shows a "maturation" sequence in the hippocampal formation that roughly follows the activation sequence through the circuitry. This may indicate a general principle of sequential activity maturation.

Title: Voltage based spike-timing dependent myelin plasticity

Authors: *S. BERTEAU[1], A. YAZDANBAKHSH[2];
[2]Psychological & Brain Sci., [1]Boston Univ., Boston, MA

Abstract: There is an increasing body of evidence from both in vivo studies (Varela et al., 2001; Wang, 2010; Siegel, Donner, & Engel, 2010) and simulated networks (Izhikevich & Edelman, 2008; Noori et al. 2020) that the brain's processing requires synchronization of spike arrival times. One of the most promising mechanisms suggested to meet this requirement is compensating myelination, where adaptive levels of myelin insulation reduce longer conduction delays to synchronize with shorter ones (Salami et al., 2003; Vicente et al., 2008; Seidl, 2014). This compensation is produced through homeostatic regulation of myelin levels, converging onto a particular level of myelin for a given phase-locked pattern of stimulation (Domingues et al. 2016, Noori et al. 2020).
We introduce a plausible biological mechanism for the regulation of activity dependent myelin plasticity, and a computational model of this mechanism which ultimately produces stable, homeostatic dynamics analogous to voltage-based STDP models. Our model synchronizes coherently out-of-phase inputs via changes in conduction velocity, and makes predictions about the proteins, neurotransmitters, and ions involved in adaptive CNS myelin plasticity.

Title: Oxytocin normalizes altered social circuit connectivity in the Cntnap2 Knockout mouse

Authors: *K. Y. CHOE[1,2], R. BETHLEHEM[3], M. SAFRIN[2], H. DONG[2], E. SALMAN[2], Y. LI[2], V. GRINEVICH[4], O. PENAGARIKANO[5], P. GOLSHANI[2], L. DENARDO[2], N. HARRIS[2], D. GESCHWIND[2];

Abstract: Aberrant functional connectivity (FC) is frequently found in autism spectrum disorders (ASD), notably correlating with the degree of social impairment (Supekar et al., 2013). We previously reported that administration of oxytocin (OXT) improves social deficits in mice lacking an ASD risk gene, *Cntnap2* (Penagarikano et al., 2015). Given the ability of OXT to increase circuit signal-to-noise (Owen et al., 2013), we hypothesized that OXT might exert its prosocial effects via stimulating socially-relevant brain regions and rescuing potentially present FC alterations in *Cntnap2* KO mice. To test this, we used high field (7T) fMRI to measure brain-wide BOLD responses and changes to resting-state FC after administering OXT to wild-type (WT) and *Cntnap2* KO mice (n=15/group). In KO mice, we observed significantly lowered mean FC between regions with established roles in social behavior (e.g. PVN, nucleus accumbens (NAc), medial prefrontal cortex), and higher mean FC between these and other regions not typically involved in social functions (e.g. sensory cortices, thalamus; $p<0.001$ vs WT). Strikingly, OXT robustly increased the BOLD signal in various social regions, and reversed both FC phenotypes in these mice ($p<0.001$), including circuits involving the NAc. To validate these results, we assessed the brain-wide patterns of neuronal activity with lightsheet imaging of iDISCO+ cleared brains. In parallel with fMRI results, OXT strongly increased the number of c-Fos+ cells in several social brain regions in KO mice (e.g. NAc, BNST, insula), but not WT ($p<0.005$; n=5/group). Further investigation revealed a lower excitatory synaptic drive in the NAc of KO mice, latter of which was rescued by local agonist activation of OXT receptors (n=6-7 cells/group). As OXT axons directly project to the NAc, we next tested whether stimulating the terminal release of OXT onto the NAc *in vivo* is sufficient for rescuing the social impairment of adult KO mice. To do this, we selectively expressed the excitatory opsin ChETA in PVN OXT neurons (OXT-ChETA), and stimulated the NAc with blue light (457 nm at 30 Hz, 5 ms pulse width, ~10-15 mW) through bilaterally implanted optic fibers. Our results revealed that adult KO mice with OXT-ChETA spent a significantly longer time interacting with an unfamiliar juvenile WT mouse, compared to OXT-eYFP control KO mice ($p=0.03$; n=5/group), confirming that increasing endogenous OXT in the NAc is sufficient for reversing the social deficits of these mice. Collectively, these results suggest that the prosocial effects of OXT in *Cntnap2* KO mice may involve an enhancement of concerted activity across social brain areas, and identify the NAc as a key area in this process.

Title: Behavioural and neurochemical responses of oxytocin-receptor-mutant zebrafish to group and individual social stimulation: support for zebrafish autism model

Authors: *S. SHAMS, L. WESTBERG;
Pharmacol., Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Autism is a family of neurodevelopmental disorders characterized by social deficits and abnormalities in brain areas associated with social and emotional behaviour. Autism affects roughly 1% globally and no effective pharmacological treatments are currently available. Recently, intranasal oxytocin has shown promise as a potential treatment for social impairments seen in autism. Oxytocin is a neuropeptide that regulates a wide range of mammalian behaviours relevant to autism, such as bonding, social recognition, and anxiety. As the mechanisms underlying oxytocin's role in improving social function in autistic patients are not well-understood, animal models with capacity for sophisticated genetic manipulation are necessary. Zebrafish (*Danio rerio*) is a highly social vertebrate with phylogenetic conservation in oxytocin and key neurotransmitter systems and we exploit these features to develop an animal model of autism. Our aim was to investigate social interaction and neurochemistry in zebrafish mutants with genetically manipulated oxytocin system. Using adult male and female CRISPR-Cas9-mutants lacking either of the two zebrafish oxytocin receptor genes, *oxtr* and *oxtrl*, we measured socialization between four fish (same-genotype, $n \geq 20$ for each group) in a large open-field (40x body length). We measured shoaling, group excursions, general locomotion, and specific motor patterns of mutant and wild-type fish in the large pool. Following stimulation with automated visual-only social stimulus individually, we also measured the levels of neurotransmitters and amino acids (dopamine, serotonin, norepinephrine, glutamate, GABA, and glycine) in multiple brain regions of these mutants using high precision liquid chromatography and compared them with wild-type control fish. Our data show that zebrafish lacking oxytocin receptors display social deficits and changes in anxiety-related behaviour, in a receptor-specific and context-dependent manner. We also found significant differences in neurotransmitter levels in the measured brain regions (olfactory bulbs and telencephalon, mesencephalon, diencephalon, cerebellum & hindbrain), indicating a role of oxytocin in regulation of neurotransmitters associated with social and emotional behaviour. These results suggest that the two oxytocin receptor play important but distinct roles in zebrafish social behaviour. These findings advance our understanding of neural mechanisms underlying oxytocin-regulated social interaction in zebrafish and highlight the potential of future investigation of zebrafish oxytocin system towards generating better therapeutic treatments for autism.

Title: Altered connectivity of dopaminergic projections from the ventral tegmentum to prefrontal cortex in a mouse model of autism/macrocephaly syndrome

Authors: *A. LISH[1], A. ZUCCA[2], A. CLIPPERTON-ALLEN[2], J. SEJOURNE[2], H. SWICK[2], D. PAGE[2];
[1]Harvard Med. Sch., Boston, MA; [2]Scripps Res. Inst., Jupiter, FL

Abstract: Dysregulation of the dopamine system has been hypothesized as a factor contributing to behavioral and cognitive deficits in autism spectrum disorder (ASD) based on the role of dopamine in processing natural and conditional rewards and social behavior. Previous findings of social behavioral deficits in a mouse model of conditional deletion of the autism risk gene *Pten* in dopaminergic neurons further implicates the dopamine system in ASD-relevant behavioral phenotypes. *PTEN* is mutated in approximately 15% of individuals with autism spectrum disorder and macrocephaly and is a negative regulator of the PI3K-Akt-mTOR pathway. Signaling through mTOR is a critical effector of neuronal growth and connectivity; however, the role of dysregulated mTOR signaling in the development of dopaminergic circuitry underlying social behavior is unknown. We hypothesized dopaminergic neurons in the ventral tegmental area (VTA) and their projections to the mPFC (an area previously found to be hyperexcitable in *Pten* mutant mice) will be increased in germline $Pten^{+/-}$ mice, which are a model of macrocephaly/autism syndrome, due to dysregulated mTOR signaling. To test this hypothesis, we immunostained VTA and mPFC sections of wildtype and *Pten* mutant mice with anti-tyrosine hydroxylase and phospho-S6, a marker for mTOR activity. Measurements of soma size and axon fiber density were collected and analyzed blind to genotype. Our findings demonstrate that the soma of dopaminergic neurons residing in the VTA are enlarged in $Pten^{+/-}$ mice compared to WT controls. Dopaminergic neurons in the VTA also display greater mTOR activity compared to non-dopaminergic cells in $Pten^{+/-}$ mice. Analysis of VTA to mPFC axonal projections reveals that the distribution of dopaminergic axons in the mPFC is altered in $Pten^{+/-}$ mice, with deeper layers receiving greater axon innervation compared to upper layers. Increased axon fiber density in deeper layers may drive increased activity in the mPFC in response to social stimuli, leading to social behavioral deficits. To test this hypothesis, we attempted a rescue by reducing VTA to mPFC neuronal activity using chemogenetics (DREADDs). Upon reducing VTA to mPFC neuronal activity, social interaction increased in $Pten^{+/-}$ mice. Our findings suggest *Pten* mutations drive aberrant dopaminergic projections to the mPFC and decrease social interactions due to dysregulated mTOR signaling, pointing to a novel candidate pathophysiological mechanism in macrocephaly/autism syndrome for further investigation.

Title: Altered interval timing in the Nrxn+/-mouse model of Autism spectrum disorder

Authors: K. M. RODDICK[1], E. B. HABIB[1], F. BALCı[2], *R. E. BROWN[1];
[1]Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada; [2]Koç Univ., Istanbul, Turkey

Abstract: Autism spectrum disorder (ASD) is characterized by impaired social interaction and communication and increased repetitive and stereotypical behavior. Neuroimaging shows functional abnormalities in brain areas involved in temporal processing of ASD patients (Allman & Meck, 2012, Brain, 135:656-77), and individuals with ASD show deficits in interval timing (Allman & Falter, 2015, In: Time Distortions in Mind:37-56). Neurexin (Nrxn) genes have been identified in a wide variety of neuropsychiatric disorders, including ASD, and *Nrxn1+/-* mice possess a mutation that disrupts both alpha and beta isoforms of Nrxn1, a gene that is involved in the structure of synapses (Flaherty et al., 2019, Nat Genet, 51:1679-90). We investigated the interval timing abilities of the *Nrxn1*+/- mouse model of ASD in the peak interval procedure with a 15s target interval. Two-month-old male *Nrxn1*+/- and C57BL/6J littermate control mice were trained to obtain sucrose liquid rewards 15s after the onset of a discriminative stimulus (discrete fixed-interval training) and their timing responses were tested in probe trials that lasted much longer and reinforcement was omitted. We found that the *Nrxn1+/-* mice responded earlier than the control mice on the probe trials, resulting in a leftward shift in their average response curve. This shift in response is typically seen in animals with hippocampal lesions (Balcı et al., 2009, In: Animal models of human cognitive aging:161-201), and is similar to the shift in timing responses of the 5xFAD mouse model of Alzheimer's disease on the same task (Gür et al., 2019, J Neurosci Res. 97:817-27). No differences were found in measures of temporal differentiation, response rate, or response amplitude. While a prior study of timing behaviour in individuals with ASD found a similar leftward response shift (Allman et al., 2011, Am J Intellect Dev Disabil, 116:165-78), another study found no such shift (Doenyas et al., 2019, Autism Res, 12:239-48). Leftward shifts were also found in a study of a different mouse model of ASD (Acosta et al., 2018, Eur J Neurosci, 47:19-630). In conclusion, these findings are suggestive of hippocampal dysfunction in the *Nrxn1+/-* mouse model of ASD, and add to the growing knowledge of timing behaviour in ASD.

Title: Examining the impact of neuroimmune dysregulation on social play behavior of male and female juvenile rats

Authors: *E. MCAULEY, J. SCHWARZ, A. TURANO;
Univ. of Delaware, Newark, DE

Abstract: Recent literature indicates that along with genetic risk factors, there also are perinatal environmental factors that contribute to the risk of developing Autism Spectrum Disorder (ASD). These environmental factors are known to activate the immune system, such that dysregulation of the immune system early in life may have negative consequences on neural function and the development of appropriate social behavior. Our experiment is designed with the intent of modeling the multitude of social behavior deficits seen in many neurodevelopmental disorders, including autism and schizophrenia. We hope to be able to eliminate some of the questions still present in these disorders. Microglia, which are the immune cells of the brain when activated, release inflammatory cytokines throughout which in effect “primes” these cells. The exaggerated cytokine release from the microglia, as well as a second “hit” later in life, alters neuronal function and leads to behavioral disorders. Our model introduces an immune challenge to rats on day 4 of life (P4) and then again on day 25 (P25). This result stems from a technique called a “two-hit model of neuroinflammation," the model that we currently use in our experiments. Play behaviors such as pouncing, pinning, chasing, and social exploration were observed and analyzed in juvenile male and female rats. Our previous work shows these play behaviors for a juvenile dyad consisting of one control animal and one experimental animal (treated with two-hit model). New data consisting of the same play behaviors and dyad were scored by looking at behaviors for the experimental animal alone. With this data we can observe the differences in the participation vs initiation in a play bout with our experimental animals compared to controls. Our goal is to further understand the impact of the two-hit model of neuroinflammation on the development and expression of social play behaviors in male and female juvenile rats. Additionally by looking at this data we can further investigate the differences present between the sexes. Funding: NIH R01MH16553 to JMS.

Title: Examining the impact of neuroimmune dysregulation on locomotive activity in male and female juvenile rats

Authors: *M. MUENCH[1], A. TURANO[2], J. M. SCHWARZ[3];
[1]Psych and Brain Sci., [3]Psychological and Brain Sci., [2]Univ. of Delaware, Newark, DE

Abstract: Evidence suggests that microglia, the immune cells of the brain, have an important role in the development of brain circuits. As a result, activation of the immune system early in life significantly increases the risk of various neurodevelopmental disorders, including AutismSpectrum Disorder. Perinatal exposure to infectious pathogens is suggested to be an environmental risk factor that has a role in activating the developing immune system, and the subsequent onset of neurodevelopmental diseases. Furthermore, the "two-hit hypothesis of immune activation" suggests that not just one, but multiple exposure to immune activation further increases the risk of neurodevelopmental disorders. That is immune activation during a"sensitive period" of neurodevelopment may result in an exaggerated immune response to subsequent immune challenges and the onset of behavioral disorders during the juvenile period.Microglia number and activation profiles differ between males and females during early development. Thus, males might be more susceptible to the consequences of immune activation as a result of the two-hit model, thereby leading to a greater prevalence of males diagnosed with neurodevelopmental disorders. In order to better understand the two-hit model of neuroinflammation and its effect on the expression of social behaviors in males and females, we tested the impact of neonatal bacterial infection (E.coli) and a subsequent juvenile immune challenge (lipopolysaccharide, LPS) on two well established tests of rodent social behavior - social interaction and social recognition. Using an open-source ImageJ plugin, MouBeAt, locomotive behavior; such as total distance traveled, total freezing time, average velocity and more were examined during these behavioral tests. Preliminary analysis of the data thus far indicates that the timing (neonatal or juvenile) and nature (E.coli or lipopolysaccharide) of the neuroimmune activation have a different effect on the expression of locomotive activity in male and female juvenile rats during a social behavior test.

Title: Impact of Clostridium celatum on behavior in a murine model of Autism Spectrum Disorder

Authors: *G. E. DEITZLER[1], A. PHILLIPS[1], P. SINGLA[1], A. MARTIN-VARNUM[1], M. M. DAVID[2];
[1]Microbiology, [2]Microbiology, Pharm., Oregon State Univ., Corvallis, OR

Abstract: Autism Spectrum Disorder (ASD) has become increasingly prevalent in recent years, withthe CDC estimating that it now affects 1 in 59 children. Recent studies have linkedneuropsychiatric phenotypes of ASD to both genetic and environmental factors,and amongthem have established a promising link between the gut microbiome and autisms. Mousestudies for example have highlighted the growing importance of the role of the gutmicrobiota in ASD, and neurotypical behaviors were rescued in a mouse model of autismusing the commensal bacteria *Bacteroides fragilis,* establishing a direct association betweenthe gut microbiome and ASD. In human subjects, studies comparing the microbiomes ofASD-affected and neurotypical children found that the former were depleted of*Bifidobacterium* spp. and *Prevotella* spp. and enriched in *Clostridium* spp, particularly*Clostridium celatum,* a non-pathogenic bacterial taxa. In order to establish whether *C.celatum* can effectively modulate the ASD phenotype, we investigate the mechanismsunderlying these effects by using behavioral assays with and without the bacteria in anautism-like mouse Maternal Immune Activation model. Here we assess anxiogenic behavior,general activity levels, restrictive and repetitive behavior, and social cognition, and socialnovelty through the elevated plus maze, open field habituation, marble burying, andthree-chamber sociability test. In addition, gastrointestinal content has been sampled fromthe duodenum, jejunum, ileum, and caecum of selected subjects and used to assess thestructure and diversity of microbial communities of the gut using 16S analysis. Our studyfinds potential colonization of *Clostridium* in the mice and evidence for modulation of theanxiogenic phenotype between mice treated with and without the bacteria.

Title: Ash1l regulates the structural development of human neurons by modulating bdnf/trkb signaling

Authors: *J. VACHARASIN[1], S. CHEON[1], A. CULVER[1], A. BAGNELL[1], F. RITCHIE[1], M. MCCORD[1], C. PAPENDORP[2], E. CHUKWURAH[1], A. SMITH[1], M. COWEN[1], P. GHATE[1], S. DAVIS[1], J. LIU[2], S. LIZARRAGA[1];
[1]Univ. of South Carolina, Columbia, SC; [2]Brown Univ., Providence, RI

Abstract: Autism spectrum disorder (ASD) is highly heritable and associated with alterations in neuronal connectivity. Genetic studies suggest that there is an overrepresentation of chromatin regulatory genes associated with ASD. ASH1 Like Histone Lysine Methyltransferase (ASH1L) is a major genetic risk factor for ASD. ASH1L methylates Histone H3 on Lysine 36 this histone modification is proposed to be primarily involved in transcriptional activation. However, how mutations in ASH1L lead to deficits in neuronal connectivity associated with ASD pathogenesis is largely understudied. Using stem cell-derived human neurons, we found that ASH1L regulates neuronal morphogenesis by counteracting the Polycomb Repressive complex 2 group (PRC2) catalytic activity. Analysis of changes in chromatin landscape and gene expression by ATAC seq suggest that ASH1L regulates pathways associated with neurite projection development, neuronal morphogenesis, and synaptic function. In particular, we find a strong correlation of our neuronal morphogenesis phenotypes with decreased expression of the neurodevelopmentally important neurotrophin receptor TrkB. Therefore, we present here a novel mechanism regulating neuronal morphogenesis that implicates an epigenetic modifier-ASH1L as a key regulator of the BDNF-TrkB signaling pathway in humans and that might underlie ASD pathogenesis.

Title: Neuroinflammation and platelet-endothelial injury with disruption of the blood brain barrier in a genetic model of autism with GABAergic neuron-specific deletion of Semaphorin 3F

Authors: R. JAGADAPILLAI[1], Z. LI[2], *E. GOZAL[3], G. N. BARNES[4];
[1]Pediatrics (PRI), Univ. of Louisville, Louisville, KY; [2]Neurol., Vanderbilt Univ. Med. Ctr., Nashville, TN; [3]Dept of Pediatrics PRI / Univ. of Louisville, Louisville, KY; [4]Dept Neurol, Univ. of Louisville Sch. of Med., Louisville, KY

Abstract: Background: Semaphorin impacts neurogenesis and vasculogenesis and regulates cell and neurite motility of neurons and endothelial cells. Autism spectrum disorder (ASD) is

associated with neuroinflammation but vascular and blood brain barrier (BBB) involvement is unclear. We previously reported neuroinflammation, oxidative stress, epileptogenesis and ASD behavior in GABAergic interneuron-specific DLX5/6Cre+ Sema 3F KO mice. We aimed to determine whether neuroinflammation and oxidative stress involve platelet-endothelial injury and BBB dysfunction in this genetic model of ASD.
Methods: We examined the expression and distribution of platelets (CD61), platelet activation (p-selectin and serotonin) markers, fibrinogen and albumin leakage as an indicator of blood brain barrier disruption and endothelial injury, in DLX5/6Cre+FF Sema 3F KO mice. Furthermore, we examined superoxide levels (DHE staining) in the heterozygous DL5/6Cre+F/WT mouse and whether the excitatory neuron-specific EMX1-Cre+ FF mouse that shows no epileptogenesis, exhibits similar increases in oxidative markers. We also compared brain weight and electrophysiological (EEG) changes of both DLX5/6 Cre+FF and EMX1-Cre+FF Sema 3F KO mice.
Results: Sema 3F deletion resulted in 10% brain weight loss and decreased the alpha and beta frequency EEG power in the DLX5/6Cre+FF but not in EMX1-Cre+ FF mice. Increased superoxide was also detected in heterozygous DLX5/6 Cre + F/WT but not in EMX1-Cre + FF mice. Platelet deposition (CD61) and activation (p-selectin, serotonin, fibrinogen) occurred in multiple brain regions important in ASD. Finally, along with platelet activation and fibrinogen accumulation, albumin leakage and uptake suggest BBB deficits.
Conclusions: Electrophysiological changes may underlie increased epileptogenesis and ASD behavior in DLX5/6Cre+ mice. Additionally, platelet activation, with increased serotonin release that has previously been associated with the severity of ASD behavioral deficits, as well as protein leakage suggest that Sema 3F deletion in inhibitory interneurons causes platelet-endothelial injury and BBB breach, further enhancing neuroinflammation. These observations may provide some insights into new therapeutic strategies targeting platelet-endothelial dysfunction and neuroinflammatory pathways to improve symptoms and behavioral deficits associated with ASD.

Title: Novel Astn2 mutant mouse shows aberrant cerebellar synaptic structure and physiology and exhibits autism-like behaviors

Authors: *M. HANZEL[1], S. MALONEY[2], Z. HORN[1], H. BEHESTI[1], S. GONG[3], J. D. DOUGHERTY[2], C. HULL[4], M. E. HATTEN[1];

Abstract: The cerebellum has recently been recognized as an important contributor to cognition and neurodevelopmental disorders such as autism spectrum disorder (ASD). We examine the role of the predominantly cerebellar gene *ASTN2* in cerebellar circuit function and ASD-related behaviors. Copy number variations in *ASTN2* have been identified as a significant risk factor for ASD, suggesting that *ASTN2* mutations lead to altered cerebellar synaptic function. In addition, we recently reported a family with a paternally inherited intragenic *ASTN2* duplication that manifested a range of neurodevelopmental disorders, including ASD, learning difficulties, and speech and language delay (Behesti et al, 2018). Our previously published cellular and molecular studies on mouse cerebellum show that ASTN2 binds to and regulates the trafficking of multiple synaptic proteins, including Neuroligins, which have been genetically linked to ASDs, and modulates cerebellar Purkinje cell (PC) synaptic activity (Behesti et al, 2018). To provide a genetic model to study cerebellar circuit function and the role of the cerebellum in neurodevelopmental disorders, we generated a novel global *Astn2* knockout mouse line. Our electrophysiology experiments indicate that P30 mice lacking *Astn2* have a decrease in evoked excitation relative to inhibition in PCs. We found a reduced PC dendritic spine density using Golgi staining at P21, and a reduction of vGlut1 excitatory synapses between granule cells parallel fibers and PCs via immunohistochemistry at P21 and 6 months old. These results suggest a specific cerebellar circuit defect in the *Astn2* mutants. In addition, we observe motor deficits and defects in ASD-related behaviors in *Astn2* mutants. When compared to wild type littermates, *Astn2*$^{-/-}$ animals show a marked decrease in the number of calls in separation induced pup ultrasonic vocalizations (male and female P2-P14 pups), hyperactivity, anxiety, and repetitive behavior phenotypes in the open field test (male and female 8-12 week old animals), and reduced sociability and social novelty seeking in the three-chamber test (male and female 8-12 week old animals). As other findings do not indicate major defects in cerebellar development, we hypothesize that the behavioral defects we observed relate to defects in the cerebellar circuitry with underlying changes in synaptic receptor trafficking.

Title: Characterizing the role of the histone methyltransferase, Ash1I, in mouse brain development

Authors: *K. P. TOOLAN, M. L. BRINKMEIER, S. BIELAS, S. A. CAMPER;
Human Genet., Univ. of Michigan, Ann Arbor, MI

Abstract: Over 100 genes have been implicated in the genetic etiology of autism spectrum disorder (ASD). Many high confidence ASD genes are involved in chromatin remodeling, histone modifications and DNA methylation. Among these is *ASH1L* (Absent, Small, Homeotic-Like), which catalyzes histone H3K36 methylation and has a role in activating transcription by counteracting polycomb repression. ASD patients have been identified with heterozygous *ASH1L* variants that are predicted to cause loss of function, and they include premature termination, frame shifts, and missense variants throughout the protein. While ASH1L is expressed in a number of regions of the developing and adult brain, its role has yet to be defined. We hypothesize that gene expression changes caused by *Ash1l* deficiency will alter cortical development and cause molecular abnormalities in cortical layers. To investigate the role of *Ash1l* in mammalian neural development and function, we established novel mouse models of *Ash1l* deficiency with cre-loxP technology starting with the $Ash1l^{tm2a(EUCOMM)Hmgu}$ mouse line. Using FlpO, we generated an allele with loxP sites flanking exon 4, $Ash1l^{fl}$. *Cre*-mediated excision of exon 4 results in a premature stop codon in exon 5, p.V1693Afs*2, a presumptive null allele. Using an *EIIA*-cre mouse line we generated *Ash1l* heterozygous null mice ($Ash1l^{+/-}$) and confirmed that $Ash1l^{-/-}$ mice are underrepresented at postnatal day 14 ($p = 0.021$). Preliminary results revealed defects in corpus callosum development at embryonic day 18.5-P0 in $Ash1l^{-/-}$ mice relative to littermate controls. We are in the process of histological analysis of brain development in $Ash1l^{-/-}$ embryos, including assessments of cell proliferation and death, and cortical layer organization. Additionally, we used $Emx1\text{-}Cre^{ERT2}$ to induce cortical-specific knockouts of *Ash1l* and we are in the process of determining gene expression changes via single cell RNA sequencing on $Emx1\text{-}Cre^{ERT2}; Ash1l^{fl/fl}$ mouse embryos. By better understanding the role of *Ash1l* in the mouse cortex, we aim to provide insight into the developmental and molecular pathogenesis of ASD in patients with *ASH1L* loss-of-function variants. Well-characterized *Ash1l* knockout mouse strains will be a valuable for future assessment of therapeutic treatments.

Abstract: The cerebellum has traditionally been associated with motor function, however, there is increasing evidence of its role in modulating non-motor behaviors, including social cognition, which has wide implications for disorders such as autism. Indeed, several cerebellar abnormalities have been found in postmortem brain tissue of individuals with autism, including reduced number and size of Purkinje cells (PCs). Animal models provide a major avenue to test the implication of a certain neuropathology in the disorder. In humans, mutations in the CNTNAP2 gene are associated with cerebellar abnormalities in individuals with autism. To investigate its potential role in the disorder, in this study, we characterized the neuroanatomical structure of PCs in a mouse model of autism, knockout for the Cntnap2 gene, which has been shown to display cerebellar functional abnormalities.We performed biocytin injection upon patch clamp recordings of PCs in the Crus I region of the cerebellum (an area shown to be involved in social behavior) in male mice. We then reconstructed the dendritic tree of PCs and performed Sholl analysis with ImageJ to study neuronal arborizations. Furthermore, the relative spine density was also estimated semi-automatically using ImageJ.We found a reduction in PC length and number of ramifications in knockout mice, indicating a less complexity of neuronal arborization. This result could be related to an underdevelopment of this region and it could trigger alterations in the functionality of those cells. Conversely, the density of dendritic spines appears to be increased in knockout mice, perhaps to counteract that underdevelopment.Further studies are needed to identify potential functional abnormalities associated with the structural alterations observed, which will give new insights into the pathophysiology of autism.

Title: Dysregulation of autism associated genes foxg1, shank3, and homer1 following postnatal exposure to bisphenol a

Authors: *A. S. BRINKS[1], C. M. DRZEWIECKI[1], J. M. JURASKA[2];
[1]Neurosci., Univ. of Ilinois At Urbana-Champaign, Champaign, IL; [2]Psychology, Univ. of Illinois, Champaign, IL

Abstract: Autism Spectrum Disorder (ASD) is a heterozygous disorder marked by social impairments and varying levels of genetic dysregulation. Some commonly dysregulated genes including RORA and SHANK3 are modulated by actions at gonadal hormone receptors, making these genes vulnerable to the effects of endocrine disrupting chemicals. Bisphenol A is a known estrogenic compound though it is unclear what impact BPA could have on the expression of hormonally regulated genes due to BPA having distinct mechanisms at nuclear estrogen receptors. Increased postnatal levels of BPA have been associated with an increased risk of developing ASD, though it is unclear what role BPA may have in the pathology of the disorder. Decreased SHANK3 expression has been seen in children with ASD and has been linked with social deficits in mice. FOXG1 is implicated in inhibitory neuron differentiation, with increase expression of FOXG1 resulting in increased inhibitory neurons. The present study aims to assess whether postnatal exposure to BPA results in dysregulation of these hormonally regulated genes. Male and female Long Evans hooded rats were dosed from postnatal day 6 to 8 via oral gavage with either 0, 40, or 400 mg/kg BPA suspended in corn oil. A rt-qPCR was run to determine relative expression of commonly ASD associated genes RORA, FOXG1, HOMER1, and SHANK3. Males exposed to BPA had increased HOMER1 expression, which was most notable in the 400mg/kg group. SHANK3 expression was increased in males exposed to 40mg/kg BPA but decreased in males exposed to 400mg/kg BPA. FOXG1 expression was increased in males exposed to 400 mg/kg BPA. These findings suggest a dose and sex specific response to BPA, where males exposed to 400mg/kg BPA showed the highest level of dysregulation. Males exposed to 400 mg/kg BPA exhibited dysregulation of FOXG1 and SHANK3, in a similar pattern as seen in children with ASD.

Title: Functional analysis of ASD risk genes in zebrafish

Authors: *H. WEINSCHUTZ MENDES[1], T. CHEN[1], W. WU[3], J. ELIBOTT[1], B. VANDER WYK[2], A. WANG[3], E. HOFFMAN[1];
[1]Child Study Center, Program on Neurogenetics, [2]Dept. of Intrnl. Med., Yale Univ. Sch. of Med., New Haven, CT; [3]Dept. of Biostatistics, Yale Univ. Sch. of Publ. Hlth., New Haven, CT

Abstract: Autism spectrum disorders (ASDs) are a group of complex neurodevelopmental disorders that affect social behavior and communication, and are characterized by the presence of repetitive, restrictive behaviors. There are still no pharmacological interventions available that target the core deficits in ASD as much is unknown about the neurobiology of the disorder. Whole-exome sequencing has recently revealed “high confidence” risk genes associated with ASD (hcASD), enabling a series of more in depth studies, however our knowledge about the mechanisms by which hcASD gene disruption alters brain development, remains elusive. The zebrafish has become an optimal vertebrate model for genetic studies due to its fast development, transparency of its embryos, availability of efficient methods for generating mutant lines and tractability for high-throughput analyses. Using CRISPR/Cas9 technology, we have generated zebrafish mutant lines of ten hcASD genes. To investigate how gene disruption alters basic sensory processing and sleep-waking activity, we have established a novel behavioral high-throughput in vivo system. This system is used to assay visual-startle and rest-wake behavior across the different mutants and in parallel, for the screening of over 750 FDA-approved drugs to identify their effects on these behaviors. By comparing the effect of these drugs in wild-type fish to the mutant behavioral profiles, we aim to identify dysregulated pathways in mutants and potential suppressors of hcASD mutant behavioral phenotypes. Preliminary analyses have identified a range of behavioral phenotypes across hcASD mutants.. Using these profiles, we are beginning to identify pharmacological compounds that target these phenotypes and investigate the mechanisms by which certain phenotypes could be reverted with these anti-correlating drugs. The identification of phenotypes in the behavioral profile of hcASD zebrafish mutants and the discovery of new pharmacological suppressors of these phenotypes has the potential for identifying drug candidates for further investigation in ASDs. RNA-seq analysis of zebrafish brains during the same developmental stages of behavior profiling, are also being carried for all mutant lines. The exploration of disrupted pathways, gene expression and upstream regulators related to these hcASD genes, may elucidate other common molecular players of this complex neuro disorder.

Abstract: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder that affects approximately 1 in 54 children in the U.S. Whole-exome sequencing has led to the identification of at least 100 high confidence risk genes that are strongly associated with ASD. However, the mechanisms by which the disruption of risk genes alters basic neural signaling during vertebrate brain development is not well understood. To investigate this, we generated zebrafish mutants in 10 high confidence ASD risk genes in zebrafish using CRISPR/Cas9 and developed a novel pipeline for the analysis of whole-brain activity in mutants.. Because we found that zebrafish ASD risk gene mutants lack major structural abnormalities, but display behavioral deficits, we hypothesized that loss of ASD risk gene function might lead to changes in baseline brain activity. To analyze this, zebrafish mutant and sibling- or cousin-matched wild-type larvae were fixed at 6 days post fertilization and stained for phospho-ERK (pERK) and total-ERK (tERK), followed by confocal imaging. ERK is a downstream reporter of calcium signaling, such that pERK stains only active neurons, while tERK antibodies stains all neurons. Using our pipeline, confocal images were registered to a standard zebrafish reference brain and mapped onto a zebrafish brain atlas. This allows us to quantify regional differences in brain size and activity. Our findings show that zebrafish ASD risk gene mutants display alterations in baseline brain activity affecting several brain regions, though these patterns were non-overlapping in different mutants. For example, zebrafish *scn1lab* mutants show significant deficits in baseline activity throughout the brain, most prominently in the telencephalon, while *dyrk1a* mutants show deficits in the mesencephalon. These findings suggest that ASD risk gene disruption might differentially affect baseline brain activity. In future studies, we will perform in vivo functional imaging in zebrafish ASD risk gene mutants to identify changes in brain activity patterns during behavioral tasks.

Title: Alterations in the Perineuronal Nets, Microglial Cells, and Open-Field Activity of Prenatally Restricted Mice

Authors: *K. E. BERTA[1], S. LUTCHMAN[1], J. C. BRUMBERG[2];
[1]Queens College, City Univ. of New York, Flushing, NY; [2]Dept Psychology, Queens Col., Flushing, NY

Abstract: Inadequate food consumption during pregnancy can negatively impact fetal brain development, which is mediated in part by perineuronal nets and microglial cells. Perineuronal nets are a neuronal specific form of the extracellular matrix which envelop the cell bodies and proximal processes of predominantly GABAergic interneurons. As specialized macrophages, microglia clear dead neurons and other cellular debris to maintain CNS health. To study how low food consumption impacts offspring, adult female CD-1 mice were placed on a calorically restricted diet before and during pregnancy. Pups produced from this group were compared to pups born from ad libitum-fed mothers. Perineuronal nets and microglia in pups were visualized using histochemistry to better understand how maternal caloric restriction impacts offspring brain development. An open-field paradigm was also conducted in which mice were allowed to freely explore an arena while locomotor activity was measured. Mice that were calorically restricted in utero had significantly fewer perineuronal nets compared to non-restricted mice. There was also a sex difference with female offspring being more affected by maternal caloric restriction than male offspring. The microglia of prenatally restricted mice were more rammified compared to non-restricted mice. Female prenatally restricted pups also expressed less willingness to explore in the behavioral paradigm compared to the control pups. These results suggest that food shortage may have a degenerative effect on the brain plasticity and anxiety levels of prenatal offspring. From studying the impact of food restriction in mice, this data can be used to better understand the effects of inadequate caloric intake on children born to mothers during times of food shortage.

Title: Sex-specific effects of development on social recognition in rats.

Authors: *K. E. YOEST[1], M. G. HENRY[1], H. A. VELISEK[1], R. PEGUERO[2], A. H. VEENEMA[1];
[1]Psychology, Michigan State Univ., East Lansing, MI; [2]Biopsychology, Wagner Col., Staten Island, NY

Abstract: The ability to recognize previously encountered conspecifics is crucial for normal social interaction. This social recognition ability is well characterized in adults of both sexes but remains largely unexplored in juveniles. We first determined whether juvenile male and female

rats show similar temporal patterns of social recognition to adults, by testing their ability to recognize a previously encountered same-sex stimulus rat 30, 60, or 90 min following initial investigation. Similar to adults, juvenile males showed social recognition 30 and 60 min, but not 120 min, following the initial encounter. Juvenile females, however, did not show social recognition at any time point tested. We then determined at what age during development social recognition ability is established in female rats, by testing females as juveniles, adolescents, young adults, and adults. We found that only young adult and adult females showed social recognition. This developmental difference in social recognition ability was driven by a decrease in the amount of time females investigated the previously encountered (familiar) stimulus. Based on these findings, we hypothesized that social recognition is impaired in juvenile and adolescent females due to a lack of circulating estradiol. To test this, we administered estradiol benzoate (EB) 48 hours prior to testing for social recognition in juvenile female rats. EB treatment induced a preference to investigate the familiar over a novel social stimulus, the opposite behavioral pattern observed in typical rodent social recognition. Also, EB treatment increased investigation of the social stimulus during the initial investigation period. Together, this suggests that additional factors contribute to the lack of social recognition ability in juvenile females. This may include sex and age differences in activation of the bed nucleus of the stria terminalis, a brain area implicated in adult social recognition which shows social stimulus-induced activation in juvenile females, but not males. These findings provide the first evidence of a development-specific sex difference in social recognition ability. Ongoing work seeks to tease apart the underlying neurobiological mechanisms by investigating the phenotype of BNST cells activated following social investigation, as well as the role of ovarian hormones during development on social recognition ability. Title: The sex-specific effects of adolescent omega-3 supplementation and exposure to environmental enrichment on adulthood anxiety and avoidance behaviour in Wistar rats

Authors: *A. MORIN, M. POITRAS, J. RAYMOND, H. PLAMONDON;
Behavioural Neurosci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The adolescent period is known as a critical stage for brain development and for its vulnerability to various external influences. In fact, dietary supplementation of omega-3 (n-3)

and exposure to environmental enrichment (EE), defined as housing rodents in larger, more stimulating cages equipped with toys, running wheels, and more cagemates, have both separately shown beneficial effects on synaptic plasticity, glucocorticoid receptor (GR) expression, and anxiety when exposed during the developmental period. However, as of now, no study has assessed the long-term behavioural and molecular effects of their combined time-limited exposure. This study aimed at investigating putative synergistic and sex-specific actions of n-3 and EE during adolescence on anxiety-like behaviour and fear avoidance in adulthood. Wistar rats (n=32 males; n=32 females) aged 23 days old arrived at facility and were assigned to one of four conditions based on dietary supplementation [fish oil (FO; n-3 (20-31%); eicosapentaenoic acid (10-15%); docosahexaenoic acid (8-15%)) or control soybean oil (CSO)] and housing [EE or regular cages (RC)] (n=8/group). Supplementation regimen (0.3 ml/100 g body weight) took place from postnatal day (PND) 28 to 47 and EE was provided between PND 28-58, after which all rats returned in RC. In adulthood (PND 90), a modified version of the forced swim test was used to trigger stress response. The following days, anxiety-like behaviours were assessed using the Open Field Test (OFT) and Elevated-Plus Maze (EPM - PND 92) and measures of aversive conditioning memory were obtained with the Y-Maze Passive Avoidance Task (YMPAT) on PND 94. Brain tissue was collected on PND 97 and immunohistochemistry was used to quantify GR expression in the CA1 and CA3 hippocampus sublayers. In the OFT, exposure to EE during adolescence reduced adult anxiety-like behaviours in males having received CSO, in part due to elevated global activity. Overall, females displayed more anxiety-like behaviours than males. No significant differences were observed in the YMPAT. In the CA3, females showed elevated GR expression compared to males, as did CSO- compared to FO-treated groups. These results did not support adolescent FO exposure to have beneficial effects on delayed anxiety-like behaviours. Concordant with other studies, females showed heightened emotional/neuronal response to anxiogenic environments. No treatments affected fear-associated learning. Taken together, these results provide a better representation of complex, sex-specific, and long-term effects of adolescent diet-environment interactions on adulthood behaviour and neuronal function.

Title: Maternal hyperglycemia and snack intake effects on offspring sucrose preference and behavior in adolescence

Authors: ***M. G. MARTINS**[1,2], J. A. C. HORTA, Jr.[1], B. WOODSIDE[3], A. C. I. KISS[1,2];

Brazil; [2]Dept. of Physiol., Inst. of Biosci. of the Univ. of São Paulo, São Paulo, Brazil; [3]Psychology, Ctr. for Studies in Behavioral Neurobio., Montreal, QC, Canada

Abstract: The effects of maternal diabetes and diet manipulation have been thoroughly studied separately. Previous studies have shown that snack intake during pregnancy and lactation further impair glucose tolerance on hyperglycemic female rats. Nonetheless, there is no evidence of how diet manipulations may aggravate behavioral and metabolic impairments in the offspring of hyperglycemic dams. Since maternal metabolism and nutritional status are key factors for a healthy offspring intrauterine and postnatal development, the aim of the present study was to investigate the impact of mild hyperglycemia associated with snack intake on offspring behavior in adolescence. Newborn female Wistar rats were divided into Control (citrate buffer, s.c.) or STZ (streptozotocin, 100 mg/kg, s.c.) groups. On postnatal (PND) 90, rats from both groups were mated and subdivided into four groups: females fed with standard chow (Control, n = 22; STZ, n = 23); and females fed with standard chow plus potato chips and 1.5% sucrose solution from pregnancy day 0 to lactation day 14 (Control-snack, n = 23; STZ-snack, n = 23). Dams gave birth naturally and on PND 1, litters were culled to 6 pups (3 males, 3 females). On PND 30, male and female offspring were evaluated in the open field arena and the elevated plus maze, followed by a glucose tolerance test and a sucrose preference test. All experimental procedures were approved by the local ethics committee (Protocol number 919). As expected, female offspring explored more the open field arena, but neither maternal metabolism nor snack intake impaired exploratory behavior. Maternal snack intake increased open arms entries in the elevated plus maze in both sexes, as well as the time female offspring spent in open arms. Regarding sucrose preference, the association between maternal metabolism and snack intake had opposing effects in male and female, leading to a decreased preference in the former and an increased one in the latter. Finally, offspring from snack-fed dams, regardless of maternal metabolism, showed lower glycemic levels during the oral glucose tolerance test. In conclusion, snack intake during pregnancy and lactation reduced anxiety-like behavior in adolescent offspring and changed sucrose preference in a sex-dependent way. Further studies will analyze if offspring behavior is affected by this impaired maternal metabolism in adulthood.

Title: Open-field behaviors in adolescent rats: Influence of sex and immune activation on variable reliabilities and intercorrelations

Authors: *I. BISHNOI[1], K.-P. OSSENKOPP[2], M. KAVALIERS[3];
[1]Western Univ., London, ON, Canada; [2]Univ. of Western Ontario, London, ON, Canada; [3]Univ. Western Ontario, London, ON, Canada

Abstract: Introduction. This study examined the reliabilities of open-field (OF) locomotor and anxiety-like behavioral measures in adolescent rats. The OF is an apparatus frequently used in rodent behavioral studies. Some previous examinations of reliabilities of OF variables exist, but we expanded the range of variables, examined sex differences and the effects of an immune stressor (lipopolysaccharide [LPS]) during early adolescence on OF variable reliabilities and cross-correlations in later adolescence. We predicted that score aggregation would increase reliabilities across test days, exposure to LPS would decrease reliabilities and/or cross-correlations and that the effects would be more pronounced in females than in males.
Methods. Long-Evans male (n = 32) and female (n = 32) rats were injected with LPS (200 μg/kg) or vehicle control on postnatal day [PND] 30 and 32. Locomotor and anxiety-like behaviors were measured in an OF on PND 38-40. The locomotor variables included total horizontal distance moved (TD), number of horizontal movements (NHM), distance per horizontal movement (D/HM), vertical time (VT), and number of vertical movements (NVM). The anxiety-like variables included central duration (CD), central nosepokes (CNP), number of peripheral to central OF transitions (NT), time per vertical movement (T/VM), and thigmotaxis ratio (THIG).
Results. High positive correlations were found for both locomotor and anxiety-like behavioral measures from PND 38 - 40 (range = .401 - .842). These correlations increased substantially when the data was aggregated across the 3 test days (range = .723 - .945). When cross-correlations among the aggregated OF variables were examined, the male rats had significantly reduced correlations for the LPS relative to the vehicle control group for locomotor variables correlated with NHM. Significant differences were also found for correlations between NHM and CNP and NT, and D/HM correlated with CD and NT, in the males. In the females there were significant differences between the vehicle control and the LPS group in THIG correlated with NVM and CNP as well as TD and NVM.
Discussion. In line with our predictions, aggregation increased the reliability of both locomotor and anxiety-like behavioral measures. Exposure to LPS decreased the cross-correlations for some locomotor measures. Contrary to our predictions, LPS related changes were more pronounced in males than in females. These results suggest that the OF locomotor and anxiety-like behavioral measures are reliable. However, when rats are previously exposed to an immunogen, such as LPS, the cross-correlations, especially of locomotor measures in male rats, are reduced.

Title: The role of puberty in Esr2 expression in the rat medial prefrontal cortex, motor cortex, and striatum: An RNAscope analysis

Authors: *E. P. SELLINGER[1], C. M. DRZEWIECKI[1], J. M. JURASKA[2];
[1]Neurosci. Program, Univ. of Illinois, Champaign, IL, Univ. of Illinois Urbana-Champaign, Champaign, IL; [2]Psychology, Univ. of Illinois, Champaign, IL

Abstract: Adolescence, often characterized as the period encompassing puberty, is a unique time of neurodevelopment within the medial prefrontal cortex (mPFC). Our laboratory has previously demonstrated extensive neuroanatomical changes occurring during adolescence in the mPFC. For example, a significant reduction in neuron and synapse number occurs during adolescence, and these changes tend to coincide with pubertal onset, suggesting a role for gonadal hormones in these processes. Recently, we have examined the number of perineuronal nets (PNNs), components of the extracellular matrix that preferentially surround parvalbumin (PV) expressing interneurons, during adolescence and have shown that they are significantly downregulated 24 hours after pubertal onset in females (Drzewiecki et al, 2020). Estrogen receptor beta (ERβ) is the prominent ER present in the adult mPFC, and it is highly colocalized with PV, providing a candidate mechanism for the neural reorganization occurring during adolescence. Several studies have shown that ERβ expression is altered in the presence of estrogens, though the direction of these effects is region specific (Osterlund et al., 1998; Patisaul et al., 1999). We therefore examined the expression of *Esr2*, the gene encoding ERβ, during puberty in female rats. Subjects were observed daily for pubertal onset, marked by vaginal opening. When a female reached puberty, the rat and an age- and sex-matched, pre-pubertal littermate were sacrificed 24 hours later. The brains of pre-pubertal and post-pubertal female pairs were processed using RNAScope to label *Esr2* in the mPFC. The motor cortex and striatum were also analyzed to better understand whether observed changes are unique to the mPFC. In the mPFC, there was a significant reduction in *Esr2* expression, as evidenced by decreased mean fluorescent intensity ($p = 0.04$) and fewer fluorescent puncta ($p = 0.006$) in post-pubertal subjects compared to their pre-pubertal siblings. Analyses of the motor cortex and striatum are in progress. These results indicate that ERβ is present in the mPFC at puberty and estrogen feeds back to decrease its expression. Estrogen acting at ERβ may be involved in many of the neuroanatomical changes at puberty.

Title: The impact of vicarious stressor exposure on fear expression, social behaviours and acoustic startle in juvenile male and female rats

Authors: *E. ALI[1,3], M. ANAM[2], M. GEBRE[4], J. JAMES[3], C. CAYER[3], A. ABIZAID[1], Z. MERALI[1,4];
[1]Neurosci., [2]Carleton Univ., Ottawa, ON, Canada; [3]The Royal's Inst. of Mental Hlth. Res., Ottawa, ON, Canada; [4]Psychology, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Vicarious stressors can be experienced by witnessing trauma occurring to others and rodent studies have shown that affective states are shared between a witness and a demonstrator (the subject directly experiencing the stress) such as fear expression, anxiety-like behaviours, and HPA-axis activity. In addition, there are opposing findings that suggest that prior stressor experience in witnesses is required for vicarious stress to occur in rats and mice. In addition, most studies utilize adult animals however less is known about the effects of vicarious stress during the juvenile period. The objective of this study was to explore if anxiogenic behaviours can be induced in juvenile rats that experience vicarious stress and if prior stressor exposure enhances the effects of vicarious stressor exposure. Juvenile male and female Sprague-Dawley rats were divided into four witness groups: Control (no experience and no witnessing of footshocks. n=8-10/sex), Context (experienced, no witnessing to footshocks, n=10/sex), Naive (no experience and witnessed footshocks, n=10/sex) and Experienced (experienced and witnessed footshocks, n=10/sex). On post-natal day (PD) 27, Experienced and Context groups were subjected to ten 1.0 mA footshocks over 12 minutes. On PD 28, both Naive and Experienced witnesses watched their cagemate endure the same footshock protocol the day prior from a perforated transparent barrier. Control and Context groups did not watch their cagemate experience any footshocks. Short-term (24hrs) and long-term (7 days) effects on fear expression were observed. Social interaction with a novel rat and acoustic startle response was recorded in early adolescence. Vicarious stress increased fear expression in juvenile male and female rats that had prior stressor exposure, with no significant sex differences however, the time spent freezing diminished significantly by the seventh day. In addition, sniffing and following behaviours were reduced in Experienced witnesses in females and only playfighting was significantly greater in males. The acoustic startle response at 90db, 105db, and 120db did not result in any group or sex differences. The significance of this study provides insight as to how vicarious stress alters fear expression and social interaction and that prior stressor experience is required in juvenile rats for this to occur.

Title: Adolescent fluoxetine exposure induces persistent gene expression changes in the hippocampus of adult male C57BL/6 mice

Authors: *A. THEMANN, F. J. FLORES-RAMIREZ, O. LIRA, S. D. IÑIGUEZ;
Dept. of Psychology, The Univ. of Texas at El Paso, El Paso, TX

Abstract: Fluoxetine (FLX), a selective serotonin reuptake inhibitor, is the first line of pharmacological intervention in pediatric patients suffering from affect-related illnesses, such as anxiety and depression. Although the use of this antidepressant treatment has been deemed efficacious in the juvenile population, the enduring neurobiological consequences of adolescent FLX exposure are not well understood. Thus, we explored for persistent molecular adaptations in the adult hippocampus, as a function of adolescent FLX pretreatment. To do this, we administered daily peritoneal injections of FLX (20 mg/kg/day) to male C57BL/6 mice during adolescence (postnatal day [PD] 35-49). After a 21-day washout period (PD70), whole hippocampal tissue was dissected, and subsequent qPCR analysis was ran to assess changes in the expression of genes associated with neuronal survival. Specifically, we evaluated major intracellular signal transduction pathways, including the Ras-mitogen-activated protein kinase (MAPK) and phosphatidylinositide-3-kinase (PI3K)/AKT pathways, as well as several transcription factors. Our results indicate that adolescent FLX treatment results in a long-term upregulation of mRNA levels across numerous genes from the ERK, and PI3K/AKT pathways, along with increases of the transcription factors CREB, ΔFosB, and zif268. Additionally, adolescent FLX treatment resulted in persistent increases of transcripts associated with cytoskeletal integrity (β-actin) and caspase activation (DIABLO), while decreasing genes associated with metabolism (fucose kinase) and overall neuronal activation (c-Fos). Collectively, these data indicate that adolescent FLX exposure mediates persistent alterations in hippocampal gene expression in adulthood, thus, questioning the safety of early-life exposure to this antidepressant medication.

Title: Oxycodone Conditioned Place Preference effects on Brain Derived Neurotropic Factor in the Prefrontal Cortex, Nucleus Accumbens and Cerebellum of Adult male rats.

Authors: *Z. D. SIMSEK[1], A. TORRES[2], K. S. CURTIS[3], D. B. VAZQUEZ SANROMAN[4]; [1]Dept. Pharmacol. & Physiol. - Anat. and Cell Biol., [2]Anat. and Cell Biol., Oklahoma State Univ. Col. For Hlth. Sci., Tulsa, OK; [3]Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK; [4]Anat. and Cell Biol., Oklahoma State Univ., Tulsa, OK

Abstract: Introduction: Oxycodone drug-seeking behavior involve alterations in brain-derived neurotrophic factor (BDNF) levels in the brain. Nonetheless, little information is available about whether oxycodone preferentially affects the precursor (pro-BDNF) or mature form (mature-BDNF) of BDNF. **Aim:** Here, we first assessed drug/reward-seeking behavior after oxycodone using conditioned place preference (CPP) and then evaluated mature-BDNF and pro-BDNF levels in the (PFC), nucleus accumbens (NAcc) and cerebellar vermis (Vm) of adult male rats. **Methods:** During the CPP, rats were placed and confined to the non-preferred side of the chamber and given injections of either oxycodone (3mg/kg. SC) or saline (0.9 ml/kg. S.C.) on alternating days for ten consecutive days; control groups always received saline injections. For the postconditioning test, rats have access to all CPP chambers for 15 minutes. The time spent in each comportment was recorded, and an oxycodone-CPP was derived by dividing the total duration in drug-paired compartment by the total duration in both the drug and vehicle compartments. Note that a score of 0.5 denoted no preference and a score above 0.5 denoted a preference for oxycodone. Forty-five minutes after the post conditioning test, rats were terminated, pro- and mature-BDNF levels assessed. **Results:** In drug-treated animals, oxycodone induced CPP and controls exhibit less than 0.5 score preference [$F(1, 21) = 5.31$; $p < 0.05$)]. Further analysis demonstrated that oxycodone decreased pro-BDNF levels in the NAcc [$F(1) = 14.46$, $p<0.001$] and in the PFC [$F(1,21) = 34.97$, $p<0.001$], but increases pro-BDNF levels in the Vm [$F(1,21) = 42.36$, $p<0.001$]. **Conclusion:** Our results demonstrate that pro-BDNF, in PFC , NAcc and Vm, is associated with oxycodone drug seeeking properties.

Title: Effects of prepubertal stress and AM251 on social behaviors and memory in pubescent male rats

Authors: *E. L. PERSON, J. CÔTÉ, A. MORIN, V. BOISVERT, P.-A. PARADIS, H. PLAMONDON;
Psychology, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Stress exposure during sensitive periods of development before adulthood has been associated with increased risks of developing neuropsychiatric disorders. Rodents stress models' studies have shown that juvenile and adolescent stress exposure has a negative impact on pro-social behaviours in adulthood and on cognitive functions. Previous research also showed effects of CB1 receptor antagonism on memory and stress, possibly mitigating pro-social behaviours and memory in rats exposed to stress immediately prior or during adolescence. This study aimed to investigate the effects of an heterotypic stress paradigm on prepubescent rats and the short-term consequences on pro-social behaviours and memory and learning. Male Wistar rats (aged postnatal day [PND] 30) were randomly assigned to a 10-day heterotypic stress condition or no stress condition (n = 16 per group). The heterotypic stress consisted of a 10-day paradigm alternating between two types of stressors from PND30 to PND39. On even numbered days, animals were stressed using a restrain procedure of 30 min. On odd numbered days, animals were stressed using the forced swim for 15 min. Following this period, rats were tested in the social interaction and preference test (SIT and SP) and in the Y-Maze passive avoidance test (YMPAT). Forty-five minutes prior to each test, half of the stress and no stress groups received an injection of AM251 (1mg/kg; i.p.) and the other half received only the vehicle (n = 8 per group). A rest period of 48 hours occurred between the SIT and SP, and the YMPAT. AM251-treated rats showed reduced direct exploration ratio in the SIT than vehicle-treated rats. There was also an effect of the stress exposure on the direct interaction ratio, animals that were stressed spending less time proportionally with the stranger rat than the non-stressed animals. Effects on memory of both stress and AM251 are mitigated.

Title: Adolescent fluoxetine exposure mediates a long-term anxiogenic phenotype and decreases ERK signaling in the hippocampus and prefrontal cortex of female C57Bl?6 mice

Authors: *M. RODRIGUEZ[1], F. J. FLORES-RAMIREZ[2], S. D. INIGUEZ[3];
[1]Psychology, The Univ. of Texas At El Paso, El Paso, TX; [2]Scripps Res. Inst., San Diego, CA; [3]Psychology, THE UNIVERSITY OF TEXAS AT EL PASO, El Paso, TX

Abstract: Adolescent fluoxetine exposure mediates a long-term anxiogenic phenotype and decreases ERK signaling in the hippocampus and prefrontal cortex of female C57BL/6 mice

Minerva Rodriguez, Francisco J. Flores-Ramirez, and Sergio D. Iñiguez
Department of Psychology, University of Texas at El Paso, El Paso, TX 79968
The objective of this study was to evaluate whether juvenile fluoxetine (FLX) exposure induces long-term changes in baseline responses to anxiety-inducing environments, and if so, whether its re-exposure in adulthood would ameliorate this anxiogenic-like phenotype. An additional goal was to assess the impact of adolescent FLX pre-treatment, and its re-exposure in adulthood, on serotonin transporters (5-HTT) and brain-derived-neurotrophic-factor (BDNF)-related signaling markers (TrkB-ERK1/2-CREB-proBDNF-mBDNF) within the hippocampus and prefrontal cortex. To do this, we exposed adolescent female C57BL/6 mice to FLX in their drinking water (250 mg/l) from postnatal day [PD]-35 to PD49. After a 21-day washout period (PD70), mice were either euthanized (for tissue collection) or assessed in adulthood on responsivity to the elevated plus-maze (EPM) or the light-dark box (LDB) tests – behavioral paradigms commonly used to assess anxiety-like responses in rodents. To evaluate whether FLX re-exposure would reverse the antidepressant-induced molecular and anxiety-related alterations observed in adulthood, we reinstated FLX treatment in separate groups of mice (PD70-84). Twenty-four hours later (PD85) mice were either euthanized (tissue collection) or evaluated on the EPM or LDB tests. Our results indicate that juvenile FLX history induced a persistent anxiogenic-like profile, along with decreases in BDNF-signaling markers, but not 5-HTTs or TrkB receptors, within both brain regions. Interestingly, FLX re-exposure in adulthood reversed the enduring FLX-induced anxiety-related responses across all behavioral tasks, while restoring ERK2-CREB-proBDNF markers to control levels and increasing mBDNF within the prefrontal cortex, but not the hippocampus. Collectively, the results indicate that adolescent FLX history mediates neurobehavioral adaptations that endure into adulthood, which are indicative of a generalized anxiogenic-like phenotype, and that this persistent effect is ameliorated by later-life FLX re-exposure, in a prefrontal cortex-specific manner.

Title: Lasting effects of juvenile ketamine exposure for reward-related stimuli in C57BL/6 mice

Authors: *I. GARCIA-CARACHURE[1], J. PRECIADO-PIÑA[1], A. R. ZAVALA[2], S. D. IÑIGUEZ[1];
[1]Psychology, The Univ. of Texas at El Paso, El Paso, TX; [2]Psychology, California State Univ. Long Beach, Long Beach, CA

Abstract: Ketamine, a non-competitive N-methyl-D-aspartate (NMDA) receptor antagonist, induces rapid antidepressant efficacy in adolescent treatment-resistant MDD patients. However, the long-term effects of ketamine exposure during early development are unknown. To address this gap in the literature, we examined whether adolescent exposure to ketamine and/or vicarious defeat social stress (VDS; where a rodent witnesses the physical defeat of a conspecific), results in long-lasting changes in sensitivity to the rewarding properties of cocaine and sucrose in adulthood using male C57BL/6 mice. Specifically, mice received ketamine (0 or 20 mg/kg) after each 10-minute VDS exposure for 10 consecutive days during adolescence (Postnatal Day [PD] 35-44). Once mice reached adulthood (PD70), we assessed their behavioral responsivity to sucrose (1%) on a 2-bottle choice test, or cocaine (0, 5, 10 mg/kg) using the conditioned place preference test. Our results show that adult mice pre-exposed to ketamine or VDS alone, displayed an enhanced preference for sucrose and environments paired with cocaine. However, no long-term differences in these behavioral measures were evident between the groups when adolescent mice underwent concomitant social stress (VDS) and ketamine treatment. Collectively, we demonstrate that in the absence of social stress history, adolescent ketamine exposure increases the rewarding valence of sucrose and cocaine in adulthood.

Title: Examining Litter Specific Variability in Mice and its Impact on Neurodevelopmental Studies.

Authors: *V. VALIQUETTE[1,4], E. GUMA[1,4], R. PATEL[2,4], E. PLITMAN[3,4], D. GALLINO[4], G. A. DEVENYI[4,3], M. CHAKRAVARTY[3,4,2,1];

Abstract: Our current understanding of litter variability in developmental studies using mouse models limits the translation and replicability of findings. Higher variance of measures across litters than within may be attributable to maternal care, intrauterine, and postnatal environment. Here, we seek to characterize variability across litters through development.
Behavioral assessments (marble burying, prepulse inhibition, and open field tests) were

performed at postnatal day (PND) 38 and 90. T1-weighted magnetic resonance images (MRI; 100 um3 isotropic voxels) were previously acquired on 42 C57bl/6 mice (9 litters: 20F, 22M; litter 6-7 one sex only) at PND 21, 38, 60, and 90 using a 7T Bruker small animal MRI scanner. Volumes of 72 brain structures were obtained using the MAGeT brain pipeline. Levene's test was used to evaluate within- and between- litter variance per timepoint. Subsequently, principal components analysis (PCA) was performed across all brain measures to find patterns explained by the litter-effect. Finally, a partial least squares (PLS) analysis was used to evaluate patterns of covariance between behavior and anatomy. K-means clustering was used to evaluate grouping of PCA and PLS results by litters.

Levene's test revealed significant variability, after multiple comparisons correction in the thalamus ($q < 0.02$) at PND38 and for specific prepulse inhibition results ($q < 0.04$) at PND38 and 90. The first latent variable derived from PLS (var. expl.: 38%, $p = 0.01$) at PND38 revealed relationships between specific covariant brain regions (Principal component (PC) 4, var. expl.: 6%) and exploratory behaviors (Figure 1). Clusters corresponding to the number of litters were found in PC4 and LV1 (n=7; silhouette score: 0.58-0.60).

Factors specific to a litter modulate mouse development. Our results show greater variability between- than within- litter, mainly in the adolescence period (PND38). Improved analysis decisions, such as including litter as a random effect in statistical models, should be considered to better account for this litter-effect.

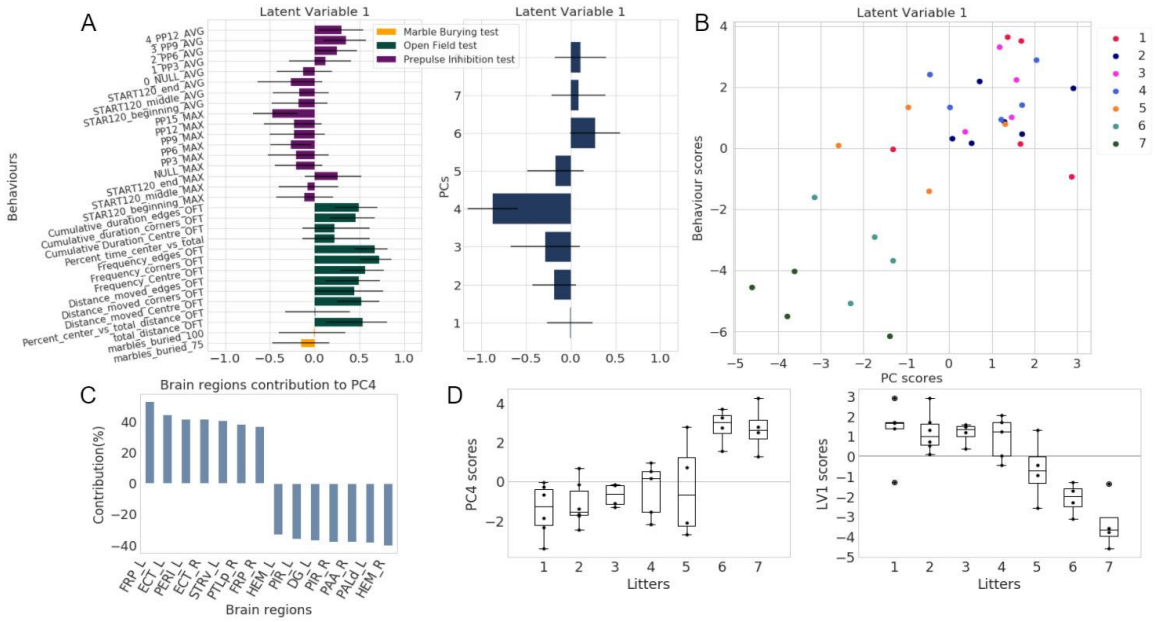

Figure 1: Results from PCA and PLS analysis at PND38 A) Behavior and PCs weights/correlation for each variable to LV1, B) Correlation of behaviour and PC scores for LV1, C) Percentage of contribution (%) of each regions to PC4, D) Distributions of PC4 and LV1 scores by litters. Title: Characterizing the Dopaminergic-Circadian Rhythm Network Across Time and Age

Authors: *S. BARKER, H. PARTINGTON, J. NUTTER, J. B. EELLS;
East Carolina Univ. BSOM, Greenville, NC

Abstract: The circadian rhythm is strongly implicated in many neuropsychiatric and neurodegenerative disorders, all of which are associated with altered dopamine (DA) neurotransmission in the substantia nigra and ventral tegmental area. Progress has been made in elucidating the circadian rhythm-dopaminergic network and its role in the onset of neuropsychiatric and neurodegenerative disorders. Previous research suggests that circadian rhythm transcription factors are responsible for directly regulating the DA phenotype; however, it is currently unknown what the relationship between the circadian rhythm and dopaminergic regulators looks like with respect to age and time of day. Using a transgenic mouse model with Cre recombinase expression under control of dopamine transporter (DAT^{Cre}) and yellow fluorescent protein (YFP) Cre reporter and immunohistochemistry techniques, we are able to differentiate between 'former' and 'current' DA neurons in the ventral midbrain. Current DA neurons are identified using tyrosine hydroxylase (TH), the rate limiting enzyme in DA synthesis; whereas former DA neurons are YFP+/TH- demonstrating that they expressed DAT at some point in their lifecycle but are not currently synthesizing DA. Previous research in our lab has revealed that the DA neuron phenotype is regulated by the circadian rhythm, as demonstrated by significant differences in the number of DA neurons throughout a 24-hour circadian cycle. In this study, mice transgenic for DAT^{Cre}/YFP were analyzed at postnatal day 0 (P0), P21, P35 and adulthood (>P70). Each time point included mice taken at subjective dawn (circadian time 0) and subjective dusk (CT12), excluding P0 mice. Results revealed that between P21 and P35, there was a significant loss of the dopamine neuron phenotype at CT12, as compared to CT0. There was no statistical difference between P35 and adults at CT0 or CT12. This suggests that between P21 and P35, dopamine neurons begin to transition to a 'former' phenotype throughout the circadian rhythm. Additionally, qRT-PCR data revealed abnormal circadian rhythm gene mRNA levels at P21. Elucidating the molecular characteristics of these dopamine neurons is crucial to understanding the biological mechanisms behind the dopaminergic-circadian rhythm network, which will have future implications in understanding neuropsychiatric and neurodegenerative disorders.

Title: Effects of early maternal separation on behavior in rats

Authors: S. ROBERTS, L. D. GRIFFITH, A. L. BUCKLER, C. PANIAGUA-UGARTE, Z. HANNABASS, H. A. DAVIS, *P. A. JACKSON;
Psychology, Radford Univ., Radford, VA

Abstract: Extended maternal separation in mammals in early development has been shown to have lasting negative effects on maturation and sociability, causing long term disruptive effects on brain structure and individual behavior (Haller et al., 2014; Lundberg et al., 2017). Maternal contact in the early postnatal period is vital for development. Our goal was to assess if contact with siblings or proximity to the dam (mother) during repeated separations decreased the lasting negative effects. Litters were randomly assigned to a separation period of either 180 minutes (experimental group) or 15 minutes (control group) during postnatal days 1-14 (PND). Within each litter, rat pups were randomly assigned to either isolation in a cage with a dividing wall between the pups and the dam, or in the same barrier-type cage without the dam present. Pups were then assigned to be either alone in isolation or with siblings. Preliminary results showed that pups separated from the dam for a significantly longer period had lower body weights and increased signs of discomfort. There were significant gender differences. Females were more strongly affected by the 180-minute isolation and males were more strongly affected by no dam present. Behavioral data collection is ongoing. One male and one female rat from each group (per litter) was tested during adolescence for anxiety-like behavior and sociability. The first behavioral task (on PND 50) was the elevated-plus-maze (EPM). On PND 55, after a 4-day break, we conducted open-field testing (OF). On PND 56 rats were placed in the same OF apparatus with walls inserted to create a three-chamber test of sociability. Experimental rats were placed in the center chamber and the chamber to either side contained a cage, one empty and the other with a same-sex, unfamiliar conspecific in it. Social discrimination was assessed by measuring interactions with the familiar rat and a new stranger rat 24-hours later. The implications of this study can be applied to scenarios where young children are developing in an environment where contact with the maternal figure is limited, such as premature infants in the Neonatal Intensive Care Unit (NICU). If negative long-term effects of maternal separation can be lessened by having siblings present, it could have major implications for children in foster care (Turney & Wildeman, 2016). Having the dam present but not accessible could be compared to parents that use the TV as a babysitter as well as ‘latchkey kids’. This study adds to existing literature and presents a novel test of sibling separation and dam proximity.

Title: Altered excitability of infralimbic glutamatergic pyramidal neurons as a potential mechanism behind adolescent stress induced resilience

Authors: ***N. NAWREEN**[1], E. COTELLA[1], K. OSHIMA[1], M. L. BACCEI[3], J. P. HERMAN[2]; [2]Dept Pharmacol. and Systems Physiol., [1]Univ. of Cincinnati, Cincinnati, OH; [3]Anesthesiol, Univ. of Cincinnati Dept. of Anesthesiol., Cincinnati, OH

Abstract: Adolescence is a critical period of brain development in humans as well as in other mammalian species. The match-mismatch hypothesis of brain development postulates that certain forms of early life adversity can promote an adaptive phenotype later in life, allowing individuals to cope with adverse situations in adulthood and contributing to resilience. Preliminary data from the lab indicate that subjecting adolescent rats to chronic variable stress (CVS) prevents traumatic single prolonged stress (SPS)-induced enhancement of fear responses in adulthood, suggesting that early life stress may promote stress resilience under certain circumstances. SPS causes infralimbic (IL) prefrontal cortex hypoactivity which is thought to underlie exaggerated fear responses and abnormal fear extinction. Therefore, we tested the hypothesis that adolescent stress leads to greater prefrontal drive in adulthood, helping to protect against SPS induced plasticity in the IL cortex. Patch clamp electrophysiology was used to test intrinsic excitability and firing frequency of IL pyramidal neurons. Our results show SPS-induced decreases in excitability were prevented by adolescent CVS. Our results suggest that adolescent CVS increases the excitability of IL pyramidal neurons, leading to greater prefrontal drive and top-down control when exposed to SPS in adulthood, resulting in resilience to SPS impairment in extinction of fear conditioning. Our findings hint at potential mechanism of altered excitability of IL glutamatergic pyramidal neurons towards developmental stress induced resilience.

Title: Effects of juvenile immune challenge with lipopolysaccharide (LPS) on learning in context fear-conditioning paradigms

Authors: *M. B. BIELICKI, J. M. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Early-life immune activation has been linked to learning deficits commonly associated with neurodevelopmental disorders such as Autism, ADHD, and Schizophrenia. Microglia, the immune cells of the brain, are thought to be important for the formation of circuits during development which underlie learning. The Context Pre-exposure Facilitation Effect (CPFE) is a fear-conditioning paradigm in which context learning, acquisition of a context-shock association, and expression of contextual fear are separated across three days. Whereas, in standard contextual fear conditioning (sCFC), context learning and acquisition of the context-shock association occur on the same day. We have found that immune activation with lipopolysaccharide (LPS), on P21 in rats, produces learning deficits in the CPFE paradigm from P24-P26. Thus, we sought to elucidate the involvement of hippocampus (HP) and medial prefrontal cortex (mPFC) in the observed LPS-induced learning deficits. Male and female Sprague-Dawley rats were treated with LPS (100 ug/ml; i.p.) on P21. Rats were then tested in sCFC from P24-P25 and in a variation of CPFE from P24-P26 that included a measure of freezing immediately after the shock on Day 2. In CPFE, there was a main effect of treatment such that LPS-treated rats showed deficits in freezing both post-shock on Day 2 (P25) and during testing on Day 3 (P26). This suggests that P21 LPS prevents rats from learning the context on Day 1 (implicating PFC or HP processing) and/or expressing a post-shock fear response on Day 2 (implicating HP processing). Moreover, in sCFC, LPS-treated rats showed no deficits in learning during testing on Day 2 (P25), as compared to controls. This suggests that P21 LPS either does not disrupt HP functioning or that neocortical systems are compensating for LPS-induced HP dysfunction in sCFC. Overall, these findings suggest that context fear-conditioning learning deficits, induced by LPS immune activation, are likely not driven exclusively by changes in mPFC functioning, but likely involve alterations in HP functioning.

Title: Enduring effects of cannabinoids in adolescence on inhibitory control

Authors: *G. A. HERNANDEZ[1], A. FALLAHI[2], D. NUEL[1], B. LIVINGSTON[2], N. ZLEBNIK[4], J. F. CHEER[5], C. FLORES[3];
[1]Douglas Res. Inst., Montreal, QC, Canada; [2]McGill Univ., Montreal, QC, Canada; [3]Dept of Psych, McGill Univ., Verdun, QC, Canada; [4]Univ. of Maryland, Baltimore, MD; [5]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Adolescence is a period of heightened vulnerability to psychopathology, including drug abuse. Yet, there is a gap in knowledge regarding the cellular and molecular processes underlying adolescent brain development and how drugs of abuse influence them. Dopamine axons continue to grow to the prefrontal cortex across adolescence, remaining very vulnerable to environmental changes. This gradual maturation of the dopamine input to the prefrontal cortex occurs in parallel to the development of cognitive control. In this study, we assessed the effects of cannabinoids exposure in early adolescence on the organization of dopamine connectivity in the adult prefrontal cortex and on behavioral inhibition. Male 57BL/6 mice were treated with four doses of the cannabinoid receptor - 1 (CB1-R) agonist WIN-55,212-2 (0, 0.5, 2, 4 mg/kg i.p.) every-other-day from postnatal day (PND) 21 to PND 31. In adulthood, mice were assessed for behavioral inhibition using the Go/No-Go task. Adult mice that received WIN during early adolescence showed dose-dependent improvement in performance in the Go/No-Go task when contrasted against controls. Mice that received WIN 2 and 4 mg/kg began to inhibit their behavior during earlier trials than vehicle-treated groups and had significantly fewer commission errors. There were no differences in the number of correct responses in Go trials (HITS). In a separate group of adult mice administered WIN (2mg/kg i.p.) or vehicle in early adolescence, we quantified dopamine connectivity in the pregenual prefrontal cortex using stereology. Mice that received WIN 2 mg/kg in adolescence showed a significant increase in the total number and density of dopamine varicosities in both prelimbic and infralimbic subregions compared to vehicle-treated mice. Our results contrast with previous research, carried out by our group using recreational-like doses of d-amphetamine and suggest that different drugs may affect behavioral inhibition and dopamine varicosities in opposite ways. The observed increase in dopamine varicosities might produce an increase of dopamine transmission in the medial prefrontal cortex. This increase might facilitate inhibitory control and behavioral flexibility.

Title: Prenatal ethanol exposure impairs visual processing in male and female rats, effects normalized by environmental enrichment

Authors: *R. WANG[1], C. D. MARTIN[1], A. L. LEI[1], K. A. HAUSKNECHT[1], M. TURK[1], V. MICOV[1,2], F. KWARTENG[1,2], K. ISHIWARI[1], S. OUBRAIM[1], J. B. RICHARDS[1], S. HAJ-DAHMANE[1], R.-Y. SHEN[1];
[1]Dept. of Pharmacol. and Toxicology, [2]Dept. of Biol. Sci., Univ. at Buffalo, Buffalo, NY

Abstract: Background. Individuals with fetal alcohol spectrum disorders (FASD) often show sensory processing deficits. Using an operant sensation seeking model, we tested if prenatal ethanol exposure (PE) could alter responding and habituation to contingent visual stimuli in rats. We also explored if postnatal environment enrichment could ameliorate the effects of PE. **Materials and Methods.** Pregnant Sprague Dawley rats were gavaged twice/day with 0 or 3 g/kg/treatment ethanol (15% w/v) during gestational days 8 – 20, mimicking second-trimester heavy PE in humans. The offspring were reared in the standard housing condition or underwent an environmental enrichment procedure. An operant light reinforcement experiment was conducted in adult rats, which comprised a pre-exposure phase, during which no light was presented, and a light-onset phase, during which contingent light-onset (turning on light) served as a sensory reinforcer. Both short- and long-access procedures were used. A dishabituation test was conducted to further characterize the habituation process. An additional non-operant open field test was also performed to investigate PE effects on sensory processing. **Results.** The results showed reinforcer effectiveness of the contingent light-onset in all groups. Prenatal ethanol exposure increased responding in both sexes reared in the standard housing condition. Such an effect was not observed in rats reared in the enriched condition, which led to an overall decrease in responding. Greater dishabituation and between-session recovery of responding were also observed in PE rats. Furthermore, the long-access procedure reduced responding and facilitated between-session habituation in both control and PE rats. Lastly, in the open field test, augmented locomotor responding was observed in PE rats due to blunted responses to the increase in illumination level. **Conclusions.** Prenatal ethanol exposure leads to deficits in processing of visual stimuli, including increased responding and impaired habituation in rats reared in the standard housing condition. Such effects may underlie enhanced sensation seeking/impaired habituation in individuals with FASD. The PE-induced effects could be ameliorated by postnatal environmental enrichment as well as longer exposure to the testing environment. The observation might inform a suitable animal model to study possible intervention strategies for FASD.

Abstract: Maternal alcohol exposure during pregnancy can substantially impact the development of the fetus, causing a range of symptoms, known as Fetal Alcohol Spectrum Disorders (FASDs), with the pathophysiology and mechanisms largely unknown. Recently developed cerebral organoids from human induced pluripotent stem cells are more similar to fetal brains in the aspects of development and structure being a more relevant in vitro system to study FASDs. Using human cerebral organoids, we sought to quantify the downstream toxic effects of alcohol (ethanol) on neural pathology phenotypes and signaling pathways. The results revealed that alcohol induced apoptosis, as well as ultrastructural changes, especially affecting the mitochondria. The apoptotic effects of alcohol on the organoids depended on the alcohol concentration and varied between cell types. Specifically, neurons were more vulnerable to alcohol-induced apoptosis than astrocytes. Alcohol exposure also resulted in mitochondrial dysfunction and metabolic stress in the organoids as evidenced by decreased mitochondrial respiration and an increase of non-mitochondrial respiration. Furthermore, we found that alcohol treatment affected the expression of 199 genes out of 17,195 genes analyzed. Bioinformatic analyses showed the association of these dysregulated genes with 37 pathways related to clinically relevant pathologies. This study extends for the first time animal models of binge drinking-related FASDs to a human model, allowing in-depth analyses at the tissue, cellular, subcellular, and gene levels. Hereby, we provide novel insights into alcohol-induced pathologic phenotypes, cell type-specific vulnerability, and affected signaling pathways and molecular networks, that can contribute to a better understanding of the neurotoxic effects of binge drinking during pregnancy.

Abstract: Fetal alcohol spectrum disorders (FASD) is one of the leading causes of developmental abnormalities worldwide. Maternal consumption of alcohol during pregnancy leads to a diverse range of cognitive and neurobehavioral deficits. Here, we use a model of maternal voluntary alcohol consumption throughout gestation to investigate the effects of prenatal alcohol exposure on behavioral phenotypes in mice. Metabolic studies were performed to study the effects of prenatal alcohol exposure on body composition and energy expenditure. Baseline behaviors including feeding, drinking, movement and their circadian rhythm were examined by performing home cage monitoring in adult mice. We also evaluated a range of behaviors that examined motor function, motor skill learning, anxiety-related behavior and sensorimotor gating to study the long-lasting behavioral alterations. Our data show that prenatal alcohol exposure alters offspring growth and body weight and affects body composition. Results from a battery of behavioral tests show long-lasting behavioral impairments in male and female offspring. To understand whether prenatal alcohol exposure results in persistent alterations in the synaptic proteome, we performed label-free proteomic analysis of cortical synaptosomes. We found that prenatal alcohol exposure altered proteins associated with synaptic function. Our results show that prenatal alcohol exposure (PAE) results in long-lasting behavioral impairments and alterations in the synaptic proteome.

Abstract: Mutations in the X-linked gene DDX3X account for ~2% of intellectual disability in females, often in co-morbidity with behavioral problems, motor deficits, and brain malformations. DDX3X encodes an RNA helicase with emerging functions in corticogenesis and synaptogenesis. Here, we present the first characterization of a Ddx3x haploinsufficient mouse (Ddx3x+/-) with construct validity for DDX3X loss-of-function mutations. Ddx3x+/- mice show physical, sensory, and motor delays that evolve into behavioral anomalies in adulthood, including hyperactivity, anxiety-like behaviors, cognitive impairments, and motor deficits. Motor function further declines with age. These behavioral changes are preceded by reduction in brain volume postnatally, with some regions (e.g., cortex and amygdala) disproportionally affected. Cortical thinning is accompanied by defective cortical lamination, indicating that Ddx3x regulates the balance of glutamatergic neurons in the developing cortex. While supporting face validity for a novel pre-clinical mouse model, these data shed new light on the developmental mechanisms driving DDX3X syndrome.

Title: Lrp2 receptor integrates signaling and scaffolding function to facilitate neural tube formation

Authors: *I. KOWALCZYK[1], N. MECKLENBURG[1], J. GÖRNE[1], K. FEISTEL[2], A. HAMMES[1];
[1]The Max Delbrück Ctr. (MDC), Berlin, Germany; [2]Univ. of Hohenheim, Stuttgart, Germany

Abstract: Early brain development is a complex morphogenetic process integrating various molecular and cellular mechanisms. One of the key signaling molecules at the onset of neurulation is morphogen SHH, required for ventral midline induction. In LRP2-deficient mice, SHH signaling in the ventral forebrain is disturbed, leading to holoprosencephaly (HPE; Christ et al., 2012). In addition, *Lrp2* mutants show a phenotype independent of the SHH pathway, affecting the dorsolateral neural folds. Our recent work identified that the penetrance of HPE strongly depends on the genetic background of the inbred mouse strain, suggesting that strain dependent modifiers affect the SHH pathway. However, fully penetrant, disturbed dorsal neural tube morphology indicates a new, conserved role of LRP2.
We used mouse genetics to understand the variability of HPE penetrance, comparing the severely affected *Lrp2* mutant C57BL/6N mice and FVB/N mice with a full rescue of the ventral midline defects. Transcriptome analysis identified candidate genes that trigger the SHH machinery independent of LRP2 receptor, thus rendering FVB/N mice less susceptible to SHH pathway disturbances in the ventral midline. Functional assessment of genes revealed PTTG1 as a novel component of SHH signaling, a positive regulator triggering target genes, and importantly a new component of primary cilium.
Having clarified the strain-dependent penetrance of HPE in *Lrp2* mutants, we next tried to understand the mechanisms underlying the strain independent role of LRP2. Neural plate bending and closure is a dynamic process involving cytoskeletal remodeling and apical constriction. Analysis of LRP2-deficient neural fold morphology using electron and confocal microscopy revealed impaired neuroepithelial integrity affecting the entire neuroepithelial sheet. Altered dorsolateral hinge point formation and upfolding of the neural folds was caused by impaired apical constriction in mutants, placing LRP2 in context of cytoskeletal and apical membrane remodeling. Our results strongly suggest that intracellular adaptor proteins containing PDZ domains serve as a bridge linking the LRP2 to the intracellular scaffold. Endocytic activity of the receptor facilitates apical membrane remodeling during apical constriction and simultaneously contributes to the apicobasal distribution of VANGL2, indicating a close interface between cell shape control and maintenance of planar cell polarity.
We conclude that crosstalk between signaling pathways and cytoskeletal remodeling allows LRP2 to integrate different morphogenetic processes during neurulation, thereby ensuring proper neural tube formation.

Abstract: Perinatal hypoxia is caused by prolonged oxygen deprivation to newborn infants during birth. Although the specific cellular and network changes caused by mild perinatal hypoxia (MPH) are still not well understood, this is a crucial issue since recent studies suggest that children who experienced MPH show long lasting subtle cognitive and behavioral deficits. In particular, population-based case-control studies suggested that children who experience perinatal hypoxia have a higher probability to be diagnosed with autism spectrum disorders than the general population.
Serotonin (5-HT) is essential for cognitive and social functions. Few studies have shown that severe hypoxia-ischemia lead to reduced 5-HT neurons and innervation, however whether 5-HT dysregulations contribute to MPH-induced cognitive problems is unclear.
We have recently established a mouse model of MPH, which shows long-term deficits in social interaction, attention, cognitive flexibility and memory. To investigate whether MPH affects 5-HT system development, we characterized 5-HT expression levels and innervation in the auditory and prefrontal cortex of female and male MPH mice. Preliminary data suggest both 5-HT expression and innervation complexity are reduced in adult MPH mice especially in the prefrontal cortex. We are currently investigating whether pharmacological 5-HT modulation will rescue MPH-induced cognitive impairment in adult mice. Identifying MPH effects on serotonergic system development will lead to a better understanding of how social, attention, cognitive flexibility and memory dysfunctions associated with MPH occur and may pave a path towards the development of pharmacological strategies for treating children exposed to MPH.

Abstract: Epilepsy treatments for patients with mechanistic target of rapamycin (mTOR) disorders, such as tuberous sclerosis complex (TSC) or focal cortical dysplasia type II (FCDII), are urgently needed. In these patients, the presence of focal cortical malformations is associated with the occurrence of lifelong epilepsy, leading to severe neurological comorbidities. Here, we show that the expression of the actin cross-linking protein filamin A (FLNA) is increased in resected cortical tissue that is responsible for seizures in patients with FCDII and in mice modeling TSC and FCDII with mutations in phosphoinositide 3-kinase (PI3K)-ras homolog enriched in brain (Rheb) pathway genes. Normalizing FLNA expression in these mice through genetic knockdown limited cell misplacement and neuronal dysmorphogenesis, two hallmarks of focal cortical malformations. In addition, Flna knockdown reduced seizure frequency independently of mTOR signaling. Treating mice with a small molecule targeting FLNA, PTI-125, before the onset of seizures alleviated neuronal abnormalities and reduced seizure frequency compared to vehicle-treated mice. In addition, the treatment was also effective when injected after seizure onset in juvenile and adult mice. These data suggest that targeting FLNA with either short hairpin RNAs or the small molecule PTI-125 might be effective in reducing seizures in patients with TSC and FCDII bearing mutations in PI3K-Rheb pathway genes.

Abstract: Background: CDKL5 Deficiency Disorder (CDD) is a rare brain disorder characterized by severe early-onset seizures, intellectual disability, motor and social impairments. CDD is an X-linked disorder caused by heterogenous mutations in the *Cdkl5* gene. Microtubule (MT) dynamics are fundamental for brain development and are involved in the pathogenesis of CDD. Here, we examined brain and plasma α-tubulin post translational modifications (PTMs) associated with MT dynamics in *Cdkl5*-KO (exon 4) male mice compared to age-matched wild-type (WT) mice at postnatal day (P) 20, 60 and 180. **Method:** Infrared western blot measured α-tubulin PTMs including Acetylated-Tubulin (Acet-Tub; stable MT), Tyrosinated-Tubulin (Tyr-Tub; dynamic MTs), Detyrosinated-Tubulin (Glu-Tub; stable MTs) and Delta2-Tubulin (Δ2; neuron-specific) in the cortex, hippocampus and plasma of WT and *Cdkl5*-KO mice. Tyr-Tub and Glu-Tub were analysed as a ratio, while expression of Acet-Tub and Δ2-Tub was normalized to Total-Tubulin (Tot-Tub). **Results:** Age-related changes were evident in α-tubulin PTMs including a significant increase in Acet-Tub/Tot-Tub and Δ2/Tot-Tub ratios and a decrease in Tyr-Tub/Glu-Tub ratio in the hippocampus and cortex at P60 compared to P20 in WT and *Cdkl5*-KO mice. However, Acet-Tub/Tot-Tub and Δ2/Tot-Tub are over-expressed in *Cdkl5*-KO mice at both P20 and P60 in the hippocampus and cortex, respectively compared to WT. Similarly, Tyr-Tub/Glu-Tub ratio is further downregulated in *Cdkl5*-KO mice at P20 in the cortex and P60 in the hippocampus. Intriguingly, Acet-Tub/Tot-Tub is increased is in the plasma of *Cdkl5*-KO mice compared to WT at both P60 and P180, while Tyr-Tub/Glu-Tub was not changed. **Conclusion:** These data confirm earlier findings showing age-related changes in brain α-tubulin PTMs consistent with physiological neurodevelopment. However, *Cdkl5*-KO mice exhibit alterations in α-tubulin PTMs indicating dysregulated MT dynamics during neurodevelopment; which may serve as a novel therapeutic target for CDD. Moreover, plasma Acet-Tub may represent a potential biomarker of disease progression in CDD.

Title: Vitamin D fortified diet increases percent survival, decreases microglia, but does not correct bone abnormalities in the NS-Pten mouse

Authors: *P. D. WOMBLE[1], S. L. HODGES[2], S. O. NOLAN[3], M. BINDER[4], A. HOLLEY[5], R. HERRERA[1], S. SENGER[1], E. KWOK[1], D. NARVIAZ[1], A. FAUST[1], C. J. HERNANDEZ-

Abstract: Individuals who experience recurrent spontaneous seizures are at a high risk for bone fractures (independent of seizure-related falls), as well as an increased likelihood of a comorbid diagnosis of Autism spectrum disorder (ASD). There is also evidence that individuals with epilepsy have vitamin D deficiencies. Previously, this deficit was hypothesized to be related to anti-seizure medications, however, there is a lack of consensus between studies. The neural subset-specific (NS) *Pten* knockout (KO) mouse has been well characterized to show autistic-like deficits in addition to having a lower bone mineral density. *PTEN* is an important component of the mTOR (mammalian target of rapamycin) pathway, which is important for cell proliferation and survival. As a result of the mutation, the NS-*Pten* knockout (KO) mouse exhibits hyperactive mTOR signaling pathway and has been linked in epilepsy. This study investigated whether a vitamin D enriched diet could be a potential dietary intervention to a mouse model of epilepsy, specifically the deletion of *Pten.* This study focuses on the potential of a dietary therapy where treatment mice received a vitamin D diet for a total of 5 weeks. Neuronal tissue was collected to look at downstream markers of the mTOR pathway and inflammatory markers, in addition to the scan and analysis of the mouse femurs. Mice on the vitamin D enriched diet showed a decreased level of microglia marker IBA-1 and mTOR targets like S6 and AKT. We did not find an effect of vitamin D on the bone abnormalities previously found in this mouse model, however we found that many differences between WT and KO mice including a significant reduction in bone mineral density (BMD) and an increase in bone volume and trabecular cortical expansion. Additionally, we found that females KO mice had a more significant reduction in percent bone volume over trabecular volume (BV/TV) compared to female WT mice, and this finding was sex specific as we did not see this in the male mice. Most significantly, the vitamin D fortified diet increased percent survival in male and female KO animals. Overall, these findings suggest that a vitamin D enriched diet had a significant impact on the survivability and molecular pathology of NS-*Pten* KO mice, suggesting that dietary manipulations like vitamin D supplementation could be a potential therapeutic option in addition to current epilepsy treatment, as well as an alternative for those with treatment resistant epilepsy.

Title: Disrupted trigeminal ganglion development in a mouse model of Familial Dysautonomia

Authors: *C. LEONARD, L. TANEYHILL;
Animal Sci., Univ. of Maryland Col. Park, College Park, MD

Abstract: Neurons in the trigeminal ganglion (TG) relay somatosensory information from the face and oral cavity. TG neurons arise from both neural crest cell (NCC) and ectodermal placode cell precursors that ultimately produce neurons that are specific for one sensory modality. TG neuron identity, established during embryogenesis, is determined by particular molecular markers, including mutually exclusive expression of the neurotrophin receptors TrkA, TrkB, or TrkC, which are required for long-term neuronal function and survival. While little is known about mechanisms that establish and maintain distinct neuronal subpopulations in the TG, disease studies offer some insight. Familial Dysautonomia (FD) is a hereditary neuropathy caused by mutation in *Elongator complex protein 1* (*ELP1*), which leads to reduced ELP1 levels in sensory and autonomic neurons. FD patients have clinical deficits pointing to abnormal TG function, including impaired sensation of facial pain and temperature and smaller trigeminal nerves, but no obvious signs of degeneration, indicating a role for ELP1 in TG neuron development. However, the function of ELP1 in TG neurons and the mechanisms underlying facial sensory deficits in FD are still unclear. Our preliminary data reveal Elp1 depletion from Wnt1-positive NCCs in mouse leads to abnormal TG morphology and fewer trigeminal nerve branches as early as embryonic day (E)11. Moreover, TrkA-expressing neurons, which typically function in nociception, are vulnerable to loss of Elp1 in NCCs. By E13, we observe decreased TrkA expression and fewer TrkA-positive neurons in the TG. Interestingly, TUNEL staining to assess cell death indicates progenitor cells, rather than neurons themselves, may undergo aberrant apoptosis in Elp1 conditional knockout TG. These findings confirm a role for Elp1 in the development of TG neurons, and may partially explain the loss of facial sensation experienced in FD.

Abstract: Developmental epileptic encephalopathies are clinically and genetically heterogeneous disorders. Recent studies revealed mutations in the *FASN* gene in two unrelated children with early-onset epilepsy. We have now identified a cohort of 11 children carrying recessive or *de novo FASN* mutations and presenting a spectrum of neurodevelopmental disorders, ranging from global developmental delay and intellectual deficiency to severe developmental epileptic encephalopathy.
The *FASN* gene encodes Fatty acid synthase, a multifunctional protein responsible for *de novo* lipogenesis from acetyl-Coa and malonyl-CoA in the presence of NADPH. *FASN* is ubiquitously expressed in the embryo and its loss results in prenatal lethality. However, its roles in brain development are unclear.
To investigate the mechanisms by which *FASN* mutations disrupt neurodevelopmental processes, we generated a novel mouse model carrying a patient-derived mutation using CRISPR/Cas9 gene-editing. The homozygous $Fasn^{S154N}$ knock-in mice are not viable. However, heterozygous $Fasn^{S154N}$ mice display a clinical phenotype reminiscent of the patients' phenotypes, with anxiety-like behavior, altered spatial learning, spontaneous interictal spikes on electroencephalograms (EEG), and a tendency to a reduced PTZ-induced seizure threshold.
Our work thus reveals the phenotypic spectrum of *FASN*-associated neurodevelopmental disorders, while providing a unique animal model to advance mechanistic studies that will ultimately drive therapeutic innovation for this disorder.

Title: A standardized social preference protocol for measuring social deficits in mouse models of autism

Authors: *B. REIN, K. MA, Z. YAN;
SUNY Buffalo Jacobs Sch. of Med. & Biomed. Sci., Buffalo, NY, NY

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by social communication deficits and other behavioral abnormalities. The three-chamber social preference test is often used to assess social deficits in mouse models of ASD. However, varying and often contradicting phenotypic descriptions of ASD mouse models can be found in the

scientific literature, and the substantial variability in the methods used by researchers to assess social deficits in mice could be a contributing factor. Here we describe a standardized three-chamber social preference protocol, which is sensitive and reliable at detecting social preference deficits in several mouse models of ASD. This protocol comprises three phases that can all be completed within 1 d. The test mouse is first habituated to the apparatus containing two empty cups in the side chambers, followed by the pre-test phase in which the mouse can interact with two identical inanimate objects placed in the cups. During the test phase, the mouse is allowed to interact with a social stimulus (an unfamiliar wild-type (WT) mouse) contained in one cup and a novel non-social stimulus contained in the other cup. The protocol is thus designed to assess preference between social and non-social stimuli under conditions of equal salience. The broad implementation of the three-chamber social preference protocol presented here should improve the accuracy and consistency of assessments for social preference deficits associated with ASD and other psychiatric disorders.

Title: A test for impaired behavioral flexibility in a mouse model of autism spectrum disorder

Authors: *M. YUN[1,3], J. SHIN[2], M. W. JUNG[3,2,1];
[1]Biol. Sci., [2]Grad. Sch. of Med. Sci. and Engin., KAIST, Daejeon, Korea, Republic of; [3]Ctr. for Synaptic Brain Dysfunctions, Inst. for Basic Sci., Daejeon, Korea, Republic of

Abstract: We hypothesized that impaired behavioral flexibility might underlie an array of symptoms associated with autism spectrum disorder (ASD), especially repetitive and restricted behavior. To explore this hypothesis, we tested Shank2 knockout (Shank2-KO) mice in a probabilistic reversal learning task. Two different odor cues were presented to a head-fixed mouse and paired with a reward (water) or a punishment (air-puff) each with 75% probability. Even though both Shank2-KO and wild-type mice showed higher anticipatory licking responses to the reward-predicting than punishment-predicting cues during the initial training, it took significantly longer for Shank2-KO than wild-type mice to show higher anticipatory licking responses to the new reward-predicting cue upon the reversal of cue-outcome contingency. Shank2-KO mice also showed enhanced fear responses, as measured by pupil diameter, than wild-type mice in the task, raising the possibility that enhanced fear responses might contribute to impaired reversal learning. When we trained the animals using a mild air-puff that induced similar fear responses between Shank2-KO and wild-type mice, no significant difference was found in reversal learning between the two animal groups. Moreover, when we trained the animals with only appetitive outcomes (75 versus 25% reward probabilities), no significant difference was found in reversal learning, either, between the two animal groups. These results

suggest that impaired reversal learning of Shank2-KO mice in the original appetitive-aversive conditioning is likely because of hypersensitivity to punishment rather than general inflexibility of Shank2-KO mice. Collectively, our results provide evidence against the general behavioral inflexibility hypothesis for ASD.

Title: Digging Behavior Discrimination Test to Study Burrowing and Exploratory Digging in Laboratory Mice

Authors: A. T. HELLER[1], B. M. GURAL[2], H. L. POND[3], *M. MANZINI[2];
[1]Child Hlth. Inst. of New Jersey, Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ; [2]Rutgers Robert Wood Johnson Med. Sch., New Brunwick, NJ; [3]The George Washington Univ., Washington, DC

Abstract: Digging is an instinctual behavior in mice across strains, pervasive through lab-bred generations, and often used to study mouse models of neurodevelopmental and psychiatric disorders. One of the most common behavioral digging tests used to assay repetitive behaviors like those seen in obsessive-compulsive disorder (OCD) and autism spectrum disorder (ASD) is the marble burying test which measures the number of marbles buried into deep bedding during digging. However, the literature suggests digging is a naturalistic behavior with a variety of motivations; i.e. foraging for food, burrowing for shelter, removing noxious stimuli, or even for recreation as shown for dogs and ferrets. Previous digging assays such as free digging and marble burying are unable to elucidate motivation complicating the interpretation of results. Here we present a goal-directed paradigm, the Digging Behavior Discrimination (DBD) test that uses coordinated measures of free digging and burrowing behavior adapted from the Deacon (Nature Protocols, 2006) to rapidly assess mouse digging and burrowing behavior and help to distinguish why mice dig. To distinguish between exploratory digging and burrowing, we set up a clear cage with deep corncob substrate allowing the mice to choose between a transparent tube filled with soft paper bedding in one corner and a free digging area. By collecting a variety of measures of activity, burrowing efficiency, and free digging we found that the test provides stable results in multiple cohorts. To determine whether digging preference could be shifted, cohorts of male and female mice underwent food restriction leading to 10-15% weight loss, followed by recovery with *ad libitum* feeding. Both male and female mice switched to spending more time outside the burrowing area during food restriction but only males showed a reduction in burrowing efficiency and a significant increase in free digging during that time. The DBD test was then

conducted in a mouse model for ASD and intellectual disability (ID), conditional knock-out (cKO) mice for the ASD/ID gene CC2D1A that had previously shown both hyperactivity and reduced digging in the marble burying. Male Cc2d1a cKO mice burrowed significantly less than wild type male mice and shifted towards exploratory digging, a genotype difference that was not present between female groups. These data suggest that the DBD test may be a more sensitive measure of digging also providing additional information on digging motivation. We found that digging motivation may differ between males and females and special attention must be given when discussing digging behavior, particularly in females.

Title: Autism spectrum disorder is a risk factor for PTSD-like memory formation

Authors: *A. S. AL ABED[1], A. SELLAMI[2], A. MARIGHETTO[2], A. DESMEDT[2], N. DEHORTER[1];
[1]The Australian Natl. Univ., Canberra, Australia; [2]NeuroCentre Magendie, INSERM 1215, Bordeaux Cedex, France

Abstract: Recent studies have suggested co-occurrence of post-traumatic stress disorder (PTSD) and ASD in humans. Behaviourally, ASD and PTSD display similar characteristics, including impaired emotional regulation, cognitive rigidity, and fragmented autobiographical memory. Yet, despite several shared neurological alterations, the overlap between the two disorders has remained poorly explored. To assess the susceptibility of developing traumatic memory in ASD, we tested the Contactin-associated protein 2 knock out (*Cntnap2* KO) mouse in an unpaired tone-shock fear conditioning paradigm, modified from a previously used model of PTSD-like memory, and combined with a 30min-restraint stress. Unlike control mice which displayed strong fear of the conditioning context (i.e. normal memory), stressed *Cntnap2* KO mice exhibited strong fear to the tone and little fear to the context. Such a memory profile is characteristic of a PTSD-like memory: hypermnesia for an irrelevant but salient cue, combined with partial amnesia for the context surrounding the traumatic event. Furthermore, this pathological memory was associated with a broad dysfunction of the prefrontal-hippocampo-amygdalar network. Among these structures, we established the pivotal role of the prefrontal cortex (PFC) in the development of PTSD under mild stress conditions, through the

demonstration that PFC optogenetic inhibition successfully prevented pathological memory formation in stressed *Cntnap2* KO mice. Finally, we employed a behaviour-based rehabilitation strategy to rescue traumatic memory, through re-exposure to the tone in the conditioning context. Recontextualization of the trauma after long-term retention restored normal memory. Together, this study provides the first direct demonstration that ASD is a risk factor for developing PTSD-like memory. Indeed, a stressful situation below the threshold for pathological memory in control population gives rise to PTSD in ASD. It urges for autism-specific trauma assessments to improve detection measures and specific treatment of PTSD in vulnerable population with ASD.

Title: Role of Cortical and Hippocampal Integrin β3 in Mediating Social and Repetitive Mouse Behaviors

Authors: A. LOPUCH, B. SWINEHART, E. WIDENER, Z. L. HOLLEY, K. BLAND, C. HANDWERK, H. COOK, A. KALINOWSKI, H. RODRIGUEZ, ***G. S. VIDAL**;
James Madison Univ., Harrisonburg, VA

Abstract: Many neurological diseases, such as autism spectrum disorder, Alzheimer's, and epilepsy, are thought to be associated with disorders of the synapse. Autism spectrum disorder (ASD) is characterized by repetitive behaviors, deficits in communication, and overall impaired social interaction. Integrins are heterodimeric cell adhesion molecules that bind to the extracellular matrix and regulate cell motility. These molecules are required for normal structural plasticity of dendrites and synapses, as well for construction of cortical and hippocampal circuits within the brain, but the role that Itgb3 plays in the function of social and repetitive behaviors, specifically those related to ASD, is still not well defined. We were able to test for mouse behaviors typically associated with ASD by conditional knockout (cKO) of *Itgb3* in cortical and hippocampal excitatory neurons and glia, which are known to be important for social and repetitive behaviors. We determined whether our cKO mice showed differences in anxiety-like behaviors, social behaviors, and/or repetitive behaviors, the latter two being hallmarks of ASD. Our findings indicated that there were differences in both social and repetitive behaviors between cKO and wild type (WT) mice. We found that cKO mice spent less time grooming in a novel environment and displayed a social preference for novel mice while WT showed increased time spent grooming in the novel environment compared to home cage and showed no social preference for either familiar or novel mice. These findings are markedly different from previous

results of global *Itgb3* knockout mice, suggesting that Itgb3 may be playing a unique role in the cortex and hippocampus.

Abstract: Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder diagnosed on the basis of social impairment and restricted, repetitive behaviors (RRBs). Results from animal and adult neuroimaging studies have generated interest in cerebellar contributions to ASD pathophysiology. Specifically, commentaries have posited that impaired cerebellar-mediated error signaling may account for the emergence of ASD behaviors, implicating cerebellar connectivity as a promising presymptomatic biomarker of ASD. However, supportive evidence from tests of cerebellar function in human infants is lacking. **Objective:** This project tested infant cerebellar connectivity (fcMRI) as a presymptomatic biomarker of ASD in a rigorous manner using multiple analytic approaches. **Methods:** We utilized data from the Infant Brain Imaging Study, a prospective study of infants at high and low familial risk for ASD (*n* = 94, 68 male). Brain-behavior associations were analyzed for 6-month cerebellar connections in relation to 12 and 24-month ASD-associated behaviors (joint attention, motor coordination,

repetitive behaviors) and 24-month ASD outcomes (positive/negative) using univariate, multivariate, and enrichment approaches. In hypothesis-driven tests, we focused on cerebellar-frontoparietal (the FPN has been implicated in error signaling) and cerebellar-default mode (the DMN has been implicated in prior studies of ASD) connections. **Results:** Univariate tests of cerebellar-FPN and cerebellar-DMN connections failed to implicate the cerebellum in ASD in a convincing manner (only .02% of tested connections survived multiple comparisons correction), despite > 80% power to detect medium effects. Multivariate predictive tests in high risk infants using cerebellar-FPN and cerebellar-DMN connections similarly failed to achieve above chance classification accuracy for ASD outcomes, despite utilizing procedures that achieved > 80% positive predictive value in brain-wide work. Whole-brain enrichment identified three 6-month network pairs that were strongly associated with later RRBs. However, the cerebellum was implicated at chance in these networks. **Conclusions:** Contrary to hypotheses, we failed to observe strong associations between 6-month cerebellar fcMRI and 12-24-month ASD behaviors and outcomes, casting doubt on cerebellar theories of ASD etiology and indicating that cerebellar effects, if present, are likely small. Instead, we identified brain-behavior associations between multiple 6-month network pairs and later RRBs, suggesting network-level correlates for emerging ASD behaviors that warrant future testing in independent samples.

Title: Skills profiles in minimally-speaking autistic children: Functional assessments and touchscreen interactions associate fine motor ability with expressive language

Authors: E. J. L. WEISBLATT[1], A. MCKINNEY[2], K. L. HOTSON[3], Z. B. AHMED[3], C. DÍAS[4], D. BEN SHALOM[5], J. FOSTER[6], S. S. VILLAR[1], S. MURPHY[7], A. JATKAR[8], S. LANGHORNE[9], *M. K. BELMONTE[10];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Nottingham Trent Univ., Nottingham, United Kingdom; [4]Cambridgeshire & Peterborough NHS Fndn. Trust, Peterborough, United Kingdom; [5]Ben-Gurion Univ. of the

Negev, Beer Sheva, Israel; [6]King's Col. London, London, United Kingdom; [7]Univ. of Bedfordshire, Luton, United Kingdom; [8]Univ. of North Carolina, Chapel Hill, NC; [9]Univ. of Manchester, Manchester, United Kingdom; [10]The Com DEALL Trust, Bangalore, India

Abstract: Background: Point OutWords is a caregiver-delivered, iPad-assisted intervention targeting motor and cognitive skills prerequisite to communication, designed specifically for those minimally verbal autistic children whose severe deficits in expressive language are coincident with impaired motor skills.
Objectives: Assess 1) Relationships amongst verbal and motor functioning using parent-report and direct observational measures 2) Motor functioning measured by interactions with the iPad touchscreen, within the intervention group 3) Any change with treatment.
Methods: Our parallel-groups randomised controlled design recruited 30 autistic children aged 3-15 years, speaking fewer than 100 words functionally. The intervention group used Point OutWords 5 times a week for 8 weeks; controls used other iPad apps. Communication (Vineland, Mullen), motor, oromotor (VMPAC) and daily living skills were tested at baseline and post-intervention. Data were analysed with mixed ANOVA for behavioural and questionnaire measures. Children's touchscreen interactions were separated from their caregivers' by Gaussian mixture modelling; each movement was assessed for median jerk (3rd derivative of position), mean direction error, and time to completion. These derived measures were regressed against time in treatment.
Results: Motor and especially language and social skills were impaired for age (all $p<0.001$). Gross motor skills exceeded fine ($p=0.03$). Only 2 children had stronger expressive than receptive language. All had severe impairments of oromotor control. There were no consistent effects of treatment though Mullen motor and language scores improved overall ($p=0.027$). 8 of 12 children significantly lessened the time to complete movements (each $p<0.02$), and every child showed significant increase in jerk ($t(11)=5.81$, $p=0.000118$).
Conclusion: This study recruited a highly impaired group of children with minimal spoken language. A majority demonstrated better gross than fine motor, better motor than verbal, and better receptive than expressive verbal skills. Increased jerk and faster performance suggest a change to more frequent, finer-grained movement corrections. Future work will investigate predictors of such changes and implications for augmentative and alternative communication.

Title: N170 latency delays are observed in ASD independent of visual attention to specific facial features

Authors: ***S. KALA**[1], A. BAGDASAROV[2], C. CARLOS[1], E. CUMMINGS[1], A. NAPLES[1], T. MCALLISTER[1], J. MCPARTLAND[3];
[1]Yale Univ., New Haven, CT; [2]Duke Univ., Durham, NC; [3]Yale Child Study Ctr., New Haven, CT

Abstract: Autism spectrum disorder (ASD) is associated with N170 (an event-related potential reflecting temporal face processing) latency delays, indicating slower processing. We aim to better characterize N170 in ASD by cueing attention to specific facial features and analyzing the relationship between feature-specific N170s and autistic traits. We obtained electroencephalography (EEG) data on ASD (n=8) and typically developing (TD) (n=17) subjects. Each trial consisted of a crosshair (600-650 milliseconds (ms)), a neutral face or a house (1000 ms), and an intertrial period (500-650 ms). Crosshairs were presented in four locations, cueing attention to the left eye, right eye, nose, or mouth on the face and corresponding regions on the house. Fixations were monitored with co-registered eye tracking. ASDs had longer N170 latencies for each feature than TDs (Fig. 1). Within diagnostic groups there were no differences in feature-specific latencies [ASD: $F(3,5)=1.68$, $p=.29$; TD: $F(3,14)=1.05$, $p=.40$]. Across groups left eye latency correlated most strongly with autistic traits measured by the Autism Spectrum Quotient, the Broad Autism Phenotype Questionnaire, and the Social Responsiveness Scale (Table 1). These data show that N170 latency delays in ASD are evident irrespective of visual attention to specific facial features. Across groups left eye latency exhibited largest correlations with autistic traits. These data suggest the importance of considering visual attention in EEG studies of face perception.

Figure 1: N170 latencies elicited by specific facial features in ASD and TD participants.

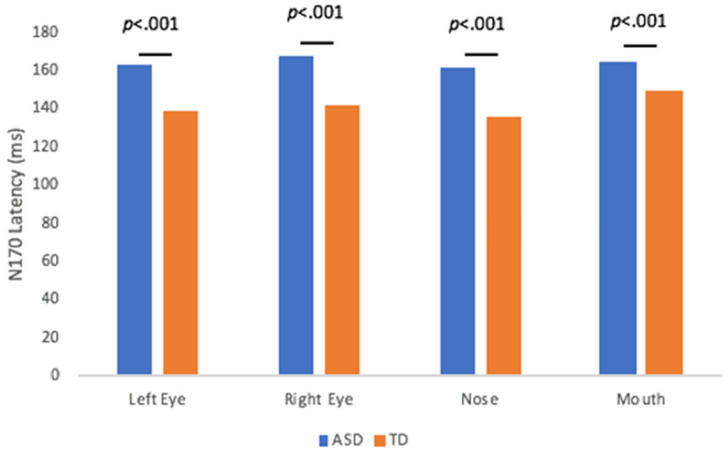

Table 1: Summary of correlations between N170 latency and ASD symptomatology according to the AQ, BAPQ, and SRS across diagnostic groups.

	Autism Spectrum Quotient Total Score		Broad Autism Phenotype Questionnaire Total Score		Social Responsiveness Scale Total Raw Score	
	r	*p*-value	*r*	*p*-value	*r*	*p*-value
Left eye N170 latency	0.441	0.027*	0.532	0.006**	0.563	0.003**
Right eye N170 latency	0.409	0.043*	0.458	0.021*	0.524	0.007**
Mouth N170 latency	0.385	0.058	0.464	0.019*	0.553	0.004**
Nose N170 latency	0.373	0.066	0.426	0.034*	0.488	0.013*

Footnote: Left eye N170 latency correlated most strongly with autistic traits measured by the Autism Spectrum Quotient (r=.441, p=.027), the Broad Autism Phenotype Questionnaire (r=.532, p=.006), and the Social Responsiveness Scale (r=.563, p=.003)

Title: Sex-specific effects on sociability following reduced midbrain Drd2 expression in mice

Authors: *A. K. OSTERMAN[1], A. KHASNAVIS[1], B. A. SULAMAN[2], B. ZUPAN[1]; [1]Vassar Col., Poughkeepsie, NY; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Dopamine (DA) modulates locomotor activity and social behavior, the dysfunction of which is a core symptom of Fragile X syndrome (FXS) and autism. We've previously reported in a mouse model of FXS, the *Fmr1*-null mouse, that both wildtype (WT) and knock-out (KO) offspring of *Fmr1* deficient dams exhibit attenuated locomotor-reducing effects of dopamine autoreceptor 2 (D2aR) activation, suggesting that maternal *Fmr1* deficiency may program altered sociability and hyperactivity by downregulating this negative feedback mechanism. Indeed, male offspring of *Fmr1* deficient dams show reduced VTA *Drd2* expression irrespective of their own *Fmr1* genotype. Here we asked if constitutive or adult-only reduction in midbrain *Drd2*

expression is sufficient to induce hypersociability. We generated *Drd2*$^{fl/+}$ DAT-Cre^{+} C57xFVB F1 hybrids with constitutive reduction of *Drd2* expression in DAT+ cells (*Drd2* knock-down (KD)). Additionally, we generated *Drd2*$^{fl/+}$ F1 hybrids and induced adult *Drd2* KD by injecting AAV-TH-Cre into the VTA. Constitutive *Drd2* KD increased sociability, reduced avoidance, and attenuated quinpirole sensitivity in female, but not male mice. This suggests that life-long *Drd2* deficiency leads to sex-specific effects on dopamine neurotransmission. Interestingly, we found opposite sex-dependent effects of adult *Drd2* KD, with male but not female mice showing increased sociability after AAV-mediated midbrain *Drd2* KD. This suggests that D2aR-dependent negative feedback of midbrain DAergic signaling has a direct modulatory role on sociability in male, but not female mice. Furthermore, our data show that reduced midbrain *Drd2* expression is sufficient to increase sociability in adult mice, phenocopying hypersociability of male mice reared by *Fmr1* deficient dams.

Title: A Minecraft mod to improve theory of other minds and empathy in autistic spectrum disorder children

Authors: *E. L. ALTSCHULER[1], R. KANGASMÄKI[2], C. COLON[1], C. PARKES[3], J. PAJARINEN[4];
[1]Physical Med. and Rehabil., Metropolitan Hosp., New York, NY; [2]Tampere Univ., Tampere, Finland; [3]ASD Services, London, United Kingdom; [4]Electrical Engin. and Automation, Aalto Univ., Espoo, Finland

Abstract: Autistic spectrum disorder (ASD) affects more than 1% of children. Major genetic determinants of ASD have yet to be found, and molecular, biochemical or neuronal cell biology based treatment is far off, if ever possible. Importantly, these may not be the correct level of reduction to treat ASD. The core deficit in ASD is a lack of appreciation of a theory of mind (ToM) of others/lack of empathy. Some years ago we suggested (Altschuler, 2008) that having an ASD child take care of a virtual pet, could force, in a fun way, the ASD child to think about the world through the eyes and needs of the pet. However, care of a virtual pet may not hold the attention of an ASD (or any) child. Conversely, ASD children greatly enjoy playing Minecraft. Given this, we have built and here describe and demonstrate a Minecraft mod to increase theory of other minds and empathy in ASD children. The mod includes a helper that can fish, farm, mine, and build a shelter inside the game world for the ASD player. The ASD player can ask the helper to perform these tasks using a graphical user interface (GUI). The helper requires tools to perform these tasks which the ASD player can provide by dropping them on the ground and

letting the helper pick them up which is standard in Minecraft. Furthermore, the ASD player can provide positive feedback through the GUI. Positive feedback allows the helper to gain new skills and use more advanced tools, and thus perform more challenging tasks. The helper tries to stay near the ASD player and gives prompts about the current situation and needs, such as danger, hunger, or boredom. The Minecraft mod is designed in such a way that to fully benefit from the helper the ASD player needs to invest in interaction and understanding the needs of the helper. We hope this will lead to the promotion of empathy and theory of mind, as well as developing the confidence of the player in engaging in social interactions. We plan to assess the mod in a small study and then after subsequent refinements in an RCT.

Title: Early life sleep disruption and genetic vulnerability interact to drive life-long behavioral deficits in a Shank3 autism model.

Authors: *J. S. LORD, S. M. GAY, K. M. HARPER, V. D. NIKOLOVA, S. S. MOY, G. H. DIERING;
UNC Chapel Hill, Chapel Hill, NC

Abstract: Sleep is essential for lifelong brain health and cognitive function. Sleep disruption is a major comorbidity in Autism Spectrum Disorder (ASD), occurring in over 80% of patients. We hypothesize that sleep disruption early in life negatively impacts brain development and drives lasting changes in brain function and behavior seen in ASD. Shank3 is a high-confidence ASD risk gene, and heterozygous mutation of Shank3 is known to cause Phelan McDermid Syndrome, a severe developmental disorder characterized by intellectual disability, autism, and disrupted sleep. Here we report findings of sleep and behavioral analysis of ASD model mice bearing C-terminal truncation (ΔC) of Shank3. Juvenile and adolescent Shank3$^{\Delta C/\Delta C}$ male and female mice showed reduced and fragmented sleep compared to wildtype littermates. In comparison, clinically relevant Shank3$^{+/\Delta C}$ mice showed mild sleep disruption phenotypes. We suspected that Shank3$^{+/\Delta C}$ mice may be especially vulnerable to the effects of developmental sleep loss. Therefore, we tested the lasting effects of early life sleep disruption (ELSD) on wild type and Shank3$^{+/\Delta C}$ mice. ELSD was induced by subjecting mice to intermittent mild mechanical disturbance from postnatal days 14-21. Following ELSD, all animals were allowed to mature undisturbed to adulthood for behavioral testing. Compared to undisturbed controls, adult male Shank3$^{+/\Delta C}$ exposed to ELSD demonstrated a marked deficit in sociability in the 3-chambered social test, reduced acoustic startle reflex, and impaired pre-pulse inhibition. Adult female Shank3$^{+/\Delta C}$ exposed to ELSD showed a reduction in anxiety-like behavior in the elevated plus

maze. These results establish a novel gene x sex x environment interaction model of ASD susceptibility and support early life sleep disruption as a significant vulnerability in the development of ASD.

Title: Short term, perinatal BPA exposure decreases juvenile social behaviors in male rats: Implications for autism spectrum disorder

Authors: *C. DRZEWIECKI[1], A. D. DOSHI[2], J. Y. KOH[1], J. M. JURASKA[3];
[1]Univ. of Illinois at Urbana/Champaign, Champaign, IL; [2]Univ. of Illinois - Chicago, Chicago, IL; [3]Psychology, Univ. of Illinois, Champaign, IL

Abstract: Bisphenol A (BPA) is an endocrine disruptor found in polycarbonate plastics. BPA exposure in humans is nearly ubiquitous and has also been linked to autism spectrum disorders (ASD), a developmental disorder characterized by abnormal social interaction. While the etiology of ASD is undoubtedly multifactorial, our laboratory has previously shown that perinatal BPA exposure disrupts social behaviors in adolescent rats (Wise et al., 2018). To further explore the relationship between BPA and symptoms of ASD, we orally fed male and female rat pups to a 0 (control), 40, or 400 µg/kg/day BPA solution between postnatal day (P)6 and P8. Subjects were left undisturbed until they underwent a social preference task at P15 and P28. This task measured the subjects' preference for a novel, age- and sex-matched conspecific vs a novel object. All subjects, regardless of sex or age, showed significant preference for the novel conspecific over the novel object. We found that at P15, only the males who received the 40 µg/kg/day BPA dose showed decreased social preference for the conspecific when compared to controls. At P28, the males who received the 400 µg/kg/day BPA dose showed decreased social preference compared to controls. BPA did not influence social preference in females at either age. Thus, short-term BPA exposure in early life can induce disruptions to social behaviors in a dose-specific pattern. These results support a growing body of literature that suggests BPA may exacerbate symptoms of ASD, particularly in young males.

Title: The effects of maternal immune activation on the behaviour of mice lacking vesicular zinc

Authors: *K. C. SANDOVAL[1,2], A. WONG[2], N. NIEWINSKI[2], S. E. THACKRAY[2], R. H. DYCK[2];
[1]Psychology, Neuroscience, Behaviour, McMaster Univ., Hamilton, ON, Canada; [2]Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Zinc is important in neural and synaptic development and neuronal transmission. Within the brain, zinc transporter 3 (ZnT3) is essential for zinc uptake into vesicles. Loss of vesicular zinc has been shown to produce neurodevelopmental disorder-like behaviour phenotypes, such as decreased social interaction and increased anxiety- and repetitive-like behaviour. Maternal immune activation (MIA) has been identified as an environmental factor for neurodevelopmental disorders, such as autism spectrum disorders (ASDs) and schizophrenia (SZ), in offspring, which occurs during pregnancy when the mother's immune system reacts to the exposure to viruses or infectious diseases. In this study, we investigated the interaction effect of a genetic factor (ZnT3 knockout (KO) mice) and an environmental factor (MIA). We induced MIA in pregnant female (dams) mice during mid-gestation, using polyinosinic:polycytidylic acid (polyI:C), which mimics a viral infection. We administered dams heterozygous for ZnT3 with polyI:C (20mg/kg) or saline, at embryonic day 12.5, as it is translational to the 2nd trimester of pregnancy in humans, a period in which MIA is thought to contribute to neurodevelopmental disorders significantly. At postnatal day 9 (P9), we recorded ultrasonic vocalizations from all pups isolated from the dams and the nest and assessed their calls. Call duration usually reaches a peak between P7-P9 in mice. In adulthood (P60-75), male and female ZnT3 KO and wild-type mice were examined using a battery of behavioural tests commonly used in rodents to assess ASD- and SZ-like behaviour: open field to assess anxiety, marble burying to assess repetitive behaviour, 3-chamber social test to assess social interaction, and pre-pulse inhibition to assess sensory-motor gating. Our results indicate that loss of vesicular zinc does not show enhanced ASD- and SZ-like phenotype compared to wild-type, nor does it show a more pronounced phenotype in male ZnT3 KO compared to female ZnT3 KO. Finally, MIA offspring demonstrated an ASD- and SZ-like phenotype only in specific behavioural tests: increased calls emitted in ultrasonic vocalizations and decreased marbles buried. Our results indicate no interaction between the loss of vesicular zinc and MIA induction in the susceptibility to developing an ASD- and SZ-like phenotype.

Abstract: The existence of a link between the gut microbiome and Autism Spectrum Disorder (ASD) is well established in mice, but in human populations efforts to identify microbial biomarkers remain limited due to a lack of appropriately matched controls, stratification of participants within the spectrum, and sample size. To overcome these limitations, we crowdsourced the recruitment of over 100 families with age-matched sibling pairs between 2-7 years old, where one child had a diagnosis of ASD and the other did not. Parents collected stool samples, provided a home video of their children's social behavior, and 365 metadata features assessing inter-and intra- family variabilities. 16S amplicon analysis from stool samples was collected for every subject at three-time points and was analyzed, alongside multi-omics data provided for the initial point of sampling. This extensive study allowed us to identify taxa and metabolic biomarkers specific to ASD, undergoing mice behavior testing.

Title: Genetic and environmental influences on brain structure in twins with autism

Authors: *J. P. HEGARTY II, J. C. MONTERREY, L. C. LAZZERONI, S. C. CLEVELAND, J. M. PHILLIPS, J. F. HALLMAYER, A. Y. HARDAN;
Psychiatry & Behavioral Sci., Stanford Univ., Palo Alto, CA

Abstract: Brain development is altered in children with autism spectrum disorder (ASD); however, the type and degree of alterations are heterogeneous. This heterogeneity may be due to the variable effects of genetic and environmental influences. This study used a twin model approach to examine multimodal neuroimaging data and compare genetic and environmental influences on brain structure between twins with and without ASD. Same-sex monozygotic and dizygotic twin pairs in which at least one twin was diagnosed with ASD or both were neurotypical controls were recruited. T1 (n=164), diffusion-weighted (n=168), and 1H proton spectroscopy (n=106) MRI data were collected and processed with FreeSurfer, FSL Diffusion Toolbox, and LCModel, respectively, in order to examine brain structure based on grey matter

morphometry (cortical thickness-CT; surface area-SA; volume-VOL; curvature-CURV), white matter microstructure (fractional anisotropy-FA; mean diffusivity-MD), and neurochemical markers of neuronal integrity (N-acetylaspartate-NAA). Intra-class correlations were computed within twin pairs, and ACE modeling for broad sense heritability (a2=additive genetics) and environmental influences (c2=shared family environment, e2=unique environment) was examined. Brain structure was predominantly genetically-mediated in control twins, with variation in cerebral and cerebellar grey matter (CT, SA, VOL), white matter (FA, MD), and neurochemical levels (NAA) primarily associated with genetic factors. The only measures that were predominantly environmentally-mediated in control twins were CURV and some region-specific CT and MD. Similarly, genetic factors also accounted for the majority of variation in brain structure in twins with ASD, potentially to a larger extent for deep brain structures like subcortical VOL and commissural FA, yet there were also greater environmental influences in twins ASD. Variation in global and regional CT as well as cerebellar (VOL and FA) and cerebral white matter (FA in projection and association fibers) were primarily associated with environmental factors in twins with ASD. As previously reported, brain structure appears to be primarily genetically-mediated during typical development, with some regional and measure-specific environmental influences that most likely represent changes from adaptive plasticity. However, children with ASD exhibit a markedly different and more pervasive pattern of environmental influences on brain structure. These results are promising because they suggest that treatments targeting the early environment could potentially alter brain development to provide some clinical benefits.

Title: Maternal docosahexaenoic acid supplementation effects on prenatal stress mouse model alleviates autistic-like behaviors in offspring

Authors: *T. WOO[1], C. KING[1], M. K. APPENTENG[1], R. LI[1], K. L. FRITSCHE[1], G. Y. SUN[1], J. CUI[1], M. WILL[1], M. K. GREENLIEF[1], D. Q. BEVERSDORF[2];
[1]Univ. of Missouri, Columbia, MO; [2]Dept Radiol, Neurol, Psychol Sci, DGS of INP, Univ. of Missouri Columbia, Columbia, MO

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by restricted social communication and repetitive behaviors. We previously reported that prenatal stress is critical in neurodevelopment and increases risk for ASD, particularly in those with greater genetic susceptibility to stress. Docosahexaenoic acid (DHA) is one of the most abundant omega-3 fatty acids in mammalian brain, and dietary omega-3 fatty acid affects the development

and maintenance of brain structure. In this study, we investigated whether prenatal supplementation of DHA alleviates autistic-like behaviors in a gene/stress mouse model and how it alters lipid peroxidation activity in the brain. Pregnant heterozygous serotonin transporter knockout (SERT-KO) and wild-type (WT) dams were placed in either non-stressed control condition or chronic variable stress condition and fed either control diet or DHA-rich (1% by wt) diet. Offspring of each group were assessed for anxiety and autism-associated behavior at post-natal day 60, including an open field test, elevated-plus maze test, repetitive behavior, and the 3-chamber social approach test. Male mice from stressed SERT-KO dams showed significantly decreased social interactions in the 3-chamber social approach test compared with male offspring from non-stressed WT dams. DHA supplementation fed to stressed SERT-KO dams mitigated these behavioral changes. This result indicates that maternal supplementation of DHA can ameliorate autistic-like behaviors caused by prenatal stress. Now we are analyzing lipid peroxidation products in the plasma, heart, and cerebral cortex. In addition, brain structures will be examined via MRI in order to identify whether autistic-like behaviors are associated with neurochemical or neuroanatomical changes.

Title: Autism diagnosis prediction from inter-subject similarity of video-evoked fMRI timeseries

Authors: *L. BYRGE[1], D. KLIEMANN[2], U. KELES[3], H. SAARIMÄKI[5], R. ADOLPHS[4], D. P. KENNEDY[6];
[1]Univ. of North Florida, Jacksonville, FL; [2]Univ. of Iowa, Iowa City, IA; [3]Caltech, Pasadenia, CA; [4]Caltech, Pasadena, CA; [5]Tampere Univ., Tampere, Finland; [6]Indiana Univ., Bloomington, IN

Abstract: Naturalistic viewing paradigms, in which participants undergo functional magnetic resonance imaging (fMRI) scanning while watching videos, have emerged as an important methodological advance toward improving ecological validity in neuroscience. Coupling these paradigms with machine learning approaches may particularly benefit clinical neuroscience, by providing the power to both inform neurobiological differences between clinical and control groups in more naturalistic contexts (Eickhoff et al., 2020), and to pinpoint specific stimulus properties that evoke robust group differences. Here, we present novel analytic approaches for predicting diagnosis using inter-subject similarity of brain responses across epochs of video watching. We used an extensively and densely sampled fMRI dataset from 29 adults with autism

(ASD) and 22 age-, IQ-, and sex- matched controls with 4 ~15-min video-watching scans (813 TR) and resting-state scans; preprocessing is described in Byrge & Kennedy (2018). Results presented here include 36-40 participants per scan (13-15 ASD) after data quality -related exclusions and employ censored timeseries for highest quality from 110 regions of interest (ROIs) from a common anatomical parcellation (Harvard-Oxford). We combine various feature selection and modeling approaches into a cross-validated inter-subject-similarity-based predictive modeling framework (c.f. Shen et al., 2017), using mean pairwise inter-subject correlations between a held-out subject and healthy controls as similarity measures (ISCs) and both permuted group assignments and resting state data as null models. Using brain-wide ISCs across the entire video, we achieve above-chance diagnosis prediction accuracy of 73.7%-80.6% for the 4 video scans. Preliminary analyses using feature selection to model only subsets of timepoints and ROIs from each scan obtain even higher accuracy. In previous work (Byrge & Kennedy, 2020), we were unable to predict diagnosis above chance levels using functional connectivity matrices derived from these same scans. Ongoing work aims to understand whether this dissociation -- diagnosis prediction from evoked brain responses but not from evoked connectomes -- arises due to statistical properties or neurocognitive differences informative about ASD. Next steps will examine whether the most informative video segments and brain regions replicate in an independent dataset, and will characterize stimulus features of those segments, providing important insights into the low-level stimulus properties and/or socio-cognitive processes driving brain response differences in ASD.

Title: FMRP ubiquitination and degradation are required for MEF2-induced synapse elimination

Authors: *J. R. WILKERSON[1], M. IFRIM[2], A. VALDEZ-SINON[3], G. J. BASSELL[4], K. M. HUBER[1];
[1]Neurosci., Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [2]Cell and Developmental Biol., SUNY Upstate Med. Univ., Syracuse, NY; [3]Cell Biol., [4]Emory Univ., Atlanta, GA

Abstract: Fragile X Mental Retardation Protein (FMRP) is necessary for experience-dependent, developmental synapse elimination and loss of function mutations in FMRP lead to excess dendritic spines and hyperconnectivity of cortical neurons in Fragile X Syndrome, a common inherited form of intellectual disability and autism. We have characterized a model of synapse

elimination in CA1 neurons of organotypic hippocampal slice cultures that is induced by expression of a persistently active transcription factor MEF2 and relies on acute postsynaptic expression of FMRP. FMRP is an RNA-binding protein that represses translation of its target mRNA in dendrites and evidence suggests that its ubiquitination and degradation are necessary for activity-induced translation of target mRNAs to mediate synaptic plasticity. An E3 ligase for FMRP, Anaphase Promoting Complex, along with its co-activator Cdh1 (APC/Cdh1), has been identified (Huang et al. Neuron 2015). Using a combination of pharmacological approaches and mutants of FMRP, that affect ubiquitination or degradation, we provide evidence for a role of APC/Cdh1 and FMRP degradation in MEF2-induced synapse elimination. In wildtype CA1 neurons, pharmacological blockade of APC/Cdh1 with apcin abolishes MEF2-triggered synapse elimination without inhibiting a MEF2 transcriptional reporter, suggesting a role for endogenous APC/Cdh1-mediated ubiquitination downstream of MEF2 activation. APC/Cdh1 interacts with FMRP via a destruction box motif (DBM). Deletion of the DBM of FMRP or mutation of 6 candidate ubiquitination sites in the KH2 RNA binding domain (K6XR-FMRP) prevents MEF2-induced synapse elimination. Dephosphorylation of S499 in FMRP triggers FMRP ubiquitination. Both phospho- and dephospho-mimics of FMRP (S499D/S499A) block synapse elimination. These results suggest that dynamic phospho/dephosphorylaiton of FMRP, APC/Cdh1 mediated-ubiquitination and degradation of FMRP are necessary for MEF2-triggered synapse elimination. Ongoing experiments are exploring whether MEF2 regulates FMRP ubiquitination and degradation in neurons using a bimolecular fluorescence complementation (BiFC) assay.

Title: Targeted modification of cortical excitatory neurons during critical developmental period regulates structural and functional circuits in mouse models of Fragile X Syndrome

Authors: *M. RAIS[1], J. W. LOVELACE[2], X. S. SHUAI[1], W. WOODARD[1], S. BISHAY[1], L. ESTRADA[1], A. R. SHARMA[1], A. NGUY[1], P. S. PIRBHOY[1], A. R. PALACIOS[1], D. K. BINDER[1], K. A. RAZAK[2], I. M. ETHELL[1];
[1]Biomed. Sci., [2]Psychology, Univ. of California, Riverside, Riverside, CA

Abstract: Fragile X syndrome (FXS) is a leading genetic cause of autism with symptoms that include sensory processing deficits. Our previous studies have shown that elevated levels of

Matrix Metalloproteinase-9 (MMP-9) contribute to the hyper-responsiveness of auditory cortex in *Fmr1* KO mice by affecting perineuronal net (PNN) formation around parvalbumin (PV)-expressing inhibitory interneurons during third postnatal week. This period between postnatal day (P) 14 and P21 coincides with the critical period of structural and functional circuit development in the rodent auditory cortex driven by sensory input. Abnormal development of PV neurons most likely contribute to abnormal electroencephalography (EEG)-based phenotypes of auditory hypersensitivity in the *Fmr1* KO mice that are remarkably similar to those seen in humans with FXS. Here, we examined whether deletion (cOFF) or rescue (cON) of *Fmr1* in cortical excitatory neurons during the critical developmental period P14-P21 is sufficient to trigger or prevent the development of abnormal phenotypes in the auditory cortex of a mouse model of FXS. FMRP was specifically deleted from the cortical excitatory neurons during the P14-P21 window through Cre-mediated deletion of floxed *Fmr1* gene in excitatory neurons using CaMK2a promoter. We found that similar to global *Fmr1* KO mice, the density of PV/PNN cells and sound-evoked responses were reduced in $Cre^{CaMK2a}/Fmr1^{Flox/y}$ cOFF mice, whereas cortical MMP-9 gelatinase activity and resting EEG gamma power were enhanced. In addition, mTOR/Akt and TrkB phosphorylation were altered in cOFF mice, which also showed increased locomotor activity and anxiety-like behaviors. Remarkably, when FMRP levels were restored in cortical excitatory neurons during the P14-P21 period, cortical MMP-9 gelatinase activity, mTOR/Akt signaling, and resting EEG gamma power were reduced in adult $Cre^{CaMK2a}/Fmr1^{Flox/Neo-y}$ cON mice, whereas the density of PV/PNN cells and sound-evoked responses were improved. In addition, the cON mice also showed an improvement in locomotor activity and anxiety-like behaviors. Taken together, these results indicate that the loss or re-expression of FMRP in cortical excitatory neurons during early postnatal development is sufficient to elicit or ameliorate abnormal cellular, electrophysiological and behavioral phenotypes in mice. These results will have broad implications in terms of prospects for gene reactivation studies by targeting specific cells and identifying optimal treatment windows.

Title: Experience-dependent Silencing of Callosal Synaptic Connections in the Absence of Postsynaptic FMRP

Authors: ***Z. ZHANG**, J. GIBSON, K. HUBER;
Dept. of Neurosci., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Abnormal functional coupling and reduced white matter integrity between cortical regions is a pathological feature in Autism Spectrum Disorders (ASD) patients. However, little is known about the synaptic and cellular bases for this developmental alteration in the inter-area long-range connectivity. Using optogenetics and slice electrophysiology, we demonstrate that *Fmr1*, which loss-of-function mutations lead to Fragile X Syndrome (FXS), is necessary for the proper development of callosal excitatory synaptic connections between homotopic somatosensory barrel cortices. Postnatal, cell-autonomous deletion of *Fmr1* in a sparse population of Layer (L) 2/3 and L5 neurons results in weakening of excitatory postsynaptic currents (EPSCs) evoked from Channelrhodopsin2-expressing axons from the contralateral hemisphere. In contrast, synaptic inputs from ipsilateral, or local L4 and L2/3 neurons are normal. These results suggest that postsynaptic *Fmr1* specifically promotes long-range synaptic connectivity. Recordings of Sr^{2+} evoked quantal events and isolated NMDA receptor EPSCs reveal a "silencing" or selective loss of AMPA receptors at callosal synapses onto *Fmr1* knock-out (KO) neurons. Interestingly, sensory deprivation of postsynaptic *Fmr1* KO L2/3 neurons, by trimming contralateral whiskers, prevents weakening of callosal synaptic inputs, whereas deprivation of presynaptic callosal projecting L2/3 neurons has no effect. These results suggest that experience driven activity of postsynaptic *Fmr1* KO L2/3 neurons leads to a silencing of callosal excitatory synaptic inputs and reveal a synaptic basis for long-range underconnectivity observed in FXS patients. Ongoing experiments are aimed at determining if activity-dependent plasticity of callosal synapses is regulated by postsynaptic *Fmr1*.

Title: Correlation between the Fragile X Mental Retardation Protein (FMRP) and the cerebral expression of the metabotropic glutamate receptor subtype 5 ($mGluR_5$) in fragile X syndrome (FXS)

Authors: *S. D. MARTIN[1], E. BERRY-KRAVIS[2], D. RUSSEL[3], D. BUDIMIROVIC[4], J. BRASIC[5];
[1]Johns Hopkins Univ., Baltimore, MD; [2]Rush Univ. Med. Ctr., Chicago, IL; [3]Inst. for Neurodegenerative Disorders, New Haven, CT; [4]Kennedy Kreiger Inst., Baltimore, MD; [5]Johns Hopkins Med. Inst., Baltimore, MD

Abstract: Objective: To assess the relationship between the Fragile X Mental Retardation Protein (FMRP) and the cerebral expression of the metabotropic glutamate receptor subtype 5 ($mGluR_5$) in fragile X syndrome (FXS).
Methods: Six men with the full mutation (FM) of the *FMR1* gene aged 21-35 years (mean 27.1, SD 4.7), one male with a mosaicism of the mutation (FXS-M) aged 56.6 years, and one female

with typical development and a premutation (TDPM) of the *FMR1* gene aged 56.3 years, tested by PCR/Southern Blot, underwent positron emission tomography (PET) with 3-[^{18}F]fluoro-5-(2-pyridinylethynyl)benzonitrile ([^{18}F]FPEB), a specific mGluR$_5$ radioligand, to measure the density of mGluR$_5$s as a proxy of mGluR$_5$ expression in key cortical and subcortical brain regions.

Results: FMRP was mean 0.047 ± 0.04 (range 0.00, 0.12) ng/microgram total protein for FXS and 0.24, FXS-M. The FMRP for the participant with TDPM was estimated by utilizing the reference mean for TD (0.87).

The density of mGluR$_5$s was approximately a standard deviation (SD) lower in the men with FXS in contrast to the man with FXS-M and the woman with TDPM (Brasic, *et al.,* Zenodo, v. 1, 2020. https://doi.org/10.5281/zenodo.4101172).Additionally, density of mGluR$_5$ in all brain regions was positively correlated to FMRP levels (P=.24) (Figure 1).

Discussion: These results suggest that marked deficits of both FMRP and mGluR$_5$ characterize men with FXS and are positively correlated. The reductions of FMRP and mGluR$_5$ in cortical and subcortical regions provides an basis for the neurobehavioral phenotype of FXS (Budimirovic, *et al.,* Brain Sci. 2020, 10, 694 https://doi.org/10.3390/brainsci10100694). Understanding this relationship could provide the bases for the development of novel interventions for FXS.

Title: Mechanisms of dysfunctional cross modal sensory processing and hypersensitivity in Fmr1 KO mice

Authors: *N. RAHMATULLAH[1], J. ROBLEDO[1], G. CHAUDHARI[2], B. TODISCO[2], C. PORTERA-CAILLIAU[2], A. GOEL[1];
[1]Univ. of California, Riverside, Riverside, CA; [2]UCLA, Los Angeles, CA

Abstract: Fragile X Syndrome (FXS) is associated with atypical sensory processing, which may translate into cognitive impairments in learning, memory, social interaction, communication, and emotion. Behavior in an environment replete with cross-modal sensory information, requires that neural circuits selectively attend to salient stimuli, while tuning out irrelevant stimuli. Multisensory processing is influenced by top-down control from pre-frontal areas of the brain and bottom-up subcortical neuromodulation. Hypersensitivity and learning deficits may result from dysfunction in this process. We recently showed impaired sensory processing in FXS contributes to delayed learning of a visual discrimination task consisting of sinusoidal gratings drifting in two orthogonal orientations (Goel et al., 2018). Here we investigated whether *Fmr1* knockout (KO) mice exhibit hypersensitivity to distracting stimuli (visual and auditory) during the same go/no-go visual discrimination task due to atypical cross-modal sensory processing. Preliminary data shows that the presence of distractors - flashing LED lights or loud tones - did not compromise task performance for expert WT mice, but performance significantly declined for trained *Fmr1* KO mice. We then tested the hypothesis that this impairment results from a state of sensory hyperarousal due to dysfunction in the disinhibitory circuit in primary visual cortex (V1), mediated by hyperactive Vasoactive Intestinal Polypeptide (VIP) interneurons. VIP cells integrate functional inputs from the medial prefrontal cortex and cholinergic input from basal forebrain, to ultimately disinhibit V1, thus enhancing visual discrimination. Our preliminary in-vivo two-photon calcium imaging data reveals enhanced visually evoked responses in VIP cells from *Fmr1* KO *mice*. We propose that 1) Elevated basal VIP function prevents detection of change in arousal associated with errors during visual discrimination 2) Reduced top-down modulation of VIP function in *Fmr1* KO mice prevents selective processing of task-relevant stimuli and enhances susceptibility to distractors. Our future goals are to investigate how dysfunctional integration of elevated subcortical input and reduced top-down input to VIP cells contribute to hypersensitivity to distracting stimuli. In addition, this study will provide fundamental insights into the neurobiological mechanisms that contribute to multisensory processing and affect other domains of behavior in FXS and autism, such as social interaction and recognition.

Title: Conditional expression of Fmr1 in the inferior colliculus rescues deficits in phase-locking in the Fmr1 mouse model of Fragile X syndrome

Authors: *A. J. HOLLEY, J. R. GIBSON, K. M. HUBER;
Neurosci., UT Southwestern Med. Ctr., Dallas, TX

Abstract: Rationale: Humans with Fragile X Syndrome (FXS), the most common monogenetic cause of autism spectrum disorder (ASD) and a common cause of intellectual disability, often present with altered sensitivity to sensory stimuli. Recently, it has been shown that patients with FXS and the mouse model of FXS, the *Fmr1* knockout (KO) mouse both show remarkably similar reductions in cortical EEG phase-locking to a chirp-modulated stimulus and a marked increase in resting gamma power (30-100Hz). Both phenotypes are proposed biomarkers of FXS. A recent study has shown that the resting EEG alterations, but not the decreased phase-locking, are prevented when *Fmr1* is deleted in only forebrain excitatory neurons. Given this data, we hypothesized that auditory phase-locking deficits may have a subcortical origin. **Methods:** To determine if *Fmr1* deletion in a subset of brain stem neurons is required for decreased phase-locking, we crossed Ntsr1-cre mice with *Fmr1* conditional on (cON) mice, both on a C57BL6/J background, to produce three functional phenotypes: cON (functionally equivalent to an *Fmr1* KO; n=16), cre-cON (expression of *Fmr1* in the inferior colliculus, or IC; n=18), and two wildtype (WT) conditions (WT and Ntsr1-cre; n=18,17). Because Ntsr1-cre expression in the brainstem is primarily in the IC, an early sensory structure of the brainstem, we can test whether the restoration of *Fmr1* in the IC, in an otherwise *Fmr1* KO mouse, can restore the deficit in phase-locking. We implanted male mice between P45 and P50 with epidural screw electrodes and after recovery measured their response to a “chirp” stimulus that efficiently presents sound from 1-100Hz over a 2-sec period. **Results:** We found that, like *Fmr1* KO mice, the cON mice showed a marked deficit in phase-locking in both auditory and frontal cortices, particularly in the beta (13-30Hz) and high gamma (65-100Hz) frequencies, compared to WT and Ntsr1-cre mice. Moreover, this deficit is at least partially rescued in the cre-cON mice. These results confirm a role for the IC in a potential biomarker for FXS. Our results also reveal a potential target for treatment in FXS and may extend to other forms of ASD where similar deficits have been reported.

Title: Proteomic analysis of fibroblasts from patients with Fragile X Syndrome to identify new therapeutical targets.

Authors: *C. TORRES[1], Y. RAMIRO-CORTÉS[2], F. PEÑA-ORTEGA[3], M. CARDENAS-AGUAYO[1];
[1]Physiol., Sch. of Med. UNAM, Mexico City, Mexico; [2]Neurodevelopment and Physiol., Inst. of Cell. Physiol. UNAM, Mexico City, Mexico; [3]Neurobio. of development and Physiol., Inst. of Neurobio. UNAM, Queretaro, Mexico

Abstract: Introduction: Fragile X Syndrome (FXS) is the most common cause of inherited mental disability. The patients exhibit major behavior disorders such as: hyperactivity, impulsiveness, anxiety, poor language performance and severe mental disability. FXS is caused by the absence of Fragile Mental Retardation Protein (FMRP) encoded by *FMR1* gene; this protein has an important role in mRNA regulation, causing deregulations especially in postsynaptic neurons. The silencing of FMRP is due to CGG triplet abnormal repeats in the promoter region of *FMR1* gene; the severity of FXS depends on the number these CGG repeats, below 55 repeats is considered normal, between 55 and 200 repeats is called a premutation where mild symptoms are shown; over 200 repeats it is considered a full mutation presenting severe symptomatology. The studies conducted to understand FXS have been performed mostly in the knockout mouse model; however the results obtained in these animal models are difficult to be translated into humans due to different reactions to drugs and treatments. Moreover, these disorders are human specific. It has been suggested to use peripheral cells such as skin fibroblasts to analyze the physiological characteristics of the disease; these show an opportunity to analyze humans with FXS in a low invasive method. Proteomics allow us to study the protein universe of FXS cells and give us information of the alterations occurring in these group of diseases, indicating important therapeutical targets and allowing to propose new treatments. Method: Fibroblasts of FXS patients and apparently healthy individuals (AHI) were obtained from the Coriell Institute (New Jersey) repository and cultured in Earl MEM salts medium with 15% non-inactivated fetal bovine serum. The cells were characterized by immunofluorescence detection of Vimentin and differential expression of FMRP. The cells were cultured to reach a monolayer on nine T300 flasks to obtain enough protein for the proteomic analysis (aprox. 1 mg). The samples were processed at USAI unit (UNAM Chemistry Faculty) where 2-DE and mass spectrometer shotgun analyses were made. Proteomics results were confirmed using Western blot techniques. Results: Proteomics show a deregulation in pathways involved in protein recycling such as Ubiquitin C protein and Ubiquitin peptidase 5, we also found a deregulation of genes related to gene expression. Conclusion: Proteomic analysis of skin

fibroblasts obtained of FXS patients show alterations in several pathways related to the pathology, meaning this tool is useful in the study and proposal of new therapeutic approaches and biomarkers.

Title: Sex-specific Associations between EEG Frontal Asymmetry and Clinical Features in Fragile X Syndrome

Authors: *J. E. NORRIS[1], L. M. SCHMITT[2], L. A. DE STEFANO[2], E. V. PEDIPATI[3], J. A. SWEENEY[4], C. A. ERICKSON[3], L. E. ETHRIDGE[1];
[1]Psychology, Univ. of Oklahoma, Norman, OK; [2]Pediatrics, [3]Psychiatry, Cincinnati Children's Hosp. Med. Ctr., Cinncinati, OH; [4]Psychiatry, Univ. of Cincinnati Col. of Med., Cinncinati, OH

Abstract: Fragile X Syndrome (FXS) has a clinical presentation that includes intellectual disability and autism-like symptoms. FXS electroencephalography (EEG) biomarkers of sensory processing have been previously demonstrated by our group, but assessment of neural differences between hemispheres and clinical outcomes is limited, particularly in regard to sex differences. Thirty-eight adolescent and adult participants with the full mutation FXS [Mean age = 25.5, SD = 10.1; 13 females], and forty age- and sex- matched controls [Mean age = 27.7, SD = 12.1; 17 females] listened to an amplitude modulated auditory chirp stimulus which changed in frequency over time during continuous EEG. Relationships between neural stimulus processing measures and neural power between hemispheres in the theta and alpha frequency bands (alpha and theta asymmetry) during the pre-stimulus period were assessed. Asymmetry measures also were correlated with clinical measures. Males and females with FXS trended toward differences on theta asymmetry, $t(34) = 1.59$, $p = .09$. Males with FXS also trended toward difference from controls on alpha asymmetry, $t(43) = -1.77$, $p = .08$. In females with FXS, increased SCQ scores correlated with increased right-hemisphere alpha power ($r = -.796$, $p = 0.01$). Increased Vineland play/leisure behaviors correlated with increased left-hemisphere theta power ($r = -.689$, $p = .03$). In males with FXS, increased left-hemisphere alpha power correlated with increased ABC inappropiate speech ($r = -.450$, $p = .05$) and increased Sensory Profile avoidance scores ($r = -.693$, $p = .01$). Increased alpha power on the right was correlated with increased ABC social avoidance ($r = .468$, $p = .04$). Theta/alpha power ratios are generally atypical in FXS and EEG frontal asymmetry may exhibit sex-effects, though groups did not significantly differ in frontal asymmetry. Alpha asymmetry may play a role in presence of social-communication deficits

associated with autism in females with FXS, whereas alpha asymmetry may play a greater role of behavioral phenotypes more specific to FXS in males. Our findings suggests a complex role for alpha/theta frequencies. Males with FXS may utilize alpha power differently in each hemisphere for specific types of baseline neural processing. Alpha asymmetry may mechanistically underlie the lateralized finding between clinical measures of sensory avoidance and social avoidance in males with FXS by modulating sensory processing differently across the hemispheres. Our study extends previous research findings that address general alpha and theta abnormalities in FXS and may be useful by adding specificity to prior established biomarkers.

Title: Repurposing Fragile X drugs to inhibit SARS-CoV-2 viral reproduction

Authors: *C. J. WESTMARK[1], M. KISO[3], P. HALFMANN[2], P. R. WESTMARK[1], Y. KAWAOKA[2];
[1]Neurol., [2]Pathobiological Sci., Univ. Wisconsin, Madison, WI; [3]Inst. of Med. Sci., Tokyo, Japan

Abstract: The COVID-19 pandemic is a global health crisis that requires the application of interdisciplinary research to address numerous knowledge gaps including molecular strategies to prevent viral reproduction in affected individuals. We propose a novel therapeutic strategy to repurpose metabotropic glutamate 5 receptor (mGluR5) inhibitors to interfere with viral hijacking of the host protein synthesis machinery. Negative allosteric modulators (NAMs) of mGluR5 are potent, non-competitive, selective and systematically active allosteric antagonists that are under study for a range of indications including fragile X syndrome (FXS) where these drugs rescue disease phenotypes in multiple preclinical models and have been safely tested in clinical trials. Herein, based on molecular modeling data, we demonstrate that SARS-CoV-2 RNA has high potential to sequester the RNA binding protein FMRP, which is absent in FXS and leads to exacerbated protein synthesis, thus preventing the normal function of FMRP to inhibit protein synthesis. We further demonstrate that mGluR5 NAMs could be a prophylactic treatment to slow viral protein synthesis in patients infected with SARS-CoV-2. Treatment of VeroE6/TPMRSS2 cells with the mGluR5 inhibitor CTEP reduced SARS-CoV-2 viral plaque load with an IC50 of 13.1 μM. The inclusion of mGluR5 NAMs as part of a drug cocktail

approach to combat COVID-19 offers the advantages of: (1) extensive preclinical research regarding its mechanism of action; (2) prior safety testing in human clinical trials of FXS; (3) numerous mGluR5 NAMs available; (4) orally dosed; (5) protein target ubiquitously expressed including the lungs; (6) less expensive to produce small molecule drugs; and (7) targets a post-transcriptional gene regulatory step in viral production not addressed by other therapies under investigation. In addition, blockade of mGluR5 activity prevents an increase in proinflammatory cytokines and chemokines, which may quell the cytokine storm. Herein, we provide a mechanistic-based hypothesis and data to support testing mGluR5 inhibitors in COVID-19.

Title: Dna methylation editing of X-linked intellectual disability genes via adeno-associated viruses

Authors: *J. A. HALMAI, C. GONZALEZ, P. DENG, J. J. WALDO, F. BUCHANAN, J. CARTER, C. WELCH, D. CAMERON, K. FINK;
UC Davis, SACRAMENTO, CA

Abstract: Despite only containing about 5% of the human genome, there are approximately 40 known X-linked intellectual disability genes present on the X-chromosome with female phenotypic expression. In females, monogenic disorders with an X-linked dominant pattern of inheritance result in a mosaic of cells expressing the mutant and wild-type alleles. One of the alleles becomes epigenetically silenced via a dosage compensation mechanism called X-chromosome inactivation. A large number of genes are able to escape from X-chromosome inactivation. These escapees have a specific epigenetic signature associated with them, particularly reduced levels of 5-methylcytosine in CpG island promoters. A potential therapeutic approach previously demonstrated by our group for a gene on the X-chromosome is to activate the silenced wild type allele in cells expressing a loss-of-function mutant allele, rewriting the epigenetic signature of an escapee. Here, we demonstrate reactivation of two genes involved in X-linked intellectual disabilities in patient-derived induced pluripotent stem cells and neural stem cells, *CDKL5* and *MECP2*. We demonstrate that gene reactivation is possible via DNA methylation editing of the promoter regions using CRISPR/dCas9. In addition, our group demonstrates that this approach is readily translatable via the employment of intein-mediated trans-splicing of large dCas9 effector fusion proteins, allowing delivery to the central nervous system *in vivo* via adeno-associated viruses. Our approach holds great promise for those suffering from X-linked dominant disorders of the CNS.

Title: Social and locomotor behaviour in MECP2 mutants: Zebrafish model of Rett Syndrome

Authors: *P. CRONELL[1], S. SHAMS[2], L. WESTBERG[3];
[1]Neurosci. and Physiol., Gothenburg, Sweden; [2]Pharmacol., Univ. of Gothenburg, Goeteborg, Sweden; [3]Inst. of neuroscience and physiology, Gothenburg, Sweden

Abstract: Rett syndrome, an X-linked neurodevelopmental disorder exclusively affects females and is characterized by slowed development, loss of purposeful use of the hands, slowed brain and head growth, seizures and intellectual disability. Another feature in children with Rett syndrome are autistic-like behaviours such as loss of social interaction and communication. Deficits in the X-linked gene methyl-CpG binding protein 2 (*MECP2*) has been identified as the genetic cause of Rett syndrome, and *MECP2* mutations are observed in other phenotypic groups such as people diagnosed with autism and X-linked mental retardation disorders. As an *in vivo* model that is easily modified genetically and allows generation of hundreds of test subjects, the vertebrate species zebrafish (Danio rerio) holds many advantages for studying *mecp2* functions. Here, using heterozygous parents, we generated and investigated social behaviour, locomotor activity, and propensity to seizures in zebrafish lacking *mecp2*, compared to wildtype siblings (n > 20). Social preference test was investigated in 21-days-old siblings to determine phenotypes for fish lacking one or both copies of *mecp2*. To determine the locomotor activity in response to a stimulating convulsant, wild-type fish and heterozygous and homozygous mutant fish (n >70) were treated with pentylenetetrazol (PTZ, 0, 5, 10 µMol solution, water immersion) and general locomotor activity and burst-like and circling movements were measured at 7-days of age. Genotypes were confirmed for all subjects following behavioural recordings. Our results show that lack of *mecp2* did not change social preference for visual social stimulus in heterozygous or homozygous mecp2 mutants at 21-days of age. In contrast, locomotor activity in response to 10 µMol PTZ solution was significantly affected in both homozygous *mecp2* mutant fish and in heterozygous *mecp2* mutant fish, compared to wildtype siblings at 7-days of age (but not for 5 µMol PTZ solution). These findings help us characterize the behavioural phenotypes resulting from manipulation of *mecp2* gene and allow modelling of social and non-social behaviours seen in developmental disorders such as Rett syndrome. Our work also highlights the potential of future investigations of zebrafish *mecp2* gene towards generating better models of Rett syndrome and other related disorders.

Abstract: Rett Syndrome (RTT, OMIM 312750) is a progressive and pervasive, X-linked neurodevelopmental disorder that predominantly affects girls, who exhibit symptoms by early childhood. The vast majority of typical RTT cases is triggered by a sporadic mutation in the methyl CpG-binding protein 2 (MeCP2) gene. Although most research has focused on postnatal mice and humans displaying clinical symptoms, recent studies have shown that MeCP2 deficiency triggers molecular and cellular defects at very early stage of embryonic brain development, prior to clinical manifestation. We used isogenic RTT patient-derived induced pluripotent stem cells to generate 3D human cerebral organoids to recapitulate these early developmental events and to better understand the molecular and cellular events that underlies RTT pathology. Previously, we showed that MeCP2 deficiency was linked to dysregulation of the AKT/ERK pathway, which led to an increase in neural progenitor proliferation and concomitant decrease in neurogenesis and neuronal migration and maturation (Mellios et al., *Molecular Psychiatry* 2018). In this current study, we further investigated the molecular underpinnings of the deficits in neuronal migration observed in RTT organoids. Using genetic expression of fluorescent markers, and immunostaining, combined with confocal and multi-photon microscopy, we found that, although the morphology and polarity of radial glial cells were mostly preserved, neuronal migration patterns (speed, trajectory, and distance) were disrupted in RTT MeCP2 mutant organoids compared to isogenic controls. We then used transcriptomic, proteomic and phospho-proteomic techniques to screen for dysregulated adhesion molecules downstream of RTT MeCP2 mutations. We found an increase in the phosphorylation of the Reelin signaling adaptor protein, DAB1, at the tyrosine (Y) 232 residue. By introducing a dominant-negative phospho-null Y232F plasmid construct, and an DAB1 overexpression construct in the ventricles of RTT organoids and isogenic controls, here we probe the contribution and mechanisms of DAB1 in migration deficits observed in RTT organoids, through the regulation of cell adhesion. By using small molecules to modulate the AKT signaling pathway, we interrogate the links between DAB1 phosphorylation, adhesion, neuronal migration and signaling. These findings will further clarify the role and mechanisms of early deficits during cortical development in RTT.

Title: Investigating the effects of genetically increasing MECP2 dosage in mouse models of typical and atypical Rett syndrome

Authors: *S. D. VERMUDEZ[1,2], R. G. GOGLIOTTI[4], B. ARTHUR[2], A. BUCH[2], C. MORALES[2], Y. MOXLEY[2], H. RAJPAL[2], P. J. CONN[1,2,3], C. M. NISWENDER[1,2,3];

Abstract: *De novo* loss-of-function (LOF) mutations in the transcription factor methyl-CpG-binding protein 2 (MeCP2) are the main cause of the neurodevelopmental disorder Rett syndrome (RTT). Seminal studies have shown that clinical symptoms are recapitulated after knock-out of the murine *Mecp2* locus or knock-in of pathogenic mutations. Furthermore, normalizing *MECP2* gene dosage rescues phenotypes in mouse models. However, this approach is complicated by a potentially narrow therapeutic window as a 0.5x over-expression of MeCP2 can cause adverse effects that resemble symptoms of a related disorder known as *MECP2* duplication syndrome (MDS). The therapeutic window is predicted to be further impacted by hypomorphic MeCP2 mutations where expression and function of MeCP2 is not completely ablated. Additionally, there are cases of atypical RTT, wherein the patient is *MECP2* mutation-negative but has another compromised gene, such as the transcription factor 4 (*TCF4*). *TCF4* LOF mutations primarily lead to the diagnosis of Pitt-Hopkins syndrome (PTHS), which has significant overlap in symptomology as RTT. **Therefore, we hypothesize that increasing MeCP2 dosage will (1) lead to MDS-like phenotypes in RTT mice harboring a hypomorphic MeCP2 mutation and (2) improve symptoms in PTHS model mice.**
We interrogated these hypotheses at the preclinical level by crossing MDS model mice (*MECP2*$^{Tg1/o}$) to RTT mice with a hypomorphic MeCP2 mutation (*Mecp2*$^{R133C/y}$ or *Mecp2*$^{R133C/+}$) or PTHS mice (*Tcf4*$^{+/-}$). Behavioral characterization was performed in mice with and without the *MECP2* transgene. In the hypomorphic mutant RTT mice, we observed reversal of RTT phenotypes in the male *Mecp2*$^{R133C/y}$ animals; in contrast, female *Mecp2*$^{R133C/+}$ mice with the *MECP2* transgene exhibited MDS-like phenotypes in anxiety, motor coordination and contextual fear learning and memory. Control experiments with heterozygous RTT mice (*Mecp2*$^{+/-}$) illustrated that these MDS-like phenotypes are due to the *R133C* mutation. Interestingly, expression of the *MECP2* transgene in the PTHS mice rescued behavioral phenotypes of hyperlocomotion, and attenuated anxiety and contextual freezing. Molecular studies showed that MeCP2 does not impact Tcf4 expression, indicating a more complex relationship between these

two proteins, which we are exploring with RNA-sequencing studies. Overall, our data suggest that the effects of a 1x increase in MeCP2 dosage is dependent on *MECP2* mutation, and safety may need to be further considered and evaluated in the context of hypomorphic MeCP2 mutations; in contrast, at present, increasing MeCP2 may induce favorable effects in disorders with overlapping symptoms to RTT, such as PTHS.

Title: Dscam overexpression replicates neuronal morphology alterations observed in human Down syndrome iPSC-derived neurons during development.

Authors: *M. AGRAWAL[1], K. WELSHHANS[3,2];
[1]Sch. of Biomed. Sci., [2]Sch. of Biomed. Sciences, Dept. of Biol. Sci., Kent State Univ., Kent, OH; [3]Dept of Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: Down syndrome results from the triplication of human chromosome 21 (HSA21). It affects 1 in every 700 live births within the United States and is the most common genetic cause of intellectual disability. Multiple genes are implicated in this phenotype, including Down Syndrome Cell Adhesion Molecule (DSCAM). *DSCAM* is located on HSA21 and regulates the formation of neuronal connectivity in the developing brain. DSCAM is a member of the immunoglobulin superfamily, a transmembrane protein and can act as a receptor for the axon guidance molecule netrin-1. Our lab has previously shown that *Dscam* mRNA is locally translated within growth cones, and dysregulation of this process interferes with proper axon growth. In the current study, we used two different models: 1) *Dscam* gain-of-function mice, which mimic the DSCAM overexpression occurring in Down syndrome, and 2) neurons derived from human induced pluripotent stem cells (hiPSCs), which were created from apparently healthy individuals and individuals with Down syndrome. In the experiments using *Dscam* gain-of-function mice, hippocampal neurons were isolated from E17 mouse pups and cultured for 2 days *in vitro*. We found that overexpression of *Dscam* leads to impaired axon growth, and reduces axon branching *in vitro*. Using the Dunn chamber axon guidance assay, Dscam-overexpressing neurons did not show axon turning in response to netrin-1, as compared to wild-type neurons. Dscam-overexpressing neurons also showed decreased soma area, and a significant reduction in the number of dendrites and total neurite length. In the experiments using hiPSC-

derived Down syndrome neurons, we observed a reduction in axon length and impaired axon branching. These neurons also had a smaller soma area and growth cone area, and a significant reduction in total neurite length. Thus, axon growth, branching, total neurite length and soma area were impaired in both *Dscam* gain-of-function mice and hiPSC-derived Down syndrome neurons. These types of changes in neuronal morphology can lead to altered neuronal connectivity. Taken together, these results suggest that *Dscam* plays an important role in the development of neuronal networks and should be further studied as a potential contributor to the connectivity deficits that occur in DS.

Title: The auditory mismatch negativity reflects accelerated aging in adults with Down's Syndrome

Authors: *C. AVANCINI[1], S. JENNINGS[1], S. CHENNU[2], V. NOREIKA[3], A. LE[1], T. BEKINSCHTEIN[1], M. J. WALPERT[1], A. J. HOLLAND[1], S. ZAMAN[1], H. A. RING[1]; [1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. of Kent, Canterbury, United Kingdom; [3]Queen Mary Univ. London, London, United Kingdom

Abstract: Down's Syndrome (DS) is associated with premature and accelerated aging and a propensity for early-onset Alzheimer's disease (AD). The early symptoms of dementia in people with DS may reflect frontal lobe vulnerability to amyloid deposition. The Mismatch Negativity (MMN) is a frontocentral event-related brain potential (ERP) component elicited by auditory violations. Predictive coding postulates that the brain creates neural predictions about future events by compiling statistical regularities from incoming stimuli. Within the MMN network, the MMN results from the failure of higher frontotemporal nodes to predict the incoming sensory input, which results in changes of coupling between the sensory and the frontotemporal cortices. In the typically developing (TD) population, the MMN response has been found to decrease with age. In the cross-sectional phase of this study, the MMN was used to investigate the premature neurological aging hypothesis of DS. The MMN ERP and the MMN Global-Field Power (GFP) were elicited with an auditory global-local task and recorded with high-density EEG for 36 (15

females) DS adults aged 20 years or more (mean age 36.81, age range 22-55) and for 39 (21 females) age-matched TD controls (mean age 39.89, age range 20-59). Furthermore, a measure of cognitive impairment was taken in DS with the neuropsychological battery CAMCOG-DS. Bayesian model comparison was carried out on multilevel linear models testing whether the MMN predicted age in the two groups. An interaction between the MMN amplitude, both expressed in ERP and GFP, and group was found. In particular, MMN amplitude predicted age in DS but not in TD. In the longitudinal phase, we evaluated the MMN as a potential predictor of cognitive decline. In a one year follow-up 34 adults with DS underwent the second administration of the CAMCOG-DS. Bayesian model comparison was carried out on multilevel linear and curvilinear models testing whether the MMN obtained at the first time-point was predictive of cognitive decline one year later as measured by changes in CAMCOG-DS scores. However, neither amplitude nor latency of the MMN predicted cognitive decline one year later. Our study shows that in our cohort the MMN amplitude reflects accelerated aging in DS but not in TD, suggesting that MMN amplitude may be a sensitive marker of early onset AD in the DS population. On the other hand, neither MMN amplitude or latency predicts cognitive decline one year later. Gender differences were not explored in our analyses, neither in the cross-sectional nor in the longitudinal phase.

Title: Distinct effects of social defeat stress in adolescence vs. adulthood on the Netrin-1/DCC pathway, prefrontal cortex dopamine and cognition

Authors: *A. H. PANTOJA URBAN*[1], P. VASSILEV*[2], M. GIROUX[4], D. NOUEL[4], G. HERNANDEZ[4], T. ORSINI[4], C. FLORES[3,4];
[1]Integrated Program in Neurosci., [3]Psychiatry and Dept. of Neurol. and Neurosurg., [2]McGill Univ., Montreal, QC, Canada; [4]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Exposure to social stress, such as bullying or domestic violence, is a risk factor for psychiatric disorders. Social stress can be especially harmful during adolescence when the brain

is still maturing, rendering it sensitive to environmental influences. An important adolescent maturational process is the gradual unfolding of the dopamine (DA) innervation to the prefrontal cortex (PFC). The guidance cue Netrin-1 and its receptor, DCC, control the growth of DA axons from the nucleus accumbens (Nacc) to the PFC throughout adolescence. Alterations in the Netrin-1/DCC pathway during this period lead to dysregulated PFC DA connectivity and to changes in cognitive performance later in life. Previous studies in rodents have shown that the response of *adult* animals to social stress involves the DA system and DCC. However, the potential age-specific impact of social stress *in adolescence* on the Netrin-1/DCC pathway and the maturing DA system has not been investigated. To this end, we established an accelerated social defeat (AcSD) stress paradigm to expose adolescent and adult male mice to social stress and categorised them as "resilient" or "susceptible" based on social avoidance behaviour. Following AcSD in adolescence, the majority of mice are resilient and exhibit less-anxious/more risk-taking behaviour, while AcSD in adulthood leads to a majority of susceptible mice without altering anxiety-like traits. AcSD in adolescence, but not adulthood, dysregulates DCC and Netrin-1 expression in mesolimbic DA regions and alters DA connectivity in the matured PFC. The nature of these changes differs between resilient and susceptible groups. Following AcSD in adulthood, cognitive function remains unaffected, but both resilient and susceptible mice exposed to AcSD in adolescence show deficits in inhibitory control when they reach adulthood. The distinct effects of social stress on the Netrin-1/DCC pathway, social behaviour, and cognition between adolescence and adulthood highlight adolescence as a unique period for vulnerability and resilience to mental illness and indicate that environmental factors change the developing and the matured brain through fundamentally different mechanisms.

Abstract: Background: Obesity is a multifactorial disorder that requires environmental influences to manifest. Some individuals are more susceptible than others to gain weight and become obese when exposed to psychosocial stress during adolescence. However, the neurobiological adaptations that contribute to this susceptibility remain unclear. Here we sought to determine the adverse synergy of an obesogenic diet and psychosocial stress (PSS) on cardiometabolic and immune function, brain structure, and behavior. **Methods:** Fifty-six adolescent Lewis rats (postnatal day, PND21) were fed for five weeks with an experimental Western-like high-saturated fat diet (*WD*, 41% kcal from fat) or a matched control diet (*CD*, 13% kcal from fat). Subsequently, a group of rats ($n = 29$) was exposed to a well-established 31-day PSS model composed of a predator exposure in conjunction with social instability starting at PND60. We assessed the effects of the WD and PSS using a comprehensive battery of standard behavioral tests. The brains were collected for neurite orientation dispersion and density imaging (NODDI) and diffusion tensor imaging (DTI) at PND107. **Results:** We found that WD/PSS rats exhibited increased weight gain (25%) relative to WD/Unexposed rats at three-weeks post-PSS. WD rats showed reduced diastolic pressure and heart rate (both 10%) compared to CD animals. WD and PSS synergized to reduce the open arm duration in the elevated plus maze (54% reduction) and social interactions in the social Y-maze (57% reduction) relative to controls. PSS significantly attenuated acoustic startle responses (28% reduction) while heightening the fear-potentiated startle (70% increase) relative to unexposed controls. NODDI/DTI identified unique brain anatomical signatures in WD and PSS rats. **Conclusions:** Our findings confirm the adverse synergy of WD and PSS on health and behavior. This study contributes to enhancing our understanding of potential neurobiological adaptations by which obesogenic environments shape the maturational trajectories of resilience networks. We anticipate that this study will continue to inform needed biomarkers and interventions for improving the quality of psychosocial stress management, particularly in overweight and obese children.

Title: Moderate and heavy alcohol exposure effects on the proteome of fetal neural stem cell-derived extracellular vesicles

Authors: *M. LAI[1], N. COLLINS[1], D. CHUNG[1], S. WEINTRAUB[2], R. MIRANDA[1];
[1]Texas A&M Univ., College Station, TX; [2]UT Hlth. San Antonio, San Antonio, TX

Abstract: Prenatal alcohol exposure (PAE) is the leading cause of neurodevelopment disability worldwide, commonly resulting in growth and neurobehavioral deficits. Neural stem cells (NSCs) are an important target of ethanol during the late first through second trimester, during the peak period of fetal neurogenesis. The NSC microenvironment is rich in sub-200 nanometer-sized extracellular vesicles (EVs), that may function as a mode of intercellular communication, transporting proteins, lipids, and RNAs between NSCs and their progeny. Using fetal mouse derived cortical neuroepithelium, cultured ex-vivo as non-adherent neurosphere cultures, we previously found that ethanol exposure resulted in significant elevation of miRNA cargo like miR-140-3p in EVs, which direct NSCs towards an aberrant lineage. EVs may amplifying PAE's temporal and spatial effects in the NSC niche, resulting in an overall decline in neurogenic capacity. For this study, we further investigated the impact of ethanol on the proteome of NSC-EVs by employing quantitative mass-spectrometry to profile the protein expression across alcohol-treated and control NSCs. Ethanol-exposed NSCs significantly altered the profile of proteins packaged within EVs. Of the 3,617 consistently expressed EV proteins, moderate ethanol exposure (26mM) differentially regulated 65 proteins compared to controls, with >95% being upregulated, while heavy ethanol exposure (70mM) differentially regulated 108 proteins compared to controls, with ~66% being upregulated (Paired t-test, $p<0.05$; effect size, Cohen's $d>0.5$, $\alpha=5\%$, $1-\beta=0.8$**)**. For cells, in contrast, out of 4,698 expressed proteins, moderate ethanol exposure differentially regulated 492 proteins compared to controls, with >92% being downregulated, while heavy ethanol exposure differentially regulated 750 proteins, with >95% again being downregulated. Due to this contrast of protein upregulation in EVs and downregulation in cells, expression of proteins that were significantly altered in EVs by ethanol exposure were compared to the expression of the same proteins in cells. For both moderate and heavy ethanol exposures, the majority of affected proteins were upregulated in EVs but downregulated in cells. Therefore, ethanol exposure results in increased loading of specific proteins into EVs, at the expense of their intracellular levels in NSCs. Ongoing studies are focused on understanding the biological effects of ethanol-exposed EVs on NSC populations.

Title: Pathway enrichment analysis of the alcohol-sensitive proteins of fetal neural stem cell-derived extracellular vesicles

Authors: *E. A. PAYNE[1], K. LE[1], M. KIM[1], D. CHUNG[2], S. WEINTRAUB[3], R. C. MIRANDA[4];
[1]Texas A&M Univ. Hlth. Sci. Ctr. Col. of Med., Bryan, TX; [2]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX; [3]UT Hlth. San Antonio, San Antonio, TX; [4]Neurosci. & Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr, Col. of Med., Bryan, TX

Abstract: Prenatal alcohol exposure (PAE) can result in growth deficits, and is the leading cause of neurodevelopment disability worldwide. Neural stem cells (NSCs) are particularly vulnerable to alcohol (ethanol) exposure during the late first through the second trimester, when they are most extensively involved in neurogenesis. NSCs reside in a complex microenvironment rich in sub-200 nanometer-sized extracellular vesicles (EVs), which are shown to traffic protein, lipid, and RNA cargo between cells, and may serve as a mode of intercellular communication. We used cortical neuroepithelium sourced from fetal mice cultured ex-vivo as non-adherent neurosphere cultures and found a significant increase of miRNA cargo in EVs as a result of ethanol exposure. The NSCs are directed toward an aberrant astroglial lineage following the significant elevation of miRNA cargo such as miR-140-3p in EVs. EVs may amplify PAE's spatial and temporal effects across the NSC niche, to further inhibit their neurogenic capacity. Using quantitative proteomics across treatment groups of 18 EVs and the 18 parent NSCs to profile the protein expression, we further investigated the effect of ethanol exposure on the proteome of NSC-EVs. Our analyses show that NSC-derived EVs express ~86% of proteins needed for eukaryotic translation initiation, implying that EVs carry with them the ability to translate mRNAs in recipient cells. Statistical and pathway overrepresentation analyses showed that moderate ethanol, ~26 mM, resulted in a significant increase in proteins of the Nonsense-Mediated Decay (NMD) pathway in EVs, whereas a higher dose, ~70 mM, resulted in EV overexpression of mitochondrial proteins that constitute a Danger-Associated Molecular Pattern (mito-DAMP) pathway. NMD is an important surveillance pathway that reduces errors in gene expression by eliminating premature stop codon-containing mRNA transcripts. Consequently, NMD pathway proteins sequestered in EVs are hypothesized to transfer neuroprotection to cells where the capacity to correct errors in protein translation may be depleted. Eukaryotic cells under high stress, expel mitochondrial proteins as a 'danger' signal that activates 'pattern recognition' receptors and pro-inflammatory responses in target cells. Consequently, mito-DAMPs in EVs from heavy-ethanol-exposed NSCs are predicted to spread inflammation through the NSC microenvironment, compromising NSC growth and differentiation. Collectively, these studies identify EVs as a novel source for communicating stress responses, in an ethanol dose-related manner, to cells within the fetal neural stem cell niche.

Title: Genetic variation in corticolimbic DCC gene networks predict impulsivity in children

Authors: *J. RESTREPO[1], I. POKHVISNEVA[2], Z. WANG[2], M. MEANEY[2], P. SILVEIRA[3], C. FLORES[3];
[2]Ludmer Ctr. for Neuroinformatics and Mental Hlth., [3]Dept. of Psychiatry, [1]McGill Univ., Montreal, QC, Canada

Abstract: By the time humans reach adolescence, most of the neuroanatomical foundations are set in place. An important exception is the establishment of dopamine connectivity in the prefrontal cortex (PFC), which reaches full maturation in adulthood. Altered PFC dopamine connectivity and function is associated with impulsive phenotypes. Given the central role of the Netrin-1/DCC signaling pathway in the delayed development of the PFC dopamine circuitry, we investigated whether a polygenic score based on *DCC* gene co-expression networks in two main mesocorticolimbic dopamine terminal regions -the PFC and the nucleus accumbens (NAcc) - would associate with impulsivity-related phenotypes in community samples of children. We created a list of genes co-expressed with *DCC* in the PFC and NAcc and explored its enrichment for potential, and then compiled single nucleotide polymorphisms from these genes in a score using the SNP-gene expression association betas described in GTEx. We investigated the ability of this novel genetic score to predict impulsive phenotypes in 3 ethnically diverse cohorts. A lower polygenic score was associated with higher impulsive choice in 6-year old children tested in the Information Sampling Task (n=197). Lower polygenic scores were also associated with greater impulsive action in 6 (n=398) and 10 (n=3318) year old kids, as measured with the Stop Signal Reaction Time Task.This novel biologically informed genetic score, which aims to capture the activity of the *DCC* co-expression networks in two key regions for developing dopamine neurons, can predict elements of impulsivity in humans, suggesting a key role for these gene networks in the proper maturation of PFC dopamine connectivity

Title: Synching the systems: an executive-functions based training is related to a greater synchronization between the somatomotor and auditory networks in dyslexia

Authors: *T. HOROWITZ-KRAUS[1], R. FARAH[2], A. DWORETSKY[3], R. COALSON[3], S. PETERSEN[4], B. SCHLAGGAR[5];
[1]Pediatrics, Cincinnati Children's Hosp. and Technion, Israel, Cincinnati, OH; [2]Technion, Haifa, Israel; [3]Radiology, [4]Washington Univ., St Louis, MO; [5]Kennedy Krieger, Baltimore, MD

Abstract: Aim: Dyslexia is a specific reading disorder characterized by phonological, sensory-motor, orthographical, and executive function (EF) deficits. In a series of previous studies, we have demonstrated that a specific EF-based intervention was associated with decreased glutamate levels in EF regions (anterior cingulate cortex, ACC), greater activation within the dorsolateral prefrontal cortex and ACC, increased functional connectivity within and between EF networks, and in event-related potentials associated with error monitoring, all related to reading improvement in children with dyslexia. There we suggested that this intervention “synchs” the functional connections between networks supporting phonological/auditory processing, visual processing, somatomotor functions, and EF abilities. Here, we aim to examine this assumption across tasks and conditions in children with dyslexia. Methods: Thirty one 8-12 years-old children with dyslexia and 46 typical readers were recruited and trained on EF-based reading program for 8 weeks, 3 times a week. Reading ability was assessed pre/post intervention. Several functional MRI tasks were acquired pre/post intervention, including a reading task, a Stroop task, story listening, sentence comprehension tasks and a resting-state fMRI condition. The task-regressed connectivity data was subjected to an omnibus test to determine whether there were whole brain differences (object-oriented data analysis; OODA) using a 300 regions-of-interest-based atlas. Next, block-wise permutation tests were performed on the connectivity matrices to determine which network blocks were driving brain-wide differences. Finally, a regression of reading improvement with network connectivity changes was performed on a subset of significant within/between-network blocks. Results: Training was related to increased word reading accuracy and was associated with greater functional connectivity between the dorsal and lateral somatomotor and auditory networks in children with dyslexia. Better word reading was also related to a greater functional connectivity within the dorsal attention network in typical readers Conclusions: The results suggest that reading improvement following the EF-based reading intervention involves two distinct paths in children with dyslexia and typical readers: whereas in children with dyslexia there is a better synchronization between the networks related

to articulation/phonology (somatomotor networks) and auditory processing networks, typical readers show greater within network connectivity related to visual processing.

Title: Comparing age dependent statistical motor biomarkers in neurodevelopmental disorders

Authors: *J. V. JOSE;
Indiana Univ..

Abstract: We have studied the motor kinematic abilities of individuals with Neurodevelopmental Disorders (NDD). In particular, subjects with Autism Spectrum Disorder (ASD), Attention Hyperactive Deficit Disorder (ADHD) and comorbid ASD and ADHD (ASD+ADHD). We used high definition kinematic sensors to measure the kinematic angular variables of *velocity, acceleration and jerk,* of the arms rotations *as well the linear acceleration and jerk of upper extremity movements. T*he subjects moved their arm towards touch screen targets appearing in the monitor. These angular and linear variables show millisecond timescale fluctuations in the trajectory, away from naked eye detection. We carefully filtered out the electronic noise from the physiological statistical fluctuations in these kinematic variables. We analyzed the probability distribution in the physiological signals during reaching and arm return to its initial lap position in terms of their corresponding nearest-neighbor (NN) kinematic fluctuations in the variables studied. To extract the relevant NDD cognitive physiological information, we introduced a **new** Fano-Factor (FF) type biomarker to describe the NN probability distribution fluctuations. Presently, we have studied 8-ASD, 13-ASD+ASHD and 4-ADHD, subjects. To enhance the analysis of our present results we have implemented a machine learning *Support Vector Machine Learning* tool. This has allowed a separation in the cognitive conditions of their diagnoses for the NDD subjects studied *as a function of age*. As found in our previous study, using a different biomarker, we did not find age changes in the FF biomarker age in the new ASD subjects studied [1]. However, we did find that subjects with ASD+ADHD show age dependent changes, as well as in the small sample of ADHD subjects so far studied. This is consistent with clinical studies that record improvement in clinical ADHD severity and impairment with age. Our preliminary results provide a new biomarker that allow us to characterize the cognitive abilities of subjects with different neurodevelopmental disorders as

seen in their motor abilities.[1] Wu, D., José, J. V., Nurnberger, J. I., and Torres, E. B. Scientific Reports (Nature), 8(1):614, 2018.

Title: Motor activity declines across adolescence in humans and monkeys

Authors: *J. L. CAMERON[1,2], S. KANG[2,3], M. XIAO[5], L. ALEXANDER[5], M. MILHAM[5], V. ZIPUNNIKOV[4], K. MERIKANGAS[2,5];
[1]Psychiatry, Univ. Pittsburgh, Pittsburgh, PA; [2]Natl. Inst. of Mental Health, NIH, Bethesda, MD; [3]Bloomberg Sch. of Publ. Hlth., [4]Johns Hopkins Univ., Baltimore, MD; [5]Child Mind Inst., New York, NY

Abstract: Background There is emerging evidence for a substantial decline in motor activity (MA), a core feature of several human disorders, across adolescent development. However, elucidation of the mechanisms is complicated by contextual factors that constrain MA in human studies. The availability of accelerometry as an unobtrusive tool to obtain objective indices of MA in both humans and non-human primates provides an ideal opportunity for cross species research on MA without the social restrictions in human samples. The aims of this poster are: (1) to evaluate the contribution of age, sex, pubertal status and contextual factors on changes in MA in a human sample of adolescents; and (2) to examine biologic, genetic, and environmental factors associated with MA in non-human primates in a natural environmental context. **Methods:**Human: 1520 youth (mean age 10.2; range 5-21) from the Healthy Brain Network, a study of a broad range of behavioral, emotional, and cognitive assessments in youth in the New York area. Accelerometry was assessed for one week with the Actigraph (wGT3X-BT). Two features derived from accelerometry including Total Log Transformed Activity Count (TLAC) across 24 hours (TLAC), and Total Sedentary Time (TST).Monkeys: 145 monkeys (n=69 females; 76 males) from the Oregon National Primate Research Center assessed with a neck worn Actical device for 3-10 days at two time points (ages 23-30 mo- pre-pubertal) and (34-43 mo-peri/post pubertal). TLAC and TST were compared at pre-pubertal and post pubertal time points among male and female monkeys. **Results:**In the human sample, there was a monotonic decline in TLAC and an increase in TST in both male and female adolescents across ages 8-12. Analyses yielded significant effects for changes in both age and pubertal status, but pubertal status was more influential in males then females. Likewise, there was a significant decrease in TLAC and an increase in TST across the pre and post pubertal assessments in monkeys, with

females having higher TLAC and lower TST than males at both time points. **Discussion:**These findings demonstrate the importance of the influence of biologic factors involved in pubertal development on the decline in motor activity in adolescents. Use of the common phenotype and measure of motor activity facilitates our ability to pursue cross species studies of the genetic, environmental and developmental influences on motor activity. The adolescent decline in MA may provide etiologic insight for several human disorders that emerge at adolescence.

AbstractAttention deficit hyperactivity disorder (ADHD) is a heterogeneous neurodevelopmental disorder affecting ~10% of children in the United States. Latrophilin-3 (LPHN3) is a brain specific G-protein coupled receptor that is associated with increased risk of ADHD and treatment response. We characterized a global *Lphn3* knock-out (KO) rat usingCRISPR/Cas9 to delete exon-3 in rats. Global *Lphn3* KO rats are hyperactive and have egocentric and allocentric learning and memory (L&M) deficits. *Lphn3* KO rats also have altered striatal dopaminergic markers and hippocampal glutamatergic markers. To understand the dopaminergic contributions to the global *Lphn3* KO phenotype, we created a *floxed Lphn3* rat and then created an *Lphn3-TH-Cre* rat (cKO). Rats were tested in home-cage activity, egocentric L&M learning (Cincinnati water maze: CWM), and spatial L&M (Morris water maze (MWM)). *Lphn3* KO and cKO rats were hyperactive in the home-cage test. *Lphn3* KO and cKO rats both had longer latencies to escape in the CWM compared with controls, but the global KO rats were

worse. In the MWM, global KO rats but not cKO rats had reduced path efficiency on acquisition, reversal, and shift trials. LPHN3 is highly expressed in the striatum, and the results suggest a role of *Lphn3* in TH-positive neurons that project to the striatum and result in hyperactivity and egocentric learning and memory deficits.

Title: Neurodevelopmental risk factors ADNP and POGZ affect convergent transcriptomic and synaptic functions

Authors: *M. CONROW-GRAHAM, J. A. MARTIN, J. WILLIAMS, P. ZHONG, B. REIN, Z. YAN;
Dept. of Physiol. and Biophysics, State Univ. of New York at Buffalo, Buffalo, NY

Abstract: ADNP and POGZ are two top-ranking high-confidence risk factors for autism spectrum disorder (ASD) and intellectual disability (ID), but how they are linked to these neurodevelopmental disorders (NDD) is largely unknown. Both ADNP and POGZ are chromatin remodelers, which could profoundly affect gene transcription and cellular function in the brain. Using postmortem tissue from patients with ASD, we found diminished protein levels of ADNP and POGZ in the prefrontal cortex (PFC), a region highly implicated in NDD (n=10 pairs). Thus, to understand the functional role of these important risk factors, we designed an exploratory study to investigate how Adnp or Pogz reduction in mouse PFC affects behavioral, transcriptomic, and synaptic function. We used viral-based gene transfer to knock down *Adnp* and *Pogz* in PFC of male and female wild-type mice. Control littermates received virus coupled to GFP only. Stereotaxic injection was done at postnatal week 4, the point of critical PFC synaptic regulation. Behavioral testing revealed impaired NDD-linked cognitive task performance with *Adnp*- or *Pogz*-deficiency (3 batches, n=12-20/group). No sex differences were observed. RNA-sequencing demonstrated transcriptional upregulation induced by *Adnp*- or *Pogz*-deficiency (n=3/group), with significant overlap in upregulated gene targets. Gene ontology and HUB gene analyses indicated that the most affected functional category was inflammation, representing 48% of the commonly upregulated genes, which show remarkable similarity to multiple human findings of increased pro-microglial signaling in NDD. Patch-clamp recording of PFC pyramidal neurons showed impaired glutamatergic signaling mediated by AMPA and NMDA receptors in *Adnp*- or *Pogz*-deficient mice (n=15-30 neurons/group). Taken together, these findings suggest that a reduction in ADNP or POGZ leads to the elevation of

inflammatory genes in the PFC, causing increased microglial activation and impaired synaptic transmission. This results in impairment of PFC-mediated cognitive behaviors. This study has provided novel insights into the convergent actions of two top risk factors for NDD and potential intervention targets.

Inst., Montreal, QC, Canada; [7]Univ. of Manitoba, Winnipeg, MB, Canada; [8]SickKids, Toronto, ON, Canada; [9]Sickkids, Toronto, ON, Canada

Abstract: With the rising prevalence of autism spectrum disorders (ASDs), its broad range of encompassed neurodevelopmental disorders (NDDs), and absence of robust treatments, novel techniques are necessary to study the shared pathologies of the highly heterogeneous disorder. Large-scale sequencing studies have identified ~100-200 ASD high-risk genes involved in gene regulation and neuronal communication; however interactions at the protein level are largely unknown in neurons. To identify the shared protein interaction networks (PINs) of these ASD genes we are using the proximity protein-labelling technique, BioID, which we have adapted for screening in primary neurons. Using primary mouse cortical neurons and a number (>50) of unstudied and functionally characterized ASD genes involved in neuronal communication and cellular signaling, many involved in synapse formation and function, we are creating a publicly accessible database for the PINs. Preliminary BioID of 17 ASD-risk genes, including DLG4 (PSD95) a scaffold protein in the excitatory post-synapse, have revealed individual protein interaction networks that possess shared interactors between multiple ASD-risk genes. For many of these genes novel interactions were identified in previously unconnected networks, for example the involvement of TAOK2 in protein translation regulation and cellular respiration. We validated these newly associated TAOK2 PINs, and showed that Taok2 KO mouse cortical neurons have altered protein translation and mitochondrial respiration, which may contribute to excitatory synaptic deficits in Taok2 KO mice. This database also incorporates the impact of patient non-truncating, de novo missense variants, from multiple databases, including SFARI and

MSSNG, on the individual and shared PINs of high-risk ASD genes to study disease pathophysiology. BioID of GRIA1 and two patient de novo missense mutations revealed significant changes in its interaction with synaptic scaffold proteins and AMPA-receptor associated proteins, suggesting a strong impact on AMPA-receptor function. Furthermore, BioID was used to probe abnormal PPIs in compartments of mutant neurons cultured from genetic models of ASD. This highlights the use of BioID as a potential screen for compartments and signaling proteins in different genetic models of ASD and potentially, in human patient iPSC-derived neurons. Identification of core shared ASD-linked PINs will create a large-scale resource to categorize multiple ASD gene subsets and elucidate their relationship with the various neuronal communication and signaling pathways.

Title: Mnk1/2 kinases regulate memory and autism-like behaviours.

Authors: *G. LACH[1], K. CHALKIADAKI[1], M. HOOSHMANDI[2], M. JAFARNEJAD[3], A. KHOUTORSKY[2], ***C. G. GKOGKAS**[4];

Abstract: Downstream of Erk (extracellular regulated kinase) and p38 (mitogen-activated protein kinase) MAPK pathways, MAPK interacting protein kinases (Mnks), exert a plethora of biological functions in response to external stimuli (e.g. mitogens). Mnk1 and Mnk2 are known to phosphorylate several targets among which the eukaryotic translation initiation factor 4E (eIF4E) on Ser 209. In most tissues and cell types examined, phopsho-eIF4E (Ser209) is considered the key effector of Mnks in the regulation of mRNA translation. Yet, in *Eif4e*^{Ser209Ala} mice, hippocampal CA1 LTP and hippocampus-dependent behaviours (e.g. spatial memory and fear memory) were intact, suggesting that Mnks may possess additional key downstream effectors, other than eIF4E. Herein, we demonstrate that *Mnk1/2* deletion (DKO) in mice impairs synaptic plasticity, hippocampal learning, and memory and engenders autism-like behaviours, in contrast to phenotypes previously shown in *Eif4e*^{Ser209Ala} mice. These phenotypic alterations are accompanied by altered mRNA-specific translation, which is pronounced in synaptic

compartments. We reveal that there is only slight overlap between the brain translatome of *Eif4e*^{Ser209Ala} and Mnk DKO mice, comprising chiefly mRNAs coding for genes of the Extracellular Matrix (ECM), suggesting that substrates other than eIF4E may dictate the effects of Mnks in regulating brain function. Quantitative mass spectrometric analysis in Mnk DKO mouse brain further revealed pervasive changes in the phosphoproteome of whole brain and synaptosomes, including new targets and known syndromic Autism Spectrum Disorders (ASD) risk genes and Fragile X Mental Retardation Protein (FMRP) targets. Together, these data establish a previously unknown link between Mnks memory and autism-related behaviours, which is amenable to pharmacological manipulation.

Title: Identifying Cellular Phenotypes of Idic(15) neurons Using CRISPR-edited iPSC-derived neurons

Authors: *M. ELAMIN[1], T. M. ROBINSON[1], A. DUMARCHEY[2], C. STODDARD[2], S. J. CHAMBERLAIN[2], E. S. LEVINE[1];
[1]Neurosci., [2]Genet. and Genome Sci., Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: Dup15q syndrome is a neurodevelopmental disorder that results from duplications in the 11.2-13.1 region of the long arm of chromosome 15. These duplications primarily occur in two flavors: idic(15) in which a supernumerary isodicentric chromosome carries two extra copies of 15q11.2-13.1 and interstitial duplication in which a single extra copy of the region lies in tandem with the normal copy. Autism and epilepsy occur in the vast majority of Dup15q patients. In addition, affected children exhibit a range of intellectual disability and developmental delay. The syndrome only manifests when the duplication occurs on the maternally-inherited, not paternally-inherited allele. UBE3A, a maternally-expressed imprinted gene encoding an E3 ubiquitin ligase, is thought to play a critical role in Dup15q syndrome. To identify cellular phenotypes in Dup15q neurons, we performed patch clamp recordings from patient-derived human induced pluripotent stem cell (iPSC)-derived neurons harboring the idic(15) chromosome. We used CRISPR-Cas9 genome editing in these iPSCs to generate an isogenic line with the idic(15) chromosome completely removed to minimize the confounding effects of genetic variability between individuals. Compared to the corrected line, Dup15q neurons showed increased sodium current, larger action potential amplitude, and a higher firing frequency.

Changes in the sodium current and action potential amplitude appeared at an early point of in vitro development (8 wks), and persisted to 19 wks. Firing frequency was only significantly increased at 19 wks. Although UBE3A overexpression has been used to model Dup15q syndrome in mice, the contribution of this gene to the cellular phenotypes in human neurons is unknown. To determine if UBE3A overexpression is necessary, we knocked it down to control levels in Dup15q neurons using antisense oligonucleotides (ASO). This prevented the increased sodium current, action potential amplitude and firing frequency when UBE3A was knocked down early (at 6 wks), indicating that UBE3A overexpression is required for the development of these cellular phenotypes. In contrast, a late knockdown (at 16 wks) was unable to reverse these phenotypes. Activating the silent copy of UBE3A in neurotypical cells will lead to UBE3A overexpression. This will determine if UBE3A overexpression alone is sufficient for the development of Dup15q phenotypes. Elucidating the role of UBE3A in the electrophysiological phenotypes of Dup15q neurons may shed light on the functions of this ubiquitin ligase in neurons. Overall, these studies may help narrow down the most impactful therapeutic targets for treating Dup15q.

Title: Neuroligin1-dependent synaptic signaling is mediated through an interaction with the GEF protein Kalirin-7

Authors: ***C. TIAN**[1], J. PASKUS[2], K. ROCHE[2], B. HERRING[1];
[1]Biol. Sci., USC, Los Angeles, CA; [2]Receptor Biol. Section, NINDS, Behtesda, MD

Abstract: Neuroligin1 (NLGN1) is a profoundly synaptogenic cell adhesion molecule that is localized at the postsynaptic side of glutamatergic synapses. However, the mechanism by which NLGN1 promotes the formation of glutamatergic synapses is unknown. We performed an unbiased proteomic analysis of the RhoGEF protein Kalirin and identified a significant interaction between Kalirin-7 and NLGN1. This interaction was validated both in vitro and in vivo. Kalirin mediates the assembly of actin filaments and is essential for synaptic transmission. To determine whether NLGN1-induced enhancement in synapse function is mediated through Kalirin-7, we performed whole-cell patch clamp experiments in cultured hippocampal slices. We

find that increasing postsynaptic NLGN1 expression in CA1 pyramidal neurons promotes glutamatergic synaptogenesis, while eliminating the interaction between the NLGN1 and Kalirin-7 prevents NLGN1's influence on glutamatergic synaptic transmission. Together, our data reveal an intracellular effector of NLGN1 function that is required for NLGN1-mediated synaptogenesis and provide a direct link between NLGN1 and synaptic actin remodeling.

Title: Understanding The Role of SYNGAP1 in GABAergic Circuit Development and Function

Authors: ***V. V. JADHAV**[1,2], M. CARRENO-MUNOZ[1,2], T. BADRA[1,2], G. DI CRISTO[1,2], B. CHATTOPADHYAYA[1,2], J. MICHAUD[1,3];
[1]CHU Sainte Justine Res. Ctr., Montreal, QC, Canada; [2]Dept. of Neurosciences, [3]Dept. of Paediatrics, Univ. of Montreal, Montreal, QC, Canada

Abstract: Haploinsufficiency of Syngap1 gene encoding the Synaptic Ras-GTPase Activating protein is associated with intellectual disability, autism spectrum disorder and epilepsy. Syngap1 is a negative regulator of Ras and of AMPA receptor trafficking to the postsynaptic membrane, involved in regulation of synaptic plasticity and neuronal homeostasis. Mouse models of Syngap1 haploinsufficiency show alterations in synaptic plasticity, behavioral abnormalities and cognitive deficits. In particular, several studies have shown that Syngap1 regulates the time course of dendritic spine maturation in excitatory neurons; in contrast, the role of Syngap1 in inhibitory, GABAergic neurons is relatively uncharted. GABAergic neurons are a diverse class

of neurons with different morphology, connectivity and physiological properties. They play an important role in neural circuit development and plasticity. Parvalbumin (PV)-expressing interneurons, one of the major classes of cortical GABAergic interneurons, form synapses onto the soma and proximal dendrites of pyramidal cells and are involved in the synchronization of the firing rate of pyramidal cell populations. Previous in-vitro studies suggest that haploinsufficiency of Syngap1 affects the formation of PV cell synaptic connectivity with reduced inhibitory synaptic activity. In continuation with these previous observations, here we study the role of Syngap1 in PV cell development, in establishing balanced synaptic connectivity and proper network. To this end, we used both germline heterozygous Syngap1 mice, and Nkx2.1Cre dependent Syngap1 conditional knockout mice, to characterize both the excitatory (VGlut1+PSD95+) and inhibitory (PV+ Geph+) inputs to PV+ and non-PV+ cells. We further characterized cognitive behavior such as attention set shifting tasks, novel object recognition and social behavior in these mice. Preliminary data suggest that alteration in synaptic connectivity of PV cells in different cortical regions do contribute to observed overall behavioral and cognitive deficits. A better understanding of the role of Syngap1 in PV cell development and function is necessary to elucidate the cognitive deficits caused by Syngap1 haplosinsufficiency.

Title: High-resolution identification of engrailed-2 transcript in the ganglionic eminence of the developing mammalian brain

Authors: *J. S. MARTINEZ-FUENTES[1], M. COGSWELL[2], A. C. CASTELLO[3], V. BORRELL[3], S. J. RUSSEK[4];
[1]Biol., [2]Boston Univ., Boston, MA; [3]Dept. of Developmental Neurobio., CSIC & Univ. Miguel Hernandez, Alicante, Spain; [4]Pharmacol. and Grad Prog for Neurosci., Boston Univ. Sch. Med., Boston, MA

Abstract: Autism spectrum disorder (ASD), currently estimated to affect 1 in 54 people in the United States, is a neurodevelopmental condition associated with deficits in social interaction and communication, restricted and repetitive behaviors, and aberrant sensory processing. While genetic and environmental factors contributing to ASD vary widely, developmental dysfunction of the γ-aminobutyric acid (GABA) system of the brain has been implicated to underlie ASD. The midbrain-hindbrain patterning homeotic transcription factor, engrailed-2 (En2), is associated with ASD in humans, and a mouse model harboring a null mutation recapitulates behavior and

neuroanatomical abnormalities reminiscent of ASD as well as epilepsy. Interestingly, studies have revealed that En2-null mice show reduced GABAergic marker expression in the hippocampus and cortex, and neural stem cells of GABAergic lineage cultured from these mice display reduced neuron differentiation. The overarching goal of this project is to uncover the role of En2 and its associated signaling networks that drive proper GABAergic circuit development. Our recent *in vivo* work draws attention to the potential role of En2 in radial glial self-renewal and subsequent differentiation, with an emphasis on the birth of GABAergic interneurons. Here, we investigate for the first time the spatial expression of *En2* mRNA at the ganglionic eminences (GE), the major birthplace of GABAergic interneurons, in wild-type E13 mouse embryos. Considering this spatial pattern of *En2* in the GE is completely unknown, we use sensitive RNAscope *in situ* hybridization with widefield and confocal fluorescence microscopy to characterize the distribution of *En2*, guided by tissue co-labeling of GABAergic lineage markers including *Gsx2* and *Dlx2* mRNA. We find that *En2* mRNA is regionally widespread, but sparse in its density across all layers of the major subregions (medial, lateral, caudal) of the GE. In analyzing individual cells of selected radial columns at the lateral GE, we observe *En2* puncta counts consistent with roughly 1-3 transcripts per cell, with ~70% of surveyed cells expressing *En2*. Analysis of *En2* at other GE regions is ongoing, including lineage marker co-expression that may suggest cell-type specific functions. Taken together with results of En2 knockdown in GE via mouse electroporation, widespread but sparse *En2* mRNA presence suggests it may play a role in developmentally important cells of the region, including radial glia progenitors. Our findings raise questions as to the function of En2 in other cell types along the GABAergic maturation trajectory and also whether this has a role in ASD and epilepsy comorbidity.

Title: Il-17a affects activity and localization of microglia in the embryo cerebral cortex

Authors: *T. SASAKI, Y. TAKLEI;
Dept. of Anat. and Neurosci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: <META NAME="author" CONTENT="佐々木哲也">Viral infection during pregnancy has been suggested to increase the probability of autism spectrum disorder (ASD) in offspring via the phenomenon of maternal immune activation (MIA). This has been modeled in rodents. Maternal T helper 17 cells and the effector cytokine, interleukin 17A (IL-17A), play a central role in MIA-induced behavioral abnormalities and cortical dysgenesis, termed cortical

patch. However, it is unclear how IL-17A acts on fetal brain cells to cause ASD pathologies. To assess the effect of IL-17A on cortical development, we directly administered IL-17A into the lateral ventricles of the fetal mouse brain. We analyzed injected brains focusing on microglia, which express IL-17A receptors. We found that IL-17A activated microglia and altered their localization in the cerebral cortex. Our data indicate that IL-17A activates cortical microglia, which leads to a cascade of ASD-related brain pathologies, including excessive phagocytosis of neural progenitor cells in the ventricular zone.

Title: Neurodevelopmental origins of cell types in human epileptic cortical malformations

Authors: *L. SUBRAMANIAN[1], A. BHADURI[1], D. D. WANG[2], K. AUGUSTE[2], E. CHANG[2], M. PAREDES[3], A. R. KRIEGSTEIN[1];
[1]Eli and Edythe Broad Ctr. for Regeneration Med. and Stem Cell Res., [2]Neurolog. Surgery, [3]Neurol., Univ. of California San Francisco, San Francisco, CA

Abstract: Mammalian Target of Rapamycin (mTOR) mediated epileptic cortical malformations like Focal Cortical Dysplasia (FCD), Hemimegalencephaly (HME) and Tuberous Sclerosis (TSC) arise due to somatic mutations in the mTOR signaling pathway. Each of these malformations have distinct neuroanatomical and etiologic features, that make it hard to examine the relationship between them. In order to understand the developmental origin and shared molecular features of these mTOR-linked epilepsies, we used single nucleus sequencing strategies in donated patient surgical specimens to characterize the transcriptomic identity, and molecular features of all cell types present within the malformations. We used de-identified tissue from surgical resections, collected with previous patient consent for research in strict observance of legal & institutional ethical regulations. Following resections, brain regions with cortical lesions & epileptogenic foci were flash-frozen & sectioned to preserve cellular architecture. Individual nuclei were isolated from the sections & barcoded according to standard protocols, followed by reverse-transcription, amplification & sequencing to generate single-nucleus expression profiles. We isolated and characterized >30000 cells from patients with cortical malformations (n = 8 FCD, 3 TSC and 2 HME patients). Using unbiased clustering approaches, we generated molecularly distinct transcriptomic clusters of cells, corresponding to identifiable cell types. We identified transcriptomically unique cell types in FCDIIB, HME and

TSC lesions that corresponded to dysplastic balloon cells and bizarre neurons. We established that these cells have a shared molecular identity irrespective of malformation type, co-expressing markers associated with progenitor cells and immature neurons, indicating a shared developmental origin. Using immunofluorescence staining, we validated our findings with marker co-expression in tissue sections. Using gene ontology analyses, we identified shared molecular pathways active in each cell type across malformations. We identified key developmental signatures, normally present in progenitor cells, within the populations of balloon cells and bizarre neurons present in FCD, HME and TSC lesions. Our findings highlight the shared neurodevelopmental origins of these malformations, along disease-relevant changes in all cell types in epileptic regions. The outcome of this study is a thorough transcriptomic characterization of all cell types in mTOR-linked epileptic cortical malformations, that will be an important community resource.

Title: Schizophrenia-linked protein tSNARE1 regulates endolysosomal trafficking in cortical neurons.

Authors: *M. PLOOSTER, G. ROSSI, M. S. FARRELL, P. F. SULLIVAN, H. WON, S. L. GUPTON, P. BRENNWALD;
UNC Chapel Hill, Chapel Hill, NC

Abstract: Schizophrenia is a severe and heritable neuropsychiatric disorder; the etiology of which is the result of genetic variation in many genes. Genome-wide association studies (GWAS) identified 145 genome wide significant (GWS) loci, implicating more than 300 candidate genes as potential risk factors for schizophrenia. However, the impact of these genes in schizophrenia pathogenesis has not been studied. The next critical step is to investigate the function of these genes and how they might be dysregulated in schizophrenia. *TSNARE1*, which encodes the protein tSNARE1, is one of the high confidence candidate genes, but the cellular or physiological function of tSNARE1 is presently unknown. Here we define the major gene products of *TSNARE1* in the human brain and their cytoplasmic localization and function in the endolysosomal system of cortical neurons. We identified four isoforms of tSNARE1 in human brain, all of which contain a syntaxin-like Qa SNARE domain. SNARE proteins are involved in

the fusion of opposing lipid bilayers, and the transmembrane domain of the Qa SNARE is thought to be critical for membrane fusion. However, RNA-sequencing data from adult and fetal human brain suggest that the most abundant isoforms of tSNARE1 lack a transmembrane domain. This suggests an exciting hypothesis in which brain tSNARE1 acts as an inhibitory SNARE (i-SNARE) to negatively regulate membrane trafficking events. We find that brain tSNARE1 isoforms localize to compartments of the endolysosomal network. The non-transmembrane domain containing isoforms, including the most abundant isoform tSNARE1c, most frequently populate compartments of the late endosome. Live-cell three-color trafficking assays suggest that tSNARE1 modulates trafficking to the late endosome and the lysosome in the developing neuron. Determining how tSNARE1 regulates trafficking is critical towards understanding how its dysfunction contributes to schizophrenia pathogenesis.

Title: Compounding maternal risk factors exacerbate neurodevelopmental and immune dysfunction and lasting health outcomes

Authors: *E. JASAREVIC[1,1], E. HILL[1], P. KANE[1], T. GYLES[1], L. FOLTS[1], K. ROCK[1], K. MORRISON[2], T. BALE[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]West Virginia Univ., Morgantown, WV

Abstract: Profound disparities exist in maternal-child health outcomes between racial and ethnic groups. Black women in the United States are significantly more likely to experience preterm birth, fetal growth restriction, and maternal-infant morbidity and mortality than white women. Thus, to examine the hypothesis that neonatal morbidity and lasting health outcomes are the result of multifaceted compounding of insults to the fetus, we established a mouse novel model that takes into account multiple compounding maternal risk-factors on offspring outcomes. After establishing key functional attributes of the human maternal microbiota on lasting outcomes in offspring, we next determined whether a combination of maternal consumption of a high-fat low-fiber diet and a history of bacterial infection during pregnancy influenced fetal development,

subsequent response to postnatal microbial colonization, and lasting health outcomes. Administration of a high fat - low fiber (HFt-LFb) diet resulted in significant differences in pre-pregnancy body weight gain, glucose intolerance, gut microbiota composition relative to females consuming a low fat - high fiber (LFt-HFb) diet, paralleling endophenotypes of pregestational obesity and diabetes in humans. Further, the disruptive effects of the HFt-LFb diet on the maternal gut microbiota persisted across pregnancy, resulted in a marked loss of taxa involved in the production of metabolites essential for offspring development. Surprisingly, the combinatorial effects of maternal diet, infection and the microbiome exhibit a significant impact on the survival of newborn mice, an observation that is consistent with clinical reports on infant mortality. Indeed, triple hit offspring showed a rate of 60% mortality relative to the 100% survival among LFt-HFb offspring. Of the triple hit offspring that survived, single-cell mass cytometry showed a significant expansion of neutrophils in the periphery, with neutrophils accounting for almost 80% of all immune cell in circulation. Tracking of offspring body weight revealed significant acceleration in the rate of body weight gain and increased body weight in the triple hit offspring that survived. Through this mouse model and application of known maternal risk factors, including human cervicovaginal microbiota, we may come closer to estimating combined risks for neurodevelopmental outcomes and to identifying causal mechanisms that may yield novel therapies and biomarkers to be further examined in clinical trials.

Title: Small molecule and genetic strategies can activate the proteasome in neonatal piglet brain for therapeutic targeting after brain injury

Authors: *N. M. EL DEMERDASH[1], C. O'BRIEN[2], M. W. CHEN[3], S. ADAMS[3], E. KULIKOWICZ[4], L. MARTIN[3], J. LEE[3];
[1]John Hopkins Sch. of Med., Baltimore, MD; [2]Johns Hopkins, Johns Hopkins, MD; [3]Johns Hopkins, Baltimore, MD; [4]JOHNS HOPKINS, Baltimore, MD

Abstract: Proteasomes degrade damaged proteins. We show proteasome loss of function in forebrain white matter of neonatal piglets with brain injury from hypoxia-ischemia (HI). The proteasome could be a therapeutic target for white matter protection. Amenability of proteasomes to in vivo manipulation is unknown. We hypothesized that the proteasome in neonatal piglet cortex and white matter can be activated by two small molecules (oleuropein [OLE] and the phenothiazine chlorpromazine [CPZ]) and by virus-mediated gene targeting2-3 day old piglets. OLE sham hypothermia: piglets received general anesthesia with overnight

hypothermia and rewarming. Piglets received OLE or vehicle (IV). Brains were harvested at 29 h (n=6). .OLE after HI received HI, OLE in at 15 min after HI, and emerged from anesthesia 3 h after HI. The brain was harvested at 4 days (n=6).3.CPZ after sham piglets received general anesthesia and CPZ 1, 5, or 10 mg/kg or saline. They emerged from anesthesia after 3 h, and brains were harvested 24 h later. .Genetic targeting with adeno-associated virus (AAV): piglets received stereotaxic microinjections of (AAV-PSME3 [PA28γ]-green fluorescent protein [GFP], AAV-PSME3-short hairpin RNA-GFP, or AAV-eGFP) with to enforce or knockdown the proteasome, or for control (n=2-3 piglets/group). Injections were into white matter and cortical gray matter.Two days later, piglets were for HI. The piglets then received overnight hypothermia, rewarming, and OLE every other hour or vehicle (IV). Brains were harvested at 29 h. subcortical white matter and cerebral cortex were assayed for proteasome activity and proteasome subunits. Values were normalized to GFP in AAV-injected brain. Naïve had higher proteasome activity in white and gray matter than shams, and gray matter had higher ($p= 0.002$) activity than white matter. Alpha-3, beta-5, and PA28γ proteasome subunits were detected in white and gray matter. In sham, proteasome activity was higher in gray matter of OLE-treated piglets compared to vehicle ($p= 0.027$), but OLE had no proteasome agonist activity in white matter., OLE did not activate brain proteasomes after HI and CPZ did not activate proteasomes in shams. Genetic enforcement of PSME3 upregulated proteasome activity in gray matter but not white matter compared to control. PSME3 knockdown inconsistently affected proteasome activity. Proteasome were not altered by AAV. Brain proteasome activity is diminished by anesthesia and hypothermia. OLE activated the brain proteasome in sham but not HI piglets. Brain proteasome activity can be enforced genetically. We conclude that the proteasome can be manipulated in vivo for potential neural protection.

Title: Disruption of mTor complexes rescues Pten KO-mediated hypertrophy in neurons

Authors: *K. TARIQ[1], W. WANG[1], M. LI[1], M. C. WESTON[2], B. LUIKART[1];
[1]Dartmouth Col., Hanover, NH; [2]Neurolog. Sci., Univ. of Vermont, Burlington, VT

Abstract: Phosphatase and tensin homolog deleted on chromosome 10 (PTEN) is a lipid phosphatase that negatively regulates AKT/mTOR signaling pathway and serves as a brake on

unregulated cellular growth. In a non-dividing neuronal cell population, PTEN inactivation leads to hypertrophy, and such neuropathology has been observed in individuals with Autism Spectrum Disorder (ASD). In mouse models of autism, conditional Pten knockout (KO) in hippocampus leads to larger soma size, dendritic hypertrophy, ectopic neuronal migration, and increased spine densities. The underlying molecular mechanisms producing such alterations in neuronal architecture remain incompletely understood. Using well-defined mouse genetic alleles and retroviral systems to specifically target developing neurons, we aimed to determine the individual roles of two mTOR complexes in the development of Pten-KO-mediated autism-associated hypertrophy. mTOR kinase regulates cell growth, proliferation and survival by operating in two multi-protein complexes, mTORC1 and mTORC2. We knocked out Raptor or Rictor, which are unique and obligatory components of mTORC1 and mTORC2 complexes, respectively. We found that disruption of mTORC1 completely rescued Pten-KO-mediated effects on soma size, migration, and dendritic arborization, while partially rescuing increases in spine density. Disruption of mTORC2 generated a partial rescued Pten-KO mediated increase in soma size, migration, spine density and dendritic arborization. The differential impact of mTORC1 and mTORC2 deletion suggests specific mechanistic pathways underlying autism-associated hypertrophy and identifies Raptor and Rictor as potential therapeutic targets for the treatment of ASD.

Title: Caspase-1 inflammasome activation mediates obesity development in NIBP knockout mice

Authors: B. BODNAR, H. SHAN, M. XIN, F. LI, Y. ZHU, Y. LIN, H. WANG, ***W. HU**; Temple Univ. Lewis Katz Sch. of Med., Philadelphia, PA

Abstract: NIBP/TRAPPC9 is a prototypical member of a novel protein family that regulates NFκB signaling and *trans*-Golgi networking. Autosomal recessive mutations of human *NIBP* lead to a novel neurodevelopmental disorder NIBP Syndrome, characterized by intellectual disability and obesity. Previous data from our lab demonstrated that global Nibp knockout mice (*Nibp*$^{-/-}$) spontaneously develop hyperphagia, obesity, and impaired glucose/insulin tolerance, even under normal chow diet. A similar phenotype occurred in hypothalamus-specific *Nibp*$^{-/-}$ mice via stereostatic injection of AAV-Cre into the arcuate nucleus (ARC) of floxed *Nibp* transgenic mice. To elucidate the molecular mechanisms underlying NIBP-deficient obesity, we explored the role of hypothalamic inflammasome activation and microinflammation. RT^2 profiler PCR arrays targeting NFκB signaling and cytokines/chemokines did not identify robust changes

in the mRNA levels of these select genes in the hypothalamus of *Nibp*$^{-/-}$ mice, supporting the existence of hypothalamic microinflammation in NIBP-deficient obesity. IL-1β production is controlled by the activation of Caspase-1 (Casp1) via an inflammasome complex consisting of NLRP3, Asc, and pro-Caspase-1. In particular, the NLRP3 inflammasome is known to contribute to obesity. However, the role of Casp1-inflammasomes in regulating hypothalamic microinflammation and obesity remains elusive. RT-qPCR analysis validated a moderate but significant increase in the mRNA expression of IL-1α (via Casp11) and IL-1β (via Casp1) in the hypothalamus of *Nibp*$^{-/-}$ mice with females showing a more dramatic increase. Interestingly, Casp1 and Asc, the key components of NLRP3 inflammasome, showed significant increase in both male and female *Nibp*$^{-/-}$ mice but mRNA expression of *NLRP3* and *NLRP1* did not change significantly. Further studies using *Nibp*$^{-/-}$/*Casp1*$^{-/-}$ double knockout mice showed that *Casp1* knockout helps ameliorate the weight gain due to *Nibp* knockout, while having no significant impact on the weight of wildtype *Nibp*$^{+/+}$ mice under normal control diet. A high fat diet further aggravated weight gain in *Nibp*$^{-/-}$ mice compared to wildtype mice. In conclusion, this study suggests that (1) Nibp deficiency promotes inflammasome pathways in the hypothalamus and (2) that Casp1 may help mediate obesity development in *Nibp*$^{-/-}$ mice. These findings highlight the importance of Casp1 in obesity development and suggest possible involvement for NIBP in regulating microinflammation in the hypothalamus.

Title: Bisphenol-a suppresses neuronal chloride exporter (kcc2) expression during early brain development

Authors: M. BUTLER[1], E. F. JONES[4], J. S. STEELE[2], R. J. MCAULEY[5], *E. B. GAHTAN[3]; [1]Chem., [2]Biol., [3]Psychology and Biol., Humboldt State Univ., Arcata, CA; [4]Univ. of Alabama, Birmingham, Birmingham, AL; [5]Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: Bisphenol A (BPA) is a synthetic endocrine-disrupting chemical that can mimic the effects of estrogens. Its widespread presence in the environment has prompted concern that accidental ingestion may disrupt estrogen's critical biological functions, including in early brain development. Animal models have demonstrated that perinatal BPA exposure can affect brain structure, function, and behavior, both acutely and long-term. One mechanism through which BPA could alter neural development and behavior is by modulating the expression of the neuronal chloride exporter, KCC2. The ion transport action of KCC2 maintains low intracellular chloride concentration in neurons, ensuring that GABA transmission activates inhibitory, inward

chloride currents. KCC2 is therefore a critical regulator of neural excitability. Several hormonal factors have been shown to influence KCC2 expression, including sex, treatment with estradiol or testosterone, and ovariectomy, and BPA itself has been shown to modulate KCC2 expression in rodents and cultured human neurons. The current study utilized a novel zebrafish transgenic reporter line, KCC2:mCitrine, to track BPA effects on KCC2 expression in vivo during early brain development. We used CRISPR-mediated transgenesis in zebrafish zygotes to insert a self-cleaving mCitrine sequence before the first exon of SLC12a5b, an ortholog to the human KCC2 gene. KCC2:mCitrine zebrafish show neuron-specific fluorescence from the time of neurogenesis onset and within all nervous system structures as they develop. We first replicated evidence of BPA's estrogenic effects in developing zebrafish by showing that BPA upregulates aromatase B expression in embryonic radial glial cells and causes behavioral hyperactivity at later larval stages. The same BPA treatment also downregulated KCC2 expression as measured by neural fluorescence in KCC2:mCitrine larvae. BPA-induced downregulation of KCC2 could cause GABA to produce paradoxical excitatory effects on neurons with long-term consequences for brain development and behavior. Our KCC2:mCitrine zebrafish provide a new way to track BPA's effects on KCC2 expression and could be used to screen other compounds with a potential to modulate KCC2 expression during early developmental.

Title: Performance in the Open Field Test of adult offspring from CD-1 mice fed with a Western Diet during pregnancy and lactation.

Authors: *R. PEDRAZA-MEDINA, N. A. MOY-LÓPEZ, J. GUZMÁN-MUÑIZ, M. F. PINTO-GONZÁLEZ, M. ORTIZ;
Lab. of Neurosciences, Univ. of Colima, Colima, Mexico

Abstract: Open field test (OFT) has been used to measure the spontaneous motor activity and exploratory behavior in rodents. It has shown changes in the control and mobility in aging mice. In addition to this, it has been observed that disturbances during embryonic development can alter the senescence process, precipitating the deterioration of mobility. One of the teratogenic factors during pregnancy that has become important in recent years is Western diet (WD), characterized as the set of processed foods, which are high in calories, fat and sugar, low in fiber, but pleasant in taste and texture. It has been well explained his relation with cognitive alterations but there are small evidence of long-term effects on mobility. The aim of the study was to evaluate the performance in the OFT of adult offspring from CD-1 mice fed with a WD during pregnancy and lactation. Thirty-six mice were used, 18 from mothers fed a WD (19.8% fat;

16.4% protein; 46.7% carbohydrates; 4.30 (kcal/g)^2), and 18 from mothers fed a control diet (3% fat; 23% protein; 49% carbohydrates; 3.15 (kcal/g)^2) during pregnancy and lactation. At weaning, the offspring of both groups have access to a control diet and water at libitum. Weight and height at birth were registered. At postnatal day (PD) 90, 180 and 360, offspring were evaluated in the OFT. Data were analyzed with Software SPSS. Experimental group were significantly heavier ($P < .0001$) and taller ($P = .019$) than control group at birth. Not differences in distance moved or speed at 90 and 180 were found. At PD 360 control group have a significant greater distance moved ($P = .046$) and were speeder ($P = .046$) than experimental group. In conclusion, the consumption of a western diet during pregnancy and lactation causes an increase in weight and height at birth. And it can have long-term effects on weight, spontaneous motor activity and exploratory behavior in rodents.

Title: Exploring neuroplastic changes through diffusion tensor imagining in response to physical therapy intervention in very preterm infants: a case series

Authors: *M. EVANS[1], S. KHURANA[1], M. S. SHALL[1], D. THOMPSON[3], C. E. KELLY[3], D. BESSOM[4], A. HARPER[2], G. VORONA[4], S. C. DUSING[5];

Inst., Parkville, Australia; [4]Radiology, Children's Hosp. of Richmond, Richmond, VA; [5]Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: Very preterm infants (<28 weeks gestation) are at high-risk for neurological dysfunction, with 50% of infants experiencing various developmental delays. The Early Intervention Program was created to match children and their families with the support services they need to enhance motor and cognitive development in young children. Despite new advances in neuroimaging, limited research is available on the neuroplastic changes in response to early intervention. Thus the primary purpose of this study was to begin to explore and quantify neuroplastic changes in response to a parent delivered physical therapy intervention, such as Supporting Play Exploration and Early Development Intervention (SPEEDI).Three very preterm infants were chosen from the SPEEDI_Brain_Behavior cohort based on their randomized group assignment, and completion of at least three study visits in a larger study (ClinincalTrials.gov

Identifier: NCT03518736). Intervention was provided as early, (starting before NICU discharge) or late, (starting at 16 weeks post baseline), or usual care. MRIs were done without sedation in a 3T pediatric dedicated scanner within 72 hours after NICU discharge, 3 months post baseline, and 6 months post baseline. Diffusion images were motion corrected, resampled to 1.5mm isotropic voxels, and brain extracted. The diffusion tensor model was fitted, and regions were parcellated using the Melbourne Children's Regional Infant Brain white matter atlas. Diffusion Tensor Imaging allowed for the quantification of neuroplastic changes in white matter tracts over time measured by Fractional Anisotropy (FA) and volumes of eight motor regions. Descriptive statistics were used to describe these cases.The left and right hemispheres were averaged together and the change over time (6-month values - baseline values) values were calculated for FA and volume. The area of most interest, the corticospinal tract (CST), displayed an increase in mean FA values, with the early group showing an increase of 0.063, the late group 0.113, and usual care 0.057. Additionally, there was an increase in the mean CST volumes with the early group reporting a volume increase of 299 mm^3 compared to the 162 mm^3 and 236mm^3 in the late and usual care groups, respectively. Initial evidence suggests that a parent delivered physical therapy intervention may lead to higher increase in FA and volume in the CST compared to usual care. However, the preliminary nature of this research limits external validity until a larger study is completed.

Abstract: Neural circuits must achieve precise wiring between distinct cell subtypes to produce appropriate behaviors. Identity specification and wiring precision in the circuit that stabilizes gaze is a particular case of this general developmental problem. Vertebrates stabilize gaze using excitatory vestibular interneurons that relay head and body destabilization to motoneurons that

counter-rotate the eyes. Precise connectivity between directionally-sensitive interneuron subtypes and particular motoneurons is therefore crucial for behavior. The developmental mechanisms that specify excitatory vestibular interneuron identity and connectivity are unresolved, though previous work has suggested a role for spatiotemporal cues and/or motoneuron-derived factors. We tested these hypotheses in the tangential nucleus (TAN) of the larval zebrafish, which contains the excitatory vestibular interneurons necessary for vertical gaze stabilization. We first developed an assay using 2-photon and swept, confocally-aligned planar excitation (SCAPE) microscopy to rapidly and reliably define functional nose-up and nose-down vestibular interneuron subtypes. We used this assay to ask whether functional subtypes are spatiotemporally organized and discovered functional organization complementary to spatiotemporal development. Our results are the first demonstration of functional sub-organization within a vestibular nucleus and reflect a putative role for spatiotemporal factors in identity specification. Next, to investigate the requirement of motoneuron-derived signals for TAN identity specification, we used these functional assays to measure changes in TAN identity following constitutive motoneuron knockouts. Our results demonstrate that TAN functional identity and organization is preserved in the absence of motoneurons, arguing against a role for motoneuron-derived cues. Taken together, we predict that spatiotemporally-linked factors organize TAN subtypes into dorsoventral and rostrocaudal microdomains. We propose that functional identity acquisition and organization occurs in a motoneuron-independent manner.

London, London, United Kingdom; [4]Paediatric Neurosciences, Evelina London Children's Hospital, St Thomas' Hosp., London, United Kingdom; [5]Wellcome Ctr. for Integrative

Neuroimaging, FMRIB, Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: In the mature brain, neural processing related to different parts of the body map to specific locations within the primary motor and somatosensory cortices. This topographical organization is reflected in patterns of functional connectivity (FC), where a given body part is most strongly connected to it's homologue in the opposite hemisphere [1]. Although a crude somatotopic organisation can be identified in the preterm human brain [2], it is unclear whether the underlying FC is similarly organised and what influences its establishment. To investigate the development of FC and its relationship with somatotopy across the perinatal period, we studied changes in inter-regional connectivity in a large group of infants. We hypothesized that maturation would be associated with an increase in inter-hemispheric FC as the brain establishes an adult-like bilateral network representation. We used high temporal resolution resting-state fMRI (TR=0.39s, voxel size 2.2x2.2x2.2 mm3, 15 minutes), acquired and pre-processed as part of the dHCP project (www.developingconnectome.org) [3]. We studied a group of 328 healthy neonates (median postmenstrual age (PMA) 40.7; range 31.4 - 44.9 weeks; 140 female) of which 59 were born and scanned preterm and the others 269 at term. We extracted the mean timeseries from 6 different regions of interest (ROI) identified from previous studies in neonates: 4 body parts (left/right wrist/ankle, localized in the contralateral hemisphere)[2] and 2 control areas (left/right primary visual cortex (V1))[4]. FC was then calculated using partial correlation between each pair of ROIs. A linear regression between partial correlation coefficients and PMA (correcting for postnatal days (pn) and pn-PMA interaction) was computed. The identified FC strength changed significantly ($p<0.01$ Bonferroni corrected) with the increase in PMA as follows: it increased between homologous regions (e.g. left/right wrist) and between adjacent cortical areas in the left hemisphere (right wrist/ankle), while it decreased between distal cortical areas (left wrist/right ankle). There was no effect of PMA on correlation strength between any of the body regions and control regions. We concluded that FC within the primary somatosensory and motor cortices is suborganized into specific patterns related to the somatotopy in the newborn brain. The rapid changes during the preterm period highlight the key importance of this stage for the establishment of the somatomotor resting state network.

Title: Phrenic-specific transcriptional programs shape respiratory motor output

Authors: *A. N. VAGNOZZI[1], K. GARG[1], C. DEWITZ[2], M. T. MOORE[1], J. M. CREGG[1], L. JEANNOTTE[3], N. ZAMPIERI[2], L. T. LANDMESSER[1], P. PHILIPPIDOU[1];

Abstract: Breathing is the most essential motor behavior. The frequency and amplitude of breathing movements are controlled by neural networks residing in the brainstem and spinal cord. Degeneration of these networks leads to respiratory disorders, such as central sleep apneas, and, eventually, respiratory failure. In mammals, contraction of the diaphragm muscle is vital for driving airflow into the lungs during inspiration. Diaphragm contraction is controlled by a single motor input, phrenic motor neurons (MNs) in the cervical spinal cord, making this MN population a critical node in the respiratory network. Despite their essential role, the molecular determinants that control the patterns of phrenic MN activity and their integration into respiratory circuits are largely unknown. We show that Hox5 transcription factors are required for robust and efficient breathing. Hox5 loss renders mice vulnerable to respiratory dysfunction in the first two weeks of life, suggesting that Hox5 mutations may contribute to early life respiratory conditions, such as sudden infant death syndrome (SIDS). We show that Hox5 proteins establish phrenic MN clustering and topography through the regulation of a network of cell adhesion molecules. We find that a subset of cadherins are specifically expressed in phrenic MNs and that loss of cadherin function through conditional disruption of downstream β/γ-catenin signaling leads to phrenic MN cell body disorganization and dendrite displacement. Remarkably, after MN-specific deletion of Hox5 genes, phrenic MN firing becomes asynchronous and erratic due to the selective loss of inhibitory inputs to phrenic MNs. Our results demonstrate that Hox5 transcription factors determine phrenic MN topography and connectivity to generate robust breathing behaviors. Our findings support a model where MN-intrinsic transcriptional programs shape the pattern of motor output by orchestrating distinct aspects of MN connectivity.

Title: A ventral visual pathway in the Xenopus laevis tadpole

Authors: U. G. UDOH, ***K. G. PRATT**;
Zoology and Physiol., Univ. of Wyoming, Laramie, WY

Abstract: Visual information in Xenopus laevis is processed in the midbrain, a brain structure that in amphibians comprises two major components along the dorsoventral axis, the tectum and the tegmentum. Retinal ganglion cells (RGCs), carrying visual information from the eye, project to the contralateral midbrain where they form synapses directly onto postsynaptic midbrain neurons. While most of these projections are known to terminate in the well-studied tectum, our electrophysiological recordings show that neurons in the ventral region of the midbrain – the tegmentum – also receive direct RGC input. Here, we compare these ventral and dorsal visual projections. For this, we use an isolated brain preparation that allows access to both tectal and tegmental neurons. RGC axons are activated by placing a stimulation electrode on the optic chiasm. We found that by developmental stage 48/49 (approximately 17-21 days post-fertilization), tectal and tegmental neurons receive similar amounts of direct monosynaptic RGC input. Interestingly, however, the earlier developmental dynamics preceding stage 48/49 were not the same: we observed a marked peak in maximum RGC input onto tectal neurons at developmental stage 45, the time when this circuit is undergoing dynamic refinement. This transient peak in maximum RGC input was not observed in the tegmental neurons, suggesting that perhaps the ventral visual pathway does not refine and that tegmental neurons may receive input from a distinct set of RGCs. We also measured maximum non-visual lateral line inputs received by the same tectal and tegmental neurons. These inputs are activated by placing a bipolar electrode on the hindbrain (HB). We found that for a given tectal neuron, its maximal RGC input is greater than the maximal non- visual (HB) input whereas in ventral tegmental neurons, the maximal HB input is greater than the RGC input. Finally, biocytin fills indicate that axons of tegmental neurons maintain a ventro-medial course, descending ipsilaterally down the hindbrain, while axons of tectal neurons tend to project ventro-laterally. Taken together, our data suggest that (1) the two visual pathways are structurally and functionally distinct, and most likely process different qualities of a visual scene, and (2) like the optic tectum, the midbrain tegmentum is also involved in multi-sensory integration. Currently, in-vivo experiments are being carried out to determine what types of visual stimuli activate the tegmental neurons.

Title: Directional retinal waves differentially influence the development of direction-selective responses in collicular versus cortical neurons

Authors: *K. ZHANG, X. GE, M. CRAIR;
Dept. of Neurosci., Yale Univ., New Haven, CT

Abstract: Before the onset of vision, the developing mouse retina spontaneously generates activity in the form of propagating waves. Previous studies have demonstrated that retinal waves are critical for the development of eye-specific segregation and topographic maps in the mouse visual system. However, it remains unclear whether retinal waves convey information beyond providing correlated activity between topographically neighboring cells and contribute to the development of higher order response properties in downstream visual neurons. Recent findings have shown that retinal waves exhibit a strong directional bias in their propagation during a transient developmental window from P7-P12 that matches an optic flow pattern that would be generated by forward self-motion after eye-opening. Here, we describe experiments that suggest that this specific spatiotemporal property of retinal waves is critical for the refinement of direction-selectivity (DS) in superior colliculus (SC) neurons. We used both pharmacological and genetic approaches to chronically disrupt the directionality of retinal waves during development and used *in vivo* two-photon calcium imaging to measure the responses of SC neurons to drifting grating stimuli immediately after eye-opening (P15). We find that both the tuning strength and direction preference of SC neurons at eye-opening are severely compromised following the loss of directional retinal waves. In addition, previous work suggests that the superficial layers of primary visual cortex (V1) gain independence from retinal drive and generate their own spontaneous activity shortly before eye-opening, while the SC and input layer of V1 faithfully replicate retinal waves throughout development. Retinal waves may therefore play a more critical role in the development of neuronal response properties in areas which are more retina-dependent throughout development, including the SC and input layer of V1, compared to superficial layers of V1. Indeed, we find that chronic manipulation of wave directionality before eye-opening only weakly disrupts the DS responses of V1 neurons in superficial layers and more strongly disrupts the DS responses of V1 neurons in the input layer. Taken together, these results suggest that retinal waves provide ethologically relevant information to the developing visual system by simulating the most likely optic flow pattern animals will receive after eye-opening, which is critical for the refinement of DS responses in

downstream visual neurons, and that retinal waves differentially influence the development of neuronal response properties in different visual areas.

Title: Binocular vs. monocular recovery experience differentially promote recovery of visual deficits in a mouse model of amblyopia

Authors: *J. D. MARTINEZ[1], M. J. DONNELLY[1], D. S. POPKE[1], D. TORRES[1], S. SHESKEY[2], B. C. CLAWSON[1], S. JIANG[1], S. J. ATON[1];
[1]Molecular, Cellular, and Developmental Biol., [2]Ophthalmology and Visual Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: Altered visual experience during monocular deprivation (MD) profoundly changes in ocular dominance (OD) in the developing primary visual cortex (V1). MD-driven changes in V1 are an experimental model of amblyopia, where alterations in vision in early life lead to poor binocular vision in adulthood. Current treatment for amblyopia typically includes patching of the dominant eye, although binocular therapies are also being used. However, the relative impact of monocular vs. binocular recovery experiences have on V1 function is not well understood. Using single-unit recording of neurons in mouse V1, we examined how different forms of recovery visual experience (binocular recovery [BR] or reverse occlusion [RO]) of identical duration and content affects recovery of visual cortical responses after MD. We also tested how the two forms of recovery differentially affect normalization of visually-driven behavior following MD. We find that BR is quantitatively superior with respect to normalization of V1 OD and visually-driven behavior (reflecting improved deprived eye acuity after BR). However, firing rate properties found in principal neuron and fast-spiking interneuron populations undergo changes after MD that do not recovery after visual experience. Additionally, binocular matching of orientation preference remains disrupted after recovery and visual response properties such as visual responsiveness are dramatically decreased after recovery for both experiences. Lastly, we used cFos immunohistochemistry to examine neuronal activity changes in binocular zone of V1 after BR and RO recovery. Thus BR and RO have differential effects on various aspects of vision that will impact the recovery of normal vision in amblyopia.

Title: Cortical feedback regulates developing thalamic activity and circuit refinement in the mouse visual system

Authors: *Y. MURATA, M. T. COLONNESE;
Pharmacol. and Physiol., George Washington Univ., Washington, DC

Abstract: Spontaneous retinal activity plays a foundational role in the establishment and refinement of connectivity during the development of the visual system. However, it remains poorly understood how the information from the retina is represented in the developing thalamus and cortex and how it guides circuit formation. Here, we investigate the characteristics and generative mechanisms of thalamocortical activity in the mouse visual system *in vivo* throughout the early postnatal period. We focus on the role of cortical feedback because recent work shows that reciprocal thalamocortical interactions are critical for the generation of activity in the developing thalamus. Using high-density multi-electrode arrays in the visual thalamus and cortex of un-anesthetized neonatal mice, we find that early thalamic firing is correlated in an eye-specific and spatial manner, presumably reflecting the spontaneous retinal wave activity from both eyes. Such correlated thalamic activity is prevalent only until postnatal day (P) 11, one to two days before eye opening. Chemogenetic reduction of cortical activity before P11 revealed that cortical feedback not only amplifies thalamic activity but also coordinates thalamic neuronal firing by increasing correlated activity among same-eye responsive thalamic neurons, thus enhancing their differences from opposite-eye responsive neurons. Furthermore, chronic reduction of cortical activity during the second postnatal week impaired eye-specific segregation of retinal axons in the visual thalamus, consistent with the role of cortical feedback in synchronizing eye-specific thalamic regions. This study shows a crucial role for the unique developmental properties of reciprocal thalamocortical interactions in the transmission of retinal activity and the formation of visual circuits.

Title: Inhibition of microglia with PLX5622 prevents developmental pruning of the glossopharyngeal nerve which is then restored following microglia replenishment

Authors: *A. J. RIQUIER[1], S. I. SOLLARS[2];
[1]Univ. of Nebraska At Omaha, Omaha, NE; [2]Univ. of Nebraska at Omaha, Omaha, NE

Abstract: The gustatory glossopharyngeal nerve (GL) projects fibers (a 'terminal field') to the nucleus of the solitary tract (NTS) of the medulla. Similar to the developmental pruning observed in other contexts, the volume of GL terminal field in the NTS reduces by approximately 66% between postnatal day 15 (P15) and P40 (Mangold & Hill, 2008). However, the GL terminal field can undergo atypical late life expansion as a result of experimental alterations to input, reversing developmental pruning (Skyberg et al., 2017; Sun, Krimm, & Hill, 2018). It therefore appears as if the GL terminal field not only prunes during development, but is also subsequently actively maintained at a reduced size for the reminder of life, although the mechanism for either are unknown. Evidence from other gustatory nerves suggest that the central macrophages microglia are the mechanism for gustatory developmental pruning (Sun et al., 2020), and possibly active maintenance of the GL terminal field. We first assessed microglia density in the NTS of rats at P11, P17, P24, and P40, observing that microglia density in the region was highest during the pruning period before reducing to adult quantities at P24 (p = .011). To test the hypothesis that microglia are required for GL terminal field pruning and maintenance, we utilized i.p. administration of the colony-stimulating factor 1 receptor inhibitor PLX5622 to deplete microglia by >99% from the developing rat from P1 to P40. Using a biotinylated dextran amine, we labeled the GL terminal field in groups of rats at either P15, P25, P40, or P68 (four weeks after ceasing treatment and allowing microglia to return). As expected, the volume of the GL terminal field was largest at P15 for both PLX5622 and vehicle treated rats. In vehicle controls, GL terminal field volume reduced by 66% by P25 (p = .023) and remained stable through P40 (p= .166). However, no such age-related reduction occurred in PLX5622-treated rats (ps > .1), indicating microglia are required for development GL terminal field pruning. When PLX5622 treatment was ceased at P40, microglia were replenished to age-matched control quantities by P43 (p = .873), and by P68 their GL terminal fields had reduced in volume to control levels (p= .440). This finding suggest that microglia retain their ability to prune well outside the canonical pruning period and may actively maintain the GL terminal field at a reduced volume after developmental pruning.

Title: The role of oxytocin signaling in sex-specific gene expression in the embryonic mouse brain

Authors: *E. A. AULINO, N. M. PLONSKI, H. PIONTKIVSKA, H. K. CALDWELL;
Kent State Univ., Kent, OH

Abstract: Recent work suggests that the oxytocin (Oxt) system's neuromodulatory actions in adolescent and adult life are contingent on its role in embryonic brain development. In the embryonic brain, there is evidence that Oxt can influence neural cell fate specification and cellular migration, as well as the timing of the GABA switch near birth. These early organizational effects may contribute to the development of brain regions and neural circuits important to the neural regulation of behavior in adulthood. Work from our lab has identified a key developmental timepoint where the Oxt system may begin to exert its effects, embryonic day (E) 16.5. Both males and females first produce Oxtr protein at this time, while females, but not males, produce *Oxt* transcripts. Further, we have evidence that a single, transient disruption of Oxtr signaling at E16.5 has sex-specific effects on adult social behaviors. Taken together, our findings indicate a sex-dependent organizational function for the Oxt system in the embryonic brain. However, what remains unknown is how Oxt's actions functionally organize the brain at this crucial timepoint. One way that we hypothesize that Oxtr signaling contributes to the sex-specific development of neural circuits is by direct effects on gene expression. To test this hypothesis, we re-analyzed available datasets from RNA sequencing experiments performed with brain tissue collected from both male and female C57BL/6J mice between E15.5 and E17.5. The raw data was analyzed using the Automated Isoform Diversity Detector (AIDD) pipeline, which combines alignment, mapping, and differential analysis using DeSeq2. Additional analysis to determine gene set enrichment and functional clustering was performed using the Gene Set Enrichment Analysis and PANTHER on differentially expressed genes identified by AIDD. Preliminary data suggests significant differences between males and females at E16.5 in gene expression associated with pathways unique to Oxtr signaling. These data will inform analysis of an ongoing RNA sequencing experiment which will examine male and female brains at E16.5 from Oxt knockout and wildtype litters, focusing on brain regions known to express the Oxtr at this time.

Title: A novel telencephalon-opto-hypothalamic embryonic domain produces most of the glutamatergic neurons of the medial extended amygdala

Authors: L. MORALES, E. DESFILIS, *L. MEDINA;
Univ. Lleida-IRBLleida, Lleida, Spain

Abstract: Deficits in social cognition and behavior are a hallmark of many psychiatric disorders. The medial extended amygdala (EAMe), which includes the medial amygdala and the medial bed nucleus of the stria terminalis, is a key component of functional networks involved in sociality. However, this nuclear complex is highly heterogeneous and contains numerous GABAergic and glutamatergic neuron subpopulations with multiple embryonic origins. Deciphering the specific connections of these different neuron subtypes is essential in order to understand how this structure regulates different aspects of sociality, and it is necessary to evaluate their differential implication in distinct psychiatric disorders. Developmental studies are offering new venues to understand the neuronal diversity of the medial extended amygdala, and are helping to establish a relation between the embryonic origin and molecular signature of a neuron with the functional subcircuits in which it is engaged. While the different GABAergic neuron subpopulations of the EAMe have been studied in detail, knowledge about the glutamatergic cells is still scarce. Using an Otp-eGFP transgenic mouse, we found that most glutamatergic neurons of the EAMe originate in a novel telencephalon-opto-hypothalamic embryonic domain, located at the transition between telencephalon and hypothalamus. This new domain produces Otp-lineage neurons co-expressing the telencephalic marker Foxg1 but not Nkx2.1 during development. Furthermore, these glutamatergic cells include a subpopulation of projection neurons of the medial amygdala, which activation has been previously shown to promote autistic-like behavior. Our data open new venues for studying the implication of this neuron subtype in neurodevelopmental disorders producing social deficits.

Title: Neurodevelopmental changes in myelination, cortical thickness and resting state functional connectivity during adolescence

Authors: J. BERO[1], Y. LI[2], A. KUMAR[2], H. LEE[1], W.-Y. AHN[3], S. HAHN[4], H. KIM[5], *D. LEE[6,1];

[1]Neurogazer, Seoul, Korea, Republic of; [2]Neurogazer, Baltimore, MD; [3]Dept. of Psychology, [4]Psychology, Seoul Natl. Univ., Seoul, Korea, Republic of; [5]Psychology, Korea Univ., Seoul, Korea, Republic of; [6]Johns Hopkins Univ., Baltimore, MD

Abstract: Changes in morphometric and cytoarchitectural features during development are accompanied by maturation in the functional connectivity. In particular, adolescence represents a time of unparalleled brain development, but the exact nature of these changes is not well understood. Here, we examined how changes in the three facets of brain development, including myelination (T1w/T2w ratio), cortical thickness (CT) and resting-state functional connectivity (RSFC) are coordinated during adolescence in children between the ages of 10 and 16. Consistent with previous studies, we found that the level of myelin in adolescent children was generally lower than in adults. We then investigated the extent of coordinated changes in three measures by computing grayordinate-level correlation matrices for each measure as well as meta-correlations among correlation matrices of different measures. We found that the meta-correlation between myelin and RSFC was more robust than those between myelin and CT and between CT and RSFC. In particular, meta-correlations among myelin, CT and RSFC tended to be maximum in the sensory-motor cortical areas. Nevertheless, compared to the results in adults, the auditory network showed particularly lower meta-correlation between myelin and RSFC in adolescent children, whereas this was higher for the salience network. We also found that the meta-correlation between myelin and RSFC showed higher values in the visual cortical areas than the meta-correlation related to CT. The results from these analyses were largely unaffected when looking at changes in meta-correlation between a young and old groups of subjects, suggesting that the inter-individual variability in the brain growth underlies the meta-correlation observed in this study. By using a permutation test, we further confirmed that there are no significant age-related changes in all three meta-correlations within the population of subjects in our study. These results demonstrate that the development of cortical myelination and thickness is closely coordinated with changes in functional connectivity among multiple cortical areas during adolescence.

Title: Accumbens-orbitofrontal functional connectivity moderates the association between the executive control system and cognitive impulsivity

Authors: *S. D. KLEIN[1], P. COLLINS[2], M. LUCIANA[3];
[1]Psychology, Univ. of Minnesota- Twin Cities, Minneapolis, MN; [2]Psychology, Univ. of Minnesota-Twin Cities, Minneapolis, MN; [3]Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: A preference for immediate smaller rewards over larger delayed rewards reflects impulsive decision-making. Critically, a maturational imbalance between reward and executive networks may underlie the increase in risk-taking observed in adolescence. The present study employed longitudinal analyses of delay discounting data in order to determine the developmental trajectory of cognitive impulsivity. In addition, we examined how changes in functional connectivity between brain regions implicated in reward processing and incentive motivation (i.e. nucleus accumbens [NAc] and medial orbitofrontal cortex [mOFC]) as well as executive-function and goal-directed behavior (i.e. dorsal caudate [DC] and dorsolateral prefrontal cortex [dlPFC]) relate to the developmental trajectory of cognitive control over impulsive decision-making. 197 participants aged 9 to 23 years completed baseline assessments at wave one, and were followed every two years for five waves (10 years total). Participants completed a delay discounting task at each wave. For each trial, participants chose between an immediate amount of money or $10 available after a delay (i.e. 1, 2, 10, 30, 180, and 365 days later). Indifference points were established within participants at each interval and plotted against time (delay), with areas under the discounting curves (AUC) calculated by summing the resulting trapezoids. The imaging protocol included a T1 weighted structural scan beginning at wave one, and resting state functional scans beginning at wave two. We employed a seed-based approach, with ROIs selected from previous work that examined the differential roles of ventral and dorsal striatum. A quadratic effect of age yielded the best fit when comparing linear and quadratic effects of age on cognitive impulsivity, with a plateau emerging in early adulthood (i.e. age 25. NAc-to-mOFC connectivity moderated the relationship between AUC and DC-to- dlPFC connectivity: individuals that displayed coupling between the reward and executive system (i.e. high or low connectivity between both NAc-mOFC and DC-dlPFC) discounted less. Results suggest that adolescents increasingly able to allocate cognitive resources towards reward maximization as they reach young adulthood, consistent with research findings that development of PFC continues into early adulthood. It appears that coupling of executive and reward networks has implications for the developmental trajectory of cognitive impulsivity.

(CoBrA) Laboratory, Cerebral Imaging Center, Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [5]Section on Developmental Neurogenomics, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: A major goal for developmental neuroscience is understanding how maturational processes are coordinated between different brain regions. This knowledge can serve to better understand the biological basis of neurodevelopmental disorders. This work is built on recent studies that have examined multiple neuroanatomical features of the cortex that are inter-related during the brain maturational process. However, the results are challenging to interpret as differences across the proposed connectivity measures cannot be interpreted as a function of a specific neuroanatomical measure. This distinction is crucial, as neuroanatomical indices such as cortical thickness (CT) and surface area (SA) arise through separate developmental processes and are differentially affected by disorders. To this end, using a novel multivariate technique known as nonnegative matrix factorization (NMF), we sought to improve our understanding of this inter-relatedness in the context of developing brain anatomy. NMF decomposes cortical features into nonnegative part-based representation to improve interpretability. We used the baseline subset of a unique longitudinal sample of structural magnetic resonance imaging acquired from 776 youths (357 F) aged 5 to 25 (M:12.4, SD:~3), provided through an extensive study conducted at the National Institute of Mental Health (NIMH; Bethesda, MD, USA). The neuroanatomical indices were extracted from preprocessed T1 sMRI scans using CIVET, a fully automated morphometric analysis pipeline. Using CT maps analyzed by NMF, we identified cortical components that were mostly bilateral, and showed local systems that divide anatomical sub-regions such as precentral and postcentral, and occipital components, and a relative resemblance of specific large-scale functional networks, such as fronto-parieto-temporal component as for language network. These components can also act as a normative scaffold for neurodevelopmental disorders. Further, SA metrics will be integrated into this framework to better understand the relationship across cortical metrics.

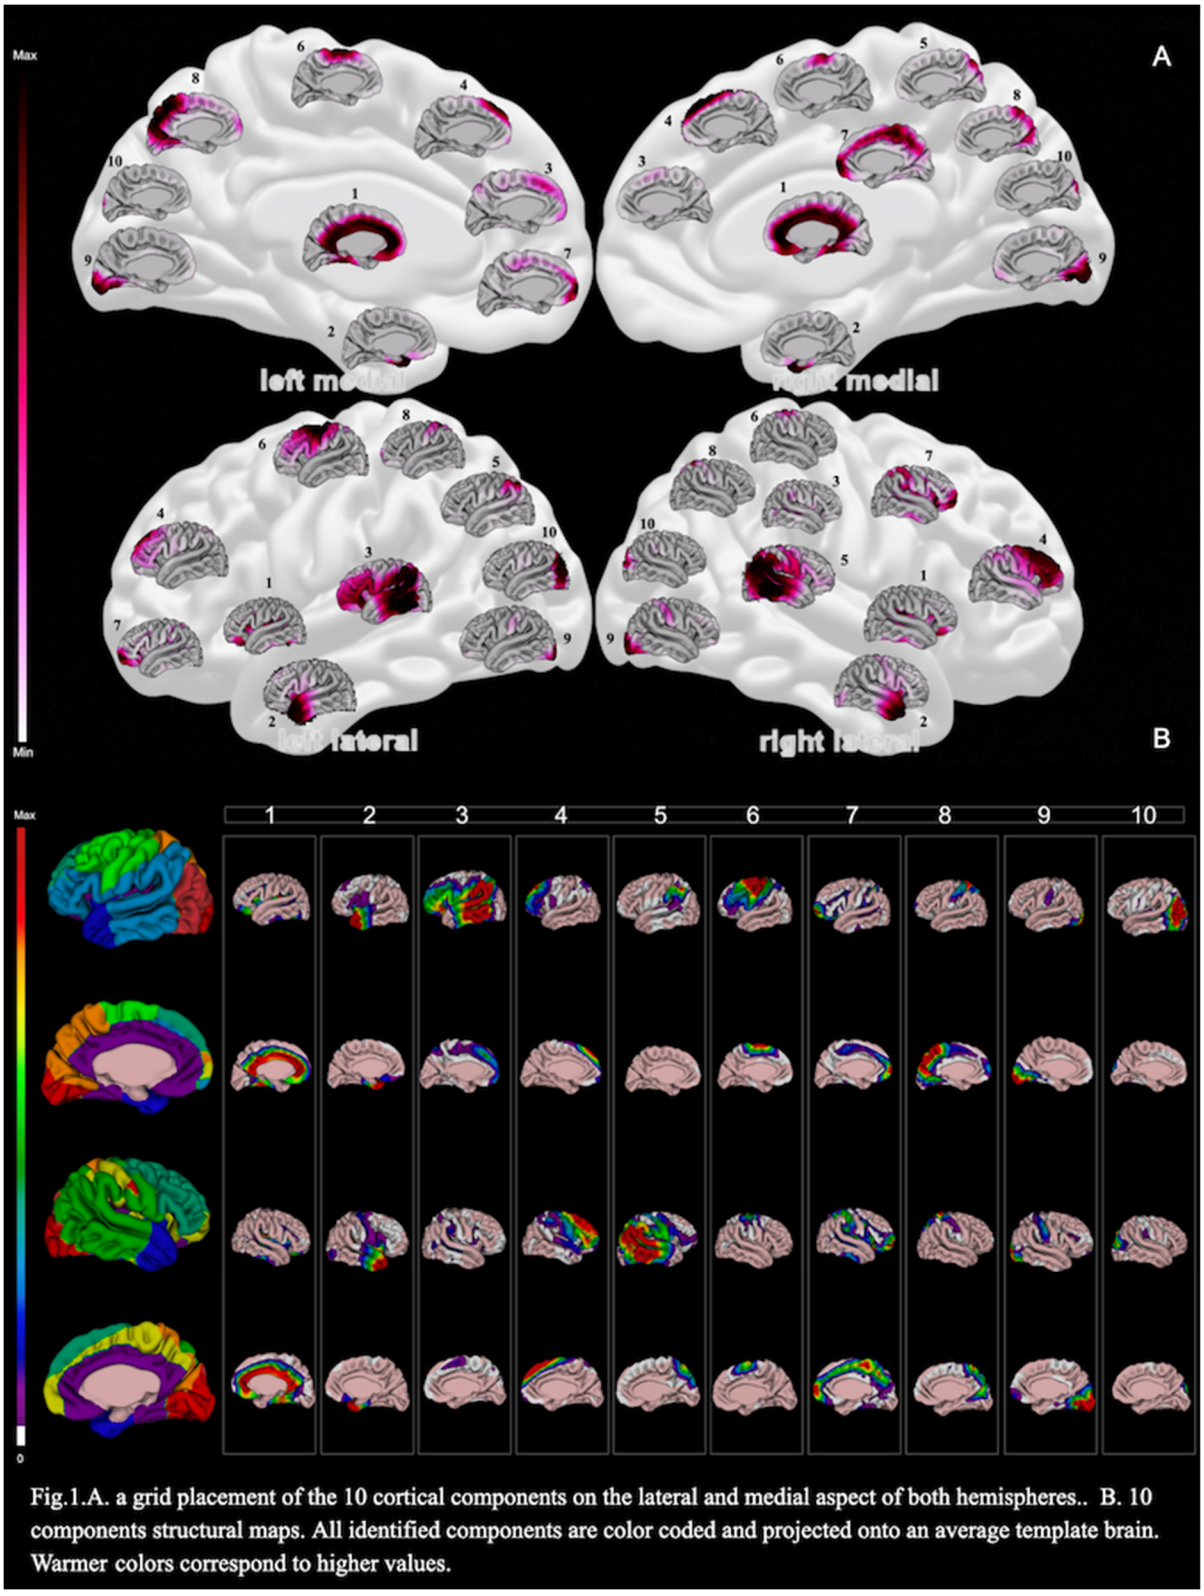

Fig.1.A. a grid placement of the 10 cortical components on the lateral and medial aspect of both hemispheres.. B. 10 components structural maps. All identified components are color coded and projected onto an average template brain. Warmer colors correspond to higher values.

Title: Impact of the Adolescent Environment on the Resting Connectome and Inhibitory Control

Authors: K. SOLDOZY[1], S. M. PARKS[2], S. J. BROOKS[2], *C. STAMOULIS[3,2];
[1]Neurosci., Princeton Univ., Princeton, NJ; [2]Med., Boston Childrens Hosp., Boston, MA; [3]Med., Harvard Med. Sch., Boston, MA

Abstract: Adolescence is a critical period of development, during which regions of the brain involved in higher-level cognitive processes (e.g., decision-making) continue to maturate and change topologically, in part as a result of positive and negative experiences. A significant body of literature has linked negative behavioral outcomes to youth's adverse environments, which have also been mapped onto differences in cognitive function and underlying neural circuitry. In contrast, few studies have analyzed how typical heterogeneity in the early adolescent environment relates to behavior and brain connectivity. Resting-state fMRI, behavioral and survey data from a sub-cohort of n = 5955 children (~51.0% females; median age = 120.0 months, interquartile range (IQR) = 13.0 months) from the Adolescent Brain Cognitive Development (ABCD) cohort were analyzed, with the goal to elucidate the impact of multiple environmental domains (family, school, neighborhood) simultaneously on the properties of the task-independent (resting) adolescent connectome as well as inhibitory control.
Statistical models were first developed to assess the association between resting connectome properties, demographic data and survey questions on youth environment. Preliminary results indicated a significant positive effect of race ($p=0.02$, white versus non-white) and socioeconomic status ($p=0.03$) and a significant negative effect of parental agreement about whether they "believe in raising their voice" ($p=0.03$) on the brain's overall resting connectivity. A second set of models assessed the impact of the environment on inhibitory control, measured by the Stop Signal Task (SST). Older youth ($p<0.01$ for age) and children from families with higher annual incomes ($p<0.01$) had a higher number of correct "Go" trials, whereas children who agreed that their families "fight a lot" had a lower number of correct "Go" trials ($p<0.01$). Additional preliminary models indicated a significant association between both resting connectome properties and environmental variables with inhibitory control measured in the SST. This included a positive effect of small worldness, a fundamental property of a topologically efficient brain ($p<0.01$) and socioeconomic status ($p<0.01$) on the number of correct "Go" trials. Although neuroscientists have long known that positive and negative youth experiences impact both behavior and the neural circuitry that supports it, to our knowledge this study is the first (at least in size and network approach) to quantify the effects of some aspects of youth environment on both properties of the resting adolescent connectome and inhibitory control.

Title: The development of the functional brain network follows puberty-dependent nonlinear trajectories

Authors: *S. ALCAUTER, **Z. GRACIA-TABUENCA**, M. B. MORENO, F. A. BARRIOS; Inst. De Neurobiologia. UNAM, Queretaro, Mexico

Abstract: Adolescence is a developmental period that dramatically impacts body and behavior, where puberty plays an important role not only in the body changes but also in brain structure and function. However, no previous study has explored the effect of pubertal status on the brain functional organization. This work aims to explore such a relationship in a longitudinal sample of children and adolescents, fitting and testing non-linear trends with pubertal status and chronological age as independent variables. The sample consisted of 98 typically developing subjects (45 male, age: 6.7 - 18.1 years old), of whom 41 and 16 returned to a second and a third session, respectively. Participants filled a 4-level pubertal development scale (PDS) and underwent a resting-state fMRI scan (3Tesla, TR = 2s, 150 volumes). Preprocessing included a rigorous artifact-based regression of 36 head-motion parameters (Satterthwaite et al., 2013). Datasets were normalized to standard space, and average fMRI time series were extracted from 264 regions of interest (Power et al., 2011). Brain network organization was assessed using graph theory measures: degree (D), clustering coefficient (C), and global efficiency (E); which accounts for centrality, segregation, and integration in terms of network organization. Generalized Additive Mixed Models (GAMM) were applied to account for nonlinear trends (smooth splines) and longitudinal effects, including average head-motion as a covariate. In a range of 1-48% of connectivity density, four different models were tested: age, PDS, age-sex, and PDS-sex interactions. The best model was selected according to the lower Akaike Information Criterion (AIC). Spline statistical significance was corrected with a false discovery rate (FDR $q < 0.05$). PDS showed lower AIC at densities above 5%, and significant (FDR-corrected) adjustments for every graph measure. D, C, and E measures showed a nonlinear concave pattern, being the turning point of every curve at level 2 of the PDS, the onset of pubertal signs. Results showed that pubertal status better explains the developmental trajectories of the brain functional network properties, compared to age and sex patterns. Also, we found nonlinear increases of functional centrality, segregation, and integration, particularly after the onset of the pubertal signs (level 2 of PDS). This study points out the importance of considering

longitudinal nonlinear trends when exploring developmental trajectories and emphasizes the impact of puberty on the functional organization of the brain in adolescence.

Abstract: Neural plasticity is an essential feature of the central nervous system, allowing it to adapt to the demands of typical development. This adaptability becomes especially relevant in cases of early assault on typical brain development, with resultant changes that can be either beneficial or maladaptive. For example, we know that neonatal stroke ultimately results in alterations to the cortical morphology of the healthy hemisphere. What remains unclear is whether similar alterations follow from neural insults later in life, during childhood and adolescence, and whether these changes are contingent on the size and site of the insult. One might hypothesize that the homologous region contralateral to the resection would exhibit alterations, such as an increase in cortical thickness or volume, as is seen in animal models of cortical ablation. In light of this, we examined the cortical morphology in the contralesional hemisphere following pediatric unilateral resection for the management of pharmacoresistant epilepsy. We found largely comparable measures of cortical morphology in the preserved contralesional hemisphere of patients relative to age- and gender-matched controls and largely independent of lesion size or site. Despite the loss of resected tissue in one hemisphere, these patients nevertheless evinced largely intact cognitive behaviors post-surgery. Altogether, this suggests that beneficial plasticity of the contralesional hemisphere may be less dependent on structural changes than on the neuronal populations' malleability to adopt different functions. This is consistent with our previous findings of widespread altered functional--but intact structural--connectivity in the contralesional hemisphere.

Title: Age-dependent population norms for resting-state functional connectivity using tolerance intervals.

Authors: ***J. JEONG**, A. MARON-KATZ, M. NARAYAN;
Stanford Univ., Palo Alto, CA

Abstract: There is great interest in understanding what constitutes normal brain function across lifespan and to quantify when individuals deviate from this reference. Tolerance intervals are a statistical tool to answer this question by guaranteeing that a targeted proportion of the population falls within a tolerance interval with statistical confidence. This tool has previously been used to detect abnormal patterns of functional connectivity (Maron-Katz et al. 2020). Here, we employ tolerance intervals to establish age-group specific population norms of resting fMRI features using the NKI resting state study. Resting state connectivity is an effective tool to study the effects of aging on cognition and memory (Ferreira et al. 2013). The NKI sample provides 896 participants between the ages of 18 and 81. Each participant has two fMRI scans at TR=1400 ms and TR=2500 ms. All datasets were preprocessed with fMRIPrep and denoised. Average BOLD signals were extracted for 100, 200, and 300 parcels derived from a previously defined functional parcellation (Schaefer et al. 2018). Using the set of 7 previously identified functional brain networks (Yeo et al. 2011), 28 network-network connectivity measures were extracted by averaging the functional connectivity across all parcel pairs that connect every pair of networks. Age-dependent norms were calculated for each network to network connectivity measure using tolerance intervals at population proportion of 80% and confidence level of 95%. To examine the differences between the age groups, bootstrap estimates of the tolerance intervals were used. For scans with TR=2500ms, nearly all connectivity measures across the age groups (18-25, 26-42, 43-52, 53-63, 64-81) were statistically significantly different, after corrections for multiple testing. The scans with TR=1400ms largely provided similar results with some inconsistencies. The discrepancies between both scan types highlight the need to investigate whether norms for functional connectivity can be generalized across temporal resolutions. In conclusion, the NKI study-specific reference distributions for levels of functional connectivity given by tolerance intervals differ across age groups. These findings are consistent with previous work (Dosenbach et. al. 2010) on the effects of brain maturity on functional connectivity. We leave the development of generalizable study-invariant reference distributions to future work. Our preliminary results demonstrate the feasibility of developing statistically rigorous age-dependent norms of normal functional connectivity which can inform the understanding of pathogenic processes in neurological disorders.

Title: Quantified morphology of the cervical and subdiaphragmatic vagus nerves of human, pig, and rat

Authors: ***N. A. PELOT**[1], G. B. GOLDHAGEN[1], J. E. CARIELLO[1], E. D. MUSSELMAN[1], K. A. CLISSOLD[2], J. A. EZZELL[2], W. M. GRILL[1];

Abstract: It is necessary to understand the morphology of the vagus nerve (VN) to design and deliver effective and selective vagus nerve stimulation (VNS) because nerve morphology influences fiber responses to electrical stimulation. We quantified the morphology of nine left cervical and nine anterior subdiaphragmatic VNs from each of three species: humans (4F/5M, 54 to 90+ years), domestic pigs (6F/3M, 10 to 15 weeks), and SD rats (4F/5M, 11 to 38 weeks). We collected samples from each species at standardized locations. The samples were post-fixed in formalin and embedded in paraffin, and transverse sections were stained with Masson's trichrome. To label the perineurium, we conducted anti-claudin-1 immunohistochemistry on human samples and anti-fibronectin immunofluorescence on pig samples. We quantified nerve size, number of fascicles, fascicle size, proportions of endoneurial, perineurial, and epineurial tissue, and perineurium thickness. Human and pig VNs were comparable sizes, but pig nerves had ten times more fascicles than human; rat nerves were ten times smaller in diameter. Human and pig VN perineurium was thicker than previously published human somatic nerve data, with thicker perineurium for larger fascicles and thicker perineurium normalized by fascicle diameter for smaller fascicles; perineurium thickness is known to significantly affect thresholds for electrical stimulation. There were substantial differences in VN morphology across specie and, secondarily, between individuals. Understanding these differences in VN morphology between preclinical models and the clinical target, as well as the variability across individuals, is essential for advancing the therapeutic efficacy of VNS.

Abstract: How have complex brain regions, circuits, and cell types evolved from simple origins? Here we investigate brain region evolution at cell-type resolution in the cerebellar nuclei, the output structures of the cerebellum. We applied single-nucleus RNA sequencing in chickens, mice, and humans, STARmap spatial transcriptomic analysis in chicken and mice, and whole-CNS projection mapping in mice. Our work revealed a conserved cell-type set containing three classes of region-invariant inhibitory neurons and two classes of region-specific excitatory neurons. This cell-type set forms an archetypal cerebellar nucleus that was repeatedly duplicated to create new regions. In excitatory neurons, duplication was accompanied by divergence in gene expression and shifts in projection patterns (neofunctionalization). By contrast, inhibitory neurons maintained their gene expression signatures (isofunctionalization). Interestingly, the excitatory cell class that preferentially funnels information to lateral frontal cortices in mice becomes predominant in the massively expanded human Lateral CN. Our data provide the first characterization of CN transcriptomic cell types in three species and suggest a model of brain region evolution by duplication and divergence of entire cell type sets.

Abstract: The middle temporal gyrus (MTG) is a cortical brain region involved in language processing and integrating sensory input. Many human-centric neurodegenerative and neuropsychiatric diseases implicate MTG in neuropathological progression. So, what makes human MTG unique compared to our closest living relatives? In this study, we explore this question in the context of transcriptomically-defined cell types. We present a comparative analysis of single nucleus RNA-seq datasets from MTG of human (n = 7), chimpanzee (n = 7), gorilla (n = 4), rhesus macaque (n = 3), and marmoset (n = 3). Brain samples were collected from postmortem adult species of both sexes (except rhesus - female only). Nuclei were stained for NeuN and captured with fluorescence-activated cell sorting (FACS) to enrich for neurons (NeuN+) while also capturing a minority of non-neuronal (NeuN-) cells. Single nucleus libraries were generated with 10x Chromium V3, and ~100,000 nuclei per species passed quality control. Layer-dissected SMART-seq V4 datasets were generated, resulting in ~14,800 human, 4,100 chimpanzee, and 4,700 gorilla nuclei. Datasets were analyzed in R using Seurat 3.2.2. To identify cell types, the datasets were checked for quality, clustered, and curated separately for each species. Curated taxonomies were then integrated to identify a cross-species taxonomy of consensus cell types across the 5 species. We present 6 robust single-nucleus RNA-seq taxonomies; one for each species, and a cross-species taxonomy of conserved cell types. Diversity of MTG cell types, their distributions throughout the cortical layers, and their proportions are remarkably well conserved across species. Despite striking levels of conservation, we report notable species differences in chandelier cell proportions, subclass level expression differences of gene families, and an expansion of diversity in L6 IT Car3 types. Lastly, we explore expression of human neuropsychiatric disease-associated genes across cell types and species.

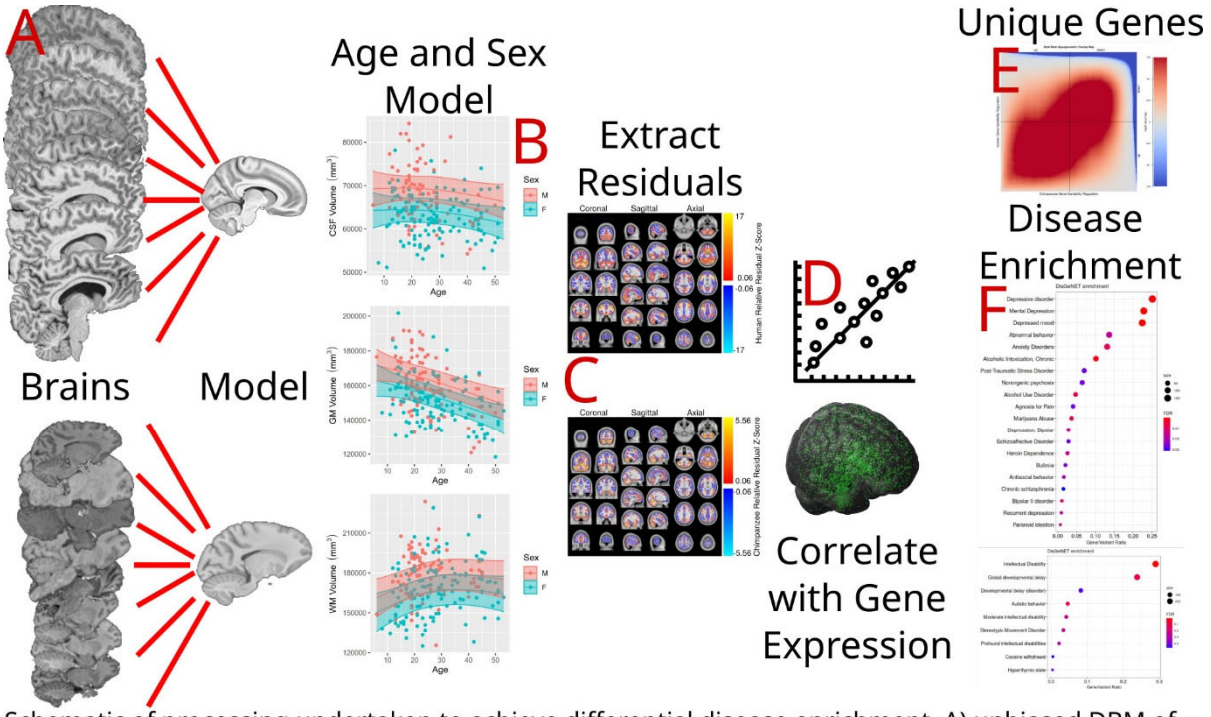
Branch, NIMH Intramural Res. Program,, NIH, Bethesda, MD

Abstract: Chimpanzees, among the closest living relatives of humans, have remarkably similar brain structure despite 6-8 million years of divergent evolution. Prior work investigating genetic expression differences between chimps and humans (Khrameeva et al., 2020; Pollard et al., 2006; Sousa et al., 2017) identified a relationship between cortical expansion and "Human Accelerated Regions" of the genome (Wei et al., 2019). We present a novel analysis of the human transcriptome related to brain regions that increase in variability through evolution. We develop the concept of “residual variability”, variability remaining in a brain measure after accounting for a population’s age and sex, and use it to examine evolutionary differences between species. Here, we test the hypothesis that brain evolution is accompanied with an increase in neuroanatomically specific variability that has a transcriptional basis.

We apply the residual variability concept to deformation based modelling of healthy adult lifespan chimp and human cohorts yielding residual variability maps, warped these maps into MNI space, correlated them with human gene expression from the Allen Human Brain Atlas, and ordered by strength of correlation. Next, we used Rank-Rank Hypergeometric Overlap, to compare the species lists and extract the uniquely up and downregulated genes. We then subjected these gene sets to gene ontology(Liao et al., 2019) and disease(Piñero et al., 2020) enrichment analyses.

Gene enrichment on molecular function, biological process and cellular components reveal several processes associated with regions of increased variability in humans, in particular, downregulated genes associated with DNA/RNA expression and transcription. Meanwhile, gene disease enrichment analysis reveals associations between upregulated genes and neuropsychiatric disorders such as depressive symptoms (q=0.0002), psychosis (q=0.02) and anxiety disorder (q=0.008). Downregulated genes are associated with neurodevelopmental disorders such as intellectual disability and developmental delay (q=0.01).



Schematic of processing undertaken to achieve differential disease enrichment, A) unbiased DBM of human and chimpanzee population, B) voxel-wise modelling of age and sex trajectories, C) extraction of voxel-wise residuals, D) correlation of residuals with Allen Human Brain Atlas in MNI space, E) rank-rank hypergeometric overlap to extract unique human genes, and finally F) gene list disease enrichment.

Title: Establishing a Functional Role for UTY in Sex-Specific Fetal Development

Authors: *K. D. ROCK, B. M. NUGENT, L. M. FOLTS, T. L. BALE;
Univ. of Maryland, Baltimore, MD

Abstract: Stress experienced early in pregnancy has been identified as a significant male-specific risk factor for neurodevelopmental disorders. Fetal development relies on a healthy and properly functioning placenta, which can be significantly impacted by changes in maternal

physiology. Primarily made up of cells that are fetal in origin, the placenta expresses fetal sex (XX or XY). Consequently, X and Y-linked genes have the potential to introduce sex-specificity in placental function and fetal development, and in cellular responses to a changing maternal milieu. In our established mouse model of early prenatal stress (EPS), male offspring show increased vulnerability to long-term disruptions in cognition, stress sensitivity, and metabolic dysfunction that are endophenotypes relevant to neurodevelopmental disorders. EPS also induces dramatic changes in the male placental transcriptome that persist throughout the duration of pregnancy. We previously identified the novel X and Y-linked epigenetic regulators, UTX and UTY, of the canonical histone repressive mark, H3K27me3, as potential mediators of male risk and female resilience to stress *in utero*. UTX and UTY are homologous genes on the X and Y chromosome that belong to the H3K27me3 demethylase gene family. While UTX is a demethylase, the exact function of UTY remains unclear. Recent studies suggest that UTY may play some functional role in metabolism, development, and sexual differentiation of the brain. To test the hypothesis that UTY contributes to male-specific developmental outcomes in response to EPS, and improve our understanding of UTY functionality, we utilized two different transgenic approaches in order to overexpress UTY (UTY-OE) either in 1) the placenta or 2) the developing brain. Pregnant dams were randomly assigned to control or EPS conditions and sacrificed at embryonic day 18.5 for fetal brain and placental collections or allowed to litter in order to track changes in offspring growth and stress reactivity. Functional profiling in the placenta revealed a significant overlap in detectable transcripts between wildtype males and UTY-OE females, and highlighted demethylase activity and hormonal signaling as important biological processes regulated by UTY. Partial recapitulation of the male-specific EPS phenotype was observed in female placental UTY-OE offspring that showed a hyperactive stress response. Taken together, these studies demonstrate a novel role for UTY in placental function and fetal neurodevelopment. Further, these studies provide some of the first evidence that UTY, similar to UTX, does function as a demethylase.

Abstract: Long-term potentiation (LTP) of synaptic transmission is known to be the basis for memory formation. The regulation of AMPA receptor (AMPARs) at postsynaptic density (PSD) is the major mechanism to maintain LTP. AMPARs form segregated clusters, called nanodomains, in an activity dependent manner and the nanodomains align with presynaptic vesicle releasing sites to form a trans-synaptic nanocolumn, which regulates the efficacy of synaptic transmission. However, the mechanism underlying remains unclear. Here we found that calcium/calmodulin-dependent protein kinase II (CaMKII) undergoes liquid-liquid phase separation (LLPS) with NMDAR subunit GluN2B through its multivalent interaction contributed by its dodecameric structure in a Ca^{2+} dependent manner as possible mechanism of the incorporation of CaMKII into PSD. The initial formation of the CaMKII-mediated LLPS was independent of its kinase activity, however, to maintain the protein condensate, the CaMKII T286 autophosphorylation is required. Interestingly, the incorporation of CaMKII resulted in the segregation of Stargazin, as a proxy of AMPAR, from GluN2B as a phase-in-phase structure. Furthermore, Neuroligin-1 (NLGN1), a neuronal adhesion molecule, which clusters presynaptic neurexin, also segregates together with AMPAR. The segregation of AMPAR and NMDAR was also observed in living neuron with dual-color direct stochastic optical reconstruction microscopy (dSTORM). This segregation was disrupted by membrane-permeable CN21 (tat-CN21) which competes and disrupts CaMKII-GluN2B interaction. Furthermore, tat-CN21 also reduced the segregation between of NLGN1 and NMDAR. These results suggest that the incorporation of CaMKII into PSD and the interaction between CaMKII and GluN2B is critical for the formation of AMPAR nanodomain and the trans-synaptic nanocolumn. We anticipate that Ca^{2+}-induced and persistent formation of LLPS by CaMKII can be a novel mechanism for synaptic plasticity and serves as molecular basis of memory by functioning as an activity-dependent crosslinker for postsynaptic proteins.

Title: Fast synaptically activated calcium kinetics in pyramidal neuron dendritic spines

Authors: K. MIYAZAKI, *W. N. ROSS;
Physiol., New York Med. Col., Valhalla, NY

Abstract: Previous studies have examined calcium changes in dendritic spines in some detail. However, there are some problems, which may make some of quantitative conclusions subject to reexamination. One issue is whether 2-photon glutamate uncaging accurately mimics synaptic release of glutamate. Electrical stimulation releases glutamate from vesicles into an area of about 0.1μm^2 while an uncaging pulse releases glutamate into a larger volume. This probably means that more NMDA receptors are activated and for longer time than synaptic stimulation, even when the electrical response to uncaging flashes is matched to mEPSCs made by AMPA receptors. A second issue is whether recordings using relatively high affinity calcium indicators are accurate. Measurements using low affinity indicators, with less buffering, like OGB-5N

should be more precise but may be difficult to record with adequate S/N. To try to overcome these problems we did experiments with minimal electrical stimulation, and detected OGB-5N fluorescence using focused laser illumination and a fast CCD camera. Preparation of mouse hippocampal slices, indicator loading, and patch recordings of CA1 pyramidal neurons were made using standard methods. Sodium transients were measured simultaneously using a high speed multiplexing protocol. We found that: (1) synaptic calcium signals had a rise time of <10 ms, with almost no variation as a function of EPSP size. The same fast rise time was detected with OGB-5N, fluo-5f, or OGB-1. (2) Synaptic sodium signals, detected with SBFI, also had faster rise times than 10 ms, probably faster than the calcium signals. Both of these fast signals were slower that the rise times of bAP calcium and sodium signals, which were both <2ms. This indicates that the EPSP in the spine, while fast, is not as fast as the bAP in the spine. Consistent with previous results, most of the calcium signal (but not the sodium signal) was blocked by APV or CPP showing that it was through the NMDA receptor. Most of the calcium signal also was blocked by NBQX. Since calcium does not enter through these AMPA receptors, this means that the AMPA driven EPSP is the main driver of calcium entry. This is consistent with the fast EPSP voltage relieving the Mg^{2+} block of the NMDA receptor. The synaptic calcium transient recovered more slowly than the calcium transient caused by a bAP (35-50 ms compared with 15-20 ms) but significantly faster than recorded with higher affinity indicators. Since the EPSP in the spine is very fast (implying that the relief of the Mg^{2+} block is short-lived) this suggests that there is an additional brief component of calcium entry through the NMDA receptor after the EPSP potential has returned to rest.

Title: Cell type specific functional impact of NRXN1-alpha splice isoforms

Authors: *M. B. FERNANDO, A. N. MURPHY, E. K. FLAHERTY, S. ZHU, G. FANG, P. A. SLESINGER, K. J. BRENNAND;
Nash Family Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Neurexins are critical pre-synaptic proteins involved in organizing synaptic connections in the brain. Extensive alternative splicing results in diverse and cell-type specific isoform repertoires across brain-regions, which show differential binding to a myriad of postsynaptic ligands. Heterozygous deletions in *NRXN1* (*NRXN1+/-*) are highly penetrant and strongly associated with a variety of neurodevelopmental disorders. Patient-specific *NRXN1+/-* neurons, derived from human induced pluripotent stem cells, show gross dysregulation of

wildtype *NRXN1* alpha isoforms and can express dozens of novel isoforms from the mutant allele. However, the cell-type specific functional impact of such isoform repertoires is poorly understood. We now seek to resolve the cell-type specific functional impact of *NRXN1* alpha splice variants in glutamatergic and GABAergic neurons, using overexpression strategies and advanced gene editing techniques (CRISPR/CasRx). We hypothesize that manipulation of wildtype and mutant *NRXN1* isoforms will produce distinct effects on synaptic neuronal function, transcriptional pathways, and protein-protein interactions. Overall, this study will dissect the cell type specific impact of *NRXN1* alpha splicing and evaluate the genotype specific mechanisms of how *NRXN1*+/- leads to aberrant neurocircuitry and disease.

Title: Gabaergic innervation of dorsal raphe-projecting layer v pyramidal neurons in medial prefrontal cortex correlates with food intake of mice in the activity-based anorexia model

Authors: *M. DU[1,2], A. N. SANTIAGO[2], C. J. AOKI[2];
[1]New York Univ. Shanghai, Shanghai, China; [2]Ctr. Neural Sci., New York Univ., New York, NY

Abstract: Anorexia Nervosa (AN) is an eating disorder characterized by voluntary food restriction and excessive exercise. With a high mortality rate but no approved pharmacological treatment, research on AN is demanding. We used the Activity-Based Anorexia (ABA) mouse model to study the neurobiology of AN. Previous studies have uncovered the role of dorsal raphe (DR) in regulating feeding behaviors of mice. Interestingly, DR does not receive any direct input from the primary sensory cortices but substantially from the Layer V pyramidal neurons in the medial prefrontal cortex (mPFC). This implies the regulation of feeding by DR may involve higher-order cognitive control, such as the voluntary food restriction even during the 2 hour window of food availability seen in ABA. In this study, we selectively activated pyramidal neurons in Layer V of mPFC projecting to DR with Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) expressed through retrograde cre-dependent gene transfer.

Surprisingly, we found that selective activation of the mPFC-to-DR pathway through sc injection of C21 (1 mg/kg) to activate hM3D(Gq)-mCherry DREADDs did not significantly alter the food intake in the ABA model of mice (N=7, female) compared to the control group (N=13, female) whose mPFC-to-DR pathways were not activated. Electron microscopic immunohistochemistry validated the effectiveness of this chemogenetic method of neuromodulation by identifying the presence of mCherry-immunoreactivity on the plasma membrane and in the cytoplasm of mPFC Layer V pyramidal neurons' cell bodies, apical dendrites, spines and axon terminals forming excitatory synapses. In addition, we found that the degree of gamma-aminobutyric acid-(GABA)-ergic innervation, captured by the percent coverage of the cell body by GABAergic axon terminals, of the DR-projecting pyramidal neurons in mPFC was significantly greater than the non-DR-projecting subgroup by ~60% ($p=0.0312$), and it correlated significantly and negatively with the food intake only on the day when the mPFC-to-DR pathway was stimulated by DREADDs ($p=0.0035$, $r=-0.9181$). These results indicate the potential roles of GABAergic innervation of DR-projecting pyramidal neurons from mPFC in regulating feeding behaviors of mice in the ABA model. It also suggests that local GABAergic interneurons may be recruited during the chemogenetic manipulation of the mPFC-to-DR pathway, which results in a counteracting effect. Overall, this research sheds light on the potential etiology of anorexia nervosa by identifying the involvement of GABAergic innervation of specific subgroup of pyramidal neurons in mPFC in murine vulnerabilities to ABA.

Title: The effect of 14-3-3 proteins on NMDAR synaptic trafficking in hippocampal and cortical neurons

Authors: *G. S. LEE, Y. ZHOU;
Biomed. Sci., Florida State Univ. Col. of Med., Tallahassee, FL

Abstract: One of the core pathogenic mechanisms for schizophrenia is believed to stem from dysfunction in glutamatergic synaptic transmission, particularly hypofunction of N-methyl d-aspartate receptors (NMDARs). Previously we have shown that 14-3-3 functional knockout (FKO) mice exhibit schizophrenia-associated behaviors accompanied by reduced synaptic NMDARs in forebrain excitatory neurons. Based on these findings, we hypothesize that 14-3-3 proteins may act as a key component of post-synaptic NMDAR complex with a positive role in regulating synaptic levels of NMDARs. To ascertain the role of 14-3-3 proteins in regulating synaptic targeting of NMDARs, we tested whether 14-3-3 proteins affect synaptic localization of

NMDARs by expressing 14-3-3 peptide inhibitor in primary neurons. We found that inhibition of 14-3-3 proteins in these neurons leads to decreased synaptic localization of NMDAR subunits. We then investigated the underlying mechanism by using a variety of biochemical and imaging assays in heterologous cells. Using surface biotinylation and immunocytochemistry, we determined that inhibition of 14-3-3 proteins leads to decreased surface expression of NMDAR subunits. In addition, we found that several 14-3-3 isoforms directly interact with GluN2A and GluN2B subunits. We will further identify 14-3-3 protein binding sites and generate 14-3-3 binding deficient mutant constructs to establish a link between 14-3-3 protein binding and NMDAR surface delivery. As NMDAR hypofunctionality is known to act as a convergence point for progression of symptoms of schizophrenia, our findings may contribute to the understanding on molecular mechanism(s) that leads to NMDAR hypofunctionality at the synapses.

Title: Glutamate-induced tonic excitatory currents in melanin-concentrating hormone neurons

Authors: *M. CHOWDHURY, S. BOWES, M. HIRASAWA;
Div. of Biomed. Sciences, Fac. of Med., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Glutamate (Glu) transporters play a major role in glutamatergic transmission by regulating the extracellular Glu levels. We previously found using whole-cell patch clamp that a robust tonic inward current (TIC) is induced by a non-specific Glu transporter inhibitor TFB-TBOA in melanin concentrating hormone (MCH) neurons in the hypothalamus. This suggests that MCH neurons, known to promote positive energy balance and sleep, are tightly regulated by Glu transporters. TBOA-induced TIC is largely blocked by NMDA receptor antagonist D-AP5, suggesting an involvement of NMDAR. This was somewhat surprising as our recording condition (holding potential = -70 mV) should not be permissive to postsynaptic NMDAR activation due to Mg2+ block. Thus, to investigate the underlying mechanism, we performed patch clamp recording on MCH neurons in rat and mouse brain slices. We first compared TBOA-TIC recorded in the absence or presence of extracellular Mg2+ while holding the cell at -70 mV and found that there was no significant difference. This confirms that the involvement of postsynaptic NMDAR is unlikely. However, Mg2+ insensitive metabotropic NMDAR signaling may be a probable mechanism. Hence, we tested MK-801 (NMDAR open channel blocker) and found that it largely blocks TBOA-TIC to a similar extent to D-AP5, indicating that ionotropic, not metabotropic signaling of NMDAR is involved. It is possible that TBOA-induced increase in

ambient Glu could indirectly excite MCH neurons by activating NMDAR on other cells. As TBOA-TIC is insensitive to tetrodotoxin that blocks neuronal activity, it may involve astrocytic NMDAR activation followed by release of gliotransmitters such as ATP, which can in turn activate excitatory P2X receptors on MCH neurons. To test this, PPADs (P2XR antagonist) was used, which blocked TBOA-TIC to a similar extent as D-AP5 or MK-801, indicating that indeed ATP mediates NMDAR-dependent TIC. Taken together, our results are consistent with the idea that ambient Glu acts on astrocytic NMDAR to trigger ATP release, which in turn stimulates MCH neurons via P2XR. This may represent a novel mechanism of astrocyte-neuron interaction that regulates the excitability of MCH neurons. Given the known role of MCH neurons, this may have functional implications on sleep and energy homeostasis.

Title: Protons as a putative second messenger in synaptic plasticity

Authors: *A. KONOMI PILKATI, S. PEDERSEN, K. MADSEN;
Copenhagen Univ., Copenhagen, Denmark

Abstract: The hippocampus is a complex structure involved in learning and memory. Its main cell type are pyramidal neurons which are glutamatergic neurons. It has been reported that upon glutamatergic, NMDA, AMPA or KCl stimulation, these neurons undergo a brief period of cytosolic acidification, reaching pH 6-6.5. The underlying mechanism of this phenomenon remains unknown, although it has been shown to be dependent on extracellular calcium. pH homeostasis is known to be crucial for proper neuronal functioning, however, it is rarely considered in neuronal activity; There is evidence showing that activity-induced changes in extracellular and intracellular pH are linked to altered neuronal excitability. Moreover, its relevance in synaptic plasticity has also been suggested. Therefore, due the potential implications of this stimulation-dependent acidification, we have investigated the role of intracellular calcium in this phenomenon, as well as exploring the source of H^+. Additionally, we have tested whether this acidic response occurs not only during neuronal stimulation but also during synaptic plasticity. To this end, we employed a novel dual biosensor approach; we used cyto-pHluorin, a pH sensing GFP variant, together with the Ca^{2+}-sensor R-GECO1.2, which allows us to correlate changes in pH to increases in cytosolic Ca^{2+} levels in response to neuronal activation within individual cells. These sensors were transfected into hippocampal primary cultures and live imaging experiments were performed under different drug conditions. To test the role of cytosolic calcium we treated the neurons with Ionomycin, Verapamil, and BAPTA-AM. These

approaches showed that a rise of intracellular calcium itself is not sufficient to trigger the pH drop and depending on the source of stimulation, cytosolic calcium can be a requirement or not for the acidification to occur. Moreover, by alkalization of the extracellular environment and therefore removing the H^+ gradient, we further obtained results suggesting that glutamate receptors might have a conductance for H^+. Finally, to test whether this activity-induced acidification occurs during synaptic plasticity, we switched to a more physiological set up; acute brain slices from adult rats transduced with the sensors were electrophysiologically stimulated to induce LTP. The recordings from CA1 neurons showed a transient cytosolic acidification under the LTP conditions. All together, these findings reveal that the activity-induced acidification mechanism and its requirements varies depending on the stimulation source and this phenomenon is taking place not only in regular activity but also during synaptic plasticity.

Title: The neuronal glutamate transporter EAAC1 reduces the excitability of D1 medium spiny neurons

Authors: *M. A. PETROCCIONE, L. D'BRANT, N. AFFINNIH, H. CHESBRO, S. ZAHID, A. SCIMEMI;
Univ. At Albany - SUNY, Albany, NY

Abstract: The neuronal glutamate transporter EAAC1 is expressed at central excitatory and inhibitory synapses. At excitatory synapses, EAAC1 limits glutamate escape from the synaptic cleft and extra-synaptic receptor activation. At inhibitory synapses, EAAC1 promotes GABA synthesis and release. The dorsolateral striatum is a region of the basal ganglia where EAAC1 is most abundantly expressed. Here, D1- and D2-dopamine receptor expressing medium spiny neurons (D1- and D2-MSNs, respectively) receive excitatory inputs from the thalamus and cortex, and inhibitory inputs from other MSNs and local interneurons. Here, regulating the time course and strength of excitation and inhibition is important to ensure coordinated movement execution. It is currently unknown whether and how EAAC1 controls various sources of excitation and inhibition. Here we use electrophysiology and optogenetics approaches to show that EAAC1 only strengthens inhibition at a subset of inhibitory synapses formed between D1-MSNs. By using compartmental models of D1-MSNs, we show that this effect leads to a multiplicative scaling of the output firing of D1-MSNs that is most pronounced at high

frequencies of incoming synaptic excitation. Together, these findings underscore some of the fundamental mechanisms that allow neuronal glutamate transporters to shape cell excitability by limiting spillover and by promoting neurotransmitter biosynthesis and release.

Title: Stimulation-evoked acetylcholine and choline release in striatum detected with genetically-encoded sensors

Authors: *D. M. LOVINGER, J. A. NADEL, L. VOYVODIC, A. G. SALINAS;
Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Acetylcholine (ACh) is a prominent neurotransmitter in the striatum derived from cholinergic interneurons (CINs) and brainstem afferents. ACh effects on striatal physiology and related behaviors are well characterized. Less is known about ACh release dynamics and extracellular levels. The ACh metabolite choline can activate α7 subunit-containing nicotinic ACh receptors. Recent development of genetically-encoded periplasmic binding protein-based (iAChSnFR) and G protein-coupled receptor-based (GRAB-ACh3.0, ACh3.0) ACh sensors allows for real-time extracellular ACh measurement. We virally expressed these sensors in dorsomedial striatum, and used brain slice photometry to examine release dynamics. Spontaneous increases in fluorescence lasting a few sec were observed in slices expressing either sensor. In slices expressing iAChSnFR, single intrastriatal electrical stimuli evoked fluorescent transients lasting 10s of seconds. Similar stimuli produced much shorter-lasting transients in slices expressing ACh3.0. The transients observed with both sensors were blocked by tetrodotoxin and reduced in low extracellular calcium. The ACh esterase inhibitor Tacrine prolonged stimulus-induced transients measured with either sensor. We examined mechanisms that might contribute to the prolonged increase observed with iAChSnFR. The transients detected with iAChSnFR showed a biphasic decay with time constants of a few seconds and 10s of seconds. Tacrine converted this to a single decay component lasting 10s of seconds. Microstimulation from a pipette electrode evoked long-lasting transients, but responses at the lowest stimulus intensities persisted for only a few sec. Optogenetic stimulation of CINs using Chrimson produced fluorescence transients persisting for 10s of sec. Unlike ACh3.0, iAChSnFR is activated by choline at uM concentrations. We observed fluorescence increases upon extracellular application of ACh (1-1000 uM) or choline (10-1000 uM) in slices expressing iAChSnFR, with sensitivity higher for ACh. To determine if enhancing choline levels leads to

fluorescence increases we applied the choline transporter inhibitor ML-352. This compound enhanced fluorescence measured with iAChSnFR. Both ACh sensors can detect stimulus-induced ACh increases with comparable sensitivity. However, iAChSnFR may also detect stimulus-induced choline increases. Stimulation-induced choline levels appear to be in the lower end of the range that can activate α7-containing nAChRs. Thus it will be interesting to determine if striatal α7 nAChRs (e.g. on corticostriatal glutamatergic terminals) can be activated by this type of stimulation.

Title: Adenosine A3 receptors couple to vitamin C transporter SVCT2 and regulate neuronal redox balance

Authors: *R. PAES-DE-CARVALHO[1], C. C. PORTUGAL[2], T. G. DA ENCARNAÇÃO[1], M. A. SAGRILLO[1], M. R. PEREIRA[1], J. B. RELVAS[2], R. SOCODATO[2];
[1]Univ. Federal Fluminense, Niterói, Brazil; [2]Univ. do Porto, Porto, Portugal

Abstract: Adenosine is a vital neuromodulator involved in several aspects of CNS physiology and development such as regulation of neurotransmitter release, myelin formation, neurite outgrowth, and neuronal survival. Adenosine activates A1, A2a, A2b and A3 receptors, widely expressed in CNS, which are all G protein-coupled receptors that classically modulate adenylyl cyclase activity. A1 and A3 receptors are usually coupled to inhibitory G proteins to decrease intracellular cAMP, while A2a and A2b receptors usually couple to stimulatory G proteins and increase intracellular cAMP. A3 receptors signal through Gi or Gq proteins, leading to adenylyl cyclase inhibition or phospholipase C stimulation and increased diacylglycerol, IP3 and intracelular calcium. Vitamin C is an antioxidant that exerts several neurophysiological functions such as the formation of the Schwann cell myelin sheath, regulation of acetylcholine release, regulation of NMDA receptor function, and acts as a co-factor in a plethora of enzymatic reactions such as the conversion of dopamine to norepinephrine and the synthesis of neuropeptides. The vitamin C oxidized form, dehydroascorbate (DHA), is taken up by glucose transporters while ascorbate, its reduced form, is taken up by the Sodium Vitamin C coTransporters SVCT1 and 2. Our previous work showed the presence of adenosine and vitamin

C systems in avian retinal cultures. Here we studied the interplay between the adenosinergic system and ascorbate transport in the cultures. We found that selective activation of A3, but not A1 or A2a adenosine receptors, modulates ascorbate transport, decreasing intracellular ascorbate content. Förster resonanse energy transfer (FRET) analysis showed that A3 receptors associate with the ascorbate transporter SVCT2, suggesting tight signaling compartimentalization between A3 receptors and SVCT2. The activation of A3 receptors increases ascorbate release in an SVCT2-dependent manner, largely altering the neuronal redox status without interfering with cell death, glycolytic metabolism and bioenergetics. We conclude that, by regulating Vitamin C transport, the adenosinergic system (via activation of A3 receptors) can regulate ascorbate bioavailability and controls the redox balance in neurons.

Abstract: Vesicular neurotransmitter transporters (VNTs) mediate selective uptake and enrichment of small molecule neurotransmitters into synaptic vesicles (SVs), and are therefore one major determinant of synaptic output for specific neurons. All the known VNTs belong to solute carrier (SLC) transporter family. Given that SLC contains more than 450 members, with ~one third of which are still orphan or poorly characterized, we hypothesize there exist novel VNTs in the SLC family, and their cognate substrates are potential novel neurotransmitters or neuromodulators. To identify putative new SV transporters, we molecularly cloned 361 human SLC transporters to fuse them in frame with a fluorescent protein, then carried out a localization profiling in cultured neurons by co-expressing SLCs with a known SV marker as well as other organelle markers. Using known VNTs' localization score as a benchmark, we identified ~30

novel transporters capable of localizing to SVs. To validate their in vivo existence, we immune-isolated native SVs from mouse brains. Proteomic analysis revealed the presence of 7 (out of 20) transporters, with a subset of orphan SLC35 subfamily transporters, SLC35D3, SLC35F1 and SLC35G2. Further ultrastructural analysis by electron microscopy confirmed SLC35D3's ability to localize on SVs. Using mass spectrometry-based metabolite profiling and radioactive transport assay, we identified and confirmed UDP-glucose, a nucleotide-sugar, as a specific substrate for SLC35D3. Finally, we performed radioactive transport assay using native SVs derived from mouse brain, and observed UDP-glucose, but not its close analog UDP-galactose, was able to be selectively uptaken into SVs in a way sensitive to vesicular proton electrochemical gradient. In sum, our localization and proteomic analysis identified unexpected rich vesicular transporter candidates and among them SLC35D3 as a novel vesicular UDP-glucose transporter. These efforts would yield new insights to the function of SLC family genes and provide better understanding of the molecular diversity of chemical neurotransmitters.

Title: Vagal nerve stimulation modulates levels of select monoamines in primate CSF

Authors: *B. T. SEATON[1], M. J. AVILA[2], D. O'NEILL[3], A. J. FUGLEVAND[3], M. L. HEIEN[1], K. M. GOTHARD[3];
[1]Dept. of Chem. and Biochem., [2]Dept. of Neurosurg., [3]Dept. of Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Vagal nerve stimulation (VNS), used successfully to treat epilepsy, depression, chronic pain, and even neuro-inflammation, brought to light evidence that increasing afferent traffic along the vagus nerve elevates the level of monoamines in the brain, increases regional blood flow in key brain areas for affect, and alters cellular activity and plasticity. Similar effects are observed in response to behavioral practices that increase vagal tone. These effects appear associated with, but not causally explained by, peripheral autonomic changes. To explore the neurochemical effects of VNS, we harvested CSF from an Ommaya reservoir implanted in an anesthetized monkey instrumented for vagal nerve stimulation. We measured the levels of monoamines in the CSF before and after low-frequency stimulation, expected to increase afferent vagal inputs to the brain, and high-frequency stimulation, expected to block traffic along the vagal nerve. Using ion-pair high performance liquid chromatography with electrochemical detection (HPLC-ECD), we monitored changes induced by VNS in the levels of dopamine and

its metabolites (HVA, DOPAC, 3-MT), norepinephrine and its main metabolite (MHPG) and the main metabolite of serotonin (5-HIAA). The baseline levels of these neurotransmitters and metabolites were comparable to those detected in CSF collected from other NHPs (from cisterna magna and lumbar puncture), as well as to those reported in the literature. Low-frequency VNS increased the CSF levels of dopamine and its metabolites, as well as 5-HIAA and MHPG, but not of norepinephrine. Following high-frequency VNS, the levels of all CSF analytes appeared to decrease. These findings replicate previously reported increases in serotonin (but not norepinephrine) metabolites induced by VNS and bring to light a significant elevation of dopamine metabolites that have been rarely reported in humans and animals undergoing VNS. Future experiments in awake, behaving monkeys will determine whether the observed elevation of dopamine metabolites was related to anesthesia or represents an outcome of low-frequency VNS.

Title: Kappa opioid receptor antagonism normalizes biochemical and behavioral phenotypes in mice expressing the ADHD-associated dopamine transporter variant Val559

Authors: *F. P. MAYER[1], M. VELEZ[1], A. STEWART[2], R. A. VAUGHAN[3], R. D. BLAKELY[2];
[1]Dept. of Biomed. Sci., Florida Atlantic Univ., Jupiter, FL; [2]Florida Atlantic University, Brain Inst., Jupiter, FL; [3]Biomed. Sci., Univ. of North Dakota Sch. of Med. and Hlth. Sci., Grand Forks, ND

Abstract: Extracellular dopamine (DA) is tightly regulated by the presynaptic dopamine (DA) transporter (DAT). The rare DAT Val559 variant, identified in individuals with attention-deficit hyperactivity disorder (ADHD), bipolar disorder and autism, mediates a constant, transporter-mediated outwardly directed leak of DA. As a result thereof, DAT Val559 KI mice reveal behavioral alterations, including waiting impulsivity, hyperactivity in response to imminent handling, elevated motivation for reward and blunted responses to psychostimulants. At a molecular level, the DAT Val559 variant in the dorsal striatum of male mice displays elevated surface trafficking, augmenting effects of efflux prone transporters and arising from the tonic stimulation of D2-type autoreceptors (D2ARs). Since kappa opioid receptors (KORs), in addition to D2ARs, regulate DAT-surface trafficking, we explored whether pharmacological manipulation of KOR-activity might normalize the aberrant trafficking of the Val559 variant and

thereby present a novel opportunity to relieve mutation induced hyperdopaminergia. Using acute coronal slices, we find that both homozygous Val559 DAT animals and WT animals are amenable to regulation via KOR, i.e. activation of KOR increases surface trafficking regardless of genotype and that this increase in surface trafficking coincides with an increase in phosphorylation at threonine 53 in Val559 DAT and WT mice. Remarkably, antagonism of KOR reduced surface trafficking of DAT Val559 but remained without significant effect on WT DAT, ultimately normalizing surface expression of Val559 DAT. Finally, using fiber photometry and microdialysis, we show that systemic administration of the KOR-antagonist nor-binaltorphimine (norBNI) normalizes DA-release in Val559 mice and reverses deficits observed in working memory (Y-maze) and anxiety-like behavior (open field test). Together, our findings support KORs as a target for the treatment of disorders that arise from tonically-elevated extracellular DA.

Title: Sexually dimorphic behavioral outcomes in DAT Val559 mice derive from sex-specific homeostatic perturbations at pre- and post-synaptic sites

Authors: *A. STEWART[1,2], F. P. MAYER[1], R. GOWRISHANKAR[1,3], G. L. DAVIS[1,3], R. PEART[1], K. SPIESS[1], R. D. BLAKELY[1,2];
[1]Biomed. Sci., [2]Brain Inst., Florida Atlantic Univ., Jupiter, FL; [3]Neurosci. Grad. Program, Vanderbilt Univ., Nashville, TN

Abstract: The release, reuptake and signaling of the powerful neurotransmitter dopamine (DA), a major determinant of reward, motivation, attention, and motor activity, and the architecture underlying dopamine-engaged brain circuitry, are increasingly understood to be modulated genetic/gonadal sex and sex hormones. Animal models expressing neuropsychiatric-disease associated variants in the DA transporter gene (DAT, *SLC6A3*), such as the Ala559Val substitution, have provided a platform to investigate the impact of sex on neurochemistry, neurophysiology and behavior in a construct-valid disease model. Here, we report a series of sexually dimorphic homeostatic DA disruptions that arise in the DAT Val559 homozygote. In male DAT Val559 mice, presynaptic nigrostriatal D2 autoreceptors (D2ARs) are constitutively-activated, driving enhanced DAT phosphorylation and surface trafficking in the dorsal striatum, an effect that is absent in DAT Val559 females. However, females show constitutive D2AR

activation of mesolimbic D2ARs, an effect that is absent in males. Multiple DAT Val559 behavioral alterations also differ by sex including male-specific blunting of acute amphetamine (AMPH)-induced locomotion, faster extinction following AMPH place preference conditioning, and decreased anorexigenic actions of AMPH following repeated exposure. Interestingly, the ability of AMPH to provoke DA elevations in the dorsal striatum was unaltered in DAT Val559 males, which we speculate may result from DAT Val559 leak antagonism in the context of AMPH-induced DA vesicular release, whereas AMPH drives DA release via DAT-mediated efflux in females. Finally, we noted that direct stimulation of postsynaptic D1Rs with the agonist SKF83822 resulted in sex-specific behavioral alterations with DAT Val559 males displaying decreased horizonal locomotion and stereotypy whereas females display reduced vertical locomotion and center occupancy. Thus, we hypothesize that loss of acute AMPH-induced locomotion in DAT Val559 males may result from desensitization, uncoupling or other disruption of D1R-dependent signal transduction. In females, the locomotor response to AMPH is likely maintained, despite reductions in AMPH-induced DA elevations, via increased sensitivity of DA-responsive striatal neurons. Overall, these studies provide striking evidence of a sexually dimorphic impact of functional DAT coding variation and reveal an important opportunity to gather insights into the sex-dependence of behavioral trajectories that attends neuropsychiatric disease risk.

Abstract: Dopamine (DA) modulates neural signaling across phylogeny. Disruption of DA signaling in humans has been implicated in multiple brain disorders including schizophrenia, addiction, ADHD, and Parkinson's disease. In C. elegans, loss of the DA transporter (DAT-1) results in a phenotype termed Swimming-induced paralysis (Swip). We previously reported the isolation of several mutant lines using a Swip-based mutagenesis screen, which has proved

effective in identifying molecular determinants of DAT activity, DA synaptic transmission and DA neuron degeneration. Here, we report the molecular basis of a Swip line involving mutation of the mitochondrial gene dhs-11. Loss of DHS-11 result in reduced mitochondrial respiration, changes in mitochondrial structure and biogenesis, elevated oxidative stress, and age-dependent DA neurodegeneration. Sequencing analysis reveals that dhs-11 is an ortholog of the human mitochondrial enzyme HSD17B8, a member of the highly conserved mitochondrial fatty acid synthesis pathway (mtFAS), which supports the synthesis of α-lipoic acid (α-LA), a key substrate for the metabolic posttranslational process of protein lipoylation. Consistent with our attribution of dhs-11 as the locus for mutation, mutants in other worm mtFAS genes resulted in DA-dependent Swip. LC-MS/MS analyses of dhs-11 extracts vs wildtype (N2) animals revealed metabolomic signatures of mitochondrial dysfunction, manifested by alteration of metabolites involved in glycolysis, TCA cycle, amino acid anaplerosis, fatty acid β-oxidation. In support of this idea, enhancing energy production via overexpression of the monocarboxylate transporter MCT-1/2, or by supplementation of α-LA, lactate or pyruvate, rescued the Swip of dhs-11 mutants. Mutation of the lipoamidase SIR-2.3/SIRT4 to stabilize mitochondrial protein lipoylation rescued dhs-11 Swip, suggesting that reduction in mitochondrial lipoylation contributes to dhs-11 Swip. Pharmacological and genetic studies also support a role for dhs-11 in regulating normal DAT activity and DA neuron excitability. Moreover, exogenous α-LA suppression of Swip requires the DA transporter DAT-1, suggesting a contribution of the mtFAS pathway in DAT-1 regulation. Additionally, α-LA treatment significantly ameliorated signs of DA neurodegeneration. Together, our results uncover an essential role for dhs-11/mtFAS pathway in regulation of DA neuron function and neuroprotection, suggesting the molecule and its regulators as potential targets for the development of therapeutics for DA-linked disease.

Title: Novel allosteric modulator attenuates HIV-1 Tat protein-induced inhibition of dopamine transporter and alleviates cognitive and cocaine rewarding effects in HIV-1 Tat transgenic mice

Authors: *J. ZHU[1], C.-G. ZHAN[2], J. P. MCLAUGHLIN[3], S. ANANTHAN[4];

Abstract: Cocaine abuse has been shown to increase the incidence of HIV-1 associated neurocognitive disorders (HAND). We have demonstrated that HIV-1 Tat protein allosterically modulates dopamine (DA) reuptake via DA transporter (hDAT). This study determined whether a novel allosteric modulator, SRI-32743, pharmacologically blocks Tat binding to DAT and alleviates Tat-potentiated cocaine rewarding effects in inducible HIV-1 Tat transgenic (iTat-tg) mice. The iTat-tg mouse model recapitulates many aspects of neurocognitive impairments observed in HIV infected individuals. SRI-32743 inhibited [^{3}H]DA uptake (IC_{50}, 9.9 μM) with a 17-fold greater inhibition than the potency of [^{3}H]WIN35,428 binding (IC_{50}, 168 μM) with 68.4% and 71.4% of its E_{max}, respectively. Tat (140 nM) induced 30% and 20% reductions in [^{3}H]DA uptake and [^{3}H]WIN35,428 binding, respectively, which were attenuated by 50 nM SRI-32743. SRI-32743 and indatraline, a competitive DAT inhibitor, increased the cocaine IC_{50} values of [^{3}H]DA uptake by 164% and 280%, respectively. The cocaine-induced dissociation rate of [^{3}H]WIN35,428 binding was similar to that induced by 50 nM SRI-32743; however, SRI-32743 slowed the cocaine-induced dissociation rate. Pharmacokinetics study shows that SRI-32743 is BBB-permeable with a 2.52 and 2.08 ratio of brain to plasma concentration (ng/ml) at 15 and 60 min, respectively. Following a 14 day-doxycycline to induce Tat protein, the iTat-tg mice exhibit a 2-fold potentiation of cocaine-CPP which was dose-dependently ameliorated by pretreatment of SRI-32743 (1 or 10 mg/kg/d, i.p.) prior to CPP. These preliminary data raise the exciting possibility of potential therapeutic interventions for neurocognitive dysfunction in HAND, particularly effective for those with concurrent cocaine abuse.

Title: Neuromodulatory influences in the hindlimb representation of the developing rat somatosensory cortex

Authors: *C. COLANGELO[1], A. ANTON-FERNANDEZ[2], A. MUÑOZ[3], J. DEFELIPE[4], S. RAMASWAMY[5];
[1]EPFL Blue Brain Project, Geneva, Switzerland; [2]Ctr. de Biología Mol. Severo Ochoa (CBMSO-CSIC), Madrid, Spain; [3]Univ. Politécnica de Madrid, Lab. Cajal de Circuitos Corticales (CTB), Madrid, Spain; [4]Inst. Cajal (CSIC), Madrid, Spain; [5]EPFL - Blue Brain Project, Geneva, Switzerland

Abstract: Neuromodulators control information processing in cortical microcircuits by regulating the cellular and synaptic physiology of neurons. Computational models and detailed simulations of neocortical microcircuitry offer a unifying framework to analyze the role of neuromodulators on network activity. In the present study, we quantified the axonal anatomy of catecholaminergic, serotonergic and cholinergic systems using immunocytochemical staining

and stereological techniques to gain insights into how the structural organization of neuromodulatory projections in the cortical neuropil regulate the emergence of network states. We systematically integrated biological data into a detailed computational model of the rodent somatosensory cortex and simulated the effects of ascending neuromodulatory projections. We predict that dose-dependent effects of neuromodulators on diverse neuron types and synapses reveal a fine-grained control of a spectrum of network activity states. Low levels of neuromodulatory signaling drive microcircuit activity into slow oscillations and network synchrony, whereas high concentrations govern fast oscillations and network asynchrony. The models and simulations thus provide a unifying in silico framework to bridge how the anatomical organization of neuromodulatory projections reconfigure the physiology of network activity in the neocortex.

Title: Laterality effect of chronic restraint stress on TPH2 expression and serotonin turnover in adrenal glands of rats.

Authors: *N. SAROJ[1], S. SHANKER[2];
[1]cellular physiology, Natl. Autonomous Univ. of Mexico, mexico city, Mexico; [2]molecular pharmacology, Escuela superior de medicina del instituto politecnico, mexico city, Mexico

Abstract: Background The adrenal gland is an essential stress-responsive organ that is part of both the hypothalamic pituitary-adrenal axis and the sympathy-adrenomedullary system (Gamallo et al.,1986). Previous studies using the viral trans neuronal tracing technique demonstrated central autonomic circuits more intense in the left adrenal gland (LAG) than the right adrenal gland (RAG) (Tóth et al., 2008). Our Previous studies, Chronic restraint stress (CRS) has been shown to magnify acute stress-induced corticosterone (CORT) secretion in rats through a mechanism involving serotonin (5-HT) via activation of 5-HT7 receptors and apparently, dissociation from ACTH secretion (García-Iglesias et al., 2013). The results of the present study are consistent with the notion that the ectopic expression of 5-HT7 receptors and 5-HT levels in adrenocortical steroidogenic cells is a glucocorticoid dependent phenomenon (Saroj et al., 2019). Furthermore, serotonin is an important neurotransmitter that broadly participates in various biological processes. As a result of evidence for the sensitivity of tryptophan hydroxylase-2 (TPH-2), the rate-limiting enzyme of the serotonin (5-HT) pathway, (Patel et al., 2004). **Abstract -** In present results we have demonstrated that the exposure of the animals to CRS for two weeks, one day 15 animals were sacrificed and both adrenal glands was collected. Adrenal weight, thymus weight and body weight gain were recorded. TPH-2 expression was

determined by immunohistochemistry, PCR and western blot and 5-HT turnover was measured by HPLC in both adrenals. Although CRS significantly increases mRNA and protein expression of TPH2 and (5-HT) turnover in the LAG as compare to RAG. These results conclude that CRS might be prompt more sensory and sympathetic neurons innervate in LAG to be the cause of more perception to the stress and increase stress related protein expression in the LAG than the RAG.

Title: Taurine plays a key role as a morphogen in the neurogenic process of Subventricular Zone progenitor cells by GABA receptors interaction

Authors: *N. E. GUTIÉRREZ-CASTAÑEDA[1], J. GONZALEZ[2], E. J. GALVAN[3], H. SANCHEZ-CASTILLO[4], L. D. OCHO-DE LA PAZ[2];
[1]CINVESTAV, CDMX, Mexico; [2]UNAM, CDMX, Mexico; [3]CINVESTAV SUR, Mexico City, Mexico; [4]Univ. Nacional Autonoma De Mexico. Fac Psicologia, Mexico City, Mexico

Abstract: The process of neurogenesis occurs throughout the life of mammals, including humans, in the subgranular zone of the hippocampal and the subventricular zone (SVZ) of the lateral ventricles. The participation of extrinsic factors, which regulate this process, has been determined. These factors include neuroactive molecules such as taurine, which play an important role in the processes of proliferation, differentiation, and migration of neural progenitor cells. The mechanism through which it participates in the neurogenesis process is not completely understood, one possibility is through the interaction with inhibitory neurotransmitters receptors, expressed in progenitor cells. Therefore, we aimed to evaluate the effect of taurine on the differentiation process of neural progenitor cells in the subventricular zone through the interaction with GABA receptors. We carried out immunofluorescence assays on cells isolated from SVZ of CD1 mice (P8) and exposed to differentiation conditions, with or without taurine. The results showed that the neural progenitor cells express Sox-2 and Nestin, both progenitor cells markers, nonetheless no signal for DCX was observed. This observation confirms that the cells obtained from the SVZ are neural progenitors. In the cultures exposed to differentiation conditions with taurine, increase the number of cells DCX+. The morphometric analysis showed a significant difference in cell morphology; the cells treated with taurine, presented a greater number of secondary and tertiary neurites, compared to the control and GABA conditions. This effect of taurine was sensitive to picrotoxin, an antagonist of GABA receptors. In conclusion, this result provides us information regarding the role of taurine as a morphogen in the neurogenic processes throughout the interaction with GABA receptors. This

work represents an advance in the morphometric effect of taurine in the neuronal differentiation process.

Title: A tale of two tracers: [11C] Raclopride and [18F] Fallypride produce related estimates of dopamine receptor binding potential across a wide range in BMI under identical, controlled clinical conditions

Authors: ***A. SCHICK**[1], V. L. DARCEY[1], J. GUO[1], I. GALLAGHER[1], M. STAGLIANO[1], L. MILLEY[1], A. COURVILLE[1], S. YANG[2], S. TURNER[2], P. HERSCOVITCH[3], K. D. HALL[1]; [1]Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD; [2]Nutr. Dept., [3]PET Dept., Natl. Inst. of Hlth. Clin. Ctr., Bethesda, MD

Abstract: Dopamine is involved in a number of diverse behaviors and experiences including mood, memory, habit formation, reward, and eating behavior. Imaging via Positron Emission Tomography (PET) allows investigation of various aspects of dopamine system function in the human brain. However, use of different radiotracers may lead to challenges interpreting and comparing results across studies. For example, though both are antagonists to the D2/D3 receptor subtypes, [18F]fallypride is selective for D2 receptors over D3 receptors, while [11C]raclopride is non-selective in terms of D2R and D3R. Furthermore, [18F]fallypride has higher affinity for

receptor while [11C]raclopride is more readily displaced from receptor by endogenous dopamine. Here, we present preliminary results of an ongoing PET study measuring striatal dopamine D2/D3 receptor binding potential (D2BP) across a wide range in BMI using two different dopamine receptor antagonist radiotracers, [11C]raclopride and [18F]fallypride, in a within-subjects design under controlled clinical conditions (ClincalTrials.gov, NCT03648892). To control the influence of recent diet and weight fluctuation on D2BP, 13 of a planned 39 healthy, weight-stable adults (8 female; age 28.4±2.2 y, BMI 30.2±2.3, range 20.9-45.1 kg/m2) completed a 5-day standardized eucaloric outpatient diet stabilization followed by a 5-day inpatient stay. Participants completed [11C]raclopride PET and [18F]fallypride PET scans in semi-random order under identical testing conditions (i.e., overnight fast, AM scan time). T1-weighted MR images were collected for coregistration of D2BP and neuroanatomical data. Freesurfer-generated region of interest masks were used to assess D2BP via time-activity curves in the caudate, putamen, accumbens, and pallidum. Preliminary analyses show a positive correlation between D2BP as measured by [11C]raclopride and [18F]fallypride in the pallidum ($r=0.851$, $p=0.002$) and a trending relationship in the caudate ($r=0.524$, $p=0.066$) suggesting a concordance between the two tracers in the dorsal and ventral striatum across a wide range in BMI. Preliminary data in the putamen and accumbens show a weak positive relationship but are not significant with $n=13$ ($r=0.383$, $p=0.197$; $r=0.358$, $p=0.230$). These preliminary findings may facilitate interpretation and comparison of results across [11C]raclopride and [18F]fallypride studies and may be important to inform methodological design of future studies of dopamine receptor availability.

Title: Rifaximin modulates TRH and TRH-like peptide expression throughout the brain and peripheral tissues of male rats

Authors: *A. E. PEKARY[1], A. SATTIN[2];
[2]Res., [1]VA Greater Los Angeles Hlthcare Syst, Los Angeles, CA

Abstract: Abstract Mental health and protection from neurodegenerative disorders, such as Alzheimer's and Parkinson's disease and major depression depends on the gut microbiome and is mediated by the vagus nerve. This is evident in the behavioral abnormalities of germ-free rodents. The antibiotic rifaximin (RF), which does not cross the gut-blood barrier, is a standard treatment for traveler's diarrhea and hepatic encephalopathy. It also has therapeutic benefit in the treatment of prostatitis. TRH and TRH-like peptides, with the structure pGlu-X-Pro-NH_2, where

"X" can be any amino acid reside, have reproductive, caloric-restriction-like, anti-aging, pancreatic-β cell-enhancing, cardiovascular, and neuroprotective effects. The TRH/TRH-R1 receptor signaling pathway is an important mediator of brain-gut axis communication via the brain medulla. TRH and TRH-like peptides occur not only throughout the CNS but also peripheral tissues, with particularly high levels in rat and human prostate. This is particularly noteworthy given the vulnerability of humans to prostatitis and prostate cancer. Bacterial infections are involved in prostate diseases. Female rats were not studied because TRH and TRH-like peptide levels fluctuate 10- to 100-fold in response to the estrus cycle. For this reason 16 young adult male Sprague-Dawley rats were divided into 4 groups. The control (CON) group remained on ad libitum chow and water for 10 days. The acute (AC) group received ad libitum chow and water for 9 days and then 1 g rifaximin (RF)/500 g rat chow for 24 h. The chronic (CHR) animals received RF in chow for 10 days. The withdrawal (WD) rats received RF chow for 8 days and then normal chow for 2 days. TRH and TRH-like peptide levels were measured in medulla oblongata (MED), frontal cortex (FCX), hypothalamus (HY), amygdala (AY), hippocampus (HC), piriform cortex (PIR), nucleus accumbens (NA), entorhinal cortex (ENT), striatum (STR), cerebellum (CBL), anterior cingulate (ACNG), posterior cingulate (PCNG), prostate (PR), liver (L), testis (T), heart (H), pancreas (PAN), adrenals (AD) and epididymis (EP). Highly significant changes in the levels of TRH and TRH-like peptides occurred throughout the brain and peripheral tissues in response to RF treatment. In brain the number of these changes (in parentheses)
declined in the order: MED(17), NA(13), PIR(12), STR(11), AY(10), FCX(9), ENT(6), ACNG (6), HC(5), PCNG(5). In peripheral tissues the corresponding order was: PR(11), AD(11), L(9), T(6), H(3), PAN(3). We conclude the high responsiveness of MED, FCX, ACNG, PCNG in brain and PR, AD, L is consistent with TRH and TRH-like peptides participating in the therapeutic effects of RF.

Title: Cgrp dose-dependently influences neuronal excitability and cortical spreading depolarization (csd) in rodents

Authors: F. GIMENO-FERRER[1], A. EITNER[1], R. BAUER[1], A. LEHMENKUHLER[2], M. KRESS[3], M.-L. EDENHOFER[3], H.-G. SCHAIBLE[1], *F. RICHTER[1];
[1]Univ. Hosp. Jena, Jena, Germany; [2]Pain Inst., Duesseldorf, Germany; [3]Med. Univ. Innsbruck, Innsbruck, Austria

Abstract: The neuropeptide CGRP plays an important nociceptive role in migraine, and modern CGRP antagonists are effective against migraine pain. CGRP has been suggested to increase neuronal excitability and therefore we tested its influence on ongoing brain activity and CSD in mice and rats. In anesthetized adult rats (sodium thiopentone, 100 mg/kg, i.p.) CSD-related DC deflections and changes in extracellular potassium concentration ($[K^+]_e$) were recorded in CGRP-treated and untreated areas of the cortex. CSD was elicited by a microinjection of 1 M KCl, and 100 µl of CGRP at concentrations of 10^{-8} M, 10^{-7} M, 10^{-6} M, or 10^{-5} M were applied topically for four hours onto the brain surface in the treatment area. In both cortical areas rCBF was measured. Leakage of the blood-brain-barrier was monitored by extravasation of intravenously injected Evans Blue. Size and shape of glial and microglial cells were evaluated by immunohistochemistry (Iba 1 and GFAP). In mouse cortical and cerebellar slices (300 µm) electrophysiological recordings were performed with multi-electrode arrays before and after application of CGRP at 10^{-7} M and 10^{-6} M. In the treated but not in the untreated area, amplitudes of CSD were reduced by CGRP (10^{-5} M to nearly 50 % of controls; 10^{-8} M to nearly 70 % of controls). CGRP slowed the propagation velocity of CSD (10^{-5} M from 3.0 to 2.4 cm/s; 10^{-8} M from 2.6 to 2.4 cm/s). Assessment of Evans Blue fluorescence confirmed blood-brain-barrier leakage. AC-filtering of the electrocorticogram revealed trains of abnormal discharge activity (series of spikes up to focal ictal discharges) in 67 % of the rats treated with 10^{-7}-10^{-5} M of CGRP in treated area only with no obvious dose-dependence. In cortical but not in cerebellar slice preparations CGRP evoked repetitive and discharging network activity that was not removed by wash. Immunostaining of Iba 1 showed fragmented glial cells in the treated area, but no change in astrocytes. Pretreatment with the antagonist $CGRP_{8-37}$ at 10^{-7} M prevented the effects of CGRP at 10^{-5} M on CSDs, and in co-application $CGRP_{8-37}$ acted as a partial agonist. Similar results were obtained when $CGRP_{8-37}$ was used in slice recordings. Thus the neuropeptide CGRP appears to affect microglia and excite neurons up to spike-like discharging, but only rarely ignites CSD waves. It slows down the propagation velocity of CSD waves possibly via plasma extravasation. Whether this decrease is a result of the increased neuronal activity or a specific action of CGRP on receptors for excitatory amino acids is currently elucidated in ongoing experiments.

Title: Proline mutations in first transmembrane domain suggest important extrinsic interactions during biogenesis of extracellular domain α4β2 nicotinic acetylcholine receptors

Authors: A. M. PERSON, ***G. B. WELLS**;
Mol. and Cell. Med., Texas A&M Univ., College Station, TX

Abstract: **Background**: Extracellular domain (ECD) receptors from α4 and β2 nicotinic receptor subunits truncated after the first transmembrane domain (M1) have functional and structural similarity to full length α4β2 nicotinic acetylcholine receptors (nAChRs). The smaller size of ECD α4β2 nAChRs is advantageous for structural studies. Their reduced complexity also might reveal contributions from ECD and transmembrane domains to the structure, function, and biogenesis of nAChRs. Mutations of the first proline of M1 greatly reduce expression of ECD α4β2 nAChRs. X-ray and cryo-EM structures of full length α4β2 nAChR suggest that interactions between this first proline and the Cys loop might contribute to that reduced expression. **Objective**: To determine whether adding a valine mutation at the second proline of M1 rescues the reduced expression caused by a valine at the first proline. Mutation of the second proline is not expected to affect expression because of the presumed lack of physical interaction between the two sites and the hypothesized importance of interactions of the first proline and Cys-loop. **Methods**: Human α4 and β2 cDNAs were truncated after M1 (α4M1 and β2M1). Along with 5 inserted residues from proximal M1 at the ECD/M1 interface, the first and second prolines of M1 in α4M1 and β2M1 were mutated to valine singly and together, leading to subunits denoted α4PP, α4PV, α4VP, α4VV and β2PP, β2PV, β2VP, β2VV. Subunits were expressed in *Xenopus laevis* oocytes. Immunoblotting and immunoisolated [^{3}H]epibatidine binding sites assessed expression of subunits and ECD α4β2 nAChRs. **Results**: Expression of α4PP/β2PP and α4M1/β2M1 nAChRs were comparable. For the second proline site, α4PV/β2M1, α4M1/β2PV, and α4PV/β2PV nAChRs showed expression comparable to α4M1/β2M1 nAChRs. For the first proline site, expression of α4VP/β2VP nAChRs was severely reduced compared to α4M1/β2M1 nAChRs. α4VP/β2M1 and α4M1/β2VP showed moderately reduced expression. Contrary to expectation, mutating both the first and second prolines, leading to α4VV/β2VV nAChRs, rescued expression. **Conclusions:** The importance of intrinsic interactions within an ECD subunit between the first proline and the Cys-loop to the expression of ECD α4β2 nAChRs needs further investigation. Because of the presumed physical isolation of the second proline site within the membrane bilayer, the rescue of expression by the second valine suggests interactions that are extrinsic to the ECD subunits also may affect the expression of ECD α4β2 nAChRs. Extrinsic interactions might involve cellular machinery that identifies and translocates transmembrane domains for correct topology during biogenesis of α4β2 nAChRs.

Title: Signaling mechanisms underlying nicotine-induced upregulation of α7 nicotinic acetylcholine receptor (nAChR)

Authors: J. PANCHAL[1], M. ISLAM[2], K. DEBOEUF[3], J. B. ANDERSON[3], ***J. FARLEY**[2]; [1]Biol. and Neurosci., [2]Neurosci., [3]PBS and Neurosci., Indiana Univ., Bloomington, IN

Abstract: α7 nicotinic acetylcholine receptors (nAChRs), the second most abundant nAChR in brain, have been shown to contribute to nicotine addiction, in part through upregulation by nicotine. Previously, nicotine-upregulation of α7 nAChRs has been reported in several studies, though the mechanisms remain unclear. We have shown ~2-fold functional and numerical upregulation of α7 Rs in *Xenopus* oocytes following 100 μM nicotine treatment. Further, we found that the nic-upregulation of α7 nAChRs was dependent upon intracellular calcium ($[Ca^{2+}]_i$) (being abolished by BAPTA-AM). In various cell types, G protein signaling regulates α7 nAChR function via modulation of $[Ca^{2+}]_i$. α7 nAChRs contain a canonical RMKR G-protein binding cluster (GPBC) within their transmembrane (TM) 3-4 cytosolic loop. Here, we demonstrate a critical role of α7 nAChR/$G\alpha_q$ protein interaction in activation of PLC β - produced increases in $[Ca^{2+}]_i$ that, in turn, inhibits endocytic pathways to cause nic-upregulation of α7 nAChRs. Mutation at GPBC completely abrogated nic-upregulation of α7 Rs. Furthermore, when exogenous wt $G\alpha_q$ was co-expressed with α7 Rs, we saw that it produced ~2X upregulation. But when dominant negative $G\alpha_q$ was co-expressed, attenuation of nic-upregulation of wt α7 Rs was observed. Anti-sense oligonucleotides (ASOs) against endogenous Gq also blocked nic-upregulation. Additionally, we found that the calcineurin inhibitor cyclosporine A produced 2X-upregulation of wt α7 Rs and occluded nic-upregulation. Other endocytic inhibitors (PitStop2 and DynaSore) produced ~2X upregulation of both wt and mutant α7 Rs and occluded nic-upregulation. Brefeldin A (BFA, inhibitor of ER-Golgi protein-transport) failed to affect nic-upregulation. Conversely, methyllycaconitine (MLA)-upregulation of α7 was independent of $[Ca^{2+}]_i$ but was inhibited by BFA. Serine-threonine kinase and tyrosine kinase-phosphorylation events have inhibitory effects on forward trafficking of α7 Rs. Nic-upregulation was unaffected when serine-365 or tyrosine-442 (from TM3-4 loop) was mutated, further supporting the hypothesis that α7 nic-upregulation arises from sustained GPCR-Ca^{2+}-signaling by α7 Rs, inhibiting constitutive endocytosis of α7 Rs.

Title: The contribution of the two agonist binding sites in the function of human nicotinic cholinergic receptor possessing the α4, β2, and β4 nAChR subunits

Authors: C. C. SWAIN, H. M. GRAY, T. T. OLSON, K. J. KELLAR, R. P. YASUDA; Pharmacol. & Physiol., Georgetown Univ., Washington, DC

Abstract: The contribution of the two agonist binding sites in the function of human nicotinic cholinergic receptor possessing the α4, β2, & β4 nAChR subunits.
Caroline C. Swain, Hayley M. Gray, Thao T. Olson, Kenneth J. Kellar, and Robert P. YasudaDepartment of Pharmacology & Physiology, Georgetown University, Washington DC 20057Disclosures: C.C. Swain: None. H.M. Gray: None. T.T. Olson: None. K.J. Kellar: None. R.P Yasuda: None.Brain regions that express the α4, β2, and β4 nicotinic acetylcholine receptor (nAChR) subunits include the hippocampus, medial habenula, interpeduncular nucleus, and cerebellum. We designed 3 cDNA plasmids that express human nAChR concatemers composed of the α4 & β2, α4 & β4, α4, β2, & β4 nAChR subunits linked together by hydrophilic amino acids and expressed in heterologous cells. The order and stoichiometry of these concatemers are β4α4β4α4β4 (β4ALL), β4α4β4α4β2 (β4β2), and β2α4β2α4β2 (β2 ALL) with the amino-terminus found on the first subunit and the carboxyl-terminus found on the fifth subunit. Each of these concatemers produces a full-length protein (>300 kDa). [^{3}H]-epibatidine binding competition curves in cells expressing the β4β2 concatemer reveals a significant 2-site fit for both sazetidine-A (Saz-A; which has higher affinity for β2-containing receptors) and AT-1001 (which has higher affinity for β4-containing receptors), while binding competition curves with these two ligands in cells expressing the β4 ALL and β2 ALL concatemers fit best to a single site with K_i values that agree with those in the literature. To study the function of these concatemers, nAChR mediated calcium (Ca^{++}) influx will be measured using an aequorin based assay. Here we describe preliminary results of our aequorin assay using heterologous cells that were transfected with the α3β4, α4β2, or α4β2α5 nAChR subunits. ACh-stimulated dose response curves resulted in EC_{50} values consistent with the literature. We will use cells expressing the concatemeric nAChRs to examine concentrations of Saz-A expected to stimulate only the α4β2 binding site or AT-1001 expected to stimulate only the α4β4 binding site and compare the responses to a maximal concentration of ACh (1 mM). These experiments should allow us to determine the degree of activation of the nAChR via a single α4β2 or α4β4 binding site in a nAChR concatemer possessing both binding sites.

Title: Role of auxiliary subunits in the biogenesis of AMPA receptors

Authors: *N. CERTAIN[1], Q. GAN[3], L. P. WOLLMUTH[2];
[1]Pharmacol. Sci., [2]Neurobiol & Behavior, Stony Brook Univ., Stony Brook, NY; [3]Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: AMPA receptors (AMPARs) transmit the majority of fast excitatory synaptic transmission. Changes to the composition and number of AMPARs at the postsynaptic membrane underlie synaptic plasticity, a cellular correlate of learning and memory, and are implicated in various brain disorders. The molecular mechanisms that regulate the pools of available AMPARs to drive changes in synaptic transmission remain unclear. Native AMPARs associate with auxiliary subunits that can affect the availability receptors, but how they do so is not well understood. Here, we addressed the role of auxiliary subunits in the assembly of AMPARs using blue native gel-electrophoresis, immunocytochemistry, and electrophysiology. We find that cornichon-2 (CNIH-2) and cornichon-3 (CNIH-3) enhance the tetramerization process, whereas stargazin (TARP-2) is less able to do so. To study the basis for this, we mutated key residues in the transmembrane domain which attenuate but do not remove tetramerization and co-expressed mutant AMPARs with auxiliary subunits. When the tetramer was destabilized this led to increased receptor dimers and significantly reduced tetramer formation. When the AMPAR mutants were co-expressed with CNIH-2 or CNIH-3, the tetramer fraction was efficiently rescued compared to co-expression with TARP-2. However, when TARP-2 was in tandem with the AMPAR mutant, the tetramer fraction was restored comparable to wildtype AMPARs. We also find that auxiliary subunits influence receptor tetramerization through the transmembrane domain with CNIHs capable of stabilizing the transmembrane region and rescuing disrupted receptor assembly. In contrast, TARP-2 has a much weaker influence on tetramerization compared to CNIHs unless in tandem when the auxiliary subunit is forced to interact with the receptor during the assembly process. We conclude that CNIHs and TARPs differ in their ability to influence the stages of AMPAR biogenesis.

Title: Increased excitation-inhibition balance and loss of GABAergic synapses in the serine racemase knockout model of NMDA receptor hypofunction

Authors: *S. A. JAMI[1], S. CAMERON[1], J. M. WONG[1], E. R. DALEY[1], K. A. MCALLISTER[2], J. A. GRAY[2];

Abstract: There is substantial evidence that both NMDA receptor (NMDAR) hypofunction and dysfunction of GABAergic neurotransmission contribute to schizophrenia, though the relationship between these pathophysiological processes remains largely unknown. While models using cell-type-specific genetic deletion of NMDARs have been informative, they display overly pronounced phenotypes extending beyond those of schizophrenia. Here, we used the serine racemase knockout (SRKO) mice, a model of reduced NMDAR activity rather than complete receptor elimination, to examine the link between NMDAR hypofunction and decreased GABAergic inhibition. The SRKO mice, in which there is a >90% reduction in the NMDAR co-agonist D-serine, exhibit many of the neurochemical and behavioral abnormalities observed in schizophrenia. We found a significant reduction in inhibitory synapses onto CA1 pyramidal neurons in the SRKO mice. This reduction increases the excitation/inhibition balance resulting in enhanced synaptically-driven neuronal excitability and elevated broad-spectrum oscillatory activity in *ex vivo* hippocampal slices. Consistently, significant reductions in inhibitory synapse density in CA1 were observed by immunohistochemistry. We further show, using a single-neuron genetic deletion approach, that the loss of GABAergic synapses onto pyramidal neurons observed in the SRKO mice is driven in a cell-autonomous manner following the deletion of SR in individual CA1 pyramidal cells. These results support a model whereby NMDAR hypofunction in pyramidal cells disrupts GABAergic synapse development leading to disrupted feedback inhibition and impaired neuronal synchrony.

Title: Differential expression of GluN2A, GluN2B and GluN2D NMDA receptor subunits in the dorsal horn of male and female rat spinal cord

Authors: *S. TEMI, C. RUDYK, J. ARMSTRONG, J. LANDRIGAN, C. DEDEK, N. SALMASO, M. E. HILDEBRAND;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: N-methyl-D-aspartate receptors (NMDARs) are excitatory ionotropic glutamate receptors expressed throughout the CNS, including in the dorsal horn (DH) of the spinal cord. The GluN2 subtypes of NMDAR subunit, GluN2A, 2B and 2D, confer NMDARs with structural

and functional variability, enabling heterogeneity in synaptic transmission and plasticity. Despite essential roles for NMDARs in physiological and pathological pain processing within the DH, the distribution and function of specific GluN2 isoforms across DH laminae remains poorly understood. Surprisingly, there is a complete lack of knowledge on GluN2 expression in female rodents. We therefore investigated the relative expression of specific GluN2 variants in the L4/L5 lumbar DH of both male and female rats. In order to detect synaptic GluN2 isoforms that are expressed in the DH (GluN2A, 2B and 2D), we used pepsin antigen-retrieval to unmask these highly cross-linked protein complexes. We found that GluN2B and GluN2D were preferentially localized to superficial regions of the DH in males, while only GluN2B was predominantly localized in the superficial DH of female rats. Furthermore, unexpectedly, we identified an enhanced expression of GluN2B in the medial division of the superficial horn versus the lateral division, in males only. These sex-specific localization patterns of GluN2-NMDAR subunits have significant implications for the understanding and treatment of pain and are relevant for future translational studies in human spinal cord tissue.

Title: Understanding the functional implications of NMDA receptor subunit rare variants associated with neurodevelopmental disorders

Authors: *M. M. VIEIRA[1], T. A. NGUYEN[1], K. WU[1], J. D. BADGER, II[1], B. M. COLLINS[2], V. ANGGONO[3], W. LU[1], K. W. ROCHE[4];

Abstract: Despite intensive research and groundbreaking advances in the genetics of neurological disorders such as autism spectrum disorders (ASDs) and epilepsy, a profound knowledge of their underlying cellular mechanisms remains elusive. Accumulating evidence from genetic analyses has uncovered two crucial factors: many of the associated genes in

epilepsy are also affected in ASDs/intellectual disability, suggesting a common mechanism of dysfunction; and specific clusters of proteins are preferentially affected at the gene level indicating that disorders arise from an overall dysfunction of protein networks. Rare variants identified in the cluster of synaptic proteins, including the N-methyl-D-aspartate receptor (NMDAR) subunits GluN2A and GluN2B, are thought to be causative in some cases of epilepsy and ASD, respectively. Because GRIN2 rare variants are heavily implicated in neurodevelopmental disorders, we investigated the functional consequences of *de novo* single nucleotide mutations in the C-terminal domain of GluN2A and GluN2B subunits of NMDARs. Since the C-terminal domain has preponderant roles in the regulation of receptor surface expression and trafficking, protein-protein interactions and in many cases excitatory postsynaptic currents (EPSCs), we hypothesized a functional impact of these variants in these parameters. We characterized the functional consequences of GluN2A/B rare variants using a combination of biochemical and imaging approaches. One particular variant, GluN2A-S1459G, led to reduced receptor surface expression, as well as concomitant spine density alterations in cultured hippocampal neurons. Using pull-down and co-immunoprecipitation assays, we found that the epilepsy variant leads to impaired binding with scaffold proteins like PSD-95, as well as with the endocytic protein SNX27. Finally, we observed that expression of GluN2A-S1459G leads to a decrease in spontaneous EPSCs. Notably, we also identified GluN2A-S1459 as a phosphorylation target, mediated by CaMKII, that modulates receptor trafficking and protein-protein interactions. Overall, our results demonstrate that the epilepsy mutant GluN2A-S1459G is a loss-of-function variant. Our results highlight the importance of understanding the functional implications of individual disease-associated NMDAR subunit variants.

Title: Using calcium dynamics to assess the clinical outcome of NMDA receptor variants

Authors: *G. MOODY, A. MUSCO, L. P. WOLLMUTH;
Stony Brook Univ., Stony Brook, NY

Abstract: Channelopathies are clinical disorders arising from alterations in ion channels. As genetic panels become more accessible in the clinic, there is a growing list of identified missense and nonsense mutations or ‘variants’ underlying these channelopathies and potentially driving neurological disorders such as epilepsy. The NMDA receptor (NMDAR) is a ubiquitously

expressed glutamate-gated ion channel that plays key roles in numerous brain functions including the plasticity underlying learning and memory. Not surprisingly, a variety of disease-associated variants have been identified in genes encoding NMDAR subunits. A critical first step to assess whether these variants contribute to their associated disorder is to characterize their effect on receptor function. Using this characterization, variants are categorized as loss- or gain-of-function to potentially guide treatment. This categorization, however, is not ideal since it often misses the complexity of ion channel function and the complex effects of variants, which rarely just affect one biophysical property, instead altering many in potentially subtle and opposing ways. As a first approximation, one can assume that the central signaling mechanism of NMDARs is to regulate Ca^{2+} influx at synapses with the magnitude of this Ca^{2+} influx modulated by their diverse biophysical properties such as voltage-dependent block by Mg^{2+}, receptor kinetics (rates of activation, deactivation, desensitization), small molecules (H^{+}, Zn^{2+}, polyamines), and post-translational modifications. Here, we characterized a diverse set of epilepsy-associated variants. We developed a means to combine multiple affected biophysical properties, including conflicting properties, into a single parameter based on the magnitude of Ca^{2+} influx. Notably, to capture the dynamics of NMDARs at synapses, we applied glutamate pulses at 100 Hz to derive a current integral and transformed this integral into a 'Ca^{2+} index' using fractional calcium data. We then compared which properties most greatly affected Ca^{2+} influx and assigned a severity to the variant depending on changes in Ca^{2+} influx. We further correlated this Ca^{2+} index across difference clinical phenotypes and identified which biophysical properties have the greatest impact on Ca^{2+} influx.

Abstract: Glycine Receptors (GlyRs) are pentameric anion-permeable ligand-gated ion channels. The glycinergic neurotransmission regulates critical physiological processes, such as respiration, motor coordination, muscle tone and sensory processing. In addition, hypo-functional GlyRs have been related to several pathological states, such as chronic pain and hyperekplexia. The modulation of GlyRs by positive allosteric modulators (PAMs) has recently emerged as a promising therapeutic approach against chronic pain. However, the GlyR pharmacology is still limited and only few studies have explored the action mechanisms of glycinergic PAMs at the functional level. Here, we studied the mechanisms of modulation of GlyRs by two glycinergic PAMs that displayed analgesic actions in behavioral studies. By using single-channel and whole-cell electrophysiology of recombinant GlyRs, we focus our functional analyses on the effects of the propofol analog 2,6-di-tert-butylphenol (2,6-DTBP) and of the tricyclic sulfonamide AM-1488. Whole cell recordings show that both 2,6-DTBP and AM-1488 exerted concentration-dependent potentiation of homomeric GlyRs. However, while AM-1488 enhanced the function of homomeric and heteromeric GlyRs in a similar fashion, 2,6-DTBP displayed minor effects on heteromeric GlyRs. Single-channel recordings revealed that the effects of 2,6-DTBP and AM-1488 are associated with different biophysical mechanisms of modulation. Kinetic analysis show that 2,6-DTBP generated longer burst time and longer channel openings, whereas AM-1488 also produced longer burst time but without modifications on the open time. Our results reveal different biophysical mechanisms of modulation for PAMs targeting GlyRs. These findings may contribute to the development of novel glycinergic PAMs with differential modulatory profiles.

Title: Picrotoxin increased the excitability of mouse retinal ganglion cells

Authors: *W. LI, J. WEILAND;
Univ. of Michigan, Ann Arbor, MI

Abstract: Title: Picrotoxin increased the excitability of mouse retinal ganglion cells
Abstract:Glycine and γ-aminobutyric acid (GABA), one of the major inhibitory neurotransmitters in the retina, is secreted from amacrine cells and regulates ganglion cells

function. This study focuses on the effect of GABA on the mice retinal ganglion cells (RGCs) to identify the regulatory role of amacrine cells in RGCs. We used *ex vivo* mouse retina and the whole-cell current clamp technique to study the effect of picrotoxin (antagonist of GABAa receptor) on the RGCs baseline and electrically evoked responses. RGCs were classified into ON, OFF, and ON-OFF types using 10 second light exposure. No significant difference in resting membrane potential was noted amongst these groups. Electrical stimulation pulses were applied via an epiretinal electrode (platinum, 75 micron diameter). Pulses were 0.5 ms, cathodic first, biphasic, with a train of 20 pulses delivered at 2 pulses/second. To obtain response data, pulse amplitude was increased in steps. Then the number of pulses that evoked spikes was counted and threshold was set at the 50% response rate. No difference was noted in threshold based on cell type. After administration of picrotoxin (100 μM), threshold decreased (control: 73.6±15.02μA; 100 μM picrotoxin: 62.36±13.95 μA, n=25, p=0.02782). RGCs spontaneous spikes rate increased after picrotoxin (control: 13.16±3.85 spikes/s; 100 μM picrotoxin: 25.27±4.65 spikes/s, n=24, $p=8.581x10^{-5}$). These implied that blocking amacrine cells GABAa receptor increased the excitability of RGCs as reflected by decreases in action potential threshold.

Title: Serotonergic effects on orbitofrontal cortex parvalbumin neurons expressing cre recombinase are unchanged after withdrawal from cocaine self-administration in rats

Authors: *A. M. WRIGHT, A. F. HOFFMAN, B. K. HARVEY, C. R. LUPICA;
Natl. Institue on Drug Abuse, NIH, Baltimore, MD

Abstract: Cocaine is the second-most used illicit drug and is responsible for the second-highest number of overdose deaths in the United States, a number that has sharply increased in recent years. As a non-specific monoamine re-uptake inhibitor, cocaine modulates a variety of brain areas. One region involved in many use disorder behaviors is the orbitofrontal cortex (OFC). This highly interconnected associative learning structure is crucial for higher order function that underlies goal-directed learning and comprehension of consequences, both of which are disrupted by cocaine self-administration (CSA). The OFC is densely innervated by serotonergic (5-HT) projections from the dorsal raphe nucleus (DRN), and 5-HT function is necessary for goal-directed OFC behaviors. Notably, 5-HT function is also altered in principal cells in the OFC several months after withdrawal from CSA in rats. However, little is known about the effects of CSA on 5-HT control of inhibitory parvalbumin fast-spiking interneurons (PVNs) in the OFC. PVNs act as regulators of cortical gamma oscillations that underlie OFC-dependent behaviors and also express 5-HT_{1A} and 5-HT_{2A} receptor mRNA in the nearby medial pre-frontal cortex

(mPFC). Here, 5-HT function was assessed via a novel parvalbumin-Cre rat using electrophysiology and optogenetics, including sex as a biological variable. Direct application of 5-HT to OFC PVNs in brain slices elicited 5-HT_2-dependent inward depolarizing currents in PVNs, in line with previous frontocortical studies. In a minority of cells (4/28, 14.3%) from male rats, 5-HT produced outward, inhibitory currents that were putatively 5-HT_{1A}-dependent, while PVNs from female rats demonstrated no outward currents under similar conditions. Furthermore, whereas 5-HT treatment markedly increases glutamatergic transmission in principal cells, it had no effect on glutamatergic afferents to PVNs, suggesting 5-HT selectively regulates OFC network control in a target-specific manner. In contrast to our previous study with OFC principal cells, neither the magnitude nor the proportion of 5-HT effects in PVNs were altered following withdrawal from CSA, demonstrating a cell-type specific perturbation by cocaine. This variable impact on excitatory output cells and inhibitory PVNs likely alters the overall excitatory/inhibitory balance in the OFC, and this may underlie the behavioral abnormalities seen following withdrawal from CSA.

Society, Med. Res. Ctr., Mumbai, India; [6]Tata Inst. Fundamental Res., Mumbai, India

Abstract: In neurons, mitochondria are essential to regulate bioenergetics, facilitate synaptic transmission and plasticity, as well as modulate survival under stress. We have recently demonstrated a direct link between the neurotransmitter serotonin (5-HT) signaling and the regulation of mitochondrial metabolism, biogenesis and function in cortical neurocircuits. We further characterize early events following 5-HT_{2A} receptor stimulation, which are a precursor to enhance mitochondrial biogenesis. 5-HT_{2A} receptor stimulation with the agonist DOI, results in enhanced mitochondrial biogenesis, ATP production and spare respiratory capacity in rodent

cortical neurons. Conversely, 5-HT_{2A} receptor blockade or genetic loss of function abrogates the effects of 5-HT on mitochondrial biogenesis and ATP production. 5-HT_{2A} receptor stimulation of cortical neurons, resulted in a dose and time-dependent increase in *Sirt1* levels, which was blocked by the 5-HT_{2A} receptor antagonist MDL100,907. The increase in *Sirt1* was mediated via the PLC and MAPK signaling pathways. The increase in mitochondrial biogenesis and function, via 5-HT_{2A} receptor stimulation required SIRT1. Chronic 5-HT_{2A} receptor stimulation with the agonist DOI, increased cortical mitochondrial DNA and ATP levels in a SIRT1-dependent manner. Seahorse analysis performed on isolated mitochondria derived from cortices of vehicle- and DOI-treated rats revealed enhanced state-2 (via complex-I/II) and state-3 (complex II-dependent) respiration and ATP production rate following DOI administration, demonstrating an increase in OxPhos efficiency. Further, 5-HT_{2A} receptor stimulation was found to be neuroprotective and mediate stress adaptation against excitotoxic and oxidative stressors, an effect that required SIRT1. Our present work highlights the 5-HT_{2A} receptor-SIRT1 axis as a potential therapeutic target to ameliorate mitochondrial dysfunction, which has implications in aging, neuropsychiatric and neurodegenerative diseases.

Title: Transcriptional investigation of the effects of PACAP loss: Acute versus developmental effects

Authors: *D. BAKALAR, H. ZHANG, S. SWEAT, Z. JIANG, B. SAMAL, L. E. EIDEN; Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Since the advent of gene knockout technology in 1987, insight into the role(s) of neuropeptides has been gleaned by examining loss or alteration of function in animals constitutively engineered to be deficient in transcription of either neuropeptide prohormones or their cognate G-protein coupled receptors. These results are often interpreted as indicating that expression of the gene in question *at the time of the experiment* is required for normal function, complementing lines of experimentation in which the peptide is infused into the brain or transcription blocked acutely. In the case of PACAP, the effect is generally assumed to be via the PAC1 receptor, to which PACAP binds with high affinity. However, neuropeptides such as PACAP play numerous developmental roles: When a gene is constitutively knocked out, long-

term effects of its loss may alter the baseline physiology of the animal. A way to support 'real-time' interpretations of neuropeptide gene knock-out is to demonstrate that the wild-type transcriptome, except for the deliberately deleted gene(s), in tissues of interest, is preserved in the knock-out mouse. Here, we show in adult mice that there is a cohort of genes (constitutively PACAP regulated genes, or cPRGs) whose basal expression is affected by constitutive knock-out of the Adcyap1 gene in multiple neuroendocrine tissues of C57Bl6/N Adcyap1 knockout mice, and additional genes whose expression is altered acutely (aPRGs) in response to physiological challenge. Further, we uncover a surprising lack of transcriptional phenocopy between the PACAP knockout and PAC1 knockout models, mirroring their puzzling divergent behavioral phenotype: While PACAP KO mice perform stereotyped repetitive jumping, PAC1 KO mice do not. Distinguishing constitutive and acute transcriptomic effects of neuropeptide deficiency on physiological function and behavior in mice may prompt a reevaluation of the mechanisms of actions and actual functions of neuropeptides themselves, in the central nervous system, throughout the lifespan.

Title: Acute lithium administration enhances Gq/PLC-mediated signaling

Authors: C. SANCHEZ[1], F. MANTILLA[1], C. GUEVARA[1], *M. GOMEZ[1], **E. NASI**[2]; [1]Biol., [2]Inst. de Genetica, Univ. Nacional De Colombia, Bogota, Colombia

Abstract: Although lithium has long been one of the most widely used pharmacological agents in psychiatry, its mechanisms of action remain poorly understood. Biochemical observations link Li to inositol lipid metabolism, but physiological evidence of effects on phosphoinisitide-mediated signaling is lacking. Having garnered robust preliminary evidence on the potentiating effect of Li^+ on Ca mobilization in HEK-293 cells, we turned to SHSY5Y, a human neuroblastoma cell line, as a more pertinent model to probe the effects of acute Li exposure in a neuronal context. This line expresses key elements of the PLC pathway, and in response to carbachol it produces an increase of cytosolic Ca, monitored with Fluo-4, that is largely unaffected by removal of external Ca and is suppressed by U-73122, thus reflecting PLC-dependent release from internal stores. Low millimolar Li significantly enhanced the Ca-fluorescence signal in a reversible way. Cholinergic stimulation also evokes an inward current mostly carried by Na, that is suppressed by PLC inhibition. The amplitude of this current was also robustly enhanced by Li, and its time course accelerated. In an attempt to narrow down the

site of action of this effect, we examined the impact of Li exposure when the muscarinic pathway was directly activated at selected downstream links. The enhancement was still evident when the current was stimulated by GTP-γ-S, but disappeared if direct PLC activation was induced by m-3M3FBS. Comparison of reversal potentials and the use the inert form o-3M3FBS strengthened the contention that it was the same current triggered by carbachol. The observations indicate that Li effects occur at the level of the G_q protein and its interaction with PLC-β. The generality of such results is being explored in primary vertebrate neurons, where preliminary experiments indicate a modulatory action of Li on the metabotropic glutamatergic response of Purkinje cells isolated from the cerebellum. These observations document an up-regulation of Gq/PLC/IP3-mediated signaling by acute exposure to lithium at near-therapeutic levels, manifesting itself in defined physiological responses monitored in individual cells.

Abstract: Introduction: The G-protein coupled receptor 39 (GPR39) is activated by zinc ions and has been suggested as a novel drug target for epilepsy. Our *in vivo* results mostly argue against the hypothesis that activation of GPR39 alleviates seizure. We have observed that TC-G 1008, a potent and selective agonist of this receptor, facilitated the development of pentylenetetrazole (PTZ) kindling and inhibited phosphorylated cyclic-AMP response element binding (p-CREB) and high-affinity tropomyosine-related kinase B receptor (p-TrkB). There is an association between total serum zinc and epilepsy in patients and between free zinc and status epilepticus in experimental animals. Unlike total serum zinc, the free zinc is responsible for signaling. We examined these fractions of zinc following administration of TC-G 1008 in the PTZ model of epilepsy. **Methods:** The PTZ kindling was performed in male Albino Swiss mice (bodyweight range 25-30 g) (approval no 38/2017). The mice received TC-G 1008 (10 mg/kg i.p.) 30 min (based on previous pharmacokinetic analysis), a non-selective GPR39 agonist, zinc

(given as zinc chloride, $ZnCl_2$) (8 mg Zn/kg) or valproic acid (VPA) (150 mg/kg) before each dose of PTZ. Control mice received the respective doses of drugs and vehicle (VEH) instead of PTZ. 24 h after the last dose of PTZ, tissue was harvested. Serum zinc levels were measured using Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES). Free zinc levels were measured in hippocampal sections using membrane-permeable fluorescent probe Zinpyr-1. The sections were double stained with DAPI. Additional sections were treated with membrane-permeable zinc chelator, TPEN, before staining with Zinpyr-1 and DAPI. The sections were imaged using Leica DM6000 B microscope. Data were analyzed using Image J and Graph Pad Prism v. 5.03, by the Two-way ANOVA followed by a Bonferroni post hoc test.**Results:** The changes in serum zinc were not parallel to changes in hippocampal free zinc concentration. Chronic administration of $ZnCl_2$ but not of zinc-receptor agonist or VPA, increased serum zinc in both control and PTZ-kindled mice. The PTZ-kindling increased free zinc in the CA3 and CA1 areas of the hippocampus, compared to mice that received VEH instead of PTZ. Treatment with TC-G 1008 or $ZnCl_2$ decreased free zinc in the CA1 of PTZ-kindled mice, but not in control mice. **Conclusion:** Our data show the association between epileptogenesis and free zinc in the PTZ model. The changes in free zinc may have consequences for signaling as they may be associated with changes in hippocampal p-CREB and p-TrkB, which we have previously observed following treatment with TC-G 1008 in this model.

Title: The combined effects of the kratom (*Mitragyna speciosa*) alkaloid mitragynine and its *in vivo* metabolite 7-hydroxymitragynine

Authors: *A. PATEL[1], J. D. ZUARTH GONZALEZ[1], S. OBENG[2], V. L. C. PALLARES[1], R. PATEL[1], M. PATEL[1], L. R. GAMEZ-JIMENEZ[1], N. P. HO[1], F. LEÓN[3], M. MOTTINELLI[3], C. R. MCCURDY[3], L. R. MCMAHON[1], T. HIRANITA[1];

Abstract: Kratom (*Mitragyna speciosa*) is a widely used botanical that contains numerous alkaloids. One of the most abundant, mitragynine (MG), is converted into an *in vivo* metabolite: 7-hydroxy-MG (7-OH-MG). Both alkaloids bind to mu-opioid receptors (MOR); MG has lower

MOR efficacy (i.e., intrinsic activity) than 7-OH-MG. We hypothesized the difference in efficacy between MG and 7-OH-MG imparts a difference in the degree to which they exert agonist and antagonist activity. In a [35S]GTPγS functional assay at human MOR, we confirmed the difference in efficacy: MG did not exhibit agonist activity up to 100 μM, whereas 7-OH-MG produced a maximum stimulation of 41.3% of DAMGO (i.e., was a partial agonist). When combined with 7-OH-MG, 10-fold higher concentrations than the Ki values of MG (7.09 μM) and the opioid antagonist naltrexone (18.4 nM) produced 22- and 69-fold rightward shifts, respectively, in the 7-OH-MG concentration-effect curve. In rats, MG (up to 56 mg/kg, i.p.) did not significantly increase latency to respond on a hot plate warmed to 51°C and 52°C. 7-OH-MG robustly increased hotplate response latency (respectively, ED50s= 6.44 and 8.66 mg/kg, i.p.) at both temperatures, as did the MOR agonist morphine. The low efficacy agonist buprenorphine produced full antinociception (100%) at 51°C, and partial antinociception (67.2%) at 52°C (respectively, ED50s= 0.173 and 0.692 mg/kg, i.p.). In contrast to the antagonism obtained with MG *in vitro*, MG (56 mg/kg, i.p.) produced modest leftward shifts in the dose-effect functions of 7-OH-MG (2.1-fold) and morphine (2.2-fold). At 52°C, buprenorphine (0.32 mg/kg, i.p.) reduced the effects morphine down to the effects produced by buprenorphine alone, and antagonized morphine 7.3-fold. These results show markedly (i.e., quantitatively and qualitatively) different effects of MG and 7-OH-MG evidenced by antagonistic activity *in vitro*, and apparent synergistic activity *in vivo*. Apparent rank order efficacy is 7-OH-MG>buprenorphine>MG; this unique pharmacological profile could render MG and its 7-OH metabolite effective replacements for other clinically used opioids.

Abstract: Varenicline increases δ and θ band power and attenuates the 5-HT_{2A}R induced head-twitch response

A. Contreras, R.M. Hines, D.J. Hines. Psychological and Brain Sciences, University of Nevada, Las Vegas, Las Vegas, NV

Pre-Columbian Mesoamerican practitioners expertly utilized hallucinogens in combination with *Nicotiana rustica* (tobacco) during ritualistic practices to treat ailments in their communities.

Modern Westernized medicinal practices are beginning to understand the potential of hallucinogens in treating psychiatric and mood disorders, but less is understood about the synergistic effects that activation of serotonin and nicotinic acetylcholine receptors have on hallucinogenic-induced changes in arousal. Utilizing both the open field and EEG, we characterized the head-twitch response (HTR), a behavioral assay for 5-HT_{2A}R activation and its hallucinogenic effects in rodents following combined administration of the α7 nAChR agonist varenicline and the highly selective 5-HT_{2A}R agonist 25I-NBOH. We identified an increase in time stopped and a robust attenuation of the HTR in the open field, as well as a sustained enhancement of δ and θ power in EEG recordings which became pronounced at least 30 minutes after dual administration of varenicline and 25I-NBOH. These findings contribute to our understanding of specific α7 nAChR agonism in modulating the effects of 5-HT2AR activation. Taken together, these findings have major implications for clarifying the therapeutic potential of hallucinogens.

Abstract: Voltage gated sodium channels (VGSC) generate action potentials and thereby mediate intra and inter cellular communication in excitable cells. VGSC current inhibition is an important mechanism for a wide range of therapeutics. A number of endogenous ligands block VGSC currents indicating that VGSC modulation may impact excitability physiologically. The endogenous cannabinoid, anandamide (AEA), has been proposed to directly inhibit a number of isoforms of the VGSC in expression systems. Here we report that anandamide almost completely blocks VGSC currents in voltage-clamped mouse, cultured, neocortical neurons that express VGSC α-subunits Nav1.1, 1.2, 1.3 and 1.6. The effect is widespread, being present in >99% of neurons tested. We tested if AEA blocked VGSC currents via cannabinoid CB_1 receptors. The CB_1 antagonist, AM 251, did not alter AEA inhibition of VGSC current (93 ± 1%) suggesting that this inhibition is independent of CB_1 receptors. To determine if the AEA-induced block of VGSC current relied on G-protein signaling, we tested the effect of GDPβS which inhibits G-protein cycling. AEA (10 μM) inhibited VGSC current by 71 ± 7% (n = 8), measured 250 s after

onset of application. In contrast, AEA reduced VGSC current by only 3 ± 3% (n = 6) following inclusion of GDPβS (2 mM) in the pipette solution ($P = 5 \times 10^{-6}$). We next tested if AEA block of VGSC currents was voltage-dependent. Peak VGSC currents were elicited by a 30 ms step to -10 mV (5 s duty cycle) at holding potential (V_h) of -60, -80, or -100 mV (N = 21). The fractional inhibition by AEA, 200 s after application, was increased 20-fold as V_h was depolarized from -100 to -60 mV ($P=4x10^{-7}$). Like some other indirect VGSC blockers, the time course of inhibition by AEA was described well by f(t) $=A+Be-(t/\tau)2$ where t, A and B, and T represent time, constants, and the time constant respectively. Hyperpolarization of V_h over the voltage range increased T 14-fold ($P= 6 \times 10^{-8}$). These data indicate AEA block of VGSCs is voltage-dependent. AEA may act to preferentially stabilize the inactivated VGSC state. To examine this possibility we tested if hyperpolarization reversed AEA inhibition of VGSC currents. VGSC currents were elicited by two 10 ms steps (S1, S2) to -10 mV separated by a variable length recovery period at -120 mV. Before AEA application, S2 was 50% recovered by 0.8 ms In contrast, after full block by AEA, S2 recovered to 50% in 130 ms. The recovery of VGSC current with strong hyperpolarization following AEA exposure suggests that AEA acts indirectly to stabilize the inactivated state. The abundance and strength of this pathway highlights a voltage-dependent mechanism by which AEA influences cortical excitability.

Title: Cannabidiol inhibition of murine primary nociceptors: Tight binding to slow-inactivated states of Nav1.8 channels

Authors: H. X. B. ZHANG, *B. P. BEAN;
Harvard Med. Sch., Boston, MA

Abstract: The non-pychoactive phytocannabinoid cannabidiol (CBD) has been shown to have analgesic effects in animal studies but its molecular targets are not clear. We examined effects of CBD on intrinsic excitability of primary pain-sensing neurons. Studying acutely-dissociated capsaicin-sensitive mouse DRG neurons at 37°C, we found that CBD effectively inhibited action potentials evoked by current injection, with 2 μM CBD reducing the number of action potentials evoked by 80-pA 1-s current injections from 18 ± 2.6 in control to 2.2 ± 1.0 in 2 μM CBD (mean

± SEM, n = 14 pairs). Remarkably, CBD was more effective in inhibiting action potential firing than the local anesthetic bupivacaine. CBD reduction of firing was accompanied by a reduction in action potential peak, increased action potential width, reduced afterhyperpolarization, and increased propensity to enter depolarization block. In voltage clamp experiments, CBD inhibited both TTX-sensitive (TTX-S) and TTX-resistant (TTX-R) sodium currents, which had Nav1.8-like kinetics and voltage-dependence. CBD showed strong state-dependent inhibition of TTX-R channels with fast binding to inactivated channels during depolarizations and slow unbinding on repolarization. As for most Nav channels, maintained depolarization causes Nav1.8 channels to enter a "slow inactivated" state from which recovery is far slower than from regular fast inactivation. However, at least for native Nav1.8 channels in mouse nociceptors, slow inactivation of Nav1.8 channels is unusual in that it occurs at more hyperpolarized voltages than fast inactivation. By examining CBD alteration of channel availability following conditioning pulse of various durations, we found that CBD appears to bind especially tightly to slow inactivated Nav1.8 channels. The results could be fit by a model whereby CBD binds to the resting state of the channels with a Kd of 4.5 μM, to fast inactivated states with a Kd of 300 nM, and to slow inactivated states with a Kd of 120 nM. The tight binding to slow inactivated states likely contributes to CBD's efficacy in inhibiting repetitive firing of nociceptors. We conclude that CBD can likely produce analgesic effects by direct effects on neuronal excitability, with *in vivo* effects likely strongly dependent on mode of application and pharmacokinetics.

Title: Voltage-dependence of indirect sodium channel inhibition by cinacalcet

Authors: J. LINDNER, *S. M. SMITH;
VAPORHCS/OHSU, Portland, OR

Abstract: Voltage-gated sodium channel (VGSC) activation is essential for action potential generation in the brain. Allosteric calcium sensing receptor (CaSR) agonist, cinacalcet, strongly and ubiquitously inhibits VGSC current in neocortical neurons. This effect persists in CaSR-deficient neurons, indicating a CaSR-independent mechanism, and is blocked by the G-protein signaling blocker GDPβS, indicating an indirect pathway mediated by G-proteins. Here, using whole cell patch clamp, we investigated the voltage dependence of cinacalcet-mediated inhibition of VGSCs and their recovery from inactivation. The time course of inhibition was well described by the function f(t) ($f(t) = A + Be^{-(t/\tau)^2}$, where t is time, A and B are constants, and τ is

the time constant) consistent with indirect VGSC block. Similarly, in nucleated outside-out patch clamp recordings, the time course of inhibition of VGSC currents by cinacalcet was well described by the same function, eliminating concerns about voltage clamp errors distorting the time course of inhibition. The rate of inhibition, in both whole cell and outside-out patch recordings, was markedly faster at more depolarized voltages. Hyperpolarization of the holding potential over the range of -60 to -100 mV increased mean τ five-fold in whole cell recordings (n=6 at each voltage, P = 0.001), and 4-fold in outside-out recordings over the range of -80 to -100 mV (n=4 at each voltage, P = 0.04). As more VGSCs are in the inactivated state at depolarized holding potentials, the differences in blocking potency are explained if cinacalcet binds more tightly to the inactivated state. To evaluate whether cinacalcet inhibits sodium channel activity by affecting slow or fast inactivation, we implemented a voltage protocol that assays the voltage-dependence with which channels enter slow inactivation. In the presence of cinacalcet (10 μM), we observed a substantial increase in the fraction of channels recovering slowly after 5 s prepulses (96 ± 0.6%, n=6) compared to control (56 ± 4%, n=6). In addition, the voltage-dependence of slow inactivation shifted in the hyperpolarizing direction in the presence of cinacalcet, with a midpoint of -59 ± 2 mV in control (n=6) and -97 ± 1 mV (n=6; P = 0.004) in cinacalcet. Taken together, these results indicate enhancement by cinacalcet of slowly recovering channel states, though it is yet unclear whether this originates from binding to slow-inactivated channels or fast-inactivated channels from which recovery is slow. This dynamic and ubiquitous signaling pathway by which G-proteins regulate VGSC currents describes an important voltage-dependent mechanism for modulating central neuronal excitability.

Title: Use of database-obtained cryo-EM data of voltage-gated sodium channels to explain voltage electrophysiology in SCN2A mutations

Authors: *L. A. MONTGOMERY, Z. PEI, T. R. CUMMINS;
Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Mutations in brain voltage-gated sodium channels can cause epilepsy, which can be a severe condition in childhood and early development. The SCN2A gene is one of these protein-coding genes that contains many point mutations causing epilepsy. We have utilized cryo-EM data of the Nav1.2-beta2-KIIIA ternary complex from the Worldwide Protein Data Bank (PDB entry: 6J8E; Pan, X., Li, Z., Huang, X., Huang, G., Yan, N., 2019). The UCSF Chimera program

was then used to explore how point mutations affected the Nav1.2 structure. We were able to document changes in channel structure with four mutations, which we believe to have affected mobility of nearby channel segments and pore morphology. We also noted one mutation that did not significantly affect channel structure, in which the mutation had similar electrophysiology data to the control. We believe that this work suggests that analysis of cryo-EM structures can predict pathogenicity, or lack thereof, better than proximity in a primary protein sequence, which might be cited in online databases for the likelihood of pathogenicity. ClinVar marks Ala215Pro as likely pathogenic; however, it's criteria for this is based on other mutations in the same primary region of the protein. Electrophysiology data collected on this mutation was unremarkable, and our structural analysis concluded that it was likely nonpathogenic since there were no major interactions in the pore, other channel segments, or the inactivation gate. Gly899Ser is marked as likely pathogenic; we agree with the conclusion that its position in a transmembrane segment and that a change from a non-polar to a polar amino acid residue is likely to cause disease. Electrophysiology data confirms that it is likely pathogenic; however, our structural analysis furthers an explanation that interactions affecting pore morphology might better explain the data collected. Arg937Cys is reported as pathogenic and that this pathogenicity is believed to be caused by pore morphology. We were able to confirm this in our structural analysis through a predicted disulfide linkage of a nearby cysteine. Ala1333Thr is reported as likely pathogenic; we agree with the conclusion that its position in a transmembrane segment and that a change from a non-polar to a polar amino acid residue is likely to cause disease. Electrophysiology data confirms that it is likely pathogenic; however, our structural analysis furthers an explanation that interactions would occur between a nearby segment affecting its mobility in voltage sensing. In conclusion, we believe that modeling putative disease variants in cryo-EM structures may enhance predictions of pathogenicity in voltage-gated sodium channels.

Title: Cav3.1 and CaM colocalize in internal cellular structures

Authors: C. SZALAY-ANDERSON[1], H. ASMARA[2], W. NICOLA[2], C. DRUMMOND-MAIN[2], G. SAHU[3], R. W. TURNER[2];
[1]Neurosci., [2]Cell Biol. & Anat., Univ. of Calgary, Calgary, AB, Canada; [3]Dept. of Biotech., NIPER - Ahmedabad, Ahmedabad, India

Abstract: It is well established that calmodulin (CaM) exhibits a calcium-dependent association with the C-terminal region of high-voltage activated voltage-gated calcium channels. We showed that the low voltage-gated Cav3.1 (T-type) channels exhibit a constitutive association with CaM at rest that is close enough to support FRET across a wide region of tsA-201 cells. However, FRET was lost upon membrane depolarization in a manner that was dependent on Cav3 calcium conductance, followed by aggregation of CaMKII in the cytoplasm. Initial studies for FRET used GFP tagged to the Cav3.1 N-terminus as the donor molecule and CaM-mKate as acceptor. A loss of FRET thus suggested a dissociation of CaM from an IQ-like domain on the C-terminus of Cav3.1. However, the means by which CaM associated with Cav3.1 at the membrane could so quickly promote CaMKII aggregation was unsolved. An alternative explanation would be that a portion of the C-terminus bound to CaM-mKate translocates with CaM into the interior of a cell in a manner analogous to Cav1 calcium channels. To test this we first verified that FRET could be recorded between Cav3.1 tagged with GFP at the channel's C-terminus and CaM-mKate. Upon depolarization with high K+ medium, FRET between the Cav3.1 C-terminus and CaM was still lost, suggesting that the Cav3.1 C-terminus does not translocate with CaM. Given the strength of fluorescent signal supporting FRET in the cytoplasmic region we then sought to determine where Cav3.1-CaM FRET was occurring using TIRF imaging combined with Super-Resolution Radial Fluctuations (SRRF) reconstructions. We found that a large proportion of Cav3.1 and CaM colocalization was found internally with a few discrete points on the cell plasma membrane. TIRF-SRRF imaging revealed that Cav3.1 labeling had an organization highly comparable to what would be expected of the smooth endoplasmic reticular syncytium. Given these results, we will explore the relationship between Cav3.1 and CaM with endoplasmic reticular membranes using TIRF-SRRF or STORM-TIRF on images obtained during FRET and after membrane depolarizations.

Title: Effect of the geometry of the endoplasmic reticulum on astrocytic calcium signals at tripartite synapses: insights from simulations in realistic 3D geometries

Authors: *A. DENIZOT[1], C. CALÌ[2], H. BERRY[3], E. DE SCHUTTER[1];
[1]Okinawa Inst. of Sci. and Technol., Onna-son, Japan; [2]Dept. of Neurosci., Neurosci. Inst. Cavalieri Ottolenghi, Univ. of Turin, Turin, Italy; [3]F-69603, INRIA, Villeurbanne, France

Abstract: Astroglial cells have been shown to actively modulate neuronal activity at tripartite synapses. Astrocytes respond to stimuli with calcium signals of various spatio-temporal characteristics. Most of those signals occur in close proximity to synapses, in branchlets that are

< 200nm in diameter, which appear blurry with conventional light microscopy [1]. Most astrocytic calcium signals are downstream the activation of IP3R channels on the membrane of the endosplamic reticulum (ER). Because of their small size, branchlets have long been considered devoid of ER [3]. However, IP3R2-/- mice are characterized by a 50% decrease of calcium activity in branchlets [2]. A recent immuno-labelling study resolved this controversy by suggesting that ~30% of synapses in the hippocampus are < 1 µm away from astrocytic ER [4]. Here, we use computational tools to investigate the causal relationship between ER geometry in astrocyte branchlets and the spatio-temporal characteristics of the resulting calcium signals. Reaction-diffusion simulations are performed in simplified geometries and reconstructions from electron microscopy in 3 spatial dimensions characterized by various ER geometries. We propose key geometrical features that regulate signal probability and size in astrocyte branchlets, contributing to a better understanding of astrocyte function and neuromodulation at tripartite synapses.

Title: Age-dependent changes of synaptic and extrasynaptic L-type calcium channels and NMDA receptors in rats

Authors: *A. MAZIAR, S. CAREW, C. REINHARDT, Q. YUAN;
Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Age-associated impairments in learning and memory have been linked to abnormally elevated Ca^{2+} levels in hippocampal neurons. Both L-type calcium channels (LTCCs) and N-methyl-D-aspartate receptors (NMDARs) permit the entry of Ca^{2+} into cells. It is not well understood whether both channels contribute to age-related calcium overload. This study aims to investigate the intracellular distribution of LTCCs and NMDARs in the hippocampus at various age groups. Neonatal (10-14 days), adult (3-6 months), and aged (18-24 months) rats of both sexes were used. Expression of LTCCs (Cav1.2) and various subtypes of NMDARs (GluN1, GluN2A, and GluN2B) in both synaptic and extrasynaptic membranes were compared by western blotting. Immunohistochemistry and confocal imaging were employed to compare synaptic (co-labeling with PSD95) and non-synaptic Cav1.2 and GluN2B expression in dorsal hippocampal subdivisions (CA1, CA3, and DG). Preliminary western blotting results showed that GluN1, GluN2A, and GluN2B were higher in the synaptic fraction of the adult and aged hippocampus than in neonatal brains, although no difference was observed between adult and aged. In contrast, GluN1 extrasynaptic expression was higher in neonates. GluN2A/2B ratios were similar among different age groups. Western Blotting data shows that the synaptic expression of Cav1.2 appeared higher in the adult hippocampus but did not reach statistical significance. With western blotting, the specific location of this upregulation could not be determined; therefore we performed immunohistochemical analysis on hippocampal subregions. Confocal analysis of Cav1.2 in the CA1 region revealed lower synaptic expression and higher non-synaptic expression in aged brains compared to adult ones, whereas GluN2B exhibited similar levels of expression in the two age groups. These preliminary results suggest that age-related excess Ca^{2+} entry through non-synaptic LTCCs in CA1 may be a factor to explain the detrimental effect of age in learning and memory.

Title: Different roles of T-type calcium channel isoforms in hypnosis induced by an endogenous neurosteroid epipregnanolone

Authors: I. COULTER, T. TIMIC STAMENIC, *S. M. TODOROVIC;
Anesthesiol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Many neuroactive steroids induce sedation/hypnosis by potentiating gamma-aminobutyric acid (GABAA) currents. However, we previously demonstrated that an endogenous neuroactive steroid epipregnanolone [(3β,5β)-3-hydroxypregnan-20-one] exerts potent peripheral analgesia by blocking T-type calcium channels (T-channels) while sparing GABAA currents in rat sensory neurons (Ayoola et al., 2014). Here, we utilized mouse genetics to investigate potential sedative/hypnotic and immobilizing properties of epipregnanolone by assessing Loss of Righting Reflex (LORR) and Loss of Withdrawal reflex (LOWR), respectively. We found that epipregnanolone is an efficacious dose-dependent hypnotic agent when injected alone intra-peritoneally (i.p.) and also that it significantly lowered LORR and LOWR concentrations of a common volatile anesthetic isoflurane in wild type (WT) mice. To better understand the hypnotic effect on WT mice we measured EEG changes after intraperitoneal injection of epipregnanolone. We noted a rise in the total power of all frequencies except the γ frequencies. When analyzing relative power, it was discovered that there was a rise in β frequency 15 minutes after injection coinciding with the measured onset time of LORR yielded by our behavioral experiments. We also investigated hypnotic effects of epipregnanolone between different knockout (KO) models of T-channel isoforms. The CaV3.1 (CACNA1G) KO mice demonstrated decreased sensitivity to epipregnanolone-induced hypnosis when compared to WT mice, whereas no significant difference was noted between CaV3.2 (CACNA1H) and WT mice. However, when compared to WT mice, onset of epipregnanolone-induced hypnosis was delayed in CaV3.2 KO mice but not in CaV3.1 KO mice. We also found that across all genotypes, female mice were significantly more sensitive to epipregnanolone-induced hypnosis when compared to age-matched males. To our knowledge, this work is the first to report on the hypnotic properties of epipregnanolone in rodents. We speculate that distinct hypnotic effect of epipregnanolone across all T-channel isoforms is due to their differential expression in thalamocortical circuitry. Further research will be necessary to determine the exact mechanism underlying this sex difference and to what degree it will impact potential future clinical use. We posit that endogenous neuroactive steroids that target neuronal T-channels may have an important role as novel hypnotics and/or adjuvants to anesthetic agents.

Title: Voltage-gated calcium channels in skin are critical for transient hyperalgesia in mice

Authors: *R. Y. MEIR[1], E. J. LOPEZ SOTO[1], D. M. DUBREUIL[2], S. DASTE[1], A. FLEISCHMANN[1], D. LIPSCOMBE[1];
[1]Dept. of Neurosci., Brown Univ., Providence, RI; [2]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Voltage-gated calcium channels (Cav) are essential for transmitting information about noxious stimuli from detection in the periphery to perception centrally. Cav2.1 and Cav2.2 channels control excitation-dependent calcium entry at nociceptor presynaptic termini in spinal cord dorsal horn. Intrathecal Cav2.2 channel blockade relieves chronic pain in humans and rodents, but here we explore the role of peripheral Cav2.1 and Cav2.2 channels, at the point of stimulus detection in skin, in short-term sensitization of nociceptors. Nociceptors of dorsal root ganglia are pseudo-unipolar with a single axon that bifurcates, sending a branch centrally to spinal cord dorsal horn and another peripherally to innervate target organs including skin. With few exceptions, studies of Cav channels in nociceptors focus on their role controlling transmitter release at central presynaptic termini, while overlooking their potential importance at peripheral nerve endings. Here we present evidence that Cav2.1 and Cav2.2 channels are at axonal nerve endings in skin where they regulate capsaicin-induced changes in neuronal excitability but in distinctly different ways. To visualize functional Cav2.2 channels in peripheral nerve endings in skin, we used 2-photon microscopy live imaging. We imaged GCAMP6f in hind paw skin 5 and 15 mins after intraplantar capsaicin or capsaicin plus conotoxin in anesthetized GCAMP6f^{lox}/Trpv1^{Cre} mice. Capsaicin-induced Ca^{2+} signals in nociceptor projections were reduced by w-conotoxin MVIIA to ~40% of control levels indicating the presence of functional Cav2.2 channels. We next assessed the contribution of Cav channels to the robust, transient hypersensitivity to mechanical and heat stimuli that develops following prolonged activation of Trpv1 nociceptors. We used intraplantar 0.1% capsaicin, without or co-injected with w-conotoxin MVIIA or w-agatoxin IVA to inhibit peripheral Cav2.2 or Cav2.1 channels, respectively. Local inhibition of Cav2.2 channels reduced capsaicin-induced hyperalgesia selectively (not mechanical sensitivity) by 50% compared to capsaicin alone, without affecting

baseline behavioral responses to local thermal stimuli (n = 17 to 33). By contrast, local inhibition of $Ca_V2.1$ channels reduced capsaicin-induced mechanical hypersensitivity selectively (not heat) by 50% compared to capsaicin alone, without affecting baseline mechanical hypersensitivity (n = 4 to 6). Our results reveal that capsaicin-induced hypersensitivity to thermal and mechanical stimuli use two different local signaling pathways that depend on activation of two different Ca_V2 channels expressed in peripheral nerve endings in skin.

Title: A role for peripheral $Ca_V2.2$ channels in neurogenic inflammatory hyperalgesia

Authors: *A.-M. N. SALIB[1], M. J. CRANE[2], D. M. DUBREUIL[3], E. J. LOPEZ SOTO[1], A. M. JAMIESON[2], D. LIPSCOMBE[1];
[1]Dept. of Neurosci., Brown Univ., Providence, CA; [2]Dept. of Mol. Microbiology and Immunol., Brown Univ., PROVIDENCE, RI; [3]Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Voltage-gated $Ca_V2.2$ channels are essential gatekeepers between detection of noxious stimuli at peripheral nociceptive nerve endings and central perception of pain. $Ca_V2.2$ channels in nociceptors control release of glutamate, neuropeptides and ATP from presynaptic termini and soma. Neuropeptides and ATP are pro-inflammatory mediators in the spinal cord that trigger the central sensitization that accompanies neurogenic inflammation. In an accompanying abstract (Meir et al.), we show $Ca_V2.2$ channels mediate voltage-dependent calcium entry in Trpv1 nociceptor nerve endings in skin, and are essential for transient hyperalgesia induced by prolonged Trpv1 nociceptor activation. We set out to test the hypothesis that activation of $Ca_V2.2$ channels is a critical step in triggering proinflammatory signaling cascades in models of hyperalgesia. We compared behavioral responses in wild type and $Ca_V2.2$ global knockout (KO) mice following intraplantar CFA and observed reduced hyperalgesia in $Ca_V2.2$ KO mice within 1 day and up to 5 days following CFA treatment. The interleukin 1 (IL-1) family of cytokines are early proinflammatory mediators which initiate secondary inflammatory responses. Interestingly, in hindpaw skin extracts from wild type and $Ca_V2.2$ KO mice we observed 60% lower IL-1β levels in $Ca_V2.2$ KO animals compared to WT controls. These findings suggest a role for $Ca_V2.2$ channels in chronic inflammation and we therefore established methods to address this

hypothesis. We used a post-operative injury model, the dorsal subcutaneous implantation of polyvinyl alcohol (PVA) sponges, in Cav2.2KO and WT animals to quantify local cytokine levels and leukocyte populations 24 hours and 7 days post injury. Leukocyte populations were identified by flow cytometry, and 13 cytokines assessed by a multiplex bead-based immunoassay. Our analyses were similar in $Ca_v2.2$ KO and WT mice with expected early increases in neutrophils on day 1, invasion of additional innate leukocytes at day 7, and early and late cytokines released in both genotypes. Having established conditions to analyze essential components of the inflammasome, we are analyzing the interstitial fluid in mouse hindpaw to link these analyses directly to behavioral assays. We compared cytokine levels in hindpaw interstitial fluid of WT and $Ca_v2.2$ KO mice 15 mins after capsaicin injection, the peak of capsaicin-induced hyperalgesia. Our preliminary data show 70% lower IL-1α levels in Cav2.2 knockout mice as compared to wild type (6-8 animals per group). These preliminary data suggest a critical role for $Ca_v2.2$ channels in the initiation of early signaling cascades that underlie heat hyperalgesia.

Title: Identifying protein interactions of KCNQ2 channels using epitope-tagged Kcnq2 targeted mice

Authors: H. SOH[1], K. SPRINGER[1], K. DOCI[2], ***A. TZINGOUNIS**[3];
[1]Physiol. and Neurobio., [2]Univ. of Connecticut, Storrs, CT; [3]Physiol. and Neurobio., university of connecticut, Storrs, CT

Abstract: Recent human genetic studies have shown that loss or gain of function variants of the voltage-gated potassium channel KCNQ2 causes neonatal epileptic encephalopathy. It is currently assumed that KCNQ2 channels primarily associate with KCNQ3 channels in the brain; however, recent published work has suggested that KCNQ2 channels may also interact with additional transmembrane proteins. Identifying the KCNQ2 membrane complex is necessary in order to understand how KCNQ2 channels dysfunction could lead to epilepsy and to also design better therapeutics. To address this question, we have developed a new epitope FLAG-tagged mouse line allowing us to analyze KCNQ2 affinity purified complexes from the neocortex using mass spectrometry. We have now validated this mouse line using electrophysiology and immunohistochemistry and show that inclusion of a FLAG tag to KCNQ2 channels does not

interfere with KCNQ2 function in the brain. Analysis of affinity purified KCNQ2 complexes from the neocortex by mass spectrometry demonstrated that a subset of KCNQ2 channels are in a complex with not only KCNQ3 channels but also KCNQ5 channels. Our data suggest that KCNQ2 channels could form tri-heteromeric KCNQ2/KCNQ3/KCNQ5 channels in the brain.

Title: Therapeutic concentrations of 4-AP inhibit Kv3.3 channels in Purkinje neurons

Authors: *Z. NIDAY[1], B. C. CARTER[2], B. P. BEAN[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]European Neurosci. Inst., Gottingen, Germany

Abstract: 4-aminopyridine (4-AP) is a small molecule known to inhibit a number of different voltage-gated potassium channels with different concentration-dependence. 4-AP is also a therapeutic treatment for various neurological disorders, including the cerebellar ataxia episodic ataxia type 2. The mechanism of action of 4-AP on cerebellar ataxia has been proposed to center on the improvement of firing regularity of cerebellar Purkinje neurons (Alviña and Khodakhah, 2010). However, the major molecular target remains unclear. We report that the main target of 4-AP in cerebellar Purkinje neurons is Kv3.3. Performing *in vitro* electrophysiological recording from acutely dissociated Purkinje neurons at 37 °C (mice aged P13-P18), we found that 4-AP dose-dependently reduced the coefficient of variance of spontaneous firing, as previously reported for Purkinje neurons in cerebellar slice recordings. This effect was accompanied by a dose-dependent increase in action potential width. There was little effect on the frequency of spontaneous firing, but high-frequency firing driven by current injections was slowed by 4-AP. These effects of 4-AP were absent or severely diminished in Kv3.3-null mice. To define the profile of 4-AP sensitive current in Purkinje neurons, we recorded currents in voltage clamp using action potential waveforms as the voltage command (action potential clamp). We found that current blocked by 4-AP flows primarily during the repolarization phase of the spike, consistent with the fast kinetics characteristic of Kv3 channels and their prominent role in action potential repolarization in Purkinje neurons, as previously reported. Previous work showed that the Kv1.5 inhibitor diphenyl phosphine oxide-1 (DPO-1) mimicked the effects of 10 μM 4-AP on Purkinje neuron firing and that combination of the two drugs had a non-additive effect, suggesting Kv1.5 as the molecular target of low concentrations of 4-AP. However, we found that DPO-1 in the low micromolar range effectively blocked current produced by mouse Kv3.3 expressed in HEK293 cells. Taken together, our data demonstrate that Kv3.3 is the likely major molecular target of low-concentrations of 4-AP in cerebellar Purkinje neurons.

Title: Combining Kv7 openers amplifies outward current and blocks deep tissue nociceptor discharge

Authors: ***B. Y. COOPER**, T. J. NUTTER;
Oral and Maxillofacial Surgery, Univ. of Florida, Gainesville, FL

Abstract: Background: In order to repurpose analgesics for use in GWI (Gulf War Illness), we examined whether combinations of classic (Retigabine, RET) and secondary (Diclofenac, DIC; Meclofenamate, MEC) K_v7 channel openers (KVO) could retard deep tissue nociceptor activity.
Methods: Cells were harvested from the dorsal root ganglion of male rats (n=106). Delayed rectifier K^+ currents were isolated from other voltage sensitive currents using a K^+ isolation solution. A stepped voltage protocol was applied (-55 to -40 mV; V_h=-60 mV; 1500 msec) before and after KVO or vehicle (2 min; RET, DIC, MEC). Outward currents were assessed. Linopirdine (20 uM), was then applied for 3 minutes. The Linopirdine sensitive currents were determined by subtraction. The influence of KVOs was also assessed in current clamp studies where nociceptors were challenged by a muscarinic agonist known to evoke burst discharges. (Oxotremorine-M, OXO; 10 uM, 1 min). This is the first attempt to conduct such studies in confirmed nociceptors.
Results: KVOs differed widely with respect to their influence on nociceptors. MEC produced the highest maximal currents and broadest voltage sensitivity shifts (I_{max} = 6.3 pA/pF; p<.002 and p<.03, respectively; ED_{50}=60.7 uM; n=55). DIC and RET produced weaker maximal currents (I_{max} = 1.0 pA/pF DIC and 1.24 pA/pF RET; ED_{50}: 96.1 uM DIC and 62.0 uM RET; n=46 and 42, respectively), but voltage sensitivity shifts were observed only near current activation thresholds. Using subthreshold combinations of DIC (50 uM) and RET (5 uM), we observed that evoked currents were significantly amplified. The combination of DIC (50 uM) and RET (5 uM; n=8) outperformed individual applications of 90 uM DIC (p<.004) or 40 υM RET (p<.05), but there was little influence on voltage sensitivity. In contrast, the combination of DIC 70 uM and RET 2.5 uM (n=5) produced no significant current amplification in voltage clamp studies. In current clamp studies, both of the above combinations produced hyperpolarization (-3.5.48 +/-1.58 mV and -6.44 +/-1.86 mV; p<.04 and .005; n=10 and 9) and significantly blocked OXO evoked action potential bursts (p<.03 and .001, respectively, n=8, 10 and 9).
Conclusions: When used in combinations, KVOs that bind to different K_v7 subunits ($K_v7.2$ vs $K_v7.3$) can amplify evoked currents through nociceptor K_v7 channels and block action potentials evoked by a cholinergic challenge. However, current clamp studies indicated that factors other

than K_V7 opening might also be involved. Combinations of KVOs could be an effective strategy for treatment of deep tissue pain as experienced by veterans suffering from GWI.

Title: Suppression of macro- and micro-scopic Kv1.1 channel activities by beta-amyloid peptides: Involvement of both intracellular calcium-signaling pathways and direct peptide-peptide interactions

Authors: *K. DEBOEUF, M. ISLAM, N. THELEN, J. WATKINS, J. FARLEY;
Neurosci., PBS and Neurosci, Indiana Univ., Bloomington, IN

Abstract: Past studies indicate that Aβ's role(s) in Alzheimer's disease (AD) pathogenesis involves disruption of Ca^{2+} homeostasis, synaptic communication, impairment of learning- and memory-related synaptic plasticity [e.g., hippocampal LTP], and eventual cell death. The mechanism(s) underlying these effects are still unclear. Because Kv1.1 and related channels are activated during an action potential, regulate depolarization-produced Ca^{2+} influx, and inhibition of Kv1 channels can produce hyperexcitability and neurotoxicity, we have speculated that Aβ-suppression of Kv1 channels may contribute to AD pathology. Here we describe the effects of Aβ peptides on macro- and micro-scopic Kv1.1 currents using two electrode voltage-clamp (TEVC) and patch clamp techniques, respectively. Bath application of either Aβ(1-42) or "core" peptide Aβ(25-35) produced 40-50% suppression of macroscopic Kv1.1 current within 30 m (murine homomeric Kv1.1 channels expressed in *Xenopus* oocytes). Little or no suppression was produced by reverse peptide Aβ(40-1) or solvent control. Clear suppression of Kv1.2 channels by Aβ(1-42) also occurred. Suppression of Kv1.1 by Aβ(1-42) was partially dependent on intracellular Ca^{2+} and PP2B. ~25% reduction occurred when cells were loaded with BAPTA-AM or exposed to the PP2B-inhibitor cyclosporine A. Membrane capacitance measurements and Western Blot analyses failed to detect any Aβ(1-42)-produced endocytosis of Kv1.1 in these acute experiments. In contrast, clear endocytosis was observed when large increases in intracellular Ca^{2+} were produced by A23187, or by PMA-activation of PKC. Aβ-suppression of Kv1.1 involved both PP2B-dephosphorylation and direct protein-protein interaction of Aβ with Kv1.1 subunits. Exposure of the intracellular face of Kv1.1 channels in ripped-off oocyte patches to either purified catalytically-active PP2B, or Aβ(1-42), produced gradual reductions in *p*(open), followed by abrupt disappearance of Kv1.1 activity. Additional single-channel results [involving "tip-dip" and black lipid membranes (BLMs) studies] found that direct application of Aβ peptides to individual Kv1.1 channels reduced their activity, whether applied intra- or extra-cellularly. We conclude that Aβ peptides (1-42) and (25-35) suppress Kv1.1 and 1.2 channels. Suppression of these and related K^+ channels presynaptically may lead to larger and longer

spikes, greater Ca^{2+}influx, and increased release of glutamate. Postsynaptically, increased glutamate release and suppression of Kv1 channels, may lead to enhanced activation of AMPA and NMDA receptors, and thus contribute to AD hyperexcitability and excitotoxicity.

Title: Pharmacology of transient receptor potential cation (TRP) channels using different activation stimuli

Authors: A. HORVÁTH[1], T. A. GOETZE[1], I. RINKE-WEIß[1], N. BECKER[1], L. FOCKE[2], O. WEHMEIER[2], R. SCHWANDNER[3], G. OKEYO[4], T. STRASSMAIER[4], R. HAEDO[4], N. FERTIG[1], ***A. R. OBERGRUSSBERGER**[1];
[1]Nanion Technologies GmbH, Munich, Germany; [2]acCELLerate GmbH, Hamburg, Germany; [3]Assay.Works GmbH, Regensburg, Germany; [4]Nanion Technologies Inc., Livingston, NJ

Abstract: Transient Receptor Potential (TRP) channels are widely distributed throughout the mammalian central and peripheral nervous systems. They can be directly activated by ligands, heat or cold and mechano-stimulation, and are important targets in drug discovery for the treatment of pain, respiratory diseases, cancer, immune disorders and others. Here, we studied the responses of TRPA1, TRPV1, TRPV3, TRPV4 and TRPM8 assay-ready and cultured cells activated using a variety of stimuli on automated patch clamp (APC) systems.
TRPA1 and TRPM8 are crucial in sensing noxious cold and inflammatory pain, responding to irritant environmental and food compounds, and metabolites produced during oxidative stress. TRPA1 is expressed in sensory neurons of the dorsal root ganglion (DRG) and trigeminal ganglion. Thus, TRPA1, and possibly TRPM8, antagonists are considered a promising approach for the treatment of acute and chronic pain. Desensitization is one of the biggest challenges for drug screening of TRPA1 channels. Here, we compare IC_{50}s obtained with long vs short ligand exposure using a high throughput device, the SyncroPatch 384i. TRPM8 was activated repetitively activated using solution at 10°C on the Port-a-Patch using temperature-controlled perfusion system at 10 °C. Capsazepine (10 μM) was used to block the activated current.
The TRPV1, 3 and 4 channels are ligand-gated, non-selective cation channels widely expressed in the peripheral and central nervous system and, like TRPA1, are involved in nociception. In addition, TRPV3 is robustly expressed in keratinocytes, and TRPV4 in various tissues, including human T cells and a range of epithelial (cornea, retina, trachea, lung) and endothelial (eye, liver, heart, kidneys) cells. The TRPVs respond to elevated temperatures as well as various compounds, and identifying compounds with differing effects on ligand- vs heat activation may be crucial in the discovery new treatments for pain with fewer side effects. Here, we developed

robust methods for temperature and pharmacological activation to study differential effects of blocker using APC systems (Patchliner and Port-a-Patch). Heat activation of TRPV1, 3, 4 channels was performed repeatedly by the heated pipetted (37-45°C) of the Patchliner. Ligand activation could be also performed on the Patchliner (10 µM Capsaicin - TRPV1, 200 µM 2-APB - TRPV3, 100 nM GSK1016790 - TRPV4). Various blockers were used to inhibit the response. Experiments involving TRPV4 were also performed on the Port-a-Patch. The channel was by heat (38°C) and partially blocked by ruthenium red.

Title: Structure-function analysis of Pannexin-1 permeability to anandamide

Authors: *C. L. ANDERSON, R. J. THOMPSON;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Pannexin-1 (Panx1) is an ion and metabolite channel with broad cell/tissue expression, including neurons and glia of the central nervous system. Panx1 is best known for its efflux of ATP, contributing towards a multitude of pathological and physiological mechanisms. With the Panx1 cryo-EM structures recently reported, unique gating mechanisms of multiple small-molecule conduction pathways have been reported. These could explain the size- and charge- exclusion of certain molecules depending on channel conformation and pore access. We recently described a novel role for Panx1-dependent regulation of the extracellular concentration of the endocannabinoid, anandamide (AEA). Here, we hypothesize that Panx1 facilitates AEA permeation across the neuronal membrane to regulate fast synaptic uptake of AEA for extracellular clearance and degradation. Using combinations of electrophysiology and

fluorescent dye flux in HEK293T cells over-expressing Panx1, we are investigating site-specific interactions within Panx1 that may govern AEA transport. Our data show that AEA attenuates wild-type Panx1 currents in a concentration-dependant manner, in addition to altering charge-specific fluorescent dye uptake. This suggests these small molecules may 'compete' for channel permeation. We predict that mutating single or select groupings of residues will alter this putative interaction between Panx1 and AEA and decrease uptake.

Title: Gaba co-release from midbrain da neurons requires the membrane transporter gat1

Authors: *R. MELANI[1], N. X. TRITSCH[2];
[2]Neurosci. and Physiol., [1]New York Univ. Sch. of Med., New York City, NY

Abstract: There is a growing appreciation that many neurons throughout the central nervous system synaptically release multiple neurotransmitters. Amongst them, midbrain dopaminergic (DA) neurons in the Substantia Nigra pars compacta (SNc) have been shown to release GABA and glutamate along with dopamine onto target neurons in dorsal striatum. We previously demonstrated that GABA co-release does not rely on a canonical GABA synthetic machinery, as DA neurons do not express GAD65 and GAD67. Instead, we showed that DA neurons express the plasma membrane GABA transporter GAT1 (Slc6a1), and suggested that GABA uptake by GAT1 is necessary to sustain GABAergic transmission from DA neurons. However, it has been reported that DA neurons synthesize GABA by a non-canonical synthesis pathway involving Aldh1a1. To more directly test the role of GAT1 in GABA co-release, we generated a conditional knocked out (cKO) mouse in which GAT1 is selectively ablated from DA neurons. Using whole-cell voltage-clamp recordings from striatal projection neurons, we find that GABA co-release from midbrain DA neurons is entirely abolished, but that glutamatergic co-transmission is unimpaired. Tonic GABA is not affected in GAT1 cKO mice, indicating that the loss of GABA co-release is not secondary to a decreased GABA availability or increased tonic inhibition. In adult GAT1 cKO mice, viral expression of GAD65 and GAD67, as well as GAT1, fully restore GABA co-release, while Aldh1a1 overexpression is not sufficient. These results indicate that GAT1 deletion does not impair DA neuron survival or vesicular exocytosis, confirm that GABA co-release from midbrain DA neurons relies on GABA uptake from the extracellular milieu, and pave the way for future studies investigating the contribution of GABA co-release in modulating striatal function and behavior.

Title: Metformin: possible potentiation of glutamate-stimulated norepinephrine release in rat cerebral cortical slices

Authors: *Y. M. ALJOHANI, M. ROSS, F. WU, K. KELLAR, G. DEZFULI;
Dept. of Pharmacol. and Physiol., Georgetown Univ., Washington, DC

Abstract: Metformin: possible potentiation of glutamate-stimulated norepinephrine release in rat cerebral cortical slices.
Yousef M. Aljohani, Madison Ross, Fan Wu, Kenneth J. Kellar and Ghazaul Dezfuli Department of Pharmacology & Physiology, Georgetown University, Washington DC 20057 Disclosures: Y.M. Aljohani: None. M. Ross: None. F. Wu: None. K.J. Kellar: None. G. Dezfuli: None.
Metformin is the most widely prescribed medication for type-2 diabetes. Studies on metformin's actions in the CNS (unrelated to glucose metabolism) reveal several kinds of effects, but few, if any, of these mechanisms reveal insight into metformin's potential effects on neurotransmission in the brain. The purpose of the present study was to assess the effects of metformin on glutamate-stimulated norepinephrine (NE) release using a highly reliable *in vitro* assay. To this end, experiments were performed in both young (2-3 months old) and aged (18-24 months old) Fischer 344 rats, and the glutamate-stimulated NE release was measured in the slices from the cerebral cortex. Our results show that (a) glutamate-stimulated NE release is mediated by n-methyl-d-aspartate (NMDA) receptors and (b) that metformin increases glutamate-stimulated NE release in the cerebral cortex of young Fischer 344 rats. Furthermore, in aged Fischer 344 rats, which demonstrate a significant decline in cortical glutamate-stimulated NE release (Dezfuli *et al.,* 2019), we found that metformin rescues the deficit in the release, restoring it to the levels seen in young rats. Our preliminary results indicate a novel mechanism of action for metformin in the brain, namely, to potentiate glutamate-stimulated NE release. These data have possible implications for the effects of aging on CNS functions, including on cognition and conditions stemming from dysregulated monoamine signaling.No authors have a conflict of interest.

Title: A role for synapsin IIa oligomerization in maintaining a reserve pool of synaptic vesicles

Authors: *M. ZHANG, G. J. AUGUSTINE;
Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: Although it is known that synapsins are involved in maintaining a reserve pool (RP) of synaptic vesicles (SVs) within presynaptic terminals, the precise mechanism involved in this action remains elusive. We have tested the role of synapsin oligomerization in this process by examining the ability of an oligomerization-deficient mutant of synapsin IIa to rescue the RP defect of cultured glutamatergic neurons from synapsin triple knock-out (TKO) mice. First, photobleaching of labelled SVs in individual presynaptic boutons was used to monitor how synapsins limit movement of SVs between boutons: the level of fluorescence recovery after bleaching SVs within one bouton reflects the mobility of SVs coming from neighboring boutons. In TKO neurons, a high level of fluorescence recovery showed that SVs were highly mobile. Expression of wild-type synapsin IIa could immobilize SVs in TKO neurons, indicating that synapsin IIa traps SVs within a bouton (*J. Neurosci.* 32:3969). However, expression of the oligomerization-deficient synapsin IIa mutant did not immobilize SVs. This reveals that the mutant is not able to confine SVs locally and therefore cannot retain SVs within the RP. Next, mobilization of SVs from the RP to the readily-releasable pool was monitored by examining the kinetics of short-term synaptic depression. Whole-cell patch clamp recordings were used to measure the amplitude of excitatory postsynaptic currents (EPSCs) during trains of stimuli (10 Hz). In wild-type neurons, mobilization of SVs from the RP slows the activity-dependent decrease in EPSC amplitude during such stimulus trains. Synaptic depression was very rapid in TKO neurons, indicating very little RP mobilization. Expression of wild-type synapsin IIa in TKO neurons slowed depression, reflecting rescue of RP mobilization (*J. Neurosci.* 28:10835). However, such rescue was minimal in neurons expressing the mutant synapsin IIa. Thus, oligomerization is important for mobilization of SVs from the RP. In summary, our results support the idea that oligomerization of synapsins is important for maintaining glutamatergic SVs within the RP, thereby providing a supply of SVs during sustained synaptic activity.

Title: Rare patient mutation in presynaptic calcium channel affects localization and synaptic function

Authors: *M. ZULUAGA FORERO[1,2], P. T. KURSHAN[2], H. SNELL[2], K. KHODAKHAH[2];
[1]Dept. de Biología, Univ. Nacional De Colombia, Bogotá, Colombia; [2]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Channelopathies cause a wide variety of disorders, but understanding how specific mutations lead to disease has been complicated by gene redundancy and compensatory effects in a variety of classical and complex vertebrate models. We use C. elegans to evaluate the functional and behavioral effect of a rare and novel human patient-derived point mutation (D1634N) in the P/Q-type voltage-gated calcium channel (CACNA1). Mutations in this channel are typically associated with autosomal dominant neurological disorders like familial hemiplegic migraine type 1 (FHM1), episodic ataxia type 2 (EA-2), and Spinocerebellar ataxia type 6 (SCA6), however patients with the D1634N mutation cannot be classified into any of these disorders, suggesting a novel mechanism of action. The worm has only one ortholog of the channel (UNC-2) expressed in its nervous system and shares high homology in the region of the single point mutation D1634N. Our CRISPR-generated D1634N worms show decreased channel expression at synapses and defects in locomotion resembling the human patients' ataxic phenotype. Additional interactions with presynaptic proteins are being evaluated to address the impact of this mutation on presynaptic morphology and synaptic function.

Title: The effect of acute ATP depletion on synaptic vesicle endocytosis at the ultrastructural level

Authors: *Q. GAN[1], S. WATANABE[2];
[2]Dept. of Cell Biol., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Following synaptic vesicle fusion at the presynaptic terminal, vesicular membrane and proteins must be recycled via endocytosis to replenish the vesicle pool. A previous study revealed using the pHluorin assay that local depletion of ATP at presynaptic terminals impairs the rate of vesicle cycling during sustained synaptic activity, possibly by blocking endocytosis. However, due to limitations inherent to the pHluorin approach, it is unknown which exact step in the vesicle cycling process is most sensitive to the availability of ATP. Moreover, it is unclear whether glycolysis or oxidative phosphorylation (OxPhos) is more important for supplying energy for the synaptic vesicle cycle. In the present study, we used time-resolved electron microscopy to capture rapid changes to the presynaptic membrane ultrastructure in cultured

hippocampal neurons at various time points following stimulation. We found that acute ATP depletion by blocking both glycolysis and OxPhos stalls synaptic vesicle endocytosis at a stage prior to membrane fission. In contrast, blocking OxPhos alone does not stall synaptic vesicle endocytosis. In addition, using pHluorin assay, we also found that blocking glycolysis alone slows down synaptic vesicle recycling, while blocking OxPhos has no effect. Taken together, these results suggest that membrane fission during endocytosis is the most energy-sensitive step in the synaptic vesicle cycle, and that glycolysis, but not OxPhos is the preferred energy source driving synaptic vesicle endocytosis.

Title: Plc mediates spontaneous glutamate release triggered by extracellular calcium

Authors: *M. G. FELDTHOUSE[1], N. P. VYLETA[2], S. M. SMITH[3];
[1]Res. and Develop., Portland VA Med. Ctr., Portland, OR; [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]PCCM, VAPORHCS/OHSU, Portland, OR

Abstract: Evoked and spontaneous glutamate release pathways are different in many ways. The underlying vesicle pools are distinct, are modulated by different receptors, and the two mechanisms are differentially affected by extracellular $[Ca^{2+}]$ ($[Ca^{2+}]_o$). Physiological decreases in $[Ca^{2+}]_o$ occur with increased neuronal excitability and these changes in the microenvironment reduce evoked and spontaneous glutamate release. While Ca^{2+} entry via voltage-gated calcium channels transduces the action of $[Ca^{2+}]_o$ for evoked release, the same pathway does not contribute to spontaneous release. A number of G-protein coupled receptors appear to link $[Ca^{2+}]_o$ and spontaneous glutamate release and we have tested if phospholipase C (PLC), which is activated by G protein subunits and hydrolyzes the phospholipid phosphatidylinositol 4,5-biphosphate (PIP_2), contributes to a common downstream pathway. PLC is well positioned for this role as it increases inositol triphosphate (IP_3) and diacylglycerol (DAG), both of which are known modulators of synaptic transmission. Using whole cell patch clamp in primary neocortical neuronal cultures, we confirmed that frequency of spontaneous release, measured as miniature excitatory post-synaptic currents (mEPSCs), was substantially increased (Median (Mdn) relative to baseline to 302%, n=13) by elevation of $[Ca^{2+}]_o$ from basal (1.1 mM) to high (6.0 mM), however inhibition of PLC activity with U73122 (5 μM) completely blocked this effect (Mdn=87% baseline, n=8; Dunn's multiple comparisons, $P<0.001$). The response to $[Ca^{2+}]_o$ was

intact in vehicle and inactive analog (U73343) controls. PLC β1 is the most abundant isoform in the neocortex, but interestingly the $[Ca^{2+}]_o$-dependence of mEPSC frequency was the same in neurons from PLCβ1 null mutant and litter mate controls. U73122 substantially suppressed $[Ca^{2+}]_o$-mediated increase in mEPSC frequency in the PLCβ1 null mutants (Mdn=80% baseline, n=8, Dunn's, $P<0.01$), indicating that $[Ca^{2+}]_o$-sensitivity may be mediated by other PLC isoforms. We tested if vesicles that mediate evoked release were also sensitive to PLC. Using hypertonic sucrose to probe the readily releasable pool (RRP), we determined that the RRP was depleted more quickly after PLC blockade by U73122, resulting in a 73% reduction in sucrose-induced charge transfer (SICT) compared to a pre-incubation baseline (t-test, $p=0.048$). SICT was not reduced by U73343. Addition of the DAG analogue PDBu attenuated this effect. Together these data point to a strong role for PLC in mediating changes in mEPSC frequency in response to extracellular cues and in maintaining the vesicles mediating evoked glutamate release.

Title: Somatodendritic release of cholecystokinin potentiates ventral tegmental area GABAergic synapses

Authors: *V. MARTINEZ DAMONTE[1], R. ST. LAURENT[2], J. A. KAUER[1];
[1]Dept. of Psychiatry, Stanford Univ., Stanford, CA; [2]The Gladstone Inst., San Francisco, CA

Abstract: Cholecystokinin (CCK) is a neuropeptide found in most ventral tegmental area (VTA) dopamine (DA) neurons. Intra-VTA CCK injection reportedly modulates reward-related behaviors, but its role in VTA circuitry has remained unclear. Inhibitory inputs are essential for controlling the firing pattern of DA VTA neurons, and plasticity at GABAergic synapses can powerfully shape dopaminergic output. CCK has been shown to potentiate GABAergic synapses in other brain areas. Here we explored the hypothesis that CCK can control GABAergic synaptic strength in the VTA.Previously, we used whole-cell recordings from VTA DA cells in mouse brain slices to examine synaptic plasticity with the stimulating electrode placed caudal to the VTA to elicit inhibitory postsynaptic currents (caudal IPSCs). We reported that low frequency stimulation (LFS) paired with modest depolarization (dep) induces input-specific long-term potentiation (LTP) of GABAergic synapses (131.9 ± 6.5 % of baseline, $p=0.0012$, n=9). This form of LTP (dep+LFS LTP) is NMDAR-independent, requires the depolarization of the postsynaptic dopamine cell and is blocked by a BAPTA-containing intracellular pipette solution *(St. Laurent et al., 2020; Neuron 106:624)*. We have now found that depolarization of the

postsynaptic DA cell by itself potentiates caudal IPSCs, even without LFS (145.9 ± 18.1 % of baseline, p=0.0264, n = 13). Together, these properties are consistent with the somatodendritic release of a signaling molecule as the underlying mechanism supporting dep+LFS. Somatodendritic release can occur with both classical neurotransmitters and neuropeptides, and it has been proven to be an intrinsic feature of DA cells (Geffen et al., 1976; Nature 260:258; Rice et al., 1997; J. Neurophysiol. 77:853; Beckstead et al., 2004; Neuron 42:939).We now report that bath application of CCK (0.1 μM), potentiates GABAergic synapses onto VTA DA neurons (123.9 ±7.3, p=0.0135, n = 8). CCK bath application occludes dep+LFS LTP, since after potentiation by CCK, further LTP cannot be elicited with dep+LFS (97.5 ± 11.6 % of baseline, p=0.8385, n = 7). Furthermore, incubation with the CCK_2 receptor antagonist, LY225910 (1 μM), blocks dep+LFS LTP (87.9 ± 9.3 of baseline, p=0.2407, n = 7) as well as depolarization-induced LTP (104.3 ± 5.2 % of baseline, p=0.4410, n = 6). In future experiments we will explore the mechanisms that underlie CCK-induced potentiation, and which presynaptic afferents can be potentiated by this mechanism.Our work shows for the first time that CCK promotes LTP at GABAergic afferents that regulate DA neuron firing, suggesting that somatodendritic CCK release is expected to decrease VTA DA cell excitability.

Title: Identification of factors regulating activity of corticotropin-releasing factor-producing neurons in the paraventricular nucleus of the hypothalamus

Authors: *Y. MUKAI[1,2,3,4], A. NAGAYAMA[1,2], K. ITOI[5], A. YAMANAKA[1,2,4];
[1]Dept. of Neurosci. II, Res. Inst. of Envrn. Medicine, Nagoya Univ., Nagoya, Japan; [2]Dept. of Neuromodulation, Grad. school of medicine, Nagoya Univ., Nagoya, Japan; [3]JSPS Res. Fellowship for Young Scientist, Tokyo, Japan; [4]CREST, JST, Saitama, Japan; [5]Dept. of Neuroendocrinology, Grad. Sch. of Medicine, Tohoku Univ., Sendai, Japan

Abstract: To know the nature of certain neuron is to reveal what factors regulate its activity. Corticotropin-releasing factor-producing neurons in the paraventricular nucleus of the hypothalamus (PVN-CRF neurons) are known to play a key role in the stress response as a commander of hypothalamic-pituitary-adrenal axis. To consider how the activity of PVN-CRF neurons is regulated to generate appropriate response to stress, it is important to identify factors which regulate the activity of these neurons. However, there have been few reports about regulators of PVN-CRF neurons. Since there are various type of neurons in the PVN, it has been difficult to record the activity of PVN-CRF neurons exclusively. Therefore, we performed

calcium (Ca^{2+}) imaging in PVN-CRF neurons of mouse acute brain slice to monitor neuronal activity, and screened change of the activity induced by various physiologically active substances. We created adeno-associated viral vector (AAV9-CMV-FLEX-YC) to express a calcium indicator, yellow cameleon-Nano50 (YC), in the cre recombinase expressing cells. We injected the AAV into the PVN of *CRF-iCre* knock-in mice (Itoi et al. 2014 *Endocrinology*; over 6-week-old, both male and female). Four weeks after infection, we made acute brain slices from the animal and subjected the slice to Ca^{2+} imaging. We individually applied 63 substances including neurotransmitters, neuropeptides and lipids through perfusion. As a result, we found that 12 substances increased Ca^{2+}, while 3 substances decreased Ca^{2+}. Among these substances, angiotensin II and histamine mainly increased calcium in the ventral portion of the PVN-CRF neurons via AT_1 and H_1 receptors, respectively. Conversely, carbachol mainly increased calcium in the dorsal portion of the PVN-CRF neurons via both nicotinic and muscarinic acetylcholine receptors. In this study, we established a novel universal system for screening of factors modulating Ca^{2+} signal in any cre-expressing cells by AAV infection and calcium imaging. In addition, we also got a clue to investigate how the activity of PVN-CRF neurons are regulated in terms of neurotransmitters and neuromodulators. The factors found in this study included those implicated in variety of physiological roles such as regulation of sleep-wakefulness, water intake and blood pressure. Our finding will contribute to understand how appropriate response to stress is generated through PVN-CRF neurons.

Title: Estrogen facilitates excitatory synaptic transmission in layer II of the entorhinal cortex via activation of GPER1

Authors: *A. A. BATALLÁN BURROWES, A. SUNDARAKRISHNAN, C. BOUHOUR, C. CHAPMAN;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Ovarian hormones, estrogens and progestogens, are thought to influence cognitive function via rapid synaptic changes associated with activation of their receptors and modulation of intracellular signaling. Hippocampal application of 17-β estradiol (E2) enhances excitatory synaptic transmission and improves working memory performance. Activation of estrogen receptors (ERs) can inhibit GABAergic neurons, modulate excitatory NMDA and AMPA currents, and reversibly increase CA1 pyramidal neuron dendritic spine densities.

Comparatively, progesterone (P4) can facilitate GABAergic function via its metabolite allopregnanolone. The entorhinal cortex is a significant source of cortical sensory and associational inputs to the hippocampus. However, it is unclear how ovarian hormones may impact synaptic transmission in the entorhinal cortex. The present study assessed the effects of the acute application of E2, P4, and allopregnanolone on excitatory glutamatergic synaptic transmission in layer II of the rat entorhinal cortex in vitro. On PD63, rats were ovariectomized and implanted with a subdermal E2 capsule to maintain constant low levels of circulating E2. Electrophysiological recordings were collected between PD70 and PD91. Acute horizontal brain slices were obtained and evoked field excitatory postsynaptic potentials (fEPSP) were recorded in layer II following stimulation of layer I afferents. After baseline recordings, a 20-min application of E2 (100 nM) resulted in an increase in fEPSP amplitude that reversed during the 30-min washout period. Neither application of the ERα agonist PPT (100 nM) nor the ERβ agonist DPN (1 μM) significantly altered synaptic responses compared to baseline. However, the GPER1 agonist G1 (100 nM) induced a reversible increase in fEPSP amplitudes similar to that induced by E2. Further, the GPER1 antagonist G15 (1 μM), prevented the facilitation induced by E2. The application of P4 (100 nM) or allopregnanolone (1μM) did not result in significant synaptic changes. This indicates that the rapid enhancement of excitatory synaptic transmission induced by estrogen in the entorhinal cortex is likely mediated by activation of GPER1 receptors. This enhancement may support the contribution of estrogen to cognitive function in the hippocampal region.

Title: Serotonin reduces neuronal gain in the claustrum

Authors: *K. L. L. WONG, G. J. AUGUSTINE;
Lee Kong Chian Sch. of Med., Nanyang Technological Univ., Singapore, Singapore

Abstract: The claustrum is a thin brain structure that is connected to various cortical regions. While it receives serotonergic innervation (J Comp Neurol. 526:2428), little is known about what serotonin (5-HT) does to the claustrum. Whole-cell patch clamp recordings in brain slices were used to determine the response of claustral neurons to pressure application of 5-HT. Projection neurons were identified by a classification scheme based on their intrinsic electrical properties (eNeuro 0216-20.2020). About 65% of projection neurons responded to 5-HT application, even

when polysynaptic effects were eliminated by blockade of receptors for glutamate (kynurenic acid; 100 μM) and GABA (GABAzine; 10 μM). In all five projection neuron types, 5-HT evoked a long-lasting outward current at a holding potential of -60 mV. This response was caused by a potassium conductance increase and was largely mediated by the 5-HTR-1A receptor, because it was eliminated by a specific antagonist of this receptor (WAY100635; 1 μM). To understand the functional consequences of this 5-HT response, we determined the input-output (I-O) relationship between current amplitude and action potential frequency. For this purpose, a ramp current (5 s, 0 - 400 pA) was injected into neurons while applying 5-HT. Compared to control conditions, 5-HT caused a rightward shift in the I-O curve, without changing the slope or maximal level of the I-O curve. This indicates that the 5-HT effect is subtractive. Further, the time course of the 5-HT induced change in neuronal excitability tracked the kinetics of the 5-HT induced outward current, indicating that the current reduces input gain by simply hyperpolarizing claustrum neurons. In conclusion, 5-HT reduces the response of claustrum neurons to excitatory input. Hence, 5-HT likely gates claustral function, thereby relieving the feedforward inhibition that the claustrum provides to its downstream cortical targets.

Abstract: Serotonin (5-HT), an important biogenic monoamine neuromodulator across animal phyla, has been implicated to participate in diverse physiological processes including learning and memory. In *Drosophila*, a single serotonergic DPM neuron innervates the olfactory learning center mushroom body (MB) of each hemisphere. Previous work established that perturbation of 5-HT metabolism or signaling by genetically or pharmacological means could lead to impaired olfactory learning, however, the dynamics of 5-HT *in vivo* and how it is regulated remains largely unknown, nor is clear how 5-HT may affect learning circuit in the MB. Here, capitalizing on transgenic flies that expressed our newly developed GRAB-5-HT sensor, we found physiological relevant stimuli, such as odor or aversive electrical body shock, readily triggered compartmental 5-HT dynamics *in vivo*. This compartmental 5-HT release relies on Ca2+ influx through DPM presynaptic nicotinic receptors. The DPM nicotinic receptors are in turn activated by local ACh release from upstream MB Kenyon cells (KCs). Next, we found locally released 5-HT from DPM could reciprocally act on KC terminals to turn down cAMP level as well as ACh release. Finally, by perturbation of 5-HT release from DPM neuron, we found 5-HT signaling is critical to control the length of time window where the plasticity of KC to MB output neuron may occur during odor-shock paring in γ1 compartment of MB. Thus, our work reveals *in vivo* 5-HT dynamics that may be important for optimal time window of synaptic plasticity during olfactory learning in *Drosophila*.

Title: Prenatal Ethanol Exposure Increases the Activity of Serotonin Neurons via Alterations of Endocannabinoid and Nitric Oxide Signaling in the Dorsal Raphe Nucleus

Authors: *S. OUBRAIM[1], R. WANG[1], K. HAUSKNECHT[1], M. KACZOCHA[2], R.-Y. SHEN[1], S. HAJ-DAHMANE[1];
[1]Dept. of Pharmacol. and Toxicology, Univ. At Buffalo, Buffalo, NY; [2]Dept. of Anesthesiol., Stony Brook Univ., Stony Brook, NY

Abstract: Prenatal ethanol exposure (PE) leads to several neurodevelopmental and behavioral disorders referred to as fetal alcohol spectrum disorders (FASD) by affecting the function of numerous neurotransmitter systems, including the serotonergic (5-HT). Results from early

studies have shown that the altered stress homeostasis and increased anxiety-like behaviors induced by PE are mediated by alterations in the development and function of the 5-HT system. Yet, the cellular mechanisms by which PE alter the function of dorsal raphe 5-HT neurons are not well understood. Here, we characterize the effect of PE on the excitability of dorsal raphe nucleus 5-HT neurons and on the excitatory synaptic transmission in the DRn. We found that compared to prenatal control (PC), PE leads to a persistent increase on electrical activity of DRn 5-HT neurons. This effect was associated with a potentiation of glutamatergic transmission caused by a persistent increase in glutamate release. Examination of the mechanisms underlying these effects revealed that PE-induced potentiation of glutamatergic synaptic transmission is mediated at least in part by an enhanced tonic nitric oxide (NO). Thus, pharmacological inhibition of nNOS or NO scavenging depressed glutamatergic synaptic transmission in the DRn of PE, but not in PC rats. In addition, PE also impaired tonic endocannabinoid (eCB) signaling by reducing cannabinoid type 1 receptors (CB1Rs). As such, the results of the present study unravel the impact PE nitrergic and eCB systems, which play key role in controlling the function of DRn 5-HT neurons, and impaired eCB signaling in the DRn, which may contribute to PE associated disorders. They also establish a novel interaction between NO and eCBs that tightly modulate synaptic transmission onto 5-HT neurons.

Title: Adolescent binge drinking and dysregulated stress reactivity in adulthood: interneuronal tonic inhibition in the hippocampal regulation of the HPA axis

Authors: *B. BÜYÜKDEMIRTAS;, M. L. BENN, A. ZUNIGA-ALEMAN, T. BRUNNER, A. FINNERTY-HAGGERTY, J. KWON, I.-A. WATKIS, C. GLICKMAN, L. C. MELÓN;
Biol., Wesleyan Univ., Middletown, CT

Abstract: Adolescent binge drinking increases vulnerability to Alcohol Use Disorder and causes aberrant stress reactivity in adulthood. Recent work shows that alcohol changes the expression of δ-$GABA_A$Rs on inhibitory PV interneurons (PV+INs) in the hippocampus potentially disrupting hippocampal signaling. The hippocampus is an important negative regulator of the HPA axis. We hypothesize that the effect adolescent binge drinking has on stress reactivity in adulthood involves alcohol's impact on δ-$GABA_A$ receptor mediated tonic inhibition in the ventral hippocampus. Socially housed adolescent (P28-42) male and female mice were given two weeks of access to 20%v/v ethanol or water for three separate hours during their dark cycle to induce binge drinking. All mice went through withdrawal until they reached adulthood (P60) before forced swim (FST) and social defeat stress (SDS) tests were performed. Mice were sacrificed

after SDS, and the δ-$GABA_AR$ expression on the hippocampal PV+INs was evaluated with IHC and confocal microscopy. All data were analyzed by two independent researchers who were blind to the groups. Adult females who were adolescent binge drinkers displayed higher basal CORT (M=34.1 ±6.4) compared to water controls (M=16.9 ±2.9) and exhibited significantly increased immobility in the FST. Adolescent binge drinking had no effect on the initial CORT response to FST for either sex, but caused a dysregulated return to baseline for females. Mice were exposed to an aggressor for 5 minutes to assess neuroendocrine and behavioral response to a social stressor. Males with a history of adolescent binge drinking showed a blunted CORT response (M= 377.6 ± 36.1) to social stress when compared to water controls (M= 567.2±85.9). These results suggest that adolescent binge drinking results in aberrant endocrine response to stress even in the absence of isolation. The discrepancies in the stress responses of males and females suggest sex differences in this effect. Although adult binge drinking in adult females is associated with an increase in δ-$GABA_AR$ expression on hippocampal PV+INs, adolescent binge drinkers do not show this effect. However, significant sex differences in the expression of δ-$GABA_AR$ on PN+INs was observed, with males showing lower δ-$GABA_AR$ expression than females in either group. These results propose a possible mechanism for the aberrant neuroendocrine response in adulthood following adolescent binge drinking. Currently, we are evaluating changes associated with other proteins implicated in δ mediated tonic inhibition (α4) and assessing the role that interneuronal tonic inhibition in the ventral hippocampus plays in the regulation of stress.

Title: Cell type-specific nonlinearities of multi-modal inputs to posterior parietal cortex

Authors: *D. J. RINDNER, G. LUR;
Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Top-down signals provide rich contextual and goal orientation cues to facilitate sensory processing. Nonetheless little is known about top-down and bottom-up integration at the cellular level, partially due to difficulty in manipulating input afferents with population specificity. We overcome this limitation using a dual-color optogenetic strategy to determine

spatiotemporal features of multi-modal synaptic integration in the mouse posterior parietal cortex (PPC). We expressed Chrimson, a red light-sensitive channelrhodopsin variant, in the primary auditory cortex (A1) and ChR2, a blue light-sensitive opsin, in the anterior cingulate cortex (ACC), a frontal region commonly associated with attention and working memory. This opsin combination allowed independent control of sensory and frontal inputs to the PPC. Using whole-cell patch clamp recordings in acute brain slices we show that the PPC receives direct, monosynaptic inputs from both A1 and ACC. Similarly to other cortical areas, layer 5 principal cells in the PPC show heterogeneity in their firing patterns. We found that two classes of pyramidal neurons, intrinsically bursting and regular spiking, have distinct patterns of frontal-sensory integration. Intrinsically bursting cells displayed a robust enhancement of coincident input from ACC and A1, an effect that diminished with increasing delays between inputs. Conversely, regular spiking cells showed maximal enhancement when afferents were activated with delay, and a suppression of coincident inputs. Notably, bursting cell coincidence detection is mediated by a sodium and low-threshold calcium conductance, whereas regular spiking cell delayed integration requires NMDA receptor activity. Our data suggest that frontal-sensory integration has cell type specificity in the PPC, and begins to unravel the circuit architecture of multi-modal integration.

Title: Local synaptic inhibition in mouse globus pallidus during autonomous firing

Authors: *J. JONES, M. HIGGS, C. J. WILSON;
Univ. of Texas San Antonio, San Antonio, TX

Abstract: Neurons in globus pallidus pars externa (GPe) are autonomous oscillators, but their intrinsic rhythmic firing is perturbed by synaptic input, including local inhibition from axon collaterals of other GPe cells. To characterize the local inhibition during natural firing, we recorded spontaneous IPSCs in coronal slices of GPe from male and female mice. The spontaneous IPSCs were sensitive to gabazine, and many of them were blocked by tetrodotoxin, indicating $GABA_A$ receptor-mediated, action potential-dependent events. In slices, GPe neurons fire relatively regularly, and this allowed us to identify periodic components of the IPSC time series corresponding to unitary synaptic inputs. By analyzing the periodic IPSCs, we identified the firing frequency and inter-spike interval variability (CV_{ISI}) of the presynaptic neurons and estimated the unitary synaptic reliability and the unitary IPSC amplitudes. To determine what type(s) of GPe neurons received the spontaneous inhibition, we recorded from genetically

labeled parvalbumin (PV) and NPAS1 expressing neurons. Both cell types received periodic spontaneous IPSCs with similar frequencies, suggesting a common presynaptic cell type(s). Optogenetic inhibition of PV neurons using Archaerhodopsin reduced the spontaneous IPSC rate in almost all PV neurons with active unitary inputs, whereas optogenetic inhibition of NPAS neurons rarely affected the spontaneous IPSCs in other NPAS cells. These results suggest that PV neurons provide most of the active unitary inputs to both cell types. In cells with active unitary inputs, optogenetic stimulation of striatal indirect pathway axons caused a pause and temporal resetting of the periodic input, confirming that it arose from local neurons subject to striatal inhibition. Our results show that the local inhibitory network is a powerful source of inhibition to both PV and NPAS neurons, and they suggest that the local network may influence GPe cells' responses to external synaptic input.

Title: Dopaminergic modulation of excitability and electrical synapses in the thalamic reticular nucleus

Authors: *M. J. VAUGHN, J. S. HAAS;
Biol. Sci., Lehigh Univ., Bethlehem, PA

Abstract: The thalamic reticular nucleus (TRN) is a thin shell of electrically coupled inhibitory interneurons that regulates afferent sensory signaling in the thalamus. The TRN receives dopaminergic innervation from the midbrain, and it expresses high concentrations of D_1 and D_4 receptors. Dopamine release in the TRN could add a reward valence to thalamic processing of salient sensory surround. The direct effect of dopamine on TRN neurons and synapses is largely unknown and is key to understanding modulatory control of thalamocortical processing. Synaptic communication within the mature TRN occurs exclusively through its powerful and dense electrical synapses. Dopamine has been shown to modulate electrical synapse strength in other systems, including retina and the goldfish Mauthner synapse. To characterize how dopamine affects neuronal excitability and electrical synapses in the TRN, we utilized paired whole-cell patch clamping. Each cell of a patched pair was injected with 500-ms current pulses to measure resting membrane potential, input resistance, threshold, spiking frequency, spontaneous synaptic inputs, and coupling conductance. Measurements were taken before and after bath application of dopamine, a D_1 agonist, or a D_4 agonist. Our results show that bath application of dopamine results in heterogeneous alternations to tonic spiking frequency, input resistance, and electrical coupling in the TRN. Next, using specific receptor agonists, we determined that the bidirectional

effects of dopamine can be explained by contributions from different receptor subtypes. Agonization of D_4 receptors consistently decreased tonic spike frequency, while agonization of D_1 receptors consistently increased tonic spike frequency. Further, D_4 receptor agonization consistently depressed electrical synapses, while D_1 agonization had no consistent effect on electrical synapse strength. Taken together, our results show that dopamine release can regulate excitability and electrical connectivity in the TRN in a manner wherein valence of modulation is specific to the receptor subtype activated. We hypothesize that dopamine receptors recruit multiple intracellular signaling cascades with opposing effects on gap junction conductance, and the availability of each cascade determines whether dopamine receptors potentiate or depress electrical synapses. We further hypothesize that dopaminergic inputs modulate the intensity and coordination of inhibitory signals sent to thalamus by TRN neurons, and consequently affect cortical attention to the sensory surround.

Title: Characterization of connexin36 at mixed chemical/electrical synapses formed by mossy fiber terminals in rat ventral hippocampus

Authors: *D. THOMAS[1], J. I. NAGY[2], A. BEYER[1], M. JACKSON[1], B. LYNN[1], J. SENECAL[1];
[1]Univ. of Manitoba, Winnipeg, MB, Canada; [2]Physiol. & Pathophysiology, Univ. Manitoba, Winnipeg, MB, Canada

Abstract: Granule cells in the hippocampus project axons to hippocampal CA3 pyramidal cells, where they form large mossy fiber terminals known for their higher transmission fidelity. We reported that these terminals contain the gap junction protein connexin36 (Cx36), specifically in the stratum lucidum of rat ventral hippocampus, thus creating morphologically mixed synapses that have the potential for dual chemical/electrical transmission. There is some electrophysiological evidence that these terminals have a gap junction-mediated electrical transmission component under some conditions. Here, we have used immunofluorescence approaches to examine distinguishing molecular features of Cx36-containing gap junctions at mossy fiber terminals and their postsynaptic elements in combination with electrophysiological measures to probe functional consequences of having mixed synapses in the ventral hippocampus. In the CA3b and CA3c hippocampal regions, the vast majority of these terminals, identified by their selective expression of vesicular zinc transporter-3 (ZnT3), displayed multiple, fine immunofluorescent Cx36-puncta representing gap junctions, which were absent at

mossy fiber terminals in the dorsal hippocampus. Among those ZnT3+ terminals displaying Cx36-puncta in the ventral hippocampus, analysis of numerous terminals showed that they contained an average of 2.4 ± 0.2 puncta per terminal that were 3-5 μm in diameter. These puncta were invariably found in close proximity to the protein constituents of adherens junctions (i.e., N-cadherin and nectin-1) that are a structural hallmark of mossy fiber terminals that contact dendritic shafts of CA3 pyramidal cells, thus indicating the loci of gap junctions at these contacts. Cx36-puncta were also associated with adherens junctions at mixed synapses in other regions of the CNS. Mossy fibers exhibit multiple types of terminals on their way to the stratum lucidum. In the hilus, where they form collaterals that synapse onto interneurons and mossy cells, Cx36-puncta were very sparsely distributed, and none of these Cx36-puncta were associated with ZnT3+ mossy fiber terminals, suggesting these collaterals do not form mixed synapses with their postsynaptic targets. Electrophysiologically induced long-term potentiation of field responses evoked by mossy fiber stimulation was greater in the ventral than dorsal hippocampus, and it remains to be determined whether the electrical component of transmission at mossy fiber terminals contributes to the enhancement of these responses.

Title: Baseline acetylcholinesterase activity of blood and tissue in pediatric and adult rats

Authors: *A. N. SANTORO[1], J. H. MCDONOUGH, Jr.[2];
[1]USAMRICD, Gunpowder, MD; [2]Nerve Agent Countermeasures, Neurosci. Program, US Army Med. Res. Inst. Chem Def, Gunpowder, MD

Abstract: Chemical warfare nerve agents cause profound peripheral and central nervous system effects. Nerve agents exert their toxic effects by inhibiting the cholinesterase (ChE) family of enzymes, including acetylcholinesterase (AChE). These agents bind to the active site of the AChE enzyme, preventing it from hydrolyzing the neurotransmitter acetylcholine (ACh) and causing hyper-stimulation of the cholinergic system. This leads to detrimental physiological effects including miosis, muscle fasciculations, tremors, loss of respiratory control, and, most devastating to the central nervous system, repetitive seizures (McDonough, 2002). In the event of civilian nerve agent exposure, children would likely be among the worst casualties as they are more susceptible to seizures than are adults (Haut et al., 2004; Rakhade & Jensen, 2009; Sidell et al. 2008). In 2016, Wright and colleagues illustrated that toxicity of nerve agents differs greatly

across developmental ages in rats, such that immature animals were 2.7-fold more sensitive to the lethal effects of G series agents than were older animals. Toxicity of nerve agents results from the inhibition of AChE; therefore, the present study determined differences in baseline AChE levels in blood and tissues (brain and peripheral) across developmental ages. Red blood cells, whole blood, brainstem, cerebellum, cortex, hippocampus, midbrain, spinal cord, striatum, perirhinal, diaphragm, heart, and skeletal muscle tissue were collected from post-natal day (PND) 7, 14, 21, 28, and 70 male and female rats ($N = 6$/group) and were assayed using a modified Ellman assay (Shih et al., 2010) to determine baseline level of AChE activity across age groups. Significant differences in baseline AChE activity in both tissues and blood were found. Generally, results indicated a trend of increasing AChE activity in brain tissue as animals matured (i.e., brainstem, cortex, hippocampus, striatum, perirhinal, $p < .001$), while there was a trend of decreasing AChE activity in skeletal muscle ($p < .001$) and red blood cells ($p < .001$) as animals matured. There were no differences between sexes within age groups. Overall, pediatric animals had lower AChE activity, providing a biological basis supporting the findings of Wright et al. (2016). Because baseline AChE levels differ across age groups, we can hypothesize that nerve agent exposure in humans would differentially impact children and adults.

Title: Cholinergic signals optimize information transmission and learning in the hippocampus

Authors: *R. SHARMA, S. NADKARNI;
IISER-PUNE, Pune, India

Abstract: Neuromodulators are essential to regulate and fine-tune nonlinear membrane and synaptic properties. This provides neural circuits with flexibility in function and across behavioral states. We focus on acetylcholine, in particular, released during active waking in the cortex and hippocampus. In the hippocampus, acetylcholine modulates neuronal activity predominantly via its action of the M1 and M4 metabotropic receptors. Their distinct localizations and biophysical properties produce rich dynamics across multiple timescales. We have developed a detailed biophysical model for the presynaptic activation of M4 and postsynaptic activation M1 receptors in the hippocampus. Our model describes activation of M1 receptors leading to IP3 production from membrane PIP2 molecules. Binding of IP3 to IP3 receptors ultimately causes calcium release from the endoplasmic reticulum (ER). The additional calcium release from the ER enhances the action of potassium channels like the calcium activated SK channels and modifies other downstream synaptic signaling. Interestingly, an

opposing effect of M1 receptors is to directly suppress SK channels and the voltage activated KCNQ2/3 channels. We quantify the effect of enhanced calcium signaling from the ER and antagonistic effects on SK channels via M1 receptor activation on long term plasticity of the schaffer-collateral synapse in the hippocampus. Our model also describes presynaptic reduction of the voltage sensitivity of voltage gated calcium channels (VGCCs) and resulting suppression of the neurotransmitter release via M4 receptors. We characterize the influence of apparent dichotomy of suppression of synaptic transmission by M4 and enhanced neuronal excitability by M1 on synaptic signaling and information transmission in a range of physiologically relevant activity regimes.

Title: Modeling the synaptic effects of anesthesia and cortical cholinergic reversal

Authors: *B. P. ENIWAYE[1], A. G. HUDETZ[2], M. ZOCHOWSKI[3], V. BOOTH[4];
[1]Applied Physics, [2]Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [3]Physics, [4]Mathematics, Univ. of Michigan, ANN ARBOR, MI

Abstract: General anesthetics work through varied molecular mechanisms while leading to similar end points of sedation and loss of consciousness. The effects of general anesthesia range from alteration of global brain functional connectivity to changes in synchronization at the scale of neural populations. It is poorly understood, however, how these global and local changes are caused and how this leads to different states of awareness. At the cortical level, anesthesia leads to changes in spontaneous spiking activity and can be characterized by changes in cortical complexity. At the receptor level, the administration of common inhalation anesthetics generally leads to decreases in synaptic excitation while promoting synaptic inhibition (Rudolph & Antkowiak, 2004). Because $GABA_A$ receptors are known targets of common anesthetic agents such as Propofol, variations in $GABA_A$ synaptic efficacy have been extensively modeled and have been shown to correctly model biphasic changes in EEG power spectra (Hutt & Longtin, 2010). Beyond the effects at the synapse, it is shown that region-specific changes in acetylcholine concentration (and its agonists) can lead to partial reversal in the level of sedation in rats (Pal et al., 2018). To study the effects of these synaptic changes and induced reversal we develop a computational model that tracks changes in synaptic inhibition and excitation as well as accounts for the neuromodulatory effects of acetylcholine and compare the resultant network dynamics with observed changes in visual cortex spiking activity in rats under the administration of Desflurane. Specifically, by potentiating the synaptic effects at $GABA_A$ receptors and inhibiting the effects at NMDA receptors we can recover changes in spiking dynamics including changes in firing rate and synchronization associated with anesthesia administration. Moreover,

by introducing the effect of acetylcholine in our model we can undo the changes associated with the synaptic effects. This provides a framework in which induced recovery from anesthesia can occur by redundant mechanisms that increase network excitability.

Abstract
Anti-Müllerian hormone (AMH) is a paracrine factor generated by the gonads to regulate gonadal function in adult mammals. We recently reported that AMH-specific receptor is expressed in the hippocampus, and exogenous AMH protein addition rapidly increased synaptic transmission and long-term synaptic plasticity at the CA3-CA1 synapses. Therefore, in this study, we aimed to investigate the mechanism of the boosting effect of AMH in regulating CA3-CA1 excitatory synaptic transmission in the hippocampus. Brain tissue was obtained from CD-1 mice (6-8 weeks old). The direct actions of AMH on synaptic transmission were examined by whole-cell recordings in hippocampal slices with and without 0.4 nM recombinant human AMH protein addition. Evoked excitatory postsynaptic currents (EPSCs) and excitatory postsynaptic potentials (EPSPs) were measured under different conditions. Data from whole-cell voltage-clamp recordings showed that AMH did not affect AMPA-mediated EPSCs at -70 mV (99.9 ± 12.0 %; $p = 0.72$) or isolated NMDA-mediated EPSCs at -30 mV (93.1 ± 19.6 %; $p = 0.50$). These results suggested that neither AMPA nor NMDA receptors contribute to the boosting effect of AMH on synaptic transmission. The small-conductance Ca^{2+}-activated K^+ channel SK2 and voltage-gated K^+ channel Kv4.2 modulate evoked synaptic responses in CA1 pyramidal neurons. To determine whether AMH modulates SK2 or Kv4.2 activity, EPSPs were recorded with either apamin or 4-aminopyridine (4-AP) to block SK2 or Kv4.2 channels, respectively.

Whole-cell current-clamp recordings showed that blocking SK2 with apamin did not alter the AMH effect on increasing EPSPs (162.5 % ± 19.1 % in apamin versus 163.1 ± 16.3 % in control; $p < 0.01$). However, AMH treatment no longer increased EPSPs in CA1 pyramidal neurons when 4-AP was present either in external bath (89.5 % ± 15.1 %; $p = 0.54$) or internal pipette solution (72.5 % ± 18.8 %; $p = 0.14$). These results show that Kv4.2, but not SK2, channels are required for the rapid action of AMH on boosting synaptic transmission. Our findings provide functional evidence that AMH directly enhances synaptic transmission through Kv4.2 channel in the hippocampus, suggesting a possible role of Kv4.2 channel in AMH-regulated neuronal process underlying learning and memory.

Title: Using the motor units of Drosophila to screen pharmacological therapeutic agents- riluzole and levetiracetam

Authors: *R. L. COOPER[1], S. MCCUBBIN[2], N. DECASTRO[2];
[1]Biol., [2]Univ. of Kentucky, Lexington, KY

Abstract: The attributes of the larval Drosophila neuromuscular junction (NMJ) allow one to assess effects of compounds on the motor unit of neurons as well as the postsynaptic attributes of synaptic transmission. The ability to follow through with genetic studies to examine potential mechanisms of action in pharmacological agents serves a screening ground for future targeted investigations. The larval NMJ is glutamatergic and produces graded evoked excitatory junction potentials. There is also a high frequency of spontaneous quantal events which are readily able to be indexed. To aid in understanding the effects of two compounds currently used as therapeutics, in which the mechanisms are not fully determined we tested their effects on synaptic transmission at the larval NMJ. Riluzole (Rilutek) and levetiracetam (Keppra) are used to alter neural function in humans; however, the various effects are still being investigated. It appears riluzole blocks neuronal excitability by inhibiting action potential propagation without altering glutamate receptivity or frequency of spontaneous quantal events. Thirty minute preincubation to levetiracetam (1 mM) had no effect on the amplitude of evoked junctional potentials with low frequency stimulation but enhanced synaptic depression with higher frequency stimulation. Comparisons with NMJs of crayfish reveal levetiracetam enhanced evoked transmission but similar results occurred for riluzole.

Title: Adaptations in Excitatory Signaling Onto Deep-Layer Prelimbic Cortical Pyramidal Neurons After Chronic Alcohol Exposure

Authors: *B. HUGHES, T. K. O'BUCKLEY, G. BOERO, M. A. HERMAN, A. MORROW; Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Chronic alcohol use impairs cognition resulting in working memory deficits, anxiety, and excessive drinking that are associated with prefrontal cortical (PFC) dysfunction. Our laboratory have shown multiple impairments in GABAergic neurotransmission onto deep-layer principal cells (PCs) in PFC that indicate reduced inhibitory tone and suggest dependence-induced cortical dysfunction is the product of overexcitability in these cells. The present work sought to further determine whether deep-layer PCs displayed coincident adaptations in excitatory signaling that further promote hyperexcitability, using a chronic exposure model previously employed by our laboratory (e.g. 5.0 g/kg, i.g., 15 days) in male and female Sprague-Dawley rats. Whole-cell electrophysiological experiments were conducted 24 hours after final administration in deep-layer prelimbic PCs, and electrically-evoked AMPA-mediated excitatory post-synaptic currents emanating from Layer II/III PCs recorded across a range of stimulation frequencies. We observed a robust shift toward paired-pulse depression after alcohol exposure in sub-cortically projecting Type-A PCs with no apparent change in intra-cortically projecting Type-B cells in males, but not females. This shift toward paired-pulse depression is indicative of enhanced glutamate release probability from superficial PCs onto deep-layer PCs, as modulating extracellular calcium concentration elicited differential enhancements of paired-pulse ratio in Type-A cells consistent with this conclusion. Given reports that PFC afferents regulate anxiety-like behavior, we next evaluated elevated plus maze behavior as a proxy measure of changes in Type-A cell activity, and observed significantly elevated responses after ethanol exposure. Ethanol exposure did not affect working memory performance, consistent with no changes in Type-B cell signaling and activity. Interestingly, alcohol-exposed females displayed enhanced working memory performance with no effect on anxiety-like behavior, suggesting fundamental differences between sexes. In sum, these observations demonstrate that excitatory signaling onto Type-A cells is particularly sensitive to the effects of chronic alcohol exposure in male rats and appear crucial for the expression of alcohol-induced behavioral changes. Furthermore, these findings show that alcohol effects on cortical function cannot be assumed equivalent between sexes. Additional experiments will delineate the pre- and post-synaptic mechanisms governing altered signaling among PC subtypes, and discern the potential causal role of Type-A cells in dependence-like behaviors.

Title: Sex specific effect of Prenatal Alcohol Exposure on NMDARs functionality in orbitofrontal cortex pyramidal neurons.

Authors: *V. LICHERI[1], J. CHANDRASEKARAN[1], C. W. BIRD[1], F. C. VALENZUELA[1,2], J. L. BRIGMAN[1,2];
[1]Dept. of Neurosciences, Univ. of New Mexico, Albuquerque, NM; [2]New Mexico Alcohol Res. Ctr., Albuquerque, NM

Abstract: Alcohol consumption during the pregnancy represents a major public health problem. It is estimated that 10% of pregnant women drink alcohol. The most disabling outcomes of drinking during pregnancy are indicated with the term Fetal Alcohol Spectrum Disorders (FASDs). FASDs include deficits in learning, working memory, social behavior and executive function during early life and persist into adulthood. Using a moderate prenatal alcohol exposure (PAE) combining with touch screen behavioral tasks and in vivo electro-physiology we found a significant impairments in orbitofrontal cortex (OFC)- mediated reversal learning (Marquardt et al., 2014b), and also an altered firing of OFC pyramidal neurons (Marquardt et al., 2020). N-Methyl-D-Aspartate receptors (NMDARs) play a key role in the control of synaptic plasticity, moreover previous studies have shown that NMDAR containing GluN2B-subunit resulted to be altered by moderate PAE. Given that the PAE effects on NMDARs in OFC are less well investigated, here we studied possible changes in NMDARs function integrating a well-established voluntary drinking paradigm for moderate PAE with ex-vivo electrophysiology. Whole-cell patch clamp recordings were performed in slices coming from saccharine controls (SAC) and PAE male and female mice sacrificed at postnatal day (PND) 90-100 days. NMDA receptor-mediated evoked excitatory post-synaptic currents (NMDA-eEPSCs) were acquired at +40 mV and in the presence of the AMPAR antagonist NBQX (10 μM). GluN2B mediated currents were isolated pharmacologically using Ro25-6981 (1 μM). At the end, the NMDA receptor component was verified applying NMDAR-antagonist (APV 50 μM). Comparison of SAC and PAE showed that PAE females have significantly larger NMDA -eEPSCs amplitude than PAE males. Moreover, PAE males showed a significant decrease in current density. While, pharmacological isolation of GluN2B subunit mediated currents revealed that PAE treatment may positively modulate GluN2B function in PAE males. These findings help to elucidate the

molecular mechanism of cognitive impairment in FASDs and give an important tool for developing pharmacological therapies for executive dysfunction in FADSs.

Title: Sex differences in the acute ethanol modulation of GABAergic inputs to principal neurons of the basolateral amygdala

Authors: S. MUNSHI, J. G. TASKER;
Tulane Brain Institute, Dept. of Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: Alcohol use disorder (AUD) is a chronic relapsing brain disorder characterized by compulsive use of alcohol and a loss of control of alcohol intake. Recent studies suggest there are sex-dependent behavioral changes following alcohol administration, as evidenced by rapid acquisition of self-administration of alcohol, rapid escalation of alcohol intake with extended alcohol administration, and less withdrawal with more recovery in females compared to males. In addition, findings in humans suggest that women are at higher risk of developing alcohol-related health disorders compared to men. Therefore, it is imperative to understand the underlying neurobiological substrate of the sex differences in alcohol effects in order to develop sex-specific therapeutic targets. The basolateral amygdala (BLA), which consists of both glutamatergic projection neurons and GABAergic interneurons, is known to play an important role in the development of AUD. The overall excitatory activity of the BLA is tightly regulated by GABAergic interneurons. The alcohol regulation of excitatory and inhibitory circuits of the adult BLA is not well understood. Thus, determining the effect of alcohol on the activity of specific GABAergic interneuron circuits in the BLA is crucial to understanding the neuronal basis for the neurophysiological and behavioral effects of alcohol consumption. In the present study, we tested the hypothesis that ethanol modulates GABA inhibitory inputs to BLA principal neurons from specific interneuron subpopulations, thereby regulating BLA principal neuronal outputs, in a sex-specific manner. Using *ex vivo* whole-cell patch-clamp recordings from BLA pyramidal neurons in amygdala slices from adult male and female Wistar rats, we investigated the effects of acute ethanol application on GABAergic inhibitory postsynaptic currents (IPSCs). Ethanol (44 mM) increased the frequency of miniature IPSCs (mIPSCs) without affecting mIPSC amplitude or decay-time. This ethanol-induced presynaptic modulation of GABA release was found to be dependent on P/Q-type calcium channel activity, but not N-type calcium channels, suggesting that it is specific to parvalbumin neurons. In BLA principal neurons from

females, on the other hand, there was no effect of ethanol on inhibitory synaptic inputs. These data suggest that ethanol causes a spike-independent, presynaptic modulation of GABA inhibitory inputs from parvalbumin interneurons to BLA principal neurons in adult male, but not female, rats. This sex difference in ethanol modulation of specific inhibitory synaptic circuits in the BLA may play a role in the differential susceptibility of males and females to AUD.

Abstract: Repeated exposure to visual stimulation induces connectivity changes in layer 4 of the primary visual cortex (V1) that have been associated with Hebbian synaptic plasticity and perceptual learning. However, the effects of this stimulation on the activity pattern of supragranular V1 excitatory neurons as well as on their synaptic structure and composition remain elusive. Here, we use longitudinal 2-photon imaging to monitor neuronal activity and synaptic AMPA receptor (AMPAR) expression in V1 layer 2/3 (L2/3) of awake mice during repetitive visual stimulation. Visual stimulation consisting of phase-reversing gratings in 6 different orientations recruits a subset of neurons that present phase specificity and within-session habituation. Moreover, this pool of responsive neurons decreases with daily stimulation, leading to a sparser neuronal response profile across all orientation preferences. In addition, we observe an overall increase in synaptic AMPAR levels in the dendritic spines of a subset of V1 L2/3 neurons with repeated exposure to visual stimulation. Together, our results demonstrate the capacity of sensory stimulation to refine circuitry and induce synaptic potentiation in their corresponding primary cortical areas.

Title: Aav-mediated conditional pten deletion in adult dentate granule cells triggers robust de novo neuronal growth without disruption of connectional specificity

Authors: *J. M. YONAN[1], O. STEWARD[2];
[1]Univ. of California Irvine, Irvine, CA; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Phosphatase and tensin homolog (PTEN) is an important negative regulator of the mechanistic target of rapamycin (mTOR) pathway responsible for cell growth and proliferation during development. Studies utilizing PTEN deletion in various developmental animal models have reported alterations to neuronal growth and cell morphology that result in the formation of aberrant circuitry, seizures, and early death. We have recently documented that PTEN deletion in adult cortical motoneurons triggers *de novo* growth of neuronal cell bodies and dendrites that continues for months, without any obvious adverse outcomes. Still, the consequences of PTEN deletion, persistent mTOR activation, and *de novo* growth of mature neurons in the adult brain are not fully understood. Here, we explore consequences of focal PTEN deletion in adult dentate granule cells on morphological features and laminar specificity of their local and distant inputs and outputs. We use the approach of deleting PTEN by injecting AAV-Cre into adult PTEN-floxed, Rosa reporter mice. This technique allows for targeted PTEN deletion in granule cells and preservation of PTEN expression in granule cell input neurons and their target cells. Immunostaining revealed complete loss of PTEN protein within dentate granule cells in the area of injection, with graded deletion spanning its septal/temporal axis. At the core of transfection, there were increases in the area of the dentate gyrus over time and dramatic increases in the size of granule cell bodies by 2 months post injection that progressed out to 6 months after deletion. Growth of cell bodies was accompanied by increases in the thickness of the molecular layer, the caliber of apical dendrites, and density of dendritic spines, implying growth and modification of granule cell dendritic arbors. Despite this growth, tract tracing of perforant path and commissural inputs to the dentate molecular layers revealed that laminar specificity of termination was largely maintained. Additionally, the axonal projections of dentate granule cells (mossy fibers) enlarged over time as evidenced by increases in the thickness of the mossy fiber tract and terminal field in stratum lucidum of the CA3. However, there was no evidence of extension of mossy fibers into CA1 or stratum radiatum of CA3. Supra-granular mossy fibers were seen in some mice at later time posts. Our present results together with previous findings indicate that deletion of PTEN in adult dentate granule cells initiates *de novo* growth in fully mature neurons, indicating

transformation to a growth phenotype regardless of neuron age or type, while maintaining overall gross input and output specificity.

Title: The transition of network topology and connection sustainability in cultured neurons

Authors: *R. IDE, Y. SHINDO, K. HOTTA, K. OKA;
Biosci. and Informatics, Keio Univ., Yokohama-shi, Japan

Abstract: During development, neurons extend their neurites and establish synapse connections to form a functional neuronal network. In the process of the neuronal network formation, the coordinated activation of neuronal assemblies is found in most physiological brain functions and influences proper network wiring during development. In cultured neurons, this coordinated neuronal activity is only observed within one month from the onset of culture and it was regulated by a small number of specific neurons. These specific neurons, with dense functional connections to many other neurons, have been known as 'hub-neurons'. However, measurement of long-term neuronal responses and assessment of functional connectivity in single cell level has not been performed yet. Thus, it is unclear that how hub-neurons have been generated and whether their properties are maintained in developing neuronal networks. Furthermore, many intracellular signals related to neuronal maturation and connectivity generation have been reported; CREB, ERK and mTOR promote synaptic plasticity, maturation of neurons, and energy metabolism. Their direct involvement in the generation of functional connectivity and maintenance is also unknown. In this study, we extracted functional connectivity by Ca^{2+} imaging and investigated the characteristics of hub-neurons in developing cultured hippocampal network. We measured neuronal responses over several days to assess the change and sustainability of the functional connectivity by using a viral vector expressing the calcium indicator. The coordinated activations of neuronal assemblies were only observed during the around second postnatal week *in vitro*. These activities were mediated by activation of $GABA_A$ receptors because they were abolished by the $GABA_A$ receptor antagonist Gabazine. The number of hub-neurons was not changed, but half of hub-neurons does not maintain its property of high connectivity. Moreover, the functional connections between hub-neuron and hub-neuron were maintained. We also evaluated several kinase activities by immunostaining after neuronal

activity measurement. Phosphorylation levels of ERK were different in hub-neurons and others, but not in CREB and 4E-BP1, a downstream effector of mTOR. These results demonstrate that hub-neurons establish many functional connections to other neurons in the early developmental stage and unnecessary functional connections could be removed by decrease of ERK phosphorylation levels.

Title: Perineuronal net (PNN) density is increased in the orbitofrontal cortex in adult rats exposed to AIE

Authors: ***C. A. DANNENHOFFER**[1], V. A. MACHT[2], H. MEEKS[2], E. SUTHERLAND[2], *A. GOMEZ-A[2], C. A. BOETTIGER[3], D. L. ROBINSON[4];

Abstract: Alcohol exposure during adolescence is detrimental to proper brain development, particularly to the prefrontal cortex which is involved in decision-making and cognitive flexibility. Our lab previously found that adolescent intermittent ethanol (AIE) exposure in rats impairs cognitive flexibility in behavioral tests and typical frontostriatal connectivity via fMRI. One mechanism integral to the molecular underpinnings of cognitive flexibility is the expression of perineuronal nets. Perineuronal nets (PNNs) are extracellular matrix components which surround inhibitory interneurons in a variety of brain regions to mediate flexibility in synaptic remodeling. As such, an increase in PNNs within the medial prefrontal cortex (mPFC) and orbitofrontal cortex (OFC) could mediate loss of cognitive flexibility evidenced after AIE. To test this hypothesis, we used immunohistochemistry (IHC) to investigate expression of the markers for the inhibitory interneuron parvalbumin (PV) as well as PNNs using the lectin *wisteria floribunda agglutinin* (WFA) after AIE or control treatment. Male rats were exposed to alcohol (5 g/kg ethanol) or water via intragastric intubation throughout adolescence (postnatal days (P)25-54) in a 2-days-on/2-days-off regimen. In adulthood, animals were perfused, and brains were collected and prepared for IHC. Tissue (including OFC and mPFC) were stained for WFA and PV using immunohistochemical procedures. Results indicate that while the expression of PV+ immunoreactivity (IR) is unchanged in the mPFC and OFC, density of WFA+IR is elevated within the OFC after AIE relative to water-treated controls. This suggests that AIE

induces an impairment in the molecular mechanisms underlying synaptic plasticity as evidenced by increased in PNNs. Future studies will investigate whether this increase in WFA is specific for PV or other types of inhibitory interneurons. These findings suggest that intermittent binge alcohol exposure during adolescence changes extracellular matrix components that regulate synaptic plasticity of inhibitory neurons such as PV. This reduced synaptic plasticity in the OFC may underlie reduced functional connectivity with other frontal and striatal regions and impaired cognitive flexibility after alcohol exposure.

Title: Understanding Neuronal Network Dynamics during Motor Skill Learning through a Model-Free Connectome Inference Method

Authors: ***S. MEAMARDOOST**[1], M. BHATTACHARYA[1], E. HWANG[2], T. KOMIYAMA[3], C. MEWES[4], L. WANG[5], Y. ZHANG[6], R. GUNAWAN[1];

Abstract: The reconstruction of neuronal connectome from large-scale two-photon Calcium (Ca) neuronal images represents an active area of research in computational neuroscience. In this work, we developed a model-free method called FARCI (Fast and Robust Connectome Inference) [1] that provides a pipeline for inferring functional neuronal connectome from time-series Ca fluorescence data of neurons. FARCI combines non-negative deconvolution, thresholding, and spike smoothing procedure for Ca fluorescence data pre-processing and produces an undirected partial correlation network describing the neuronal connectome. We assessed the performance of FARCI using the gold standard Calcium fluorescence datasets from Neural Connectomics Challenge (NCC). Our results demonstrate that FARCI provides accurate

connectome with high computationally efficiency and scalability to large connectome. Notably, FARCI outperforms the winner of the NCC in terms of accuracy and robustness to noise levels, sampling rates, network densities, and hidden (missing) neurons. Furthermore, we applied FARCI to a real dataset [2] in order to infer neuronal connectome and characterize the connectome dynamics in mouse motor cortex region (L2/3) during a motor-skill learning involving a lever pressing task in response to an auditory cue. We showed that the neuronal connectome is dynamically rewired during motor skill learning and the rewiring takes place throughout 15-day period of learning and continues even after the cue-to-reward time does not improve further. Principal Component Analysis of the neuronal connectome from FARCI showed that learning explains the main variation in the connectome across different days of the learning. Our results further demonstrated that neuronal connectome rewires to have more complex and interconnected network configurations. But, in the later sessions, the connectome rewires and adopts a less connected network state while achieving the same cue-to-reward time. Thus, we posit that there exists a two-phase process for connectome rewiring in motor cortex during the above motor-skill learning: in the first phase, the connectome is rewired in order to maximize the reward - to shorten time to reward - by increasing interconnectedness of the neurons, and in the second phase, the connectome is rewired to achieve better network efficiency while maintaining motor performance. Title: Characterization of CaMKII holoenzyme stability

Authors: *A. P. TORRES-OCAMPO[1], C. ÖZDEN[1], A. HOMMER[1], A. GARDELLA[1], A. SAMKUTTY[1], E. LAPINSKAS[1], E. ESPOSITO[2], S. GARMAN[1], M. STRATTON[1]; [1]Univ. of Massachusetts-Amherst, Amherst, MA; [2]Malvern Analytics, Northampton, MA

Abstract: Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII) is a multimeric (12-14mer) Ser/Thr kinase necessary for long-term potentiation (LTP), the underlying cellular mechanism for memory and learning (Fig. 1A). Each CaMKII subunit is comprised of a kinase domain, regulatory segment, and hub domain that is responsible for oligomerizing the subunits into a

holoenzyme (Fig. 1B and 1C). Understanding the hub domain and its dynamics (i.e., how it assembles and falls apart) is crucial, and we have pursued experiments to interrogate holoenzyme stability. We employed differential scanning calorimetry (DSC) to measure the temperature at which the protein unfolds, which reveals the overall domain stability. The hub domain alone is extremely stable, while the kinase domain is quite unstable. Interestingly, the holoenzyme (with kinases attached to the hub) stability falls in the middle. The intermediate stability of the holoenzyme indicates that CaMKII domains are not acting independently (as beads on a string), because the holoenzyme would then unfold in two discrete transitions. These data also support a model where domains within the holoenzyme interact. We also employed newly developed mass photometry to determine the molecular weight (MW) of single CaMKII molecules in solution. We measured the MW of individual CaMKII molecules at decreasing concentrations to determine the threshold where the complex started to disassemble. We compared the hub alone to the holoenzyme and determined that the holoenzyme falls apart more easily. These data suggest that within the context of the holoenzyme, the kinase and hub domains influence one another, indicating that they likely interact. These new findings critically advance our understanding of the CaMKII assembly and have clear implications on understanding the mechanism of CaMKII subunit exchange, which will allow us to manipulate exchange and determine its functional role in signaling and LTP.

Abstract: PKMζ, a neuron-specific atypical PKC isoform, is crucial for the maintenance of long-term potentiation (LTP) and long-term memory (LTM), during which the amount of the kinase is persistently increased (Sacktor & Fenton, 2018; Sacktor et al., 1993). Therefore, visualizing persistent increases in PKMζ might reveal traces of physiological LTP maintenance in the circuitry of the brain during long-term memory storage. Using quantitative immunohistochemistry validated by the lack of staining in PKMζ-null mice, we examined the amount and distribution of PKMζ in the hippocampal formation of wild-type mice during LTP maintenance and spatial long-term and remote memory storage.
In Schaffer collateral LTP maintenance for at least 2 h, compared to untetanized slices, PKMζ immunostaining increases in *stratum pyramidale* and in dendritic *strata oriens* and *radiatum* of CA1, that receive projections from the stimulated Schaffer collateral/commissural fibers, validating the rationale of the study design. During conditioned active place avoidance LTM storage, PKMζ increases in CA1 from 1 day to 1 month, paralleling the persistence of the memory in wild-type mice. In ArcCreERT2 x ChR2-eYFP mice designed to tag-memory activated neurons, the kinase preferentially increases in ensembles of CA1 pyramidal cells marked during memory training by the plasticity-dependent expression of ChR2-eYFP. Within these memory-tagged ensembles, PKMζ persistently accumulates in the principal cells in CA1, including the compartments of these cells in *strata pyramidale* and *radiatum* for at least 1 month. Because increased PKMζ is sufficient to potentiate synaptic transmission and intrahippocampal

applications of PKMζ inhibitors reverse the maintenance of late-LTP and erase the memory of active place avoidance conditioning at 1 month post-training (Ling et al., 2002; Pastalkova et al., 2006; Tsokas et al., 2016), we conclude that following memory training, the loci of persistently increased PKMζ represent sites of the endogenous molecular mechanism of LTP maintenance that sustains spatial long-term memory in hippocampus for at least a month.

Title: Glua2 and NSF interaction is not required for protein synthesis-dependent LTP

Authors: ***Q. ZHU**[1], H. L. TAN[1], A. J. H. YONG[1,2,3], R. C. JOHNSON[1], R. L. HUGANIR[1]; [1]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Physiol., Univ. of California San Francisco, San Francisco, CA; [3]Howard Hughes Med. Inst., San Francisco, CA

Abstract: Long-term potentiation (LTP), the most studied form of synaptic plasticity, is highly associated with learning and memory. It mainly involves two phases: early establishment and late maintenance. Many molecules have been implicated in the early phase of LTP, such as CaMKII, RAS, PKCs, GRIP1, SynGAP. However, the molecular mechanisms underlying LTP maintenance, which requires protein synthesis, remain elusive. N-ethylmaleimide sensitive fusion protein (NSF), which regulates synaptic targeting of AMPA receptors by interacting with the AMPAR subunit GluA2, has been reported to be necessary for LTP maintenance. Disrupting NSF-GluA2 interaction using a synthetic peptide, pep2m, impaired protein synthesis-dependent LTP. However, most of the evidence indicating a necessity of NSF-GluA2 binding in LTP heavily rely on the pharmacological intervention through the peptide pep2m. To further address the mechanism underlying LTP regulated by NSF-GluA2 interaction, we generated knockin mice in which GluA2 is mutated to prevent binding to NSF. We observe that the mutant mouse has normal synaptic transmission and intact LTP induction and maintenance at CA3-CA1 synapses compared to wild type (WT). Notably, pep2m still impairs LTP in the mutant mice. Furthermore, we utilize a more specific peptide to disrupt NSF-GluA2 binding, and again find LTP is not affected both in mutant and WT mice. These data indicate that the GluA2-NSF interaction is not required for protein synthesis-dependent LTP and that pep2m-mediated impairment on LTP is independent of NSF-GluA2 binding.

Sch. of Med., Baltimore, MD; [3]Lieber Inst. for Brain Develop., Baltimore, MD; [4]Dept. of Neurosci., Ursinus Univ., Collegeville, PA

Abstract: The memory associated protein KIBRA is encoded by a gene that is significantly associated with human memory performance. Genetic deletion of *KIBRA* in mice impairs synaptic plasticity, as well as hippocampal-dependent contextual fear learning and memory. Trafficking of AMPA receptors is an important mechanism underlying various synaptic plasticity forms essential for learning and memory. Previous studies showed that KIBRA is a crucial scaffold protein associated with AMPA receptor complexes. However, the molecular basis through which KIBRA regulates AMPA receptor trafficking is unknown. We found that *KIBRA* knockout (KO) mice have altered brain anatomy and synapse function. *KIBRA* KO mice have reduced PKC signaling in the brain compared to wild-type animals. Following chemically induced long-term potentiation (LTP) or fear learning in adult mice, KIBRA translocates to the postsynaptic density (PSD) together with AMPA receptors and PKCs. Using biochemical and pharmacological approaches, we demonstrated that activation of PKCs enables KIBRA to recruit phosphorylated AMPA receptors to the PSD to initiate LTP and learning. We further performed transcriptomic and genetic analyses in human postmortem brain and behavioral and fMRI evaluations in living human subjects. We confirmed that *KIBRA* eQTLs in the brain are associated with human memory performance, and this association can be modified by eQTLs in genes encoding PKC. Recent studies showed Dendrin (encoded by *DDN* gene) recruits KIBRA to the membrane. We also demonstrated that genetic variation associated with *DDN* expression in the human brain modifies *KIBRA* genetic association with human memory performance. Our data reveal that KIBRA is a crucial protein modulating human memory performance.

Title: "nmda receptor-mediated post-hypoxic potentiation in mice lacking glutamate antiporter, system x_c-"

Authors: *B. S. HEIT, A. CHU, J. E. RICHMOND, D. E. FEATHERSTONE, A. MCRAY, J. R. LARSON;
Univ. of Illinois at Chicago, Chicago, IL

Abstract: Ischemic stroke remains the leading cause of adult disability in the world. Efforts to reduce stroke severity, however, have been plagued by translational failure due to gaps in our understanding of cellular mechanisms leading to brain damage after metabolic insult. Loss of blood supply to brain tissue depletes neurons of energy, which induces a sequela of events within the neuronal network. Importantly, much of the "ischemic cascade" can be reproduced by transient deprivation of O_2 to *in vitro* hippocampal slices. The glial-bound cystine/glutamate antiporter, system x_c-, with specific subunit xCT, supplies 60-80% of ambient extracellular glutamate in the brain**.** Using slice electrophysiology, we have previously shown that xCT-mediated glutamate release influences both the rapidity and synchrony of depolarizing events after anoxia. Both genetic deletion and pharmacological antagonism of system x_c- provided ischemic neuroprotection by increasing latency to anoxic depolarization (AD), attenuating AD wave amplitudes, and extending AD wave durations. The sudden onset and rapid regenerative nature of AD, however, may obscure subtle, but important, antecedent differences. Partial ("graded") hypoxia, or reduced regional blood flow *in vivo*, is an ischemic condition that alters synaptic signaling, but is not noxious enough to induce glutamate excitotoxicity. Graded hypoxia elicits a suppression of synaptic transmission proportional to the degree of oxygen deprivation, ATP breakdown, and accumulation of extracellular adenosine. The present study employed graded hypoxia to better understand ischemia-induced alterations in neuronal responsiveness from WT and xCT KO ($xCT^{-/-}$)mice. Hippocampal slices from both genotypes were prepared, incubated, subjected to 30 minutes hypoxia, and fully re-oxygenated. Although WT and $xCT^{-/-}$ slices did not differ in hypoxia-induced synaptic suppression, mutant slices exhibited accelerated rate of recovery and post-hypoxic potentiation, which resembled LTP. Experiments using CPX, an A_1 adenosine antagonist, showed that this differential effect was not due to enhanced adenosine release in the $xCT^{-/-}$. Contrarily, further experimentation revealed that post-hypoxic potentiation in $xCT^{-/-}$ mice is driven by activation of NMDARs and enhanced calcium influx. Thus, post-hypoxic changes in mutant mice are propagated by mechanisms similar to those of LTP. This latter finding was remarkable as $xCT^{-/-}$ mice showed no differences in electrically-induced LTP compared to WT. Taken together, these data confirm system x_c- as a salient regulator of neuronal responses during ischemia and a therapeutic target ripe for exploration.

Med., Univ. of California, Davis, Davis, CA

Abstract: Protein kinases control nearly every facet of cellular function. These key signaling nodes integrate diverse pathway inputs to regulate complex physiological processes, and aberrant kinase signaling is linked to numerous pathologies. While fluorescent protein-based biosensors have revolutionized the study of kinase signaling by allowing direct, spatiotemporally precise kinase activity measurements in living cells, powerful new molecular tools capable of robustly tracking kinase activity dynamics across diverse experimental contexts are needed to fully dissect the role of kinase signaling in physiology and disease. Here, we report the development of an ultrasensitive, second-generation excitation-ratiometric protein kinase A (PKA) activity reporter (ExRai-AKAR2), obtained via high-throughput linker library screening, that enables sensitive and rapid monitoring of live-cell PKA activity across multiple fluorescence detection modalities, including plate reading, cell sorting and one- or two-photon imaging. Notably, in vivo visual cortex imaging in awake mice reveals highly dynamic neuronal PKA activity rapidly recruited by forced locomotion.

Title: Mechanochemical modeling of AMPAR trafficking

Authors: *M. BELL[1], P. RANGAMANI[2];
[1]Univ. of California San Diego, La Jolla, CA; [2]UCSD, La Jolla, CA

Abstract: AMPAR, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor, is a ionotropic, glutamatergic receptor that is used as a readout for synaptic plasticity. AMPAR density at the postsynaptic density (PSD) is known to change during long term potentiation (LTP) and long term depression (LTD) triggered by spine activation. The signaling pathways underlying AMPAR density modification have been studied, however, the mechanisms of AMPAR trafficking and how signaling interacts with those mechanisms is less understood and currently controversial. Here we construct a deterministic, reaction-diffusion model of the simplified signaling network underlying AMPAR dynamics to elucidate the role of biophysical factors on signaling and trafficking modalities. We find that both AMPAR endocytosis and exocytosis, and AMPAR lateral membrane diffusion play important but temporally segregated roles in AMPAR trafficking at the PSD.

Title: Comparing theories for the maintenance of LTP and long-term memory: computational analysis of the roles of kinase feedback pathways and synaptic reactivation

Authors: *P. D. SMOLEN[1], D. A. BAXTER[2], J. H. BYRNE[1];

Abstract: A fundamental problem in neuroscience is how memories are maintained from days to a lifetime, given turnover of proteins that underlie expression of long-term synaptic potentiation (LTP) or 'tag' synapses as eligible for LTP. One likely solution relies on synaptic positive feedback loops, prominently including persistent activation of Ca^{2+}/calmodulin kinase II (CaMKII) and self-activated synthesis of protein kinase M ζ (PKMζ). Recent studies also suggest positive feedback based on recurrent synaptic reactivation within neuron assemblies, or engrams, is necessary to maintain memories. The relative importance of these feedback mechanisms is controversial. To explore the likelihood that each mechanism is necessary or sufficient to maintain memory, we simulated maintenance of LTP with a simplified model incorporating persistent kinase activation, synaptic tagging, and preferential reactivation of strong synapses, and analyzed implications of recent data. We simulated three model variants, each maintaining LTP with one feedback loop: autonomous, self-activated PKMζ synthesis (model variant I); self-activated CamKII (model variant II); and recurrent reactivation of strengthened synapses (model variant III). Variant I requires and predicts that, for successful maintenance, PKMζ must contribute to synaptic tagging. Variant II maintains LTP and suggests persistent CaMKII activation could maintain PKMζ activity, a feedforward interaction not previously considered. However we note data challenging this feedback loop. In Variant III synaptic reactivation drives, and thus predicts, recurrent or persistent activity elevations of CamKII and other necessary kinases, plausibly contributing to empirically persistent elevation of PKMζ levels. Reactivation is thus predicted to sustain recurrent rounds of synaptic tagging and incorporation of plasticity-related proteins. We also suggest (model variant IV) that synaptic reactivation and autonomous kinase activation could synergistically maintain LTP. We propose experiments that could discriminate these maintenance mechanisms.

Title: Molecular mechanisms of axon initial segment plasticity

Authors: *G. D. VITELLI, A. ISHAQ, E. SPECTOR, A. R. MOORE;
Biol., Temple Univ., Philadelphia, PA

Abstract: The neuronal axon initial segment (AIS) is a region proximal to the soma and is responsible for action potential initiation. The AIS is a specialized compartment which contains a

high density of voltage-gated ion channels and has a unique cytoskeletal organization. The density of voltage-gated ion channels, including both sodium and potassium channels, as well as the length and diameter of the AIS determine the output of the neuron. Although once thought to be a rigid structure, it is now well accepted that AIS morphology continuously adapts to the surrounding environment to modulate neuronal excitability and maintain steady-state firing rates. More specifically, an increase in neuronal activity can lead to a decrease in AIS length, whereas a decrease in activity can lead to an increase in AIS length. These structural changes allow the neuron to maintain its activity within a given range, or setpoint, and can occur on a time scale of hours to days. However, despite the importance of AIS plasticity on neuronal excitability, the underlying molecular mechanisms regulating AIS length in response to neuronal activity remain largely unexplored. Here, we investigate the contribution of the protein Rem2, an activity-dependent negative regulator of intrinsic excitability, on AIS plasticity using a combination of immunolabeling and electrophysiology techniques in primary cortical neurons. Our studies, which explore the relationship between voltage-gated ion channel regulation and Rem2 function to influence AIS plasticity promise to yield significant insight into the regulation of intrinsic excitability.

Title: Role of transmitter plasticity in the generation of sustained fear

Authors: *H. LI[1], W. JIANG[1], C. CHEN[2], D. W. CLEVELAND[2], ***N. C. SPITZER**[1];
[1]UC San Diego, Kavli Inst. for Brain and Mind, La Jolla, CA; [2]Ludwig institute, UC San Diego, La Jolla, CA

Abstract: Fear is an essential emotion for survival (Rosen & Schulkin, 1998). However, when fear is sustained and disproportionate to the extent of the threat, the maladaptive response can lead to fear disorders, e.g. post-traumatic stress disorder (Fanselow & Lester, 1988). Patients with fear disorders show a shift in excitatory to inhibitory (E/I) balance in the brain (Fang et al., 2018). Neurotransmitter switching, known as the gain of one neurotransmitter and loss of another in the same neuron (Li & Spitzer, 2020), is a form of plasticity that regulates E/I balance (Spitzer, 2017) and may control sustained fear.Here we have identified a subset of serotonergic neurons in the lateral wings of the dorsal *raphe* (lwDR) of adult mice that have switched their co-transmitter from glutamate/vGluT3 (vesicular glutamate transporter type 3) to GABA/GAD67

(glutamic acid decarboxylase 67) two and four weeks after intense footshock stress. At both time points, shocked mice showed fear-related passive behaviors as they reduced exploration and increased freezing in a novel environment. We then investigated whether fluoxetine, a selective serotonin reuptake inhibitor (SSRI) that is a first-line pharmaceutical treatment for fear disorders affects transmitter switching and suppresses sustained and inappropriate fear. Our results show that immediate delivery of fluoxetine after the shock prevents both the glutamate-to-GABA switch in the lwDR and sustained fear responses. When the delivery of fluoxetine was delayed, e.g. starting two weeks after the shock, no rescue effect was seen for either the transmitter switch or the behavioral alterations. To investigate whether the loss of vGluT3/glutamate and gain of GAD1/GABA occur in the same neurons, we are now crossing a knock-in vGluT3-Cre transgenic mouse line with a Rosa-TdTomato reporter mouse line to permanently label vGluT3+ neurons and examine whether there is a higher number of TdTomato+GAD1+vGluT3- neurons in footshocked mice compared to controls. If so, this will suggest that the switch occurs in the same neurons and not in two different serotonergic neuronal populations. To study the causal relationship between the transmitter switch and sustained fear, we are using Cre-dependent adeno-associated viruses (AAVs) to express vGluT3 and/or suppress expression of GAD1 in serotonergic lwDR neurons and testing its impact on the stress-induced sustained fear responses. This study is expected to identify brain plasticity that links a prior strong fearful experience to subsequent long-lasting fear and passive behavior, and provide mechanistic understanding of the action of a pharmacological treatment for fear disorders.

Title: Transmitter switching contributes to two environmental models of neurodevelopmental disorders

Authors: *S. K. GODAVARTHI, N. C. SPITZER;
Neurobio., Univ. of California San Diego, San Diego, CA

Abstract: Neurodevelopmental disorders including autism spectrum disorders are characterized by varying degrees of enhanced stereotypic behaviors, deficits in social interaction, and defects in communication. Early environmental factors play a key role and cortical neurotransmitter imbalance is a convergent phenotype seen across different types of disorders. Neurotransmitter

switching involves loss of one transmitter and gain of another. It often changes the sign of the synapse from excitatory to inhibitory or vice versa and causes changes in behavior (Spitzer, 2017). We are testing the hypothesis that transmitter switching contributes to these disorders in mouse models. We treat pregnant females with either Poly Inosine:Cytosine (Poly I:C) or valproic acid (VPA) at embryonic day E12.5. We find a transient decrease of 6000 GAD67+ neurons and an equal increase of vGluT1+ neurons in the medial prefrontal cortex (mPFC) at postnatal day P10 in experimental mice compared to saline-treated controls that has disappeared by P90. These changes do not result from altered number of precursors (Dlx2+ and Tbr1+) or apoptosis and occur specifically in PV+ and CCK+ neurons. P90 animals demonstrate enhanced stereotypy and deficits in social interaction compared to controls. We then generated PV-Cre/CCK-Cre mice to label neurons with Cre-dependent Herpes Simplex Virus (HSV)-GFP and search for vGluT1 expression in GFP+ neurons. Stereotaxic injection of P9 PV-Cre/CCK-Cre Poly I:C-treated embryos with Cre-dependent HSV-GFP revealed vGluT1+GFP+ neurons in the neonatal mPFC at P13 demonstrating expression of vGluT1 in a subset of PV-Cre/CCK-Cre neurons in response to maternal Poly I:C treatment in both male and female mice, providing strong evidence for transmitter switching. To test the role of the transmitter switch in emergence of behavioral disorders, we restored GAD67 specifically in PV and CCK neurons in the mPFC. Previous work shows that overriding one of the two transmitter changes in a switch is sufficient to prevent the change in behavior (Li & Spitzer, 2020). We stereotactically injected Cre-dependent HSV-GAD1-GFP in Poly I:C- treated male and female PV-Cre/CCK-Cre mice at P10 and scored them at P13. Overexpressing GAD67 in PV and CCK cells restored GAD67+GFP+ neurons in experimental mice and prevented gain of vGluT1 in GFP+ neurons unlike Poly I:C-treated controls injected with HSV-GFP. Restoring GAD67 in the mPFC of PV-Cre/CCK-Cre mice rescued altered behavior in experimental male mice. Our results add to growing evidence that alteration in signaling in the nervous system during the early stages of its construction can be detrimental to the function of the mature brain.

Title: Developmental regulation of synaptic scaling and intrinsic homeostatic plasticity in mouse primary visual cortex

Authors: *W. WEN[1], G. TURRIGIANO[2];
[1]Dept. of Biol., [2]Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: Homeostatic plasticity mechanisms are crucial for maintaining both neuronal and network excitability during development. Evidence shows that the two major forms of homeostatic plasticity, synaptic scaling (SS) and intrinsic homeostatic plasticity (IHP), cooperate to restore the excitability of pyramidal neurons in primary visual cortex (V1) following monocular deprivation (MD) in juvenile mice. However, less is known about how SS and IHP are developmentally regulated, especially after the critical period (CP) window has closed. One reason for this knowledge gap is the limitation of current tools for activity manipulations such as MD, which is age-sensitive and induces complex changes along the visual pathway. In this study, we have developed a chemogenetic approach to directly suppress neuronal activity. Specifically, we unilaterally expressed inhibitory DREADD hM4Di in L2/3 pyramidal neurons in mouse V1, and delivered clozapine dihydrochloride (CNO) to the animal during CP (P24-29), either via intraperitoneal injection or drinking water, to suppress the activity for 24 hours. We recorded miniature excitatory postsynaptic currents (mEPSCs) from both the hM4Di-positive neurons and the uninfected ones in the control hemisphere. Under both delivery methods, we observed a global increase in the average mEPSC amplitude of hM4Di-positive neurons, indicating enhanced excitatory synaptic strengths. Moreover, this increase required protein interactions involving GluA2 C-tail, a hallmark of SS. We further assessed the intrinsic excitability by measuring the frequency of evoked firing in response to depolarizing current steps (f-I curves) following the same manipulation, and found that hM4Di-positive neurons exhibited an upward-shifted curve, indicating increased intrinsic excitability. Importantly, this same paradigm failed to induce changes in either mEPSC amplitudes or f-I curves in shank3 knockout mice, a model for autism spectrum disorder that shows defects in engaging homeostatic plasticity. Finally, we conducted the same experiments on older mice (P45-50) that are outside the visual system CP. While SS was still present in adult animals, hM4Di-mediated inhibition induced no change in f-I curves. Our data show that in L2/3 pyramidal neurons SS persists into adulthood while IHP does not. Thus, these two forms of homeostatic plasticity can dissociate from each other as animals age. We propose that SS and IHP subserve distinct functions within neural circuits and can be turned on and off to suit different developmental needs.

Abstract: The effect of probiotics and gut microbiome on homeostatic balance of neuronal excitability and emotional behaviors Authors*Adrian Lee[1], Juhyun Kim[2], Mikhail V. Pletnikov[3]; [1]Department of Neuroscience, Johns Hopkins University School of Medicine; [2]Department of Psychiatry Behavioral Science, Johns Hopkins University School of Medicine; [3]Department of Physiology and Biophysics, Jacobs School of Medicine and Biomedical Sciences, University at Buffalo.**DisclosuresAdrian Lee:** None. **Juhyun Kim:** None. **Mikhail V. Pletnikov**: None.**Abstract:**The microbiota-gut brain axis is a bidirectional communication system between the central and the enteric nervous system which links emotional and cognitive centers of the brain with peripheral intestinal functions. Emerging evidence have shown a strong relationship between the alteration of gut microbiome and brain disorders including neurodegenerative and psychiatric disorders. In this regard, Germ-Free (GF) mice have been a prime model for investigating the effect of gut microbiota on host function and are known to display reduced anxiety-like behavior. Using probiotics, we investigated the neurophysiological mechanism underlying gut microbiome-mediated neural circuit alterations. 5-month-old male GF mice, 6 with a daily gavaging vehicle of an LB broth solution as a control group, and 6 with the probiotic mixture of Lactobacillus and Bifidobacterium are used for this experiment . After 2 weeks-period of oral gavage, behavior tests using an open field, zero maze, and y maze and electrophysiological recordings were conducted to determine behavioral and neuronal alterations. We found that probiotic treatments to GF mice increased anxiety-like behaviors. Whole-cell patch clamp recordings performed on acute brain slices showed that the intrinsic excitability of CA1 hippocampal pyramidal neurons and amygdala excitatory neurons were significantly increased in the probiotics-treated GF mice. Interestingly, when conventionalized GF (EX-GF) mice, which had restored gut microbiome by oral gavage of stools from SPF mice, were fed with probiotics, the probiotics-EX-GF mice showed decreased intrinsic excitability in hippocampal CA1 neurons. Our result suggests that probiotics treatment changes neuronal excitability in a gut-microbiome status-specific manner, maintaining homeostatic balance of intrinsic firing capability.

Bordeaux, Bordeaux, France

Abstract: Homeostasis is a property of biological systems that serves to maintain functional stability through forms of negative feedback. In the nervous system, this is exhibited as homeostatic plasticity, whereby neurons alter their properties in response to prolonged changes in activity levels. While homeostatic plasticity is conceptually thought to oppose destabilizing positive feedback like “Hebbian” synaptic plasticity, many molecular components involved in one are crucial for the other. Both regulate synaptic strength through the control of AMPA receptors at excitatory synapses through the action of intracellular calcium, calcium/calmodulin (Ca^{2+}/CaM) dependent kinases and phosphatases. These overlapping players raise questions about the extent to which neuronal homeostasis is mechanistically distinct from Hebbian plasticity. Furthermore, computational studies using homeostatic synaptic scaling rules find that the temporal relationship between Hebbian and homeostatic plasticity remains unresolved. These observations raise several questions: What is the time course of homeostatic adaption? What distinguishes the overlapping components of homeostatic and Hebbian plasticity? What mechanistic role do they play in homeostatic responses? We discovered that homeostatic synaptic plasticity is a slow dampened oscillatory response. Furthermore, we identified that the voltage activation of Cav1.2, a calcium channel linked to both Hebbian and homeostatic plasticities, tunes these dynamics. By manipulating the voltage activation of Cav1.2, we found that Ca^{2+}/CaM kinases and phosphatases both act on AMPARs to homeostatically regulate synaptic weight by transiently appropriating elements involved in long-term potentiation (LTP) and depression (LTD). These novel findings suggest that a Hebbian-like feedback loop is nested within homeostatic negative feedback. Building on our experimental observations, we propose a novel model of synaptic homeostasis incorporating the dynamic interactions between Hebbian and Homeostatic mechanisms to elicit synaptic homeostasis.

Inst., Shenzhen, Guangdong, China

Abstract: Hippocampal synaptic plasticity is important for learning and memory formation. Homeostatic synaptic plasticity is a specific form of synaptic plasticity that is induced upon prolonged changes in neuronal activity to maintain network homeostasis. While astrocytes are important regulators of synaptic transmission and plasticity, it is largely unclear how they interact with neurons to regulate synaptic plasticity at the circuit level. Here, we show that astrocyte-secreted interleukin-33 (IL-33) actively regulates homeostatic synaptic plasticity in the adult mouse hippocampus. Local suppression of neuronal activity in the hippocampal cornu ammonis 1 (CA1) increases IL-33 expression and secretion by astrocytes. Moreover, IL-33 signals hippocampal neurons to promote excitatory synapse formation and enhance synaptic transmission through the synaptic recruitment of scaffold protein, PSD-95. Furthermore, this astrocytic IL-33 signaling is required for the chronic neuronal activity blockade-induced increase of CA3-CA1 excitatory synapses in the adult mouse hippocampus. These results collectively reveal an important role of astrocytic IL-33 in mediating the negative-feedback signaling mechanism in homeostatic synaptic plasticity, providing insights into how astrocytes maintain hippocampal network homeostasis.

Title: Modulation of synapticplasticity with transcranialdirect current stimulationin single neurons

Authors: *F. FARAHANI[1], G. KRONBERG[3], H. V. OVIEDO[2], L. C. PARRA[1];
[1]Biomed. Engin., [2]Biol. Dept., City Col. of New York, New York, NY; [3]Mount Sinai, New York, NY

Abstract: Background: Lasting therapeutic effects of transcranial direct current stimulation are thought to be mediated by synaptic plasticity. Direct current stimulation (DCS) is known to affect synaptic long-term potentiation (LTP) in vitro. We hypothesized that this is the result of a modulation of somatic spiking with DCS in the postsynaptic neuron, as opposed to indirect network effects. Previous studies with population activity provided only indirect evidence for this hypothesis. Here we aim to directly record somatic spiking in a postsynaptic neuron during LTP induction with concurrent DCS. Methods: We recorded single-neuron activity by patching the soma of individual CA1 pyramidal neurons in a rodent in-vitro slice preparation. LTP was induced with theta-burst stimulation (TBS) applied concurrently with DCS. To specifically test the causal role of somatic polarization during DCS, we manipulated this polarization via patch pipette current injections. To explain the observed effects, we used a computational multi-compartment neuron model that captures the effect of electric fields on membrane polarization and activity-dependent synaptic plasticity. Results: We find that TBS-induced LTP was enhanced when paired with anodal DCS as well as depolarizing current injections. In both cases, somatic spiking during the TBS was increased, suggesting that evoked somatic activity is indeed the primary factor affecting LTP modulation. However, the boost of LTP with DCS was less than expected given the increase in spiking activity alone. In some cells, we also observed spontaneous somatic spiking during DCS, suggesting that DCS also modulates LTP via spontaneous network activity. The computational model reproduces the observed effects of DCS on LTP and suggests that these effects are driven by both direct changes in postsynaptic spiking and indirect changes due to network activity Conclusion: DCS enhances synaptic plasticity by increasing postsynaptic somatic spiking, but we also find that an increase in network activity may limit this enhancement.

Title: Implications of presynaptic design on short-term plasticity in hippocampal mossy fiber

Authors: *N. SINGH, S. NADKARNI;
Indian Inst. of Sci. Educ. and Res., Pune, India

Abstract: Several important functions at the mossy fiber (MF) synapses are associated with profound short-term plasticity (STP) at this synapse. For example, the MF terminal triggers an action potential after a threshold number of stimuli arrives, independent of the incoming stimulus rate. This invariance to rate may be essential for filtering non-coding signals, and is governed by STP. We developed a physiologically realistic spatial model of the MF bouton to explore the role of the structural and functional relationship that regulate synaptic function. MFs, unlike the CA3 presynaptic terminal, have several release sites, each seemingly associated with a distinct source of calcium (voltage-dependent calcium channels, VDCC). Accordingly, most studies consider MF as an extension of the CA3 terminal with multiple autonomous lines of signal transmission. In a direct contrast, our in-silico approach shows not only crosstalk across multiple release sites exists, but also this communication is crucial for the observed plasticity. As presynaptic activity progresses, nonlinear coupling between calcium released through VDCC clusters and the buffering by intrinsic calcium buffers is orchestrated. Apart from the coupling between the release sites, the biophysical properties specific to a family of calcium sensors for vesicle release, synaptotagmin-7 (Syt7) contribute to the observed facilitation. Each of these (crosstalk between AZs, buffers saturation, Syt7) makes a distinct contribution essential for the synapse to carry-out important calculations. MFs indirectly inhibit CA3 synapse via barely plastic inhibitory interneurons (apart from direct excitation to the CA3 pyramidal). We show that this network motif along with STP can trigger phase precession in CA3 place cell firing activity essential for spatial navigation. Our quantitative synaptic level computational model showcases how details of synaptic organization and biophysical properties of molecular machinery at the synapse transcend levels of organization and has a profound influence on behavior.

Title: Target-specific control of piriform cortical output via recruitment of distinct inhibitory circuits

Authors: H. JIANG[1], A. GUO[1], A. CHIU[1], H. LI[1], C. S. W. LAI[3], ***C. G. LAU**[2];
[2]Neurosci., [1]City Univ. of Hong Kong, Kowloon Tong, Hong Kong; [3]The Univ. of Hong Kong, Pokfulam, Hong Kong

Abstract: Neural circuits in anterior piriform cortex (APC) are regulated by ongoing sensory activity, but the underlying circuit mechanisms remain elusive. Here we examined the hypothesis that recurrent inhibition differentially regulates layer 2 (L2) principal neuron types, semilunar (SL) and superficial pyramidal (SP) cells. Patterned optogenetic stimulation revealed that recurrent inhibition was stronger in L1 for SL cells but stronger in L3 for SP cells. This target-specific, differential inhibition across layers was largely attributed to the parvalbumin (PV), but not somatostatin (SST), interneuron. Intriguingly, activity deprivation via naris occlusion (NO) revealed that experience specifically regulated the PV, but not SST, circuit, but the overall target specificity was preserved. Together, these results indicate target-specific inhibitory wiring and heightened inhibitory plasticity of PV cells, implicating these mechanisms in odor processing.

Title: Lateralized Short-Term and Long-Term Plasticity of Somatostatin-Positive Interneurons in Female Mouse Auditory Cortex

Authors: *S. C. SONG[1], R. C. FROEMKE[2];
[1]Skirball Inst. for Biomolecular Med., New York Univ., New York, NY; [2]Otolaryngology, NYU Med., New York, NY

Abstract: Lateralized Short-Term and Long-Term Plasticity of Somatostatin-Positive Interneurons inFemale Mouse Auditory CortexSong SC[1-4], Froemke RC[1-61] Skirball Institute for Biomolecular Medicine, New York University School of Medicine, NewYork, NY, USA[2] Neuroscience Institute, New York University School of Medicine, New York, NY, USA[3] Department of Otolaryngology, New York University School of Medicine, New York, NY, USA[4] Department of Neuroscience and Physiology, New York University School of Medicine, NewYork, NY, USA[5] Center for Neural Science, New York University, New York, NY, USA[6] Howard Hughes Medical Institute Faculty ScholarThere are multiple forms of synaptic plasticity, and distinct inputs onto the same postsynapticneuron can have qualitatively different learning rules (Maheux et al. 2015). There is growingevidence that cortical inhibitory synapses are highly plastic, including differences in cell-type-specific GABAergic inputs onto layer 2/3 pyramidal neurons (Chiu et al. Neuron 2018). In theauditory cortex, we have found that an unusual left-lateralized form of short-term inhibitorydepression might help enable longer-term changes to both excitation and inhibition for enhancedresponses to pup calls in maternal mice (Marlin et al. Nature 2015, Schiavo et al. Nature 2020).Here we examined short-term and spike-timing-dependent plasticity (STDP) of differentinhibitory inputs onto layer 2/3 pyramidal neurons of adult mouse auditory cortex in slices.STDP is a method for inducing input-specific and long-term modifications of synaptic strength,where short-term plasticity reflects the dynamic synaptic strength based on recent history. Thesemechanisms might underlie the synchronization of stimulus-evoked inhibitory input duringdevelopment (Dorrn et al. Nature 2010, Field et al. Neuron 2020) and after conditioning ormaternal experience.We utilized isolated expression of channelrhodopsin-2 in various GABAergic interneurons toselectively activate these inputs. Somatostatin interneurons are distinct physiologically,expressing STDP (169% potentiated current, $n = 11$, $p < 0.05$) as compared to PV, VIP andLayer-1 interneurons. Somatostatin also demonstrate differential depression to repetitivestimulation ($df = 3$, $F = 3.26$, $p < 0.05$), depending on hemisphere, as compared to PV. Our datasuggest somatostatin interneurons are critical for laterality in the auditory cortex.

Title: A driver input from cortical layer 2/3 to layer 5

Authors: *B. J. CARROLL[1], S. M. SHERMAN[2];
[1]Neurobio., Univ. of Chicago, Chicago, IL; [2]Dept Neurobiol, Univ. Chicago, Chicago, IL

Abstract: We used a slice preparation to study the synaptic properties of the layers 2/3 to 5 projection in mouse somatosensory cortex. We specifically identified these inputs to layer 5 cells as driver or modulator. Driver inputs evoke large, depressing EPSPs with no mGluR component; modulators evoke smaller, facilitating EPSPs and can activate mGluRs. Recording single cells in layer 5, we used glutamate uncaging to minimal electrical stimulation to localize and activate presynaptic neurons in layers 2/3. As a control, we used the same approach to examine the synapse from layer 6 to 4, which has previously been shown to be modulator. 70% of layer 5 cells received a driver input from layers 2/3, and the rest, modulator input. A driver component was most pronounced for cells of layer 5a (75% of cells), which exclusively innervate other cortical areas, compared to cells of layer 5b (67% of cells), which additionally project subcortically. Because a driver phenotype is associated with the transmission of information and receptive field properties, these findings indicate an important contribution of layer 2/3 to cortical efferents to other cortical areas and subcortical targets.

Title: Endocannabinoid and BDNF-mediated enhancement of theta burst stimulation-induced long-term potentiation

Authors: F. LEMTIRI-CHLIEH, *E. S. LEVINE;
Univ. of Connecticut Sch. of Med., Farmington, CT

Abstract: It is widely accepted that exogenous cannabinoids impair short-term memory and cognition in humans and other animals. This is likely related to the inhibition of long-term potentiation (LTP) by global, sustained activation of CB1 cannabinoid receptors in the presence of exogenous agonists. The release of endogenous cannabinoid ligands, on the other hand, may enhance synaptic plasticity in a spatially and temporally specific manner. The functional roles of endocannabinoids are complex because they can modulate synaptic transmission via suppression of both GABA and glutamate release, with opposing effects on postsynaptic excitability.
In the present studies, we examined the role of endocannabinoid signaling in LTP by recording field excitatory postsynaptic potential (fEPSPs) in the CA1 stratum radiatum in hippocampal slices from juvenile mice. LTP was induced by theta-burst stimulation (TBS) of the Schaffer collaterals. Significant LTP (~50% increase from baseline) was induced by either 1 or 3 trains of TBS. This potentiation was significantly inhibited by preventing cannabinoid receptor activation with the CB1R antagonist NESS 0327 (~25% increase from baseline). In addition, LTP was

inhibited to a similar extent by preventing the synthesis of the endocannabinoid 2-AG using the DAG lipase α inhibitor DO34.
These results suggest that activation of CB1 receptors by 2-AG enhances TBS-induced LTP, leading to the hypothesis that the predominant endocannabinoid effect under these conditions is to suppress inhibition. We therefore examined LTP while blocking inhibitory synapses using the GABA-A receptor blocker picrotoxin (PTX). The addition of PTX alone caused a slight, but not significant, increase in LTP. Interestingly, PTX completely prevented the effect of blocking CB1 receptors, indicating that intact GABAergic transmission is required for the endocannabinoid effect. The presence of PTX did not unmask any enhancing effect of CB1 receptor blockade, suggesting minimal endocannabinoid modulation of glutamate release under these conditions.
We have previously shown that TBS stimulation can cause a BDNF-dependent increase in endocannabinoid release at inhibitory synapses. Consistent with this, we found that blocking TrkB receptor activation with ANA-12 inhibited LTP to the same extent as blocking CB1 receptors. Interestingly, however, the effect of TrkB antagonism on LTP was still observed in the presence of PTX. This suggests that endogenous BDNF may enhance LTP by acting directly on glutamatergic synapses under these conditions. Ongoing experiments are further exploring the role of BDNF-eCB interactions in the modulation of LTP.

Title: Sexually Dimorphic Effects of Adolescent THC on LTP in Hippocampus

Authors: A. A. LE[1], ***J. QUINTANILLA**[1], M. AMANI[1], C. M. GALL[2], G. LYNCH[3];
[1]Anat. and Neurobio., [2]Neurobio. and Behavior, [3]Psychiatry & Human Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Detrimental effects of adolescent cannabinoid exposure on memory have been described but the neurobiological bases for these changes and long term effects of cannabis exposure on specific forms of synaptic plasticity are unknown. The present studies evaluated enduring effects of adolescent tetrahydrocannabinol (THC) exposure on synaptic plasticity in hippocampus. Male and female rats were given daily injections of 5mg/kg THC or vehicle (Veh) over postnatal days 30 to 45. At least 1 month later, hippocampal slices and field recordings were

used to evaluate synaptic transmission and long-term potentiation (LTP) in the Commissural/Associational (C/A) innervation of CA1 and the lateral perforant path (LPP) innervation of the dentate gyrus. Input-output curves were used to assess the relationship between the number of axons stimulated and the size of the post-synaptic response in both fields: there were no group differences in these measures. We then tested for treatment effects on frequency facilitation to a 10-pulse train applied at 10, 20 and 40 Hz. THC treatment had no effect on the typical response facilitation in field CA1 in males or females. Similarly, for the LPP the groups exhibited nearly identical responses, with an initial increase in response size followed by a decrease toward the latter half of the train. These results indicate that adolescent THC treatment had no clear influence on basic synaptic transmission in either subfield. However, THC effects were evident in studies of LTP. Theta burst stimulation of C/A afferents to CA1 elicited robust and comparable LTP in slices from Veh- and THC-treated males (n=6,7; p=0.655, veh vs THC). However, in females CA1 LTP was robust in the Veh group but failed to stabilize in the THC group (n=13/grp; p<0.00003). Similar effects on LTP were evident for the LPP: Potentiation induced by high frequency (100Hz) stimulation was robust in males receiving Veh or THC (n=7grp; p=0.77, Veh vs THC) whereas in females LPP LTP was stable in the Veh-group but significantly attenuated in those receiving THC (n=12,14; p=0.006 Veh vs THC). These findings demonstrate that a 2-week period of THC treatment, initiated in early adolescence, has long term effects on LTP in hippocampus of female but not male rats. CA1 LTP is expressed postsynaptically, is sexually dimorphic with female dependence on estrogen, and is not dependent on endocannabinoid function. In contrast, LPP LTP is presynaptic and endocannabinoid dependent (Wang et al., 2016, 2018 A,B). The distinctions between these pathways suggest different mechanisms that may be vulnerable to cannabinoid exposure during the adolescent period.

Title: Effect of estrus and estrogen receptor activity on LTP in the dorsal striatum

Authors: *V. LEWITUS[1], K. L. BLACKWELL[2];
[1]Neurosci., [2]Bioengineering, George Mason Univ., Fairfax, VA

Abstract: The striatum is involved in a variety of learning behaviors such as motor control and habit formation. Two subregions, the dorsomedial striatum (DMS) and the dorsolateral striatum

(DLS) are responsible for goal-directed and habitual learning, respectively. The dorsal striatum also is implicated in the development of drug addiction: drug use becomes more habitual as behavioral control over drug use switches from the DMS to the DLS. Sex differences are found in drug addiction, where women tend to progress more rapidly into habitual drug use than men, but men demonstrate more goal-seeking behaviors than women. This may be due to the cellular actions of estrogen, a hormone that fluctuates across the menstrual cycle in humans and across the estrous cycle in most non-primate mammals. Estrogen influences striatal-dependent learning and neuronal physiology and has direct effects on structural plasticity in the hippocampus. To further investigate the effect of sex differences and estrogen on striatal learning, we used field recording to measure long-term potentiation (LTP), a form of learning at the cellular level, in brain slices of male and female C57Bl6 mice. We first demonstrated that the appropriate theta burst stimulation (TBS) frequencies to induce LTP in the DMS and DLS in male mice were 10.5 Hz and 5.0 Hz, respectively. We then tested these frequencies in female mice, which were grouped based on estrus status. We found that 10.5 Hz TBS induced LTP in the DMS of non-estrus female mice but not in the DMS of female mice that were in estrus. We also investigated which of the three major types of membrane estrogen receptors in the striatum - ER-α, ER-β, and GPER - are mediating the effects of estrus. Finally, using each region's TBS frequency, we tested whether LTP in the two regions differed in the requirement of two key receptors: dopamine D1 receptors and TrkB, and found that both were necessary for LTP in both regions. These results further the understanding of sex differences in the mechanisms underlying striatal-based learning and may have implications for more individualized treatment of drug addiction.

Title: Long term potentiation enhancement in prenatal alcohol- exposed animals following administration of the histamine H3 receptor inverse agonist SAR152954

Authors: *M. GONCALVES-GARCIA[1], S. DAVIES[1], D. D. SAVAGE II[2], D. A. HAMILTON[3];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM; [3]Univ. New Mexico, Albuquerque, NM

Abstract: Cognitive impairments are common consequences of Fetal Alcohol Spectrum Disorder (FASD). The hippocampus is particularly susceptible to the effects of prenatal alcohol exposure (PAE) which persist throughout an individual's life. Previous studies have identified deficits in long-term potentiation (LTP) in perforant pathway to dentate gyrus synapses as a robust consequence of PAE. Although there have been numerous investigations, PAE-induced deficits in synaptic plasticity remain poorly understood. Currently, there are no known, clinically effective pharmacotherapeutic interventions for these deficits. This study sought to investigate the effects of PAE on LTP in the dentate gyrus and the H3 receptor inverse agonist, SAR152954, as a possible agent to reverse deficits in LTP associated with PAE. We utilized a rat model of moderate PAE (60 mg/dl peak blood alcohol content). Urethane-anesthetized adult male Long-Evans rats (N=27; PAE = 18) were implanted with monopolar electrodes in the dorsal dentate gyrus and in the entorhinal cortical perforant pathway. Evoked responses were recorded at 20KHz (Stimuli: 100ms, 1/30s, 400mA). An Input-Output (I/O) curve (50-500 uA) was obtained to determine the EC40 (40% of maximal response). Rats were given a single injection of SAR152954 (0.1 or 1.0 mg/kg) or saline (vehicle) 30 min prior to the recording session. Baseline recordings were obtained for 20 min. Synaptic potentiation was induced by 5 trains of high frequency stimulation (HFS; 400Hz, 25ms duration) with 30s inter-train intervals. Post-HFS recordings were obtained for 60 min. Fractional change of the post-HFS fEPSP relative to baseline was calculated for 1 min intervals. PAE rats displayed reduced LTP relative to controls ($p = 0.05$). PAE rats receiving 0.1 mg/kg SAR152954 did not show reversal of PAE-induced deficits ($p > 0.8$). However, PAE rats receiving the 1.0 mg/kg dose) reversed PAE-induced deficits to levels comparable to the control animals ($p > 0.9$) and greater than PAE animals that received either the vehicle or low dose SAR152954 conditions ($p = 0.024$). These results indicate that H3 receptor inverse agonist SAR152954, reverses PAE-induced deficits in LTP and offer a possibility for investigating agents with this mechanism of action as novel pharmacological interventions for FASD-associated cognitive impairments. Title: Dendritic spine abnormalities and behavioral deficits in forebrain-specific Par1c/MARK1 knockout mice

Authors: *E. C. KELLY-CASTRO[1], M. SUN[1], H. ZHANG[2];
[1]Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ; [2]Neurosci. and Cell Biol., Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract: Dendritic spines are dynamic postsynaptic structures that play an important role in cognitive functions, such as learning and memory. The dysregulation of spine size, shape, and density may lead to learning and memory deficiencies, as well as neurological disorders such as autism spectrum disorders (ASD). Previous studies from our laboratory have demonstrated that partitioning defective 1 c (Par1c), also known as microtubule affinity regulating kinase 1 (MARK1), regulates dendritic spine morphogenesis and plasticity in cultured hippocampal neurons. Interestingly, studies have found multiple single nucleotide polymorphisms of MARK1 associated with ASD and bipolar disorder. However, the role of Par1c/MARK1 in synaptic plasticity and cognitive functions *in vivo* is still unknown. Therefore, we developed a conditional knockout (cKO)MARK1 mouse model to examine the effects of MARK1 depletion on spine morphogenesis and cognitive functions such as learning and memory. In this mouse model, MARK1 is depleted postnatally from pyramidal neurons of the forebrain including the hippocampus and the cerebral cortex. We found that dendritic spine density, width, and length are significantly decreased in the hippocampal CA1 region of the MARK1 conditional KO mice compared to wild type controls. The MARK1 cKO mice also show an increase of stubby spines and a reduction in mushroom-shaped spines. Furthermore, MARK1 cKO mice show a defect in spatial learning in the Morris water maze test and significantly reduced anxiety in the elevated plus-maze. Together, our studies point to an important role for Par1c/MARK1 in regulating dendritic spine morphogenesis, spatial learning and anxiety-related behavior *in vivo*.

Title: Vagus nerve stimulation induced cognitive enhancement in healthy male rats: Hippocampal DCX and BDNF correlates

Authors: *L. K. OLSEN, R. J. MOORE, N. A. BECHMANN, S. D. CUNNINGHAM, C. N. HATCHER-SOLIS;
Air Force Res. Lab., Dayton, OH

Abstract: Although vagus nerve stimulation (VNS) (an FDA approved treatment for epilepsy and treatment-resistant depression) has been reported to improve learning and memory, little is

understood about the mechanisms responsible for this cognitive enhancement. This study investigates the cognitive effects of a single 30 min session of VNS. Neuroplasticity marker brain derived nerve growth factor (BDNF) and neurogenesis marker doublecortin (DCX) were examined to determine VNS associated changes in the hippocampus. Male Sprague-Dawley rats (N = 30) 10-12 weeks of age were implanted with an electrode cuff around the VN. Fifteen 100 μs biphasic pulses at 30 Hz, 0.8 mA constant current were administered to the VNS rats every 18 seconds for 30 minutes after behavioral training for the Novel Object Recognition (NOR) and Passive Avoidance Task (PAT) tests. SHAM rats received the same treatment but no VNS. Behavior experimenters were blinded to treatment groups. Twenty-four hours later, stimulated rats demonstrated enhanced performance in NOR ($p < 0.05$, n = 11-13) and PAT ($p < 0.05$, n = 14) compared to SHAM rats. Rat brains were perfused and fixed 48 hours post-VNS for immunohistochemical (IHC) BDNF and DCX analyses. Experimenters were blinded while counting BDNF/DCX immunopositive cells. BDNF expression after VNS (compared to SHAM in t-tests) was significantly greater in the CA2 ($p < 0.05$, n = 7) and approached significance in the CA1 ($p = 0.08$, n = 7). Although DCX expression did not show any significant group differences in hippocampal regions (t-tests, $p > 0.05$, n = 7-9), DCX expression in the CA3 was significantly positively correlated to novel object preference score in NOR among VNS rats only (Pearson's correlation, $r^2 = 0.633$, $p < 0.05$, n = 7). Behavioral results demonstrate that cognitive performance can be enhanced when VNS is administered after training. IHC results suggest hippocampal BDNF and DCX expression may mediate VNS induced cognitive enhancement. A better understanding of the interplay between VNS and hippocampal neuroplasticity may improve the utilization of VNS for cognitive enhancement.

Title: Synaptic evidence for the cumulative effects of transcranial direct current stimulation in spaced learning

Authors: *M. SHARMA[1], F. FARAHANI[1], G. KRONBERG[2], L. PARRA[1];
[1]Biomed. Engin., City Col. of New York, New York, NY; [2]Icahn Sch. of Med. Mount Sinai, New York, NY

Abstract: Background: Transcranial direct current stimulation (tDCS) is thought to improve learning by modulating Hebbian synaptic plasticity. The majority of in vitro studies supporting this theory use electric fields that are much higher than those generated with transcranial stimulation in humans (20V/m vs 1 V/m). The effectiveness of tDCS has also been called into question because of the relatively small effect sizes. There is therefore a need to improve the effectiveness of tDCS at realistic field intensities. Here we leverage the observation that effects of learning in humans are known to accumulate over multiple bouts of learning, known as spaced learning. This cumulative effect has been replicated in synaptic long term potentiation (LTP) experiments in vitro.
Hypothesis: We propose that effects of DCS on synaptic LTP can accumulate over time in a spaced learning paradigm.
Methods: We studied the cumulative effects of DCS at various intensities applied during the induction of LTP in the CA1 region of rat hippocampal slices using theta burst stimulation (TBS).
Results: DCS applied during repeated bouts of TBS resulted in an increase of LTP. Spaced learning saturated quickly with strong TBS protocols, thus obscuring cumulative effects of DCS. However, with weaker TBS, we saw a cumulative effect of spaced learning, including a cumulative boost of LTP with electric fields of lower intensity.
Conclusions: These results support the notion that the effects of tDCS accumulate through an increasing synaptic strength after repeated bouts of learning.

Title: Traumatic stress exposure alters protein composition of perineuronal nets in the mouse hippocampus

Authors: *S. I. BUHAY[1,2], V. M. CHIU[2], M. ABBAS[2], J. RUAN[2], A. C. CONTI[2];
[1]Georgetown Univ., Washington, DC; [2]Wayne State Univ., Detroit, MI

Abstract: Post-traumatic stress disorder (PTSD), which can manifest itself as behavioral avoidance, emotional numbing, and/or reliving of trauma, can be described as a crippling pathological condition that arises from experiencing a traumatic event. In the United States, the

lifetime prevalence of PTSD has been found to be 7.3%. PTSD is known to induce behavioral and psychological changes including impaired fear learning, memory, and extinction of conditioned fear, all of which involve deviations in neuroplasticity. Perineuronal nets (PNNs) have been implicated in stabilizing and protecting synaptic connections predominantly formed during critical periods of neural development, however, they are regulated throughout a lifetime and may change in response to various assaults on the brain. The effect of high-level stress events, such as those that induce PTSD, on the morphology, regulation, and associated effects of PNNs on neuroplasticity is presently unknown. We aimed to identify and quantify PNNs across the dorsal hippocampal regions of adult male C57BL/6 mice exposed to mouse single-prolonged stress (mSPS), an animal model that shows validated symptoms akin to humans with PTSD, or control conditions. To examine the effect of PTSD on PNN expression patterns and associated proteins (aggrecan, brevican, and phosphacan) levels, immunofluorescence (IF), immunoblotting, and real-time polymerase chain reaction (RT-PCR) experiments were performed. Using *Wisteria floribunda agglutinin* (WFA) to identify aggrecan-containing PNNs and antibodies directed against parvalbumin (PV), we detected PNN expression surrounding PV+ neurons in the dentate gyrus and CA3 of the dorsal hippocampus (dHC) of both mSPS and control mice. In addition, RT-PCR analysis indicated that aggrecan mRNA levels did not change in mSPS-exposed mice compared to controls. However, immunoblotting results revealed a decrease in phosphacan protein levels in the dHC of mSPS-exposed mice compared to controls. These results support previous studies that indicate PNN disruption can impair long-term fear memory and suggest that alterations in the protein composition of PNNs may contribute to PTSD symptom development or presentation related to dHC function.

Title: Mechanism of Par3-mediated regulation of dendritic spine plasticity

Authors: *M. VOGLEWEDE[1], M. SUN[2], H. ZHANG[2];
[1]Rutgers Univ., New Brunswick, NJ; [2]Rutgers RWJMS, Piscataway, NJ

Abstract: Dendritic spines are small, highly polarized protrusions on excitatory neurons serving as sites ofpostsynaptic input. Plasticity of dendritic spines is necessary for learning, while stable dendritic spinesare thought to encode long-term memories. The polarized nature of dendritic spines suggests theirplasticity and stability may be mediated by polarity proteins. The polarity protein Partitioning defective(Par) 3 (Par3) regulates mature dendritic spine formation in vitro,

and several single nucleotidepolymorphisms (SNPs) and copy number variation (CNV) of Pard3, which encodes Par3, are associatedwith intelligence, schizophrenia, and autism spectrum disorder (ASD). Together, these data implicatePar3 in mature dendritic spine stabilization, which may play a role in cognition and social interaction.However, the mechanisms of Par3 in dendritic spine plasticity and cognition *in vivo* remains completelyunknown. We established a novel Par3 mouse model to conditionally knockout Par3 in postnatalforebrain pyramidal neurons. We found that loss of Par3 *in vivo* increases immature dendritic spines andincreases overall dendritic spine density in the CA1 region of the hippocampus. In addition, loss of Par3*in vivo* alters spatial learning in the Morris water maze and phosphorylation of cytoskeletal regulatingproteins. Together, our data suggest that Par3 plays a role in regulation of mature dendritic spinestability and cognitive functions.

Title: Biochemical analysis of synaptic plasticity changes induced by dark rearing in mice.

Authors: *J. D. BADGER, M. VIEIRA, T. NGUYEN, J. PASKUS, R. LOMASH, J. JEONG, K. W. ROCHE;
NINDS/RBS, NIH, Bethesda, MD

Abstract: A robust method for inducing synaptic plasticity in vivo in mice is important to expand upon findings from in vitro approaches. In particular, for biochemical analyses of changes in synaptic proteins, it is critical to activate a large number of synapses with a single perturbation. Two common methods include environmental enrichment and chemically induced stimulation. However, these assays can be either difficult to control (eg. ensuring animal participation) or too over-powering (eg. differentiating between synaptic activation and seizures). Thus, we have opted for a more natural in vivo paradigm. Dark rearing studies in rats have shown that this protocol leads to a delay in the well-characterized developmental NMDAR subunit switch (Carmignoto & Vicini 1992 Science). Interestingly, brief light exposure after a period of dark rearing induces rapid and transient NMDA receptor-dependent cortical responses (Quinlan & Bear 1999 PNAS; Philpot & Bear 2001, Neuron). This method has the advantage of being relatively simple to implement and also includes appropriate control groups, thus it is powerful for measuring the induction of protein changes. Using mice, we divide littermates into 3 groups at P21: One group is reared in a normal light/dark cycle (LR); one group is reared in complete dark for 5 days (DR; importantly, the brain is dissected in dark until optic nerve

severed); and a third group reared in the same 5 day dark environment, but then exposed to light for 2 hours before euthanasia (DR+LE). The visual cortex is then collected for all 3 groups, lysed, and western blots performed. Here we present data evaluating post synaptic proteins, including NMDA receptor subunits and associated proteins, in mice subjected to this DR+LE method. We measured the changes in protein levels in SPM (synaptic plasma membranes) or PSD (post-synaptic density) fractions comparing the 3 groups of animals: LR; DR; and DR+LE. As expected, we saw an increase in GluN2A in the SPM fraction in mice that were dark reared then exposed to light, compared to the dark reared group, which is in accordance with previously published data demonstrating activity-dependent plasticity induced by this protocol (Quinlan & Bear 1999 PNAS). We then evaluated posttranslational modifications of several synaptic proteins. We found that this in vivo activity protocol induced dynamic regulation of a variety of phosphorylation events in receptor subunits (eg. GluN2A-phosphoS1459) and adhesion molecules (eg. NLGN1 and NLGN3), leading to both increases and decreases. Thus, we are able to measure rapid changes in synaptic enrichment and biochemical correlates using the dark rearing paradigm in mice.

Côte d'Azur, Valbonne, France

Abstract: Memory formation in the hippocampal CA1 area is influenced by multiple biochemical and electrophysiological mechanisms at individual neurons and synapses triggered by on-going neuronal activity. However, not only the temporal, but also the spatial organization of synaptic inputs plays an important role in shaping synaptic plasticity at hippocampal Schaffer collateral to CA1 pyramidal cell synapses. In our study we modeled synaptic plasticity at hippocampal CA3-CA1 synapses and explored the influence of the spatial organization of the inputs on the long-term-potentiation (LTP)/long-term-depression (LTD) induction. We employed

a hippocampal CA1 pyramidal neuron model (Migliore et al., PLOS Comp Biology 2018) and used the modified NMDAr-dependent voltage-based synaptic plasticity model (Clopath et al., Front. Synaptic Neurosci., 2010). Synaptic clusters of the varying radius were formed on the proximal apical dendrites, located in stratum radiatum, and consisted up to fifty AMPA/NMDA synapses. All synapses were stimulated simultaneously applying the protocols used in the experimental studies of synaptic plasticity: low-frequency (LF) stimulation at 1 Hz for 900 s for LTD induction and high-frequency (HF) stimulation consisting of continuous 100 Hz tetanization for 1 s repeated twice at 2 s interval for LTP induction. Spatially clustered synapses underwent strong LTP following the HF stimulation and enhanced LTD after the LF stimulation. Increased radius of the synaptic clusters led to the reduced synaptic modifications or no changes for both HF and LF stimulation protocols. The cooperativity rules governing the induction of synaptic LTP and LTD strongly depend on the synaptic cluster radius and dendritic location and imply that synaptic clustering of the multiple excitatory synaptic inputs shapes synaptic modifications. Structural organization of synaptic inputs contributes to memory formation mechanisms in the hippocampal CA1 area and needs to be explored further both experimentally and theoretically.

Title: Plasticity of GluN1 at ventral hippocampus synapses in the infra limbic cortex

Authors: *Y. CASTILLO-OCAMPO[1], A. HERNANDEZ[2], P. LOPEZ[2], M. COLON[2], Y. GERENA[3], J. T. PORTER[1];

Abstract: The fear circuit involves connections between the ventral hippocampus (vHPC) and the infralimbic cortex (IL). The vHPC routes information about the environment to IL which modulates the expression of fear via the amygdala. Although IL is not thought to play a role in fear conditioning, recent experiments suggests that synaptic plasticity is occurring in IL during auditory fear acquisition as measured by changes in the NMDA receptor-mediated currents in male rats. Based on our laboratory's previous electrophysiological studies, wehypothesized that

fear conditioning decreases NMDA receptors on vHPC-to-IL synapses in rats. To evaluate synaptic changes in NMDA receptors at this specific synapse, we injected AAV particles expressing EYFP into the vHPC of male and female rats to label vHPC projections with EYFP. Since GluN1 is an obligatory subunit in all NMDA receptors, we measured GluN1 as a measure of total NMDA receptors. To test for NMDA receptor changes in the vHPC-to-IL synapses after fear learning, we used fluorescence active cell sorting (FACS) to quantify synaptosomes isolated from IL tissue punches that were positive for EYFP and GluN1. We compared rats exposed to auditory fear conditioning (AFC), contextual fear conditioning (CFC), or context and tone exposure. Females and males showed similar freezing behavior after AFC and CFC. More EYFP+/GluN1+ IL synaptosomes were isolated from male rats exposed to AFC than those exposed to context and tones only or CFC suggesting that AFC altered NMDA receptor expression in males. In contrast, females showed similar levels of EYFP+/GluN1+ IL synaptosomes in all three behavioral groups. These findings suggest that AFC induces synaptic plasticity of NMDA receptors in the vHPC-to-IL pathway in males while female rats rely on different synaptic mechanisms to encode AFC.

Title: Neuronal RhoA signaling is controlled by DISC1 with consequences on prefrontal cortical-dependent synapse stability and cognition

Authors: *K. J. BJORNSON[1], B. KERMATH[1], A. SAWA[2], M. E. CAHILL[1];
[1]Univ. of Wisconsin-Madison, Madison, WI; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Cognitive impairments are a core feature of many neuropsychiatric disorders, including, but not limited to, bipolar disorder, schizophrenia, and major depressive disorder. These impairments have proven very difficult to alleviate in most patients, resulting in impaired daily functioning. Consequently, much attention has been devoted to understanding the molecular and biochemical mechanisms that control cognitive processes and phenotypes. Genome wide association studies have identified the RhoA small GTPase as a potential hub gene relevant for human general cognitive function. Further, murine translational studies have found that excessive RhoA signaling is associated with impaired cognition, which is thought to be caused by RhoA's effects in destabilizing dendritic spines, the sites of most excitatory connections in the brain. Despite the involvement of RhoA in cognition, the precise mechanisms that control RhoA activation in neurons have received little attention. PDZ-RhoGEF is a RhoA-

specific guanine nucleotide exchange factor (GEF) whose expression is restricted to the central nervous system, with levels highest in the neocortex. Further, among RhoA-specific GEFs, PDZ-RhoGEF shows an unusually potent ability to activate RhoA. Thus, understanding the mechanisms controlling PDZ-RhoGEF function will have implications for understanding the broader regulation of RhoA in neurons. Here we show that PDZ-RhoGEF reduces dendritic spine density in cortical neurons via its ability to activate RhoA. Consistent with these spine phenotypes, we found that PDZ-RhoGEF overexpression in the prefrontal cortex of mice using viral-mediated gene transfer impairs executive function and episodic memory. Further, we show that PDZ-RhoGEF activity is largely controlled by its interactions with the DISC1 scaffold-like protein, such that DISC1 occludes PDZ-RhoGEF's ability to activate RhoA. Consistent with this, disruption of PDZ-RhoGEF's ability to bind DISC1 exasperates the adverse effects of PDZ-RhoGEF on dendritic spine stability. Current studies are aimed at determining if DISC1 hypofunction leads to PDZ-RhoGEF disinhibition and concomitant RhoA hyperactivity-mediated dendritic spine destabilization. These findings not only characterize the involvement of PDZ-RhoGEF in the control of neuronal morphological and behavioral phenotypes, but also identify a previously unrecognized involvement of DISC1 in the control of RhoA signaling in neurons via PDZ-RhoGEF.

Title: Saturation of Structural Plasticity at Individual CA1 Dendritic Spines

Authors: ***J. C. FLORES**, K. ZITO;
Ctr. for Neurosci., Univ. of California Davis, Davis, CA

Abstract: Learning is crucial for survival. One intriguing aspect of learning in humans is that efficiency of learning can be improved when there are breaks between episodes of learning. Long-term potentiation (LTP) of synaptic strength has been proposed as a cellular basis of learning and memory. Notably, LTP can saturate in the hippocampus and that this saturation can lead to deficits in behavioral learning tasks. Importantly, saturation of LTP is released over time. Thus, it is possible that release from saturation of LTP in the hippocampus contributes to the increased efficacy of spaced learning over massed learning. We propose that LTP saturates at individual synapses. In the hippocampus, most excitatory synapses occur at small protrusions on dendrites called dendritic spines. The size of a spine is strongly correlated with the strength and size of its associated synapse. Spines are dynamic and have been shown to exhibit long-term

growth, or structural LTP (sLTP), in response to high-frequency stimulation in vitro and during learning in vivo. Here, we use 2-photon glutamate uncaging and time-lapse imaging to show that structural LTP can saturate at individual dendritic spines for at least 30 minutes after high frequency stimulation. We also show that saturation of sLTP is specific to the stimulated spine. Notably, individual spines are released from saturation and can undergo further structural LTP if the second stimulus is administered at least 60 minutes after the initial stimulus. Furthermore, we show that, if the intensity of the second stimulus is increased, spines can exhibit more structural LTP, suggesting that a metaplastic shift in threshold for sLTP is responsible for the observed saturation. We hypothesize that saturation of sLTP is due to altered function of specific signaling components involved in LTP. Using 2-photon FRET fluorescence lifetime imaging and a genetically-encoded CaMKII FRET probe, we show that 30 minutes following sLTP induction at single spines, CaMKII activity is significantly reduced. We are currently investigating potential postsynaptic mechanism for postsynaptic saturation of sLTP. This work will further our understanding of the signaling mechanisms that limit LTP and thus will lead to a better understanding of learning.

Title: Investigating the effects of rab11 mutations on the localization of cell adhesion molecules and endocytic proteins at the glutamatergic drosophila neuromuscular junction

Authors: *I. SMITH, F. L. LIEBL;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Chromodomain helicase DNA-binding (CHD) domain proteins are chromatin remodelers whose loss of function are associated with pathologies such as CHARGE syndrome, epilepsy, and autism spectrum disorders. Kismet is the *Drosophila* ortholog of CHD7 and CHD8 and restricts synaptic levels of cell adhesion molecules (CAMs) and promotes endocytosis at glutamatergic neuromuscular junctions (NMJs). Kis also promotes the expression and synaptic localization of Rab11, which is a GTPase important for endosomal trafficking. Thus, Rab11 is critical for the synaptic localization of proteins including CAMs and endocytic proteins. In an effort to tease out the mechanism that links Kismet and these phenotypes, we are examining the effects of dominant negative and constitutively active *rab11* mutations on Fasciclin II, the *Drosophila* ortholog of NCAM, and the endocytic markers Endophilin A and Dynamin. If the results of these experiments mimic the phenotype observed in *kismet* loss of function mutants, then Kismet may promote Rab11 function to ensure appropriate levels of endocytic proteins and

CAMs at the synapse. These results will further illuminate the relationship between chromatin remodelers and the localization of synaptic proteins to aid in the understanding of CHARGE syndrome and autism spectrum disorders.

Title: Homeostatic control of transsynaptically aligned glutamate receptor rings

Authors: *P. MUTTATHUKUNNEL, P. FREI, M. MÜLLER;
Univ. of Zurich, Zurich, Switzerland

Abstract: The molecular organization of synapses is a key determinant of neural information processing. Neurotransmitter receptors form clusters within individual synapses. How these receptor clusters arrange within the postsynaptic density, and how this arrangement relates to presynaptic nano-architecture remains enigmatic. Moreover, it is currently unknown how synaptic nano-architecture is modulated during homeostatic plasticity. Using stimulated emission depletion microscopy (STED), we discovered that postsynaptic glutamate receptors (GluRs) are organized in ring-like arrays composed of ~6 sub-diffraction GluR 'clusters' at the *Drosophila* neuromuscular junction. Strikingly, postsynaptic GluR rings precisely aligned with presynaptic rings formed by the C-termini of the active zone scaffold Bruchpilot (Brp), suggesting transsynaptic alignment. Moreover, while GluRs containing the GluRIIA subunit predominantly localized to rings, GluRIIB-containing receptor clusters were found both, inside and outside of the rings, implying a GluR subunit-specific nano-organization. Furthermore, we observed rings of the auxiliary GluR subunit neto-β (neuropilin and tolloid-like-β), which co-localized with GluR rings, and transsynaptically aligned with Brp. Neto-β clusters were also found outside of transsynaptically-aligned rings, and GluR rings were more pronounced in *neto*^{109} mutants, because of a predominant decrease in GluR fluorescence intensity outside the rings. Interestingly, we uncovered rapid and sequential modulation of aligned Brp-GluR rings during homeostatic plasticity induced by GluR perturbation. Application of the GluR antagonist philanthotoxin-433 (PhTX) resulted in a pronounced, scaled increase of GluRIIC fluorescence intensity within minutes upon receptor perturbation. Additionally, PhTX treatment led to a significant increase in receptor cluster number within the ring. PhTX also increased Brp-fluorescence intensity and Brp-cluster number without affecting Brp-ring diameter, consistent with previous work. We also provide evidence that GluR regulation precedes Brp modulation

during homeostatic plasticity. Together, our findings provide evidence for transsynaptically-aligned rings that undergo rapid changes during synaptic plasticity.

Title: Investigating the relationship between Kismet, cell adhesion molecules, and endocytosis at the drosophila neuromuscular junction

Authors: *G. JENKINS[1], F. L. LIEBL[2];
[1]Biol. Sci., [2]Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Kismet (Kis) is the ortholog of chromodomain helicase DNA (CHD) binding protein 7, which, if mutated, is causative for CHARGE syndrome. CHD proteins alter gene expression of proteins important for synaptic plasticity. Proteins required for synaptic plasticity include cell adhesion molecules (CAMs) Neurolgins (Nlgs) and Neurexins, which stabilize and align the pre- and postsynaptic cell. CAMs are overexpressed, and endocytosis is decreased in *kis* loss of function mutants. To understand endocytic protein localization in *kis* mutants, we examined the protein levels of α-adaptin and β-adaptin, both of which link clathrin to membranes. There was no significant difference between *kis* mutants and control α-adaptin levels but, *kis* mutants possessed lower β-adaptin levels, a finding that may partially explain the decrease in endocytosis. To determine whether Kis promotes endocytosis by restricting the expression of *nlg2*, we are currently knocking down Nlg2 and assessing the levels of the endocytic proteins, Endophilin A (EndoA) and Dynamin (Dyn). EndoA and Dyn curve the membrane for vesicle formation and pinch the vesicle off from the membrane, respectively. We will next examine overexpression of Nlg2 to determine if overexpression of Nlg2 will increase EndoA and Dyn levels, similar to *kis* mutants. These experiments will aid in understanding how Kis regulates proteins important for synaptic plasticity and how disfunction of Kis and its orthologs can lead to neurodevelopmental diseases.

Abstract: There is convergent genetic evidence for the involvement of multiple components of the Arc (Activity-regulated cytoskeleton-associated protein; Arg3.1) protein complex in glutamatergic dysregulation in neuropsychiatric disorders. Functional studies of the consequence of loss of Arc on synaptic plasticity and memory consolidation in rodent systems further suggest that deficits in Arc may contribute to the pathophysiology of cognitive impairments in neuropsychiatric disorders. Conversely, overexpression of Arc has been shown to increase dendritic spine density and to restore plasticity in the adult cortex in animal studies. We conducted a high-content, image-based screen of a library of approved drugs and known bioactive small molecules in mouse cortical neurons to identify potentiators of neuronal activity-dependent induction of Arc protein. Based on our results, we performed a preliminary structure-activity relationship assay and identified specific chemical moieties that modulate Arc levels in human cortical neurons differentiated from induced pluripotent stem cells (iPSCs) of schizophrenia subjects and healthy subjects. Our studies will lead to the development of novel chemical probes to enable dissection of Arc biology in synaptic function and to undertake pre-clinical testing of our hypotheses related to the role of Arc modulation to ameliorate cognitive deficits in neuropsychiatric disorders.

Title: Maternal sleep disordered breathing during pregnancy is a previously unrecognized facilitator of autism-relevant neuronal and behavioral aberrations in the offspring

Authors: *A. M. VANDERPLOW[1], B. A. KERMATH[2], C. R. BERNHARDT[2], K. T. GUMS[2], E. N. SEABLOM[2], A. C. EWALD[2], M. V. JONES[4], T. L. BAKER[3], J. J. WATTERS[5], M. E. CAHILL[2];
[1]Univ. of Wisconsin - Madison, Madison, WI; [3]Comparative Biosci., [2]Univ. of Wisconsin, Madison, WI; [4]Dept Neurosci., Univ. of Wisconsin Madison, Madison, WI; [5]Univ. Wisconsin, Madison, WI

Abstract: Sleep disordered breathing (SDB) is characterized by recurring breathing cessations during sleep, causing intermittent hypoxia (oxygen deprivation) often several hundred times per night. Obstructive sleep apnea is the most common form of SDB in pregnancy, with a prevalence of 10-32%. Maternal SDB confers risk for complications during pregnancy, which have detrimental maternal-fetal outcomes. Complications known to result from gestational SDB are all known risk factors for the development of neurodevelopmental disorders, such as autism spectrum disorder (ASD). We posit that SDB during pregnancy may act as a priming experience for the development of long-term adverse behavioral and cognitive outcomes in the offspring. To investigate the consequences of maternal SDB on offspring, we subjected pregnant rat dams to chronic intermittent hypoxia or normoxia from gestation day 10-21 (GIH and GNX, respectively). Our findings indicate that GIH male offspring exhibit deficits in several behaviors in conjunction with an increased dendritic spine density within pyramidal neurons of the medial prefrontal cortex. Spine time-course results indicate that these spine aberrations likely arise from a lack of the normal pruning of synapses starting in late childhood and extending into early adolescence. The mTOR kinase signal transduction pathway has emerged as a critical regulator of dendritic spine formation, and dysregulation of key components of this pathway are implicated in the etiology of the increased dendritic spine density found in ASD. Our preliminary data indicate that mTOR signaling shows a biphasic pattern in male GIH offspring such that mTOR signaling is increased in juvenile offspring yet decreased in adult offspring, relative to male GNX offspring These data indicate that excessive mTOR signaling may be responsible for the lack of spine pruning in male GIH offspring, while the subsequent decrease in mTOR signaling at later stages of development could be compensatory to prevent further surges in spine numbers. Taken together, these findings indicate that maternal sleep disordered breathing not only induces autism-relevant behavioral impairments, but also mimics the heightened cortical synaptic connectivity phenotypes of ASD, largely in a sexually dimorphic manner.

Title: Plastic effects of caffeine in the superior colliculus of adolescent rats under normal and temporal retinal damage

Authors: *A. D. CAMPOS, P. CAMPELLO-COSTA;
Neurobio., UFF, Niteroi, Brazil

Abstract: Introduction: Caffeine is the most consumed psychoactive drug in the world. Our previous data have shown that caffeine induces plasticity in the retinotectal pathway of rats under normal conditions and after temporal retinal lesion (TRL), both within and outside the critical period. The aim of my work is to investigate the cellular and molecular mechanisms underlying these plastic effects. **Methods:** Lister Hooded rats (approved project 802 by CEUA) were divided into four different groups: normal animals treated with saline (1) or caffeine (2), animals submitted to TRL on postnatal day 21 (PND21) treated with saline (3) or caffeine (4). Treatment with caffeine (30 mg / kg, ip.) or saline was done daily between PND20 and PND27. In PND28, the animals were euthanized with anesthetic overdose, perfused and processed for immunofluorescence and subsequent analysis using a deconvolution microscope. **Results:** The analysis with Iba-1, a marker of microglial cells in the brain indicates that in the control group the microglial cells are branched and have a reduced cell body. On the other hand, treatment with caffeine promotes activation of these cells that partially retract their extensions. In the group with retinal injury, caffeine appears to decrease the activation of these cells compared to the normal group with caffeine. We also performed the immunostaining of the GluN1 and GluN2B subunits of the NMDA glutamate receptor. Since we only have only performed these experiments one time, our experimental number is one and we don't have statistical analysis. Our results showed that caffeine increases the expression of the GluN1 subunit in the visual layer of the superior colliculus in the control condition, which is different from the group that received saline, where the subunits are much more present in the deep non-visual areas. In the TRL group, caffeine decreases the expression of this subunit on the side contralateral to the TRL. Regarding the GluN2B subunit, the group with TRL and caffeine treatment showed an increase in the expression of this subunit in the visual layers on the side contralateral to the lesion and a decrease on the ipsolateral side in relation to the group with lesion and saline. **Conclusion:** Our preliminary results show caffeine modulation of the analyzed markers, both in the plasticity induced by temporal retinal injury and in the natural plasticity of the visual system. Taken together, these results indicate that caffeine has different effects under normal conditions and with injury. In addition, they suggest that caffeine-induced plasticity involves glial cells and the glutamatergic system.

Title: Extracellular Vesicles Derived from Mesenchymal Stem Cells Modulate Microglia-Synapse Structural Interactions after Cortical Injury in Rhesus Monkeys

Authors: *Y. ZHOU[1], V. GO[2], D. L. ROSENE[2], B. BULLER[3], T. L. MOORE[1], M. MEDALLA[1];
[1]Dept. of Anat. and Neurobio., [2]Deparment of Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [3]Dept. of Neurol., Henry Ford Hlth. Systems, Detroit, MI

Abstract: Microglia as the immune cells of the brain promote neuronal plasticity after cortical injury by contacting synaptic elements to eliminate damaged synapses, or release neurotrophic factors to facilitate synapse-turn over. Our previous work showed that treatment with mesenchymal derived extracellular vesicles (MSC-EVs) enhanced post-injury recovery in aged rhesus monkeys by promoting a shift in microglial from pro- to anti-inflammatory morphology, reducing injury-related neuronal hyperexcitability, and enhancing dendritic and synaptic plasticity in perilesional cortex. MSC-EVs are nanovesicles providing cell-to-cell signaling which can modulate neuro-immune interactions to facilitate restorative processes. Here, we assessed whether EV treatment alters synaptic markers and synapse-microglia contacts after cortical injury, by comparing tissue from the same cohort of non-lesion monkeys and lesion monkeys with vehicle (Veh) or EV treatment (EV) used in our previous studies. For Veh and EV, cortical injury was surgically induced in the hand representation of the primary motor cortex (M1). Monkeys then received either 4×10^{11} EVs/kg or vehicle (PBS) intravenously at 24 hrs and at 14 days post-injury. We used immunohistochemical labeling to quantify markers for excitatory (VGLUTs, GluRs) and inhibitory synapse (VGAT, GABARs), and microglia (Iba-1, P2RY12) in perilesional M1 gray matter directly underlying the damaged pial surface, and in gray matter of premotor cortex (PMC) with intact pial surface ~2mm distal to the lesion. The perilesional M1 showed lesion-related decreases in VGLUT2, VGLUT-microglia contacts, and $GABA_a$ α1 receptor expression. These results are consistent with previous work in rodents that phasic glutamatergic and GABAergic transmission decreased after injury. Interestingly, qPCR analyses showed elevated gene expression of tonic $GABA_a$ ∂ and $GABA_b$ ß receptor subunits that mediate tonic inhibitory currents in Veh and EV relative to non-lesion controls. No significant treatment effect was found for synaptic markers expression in perilesional M1. However, in PMC area more distal to the lesion, we found loss of VGLUT2 and GLUR2/3 in Veh but increased GLUR2/3 receptors in EV, consistent with our previous electrophysiological findings. By combining microglial labeling and intracellular filling of pyramidal neurons in PMC, we further showed greater microglial-spines contacts in Veh but not in EV compared to the non-lesion control. Our results suggest that EV treatment might dampen microglial-mediated synapse loss in PMC to regulate synaptic activity in these compensatory networks and hence facilitate recovery of function.

Title: Microrna-324-5p regulates dendritic spine density, morphology, and expression of cytoskeletal proteins in the hippocampus

Authors: *E. PARKINS[1,3], J. RYMER[4], Y.-C. HU[5,6,7], D. TIWARI[3,7], C. GROSS[3,2,7];
[2]Neurosci. Grad. Program, [1]Univ. of Cincinnati, Cincinnati, OH; [3]Div. of Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [4]Div. of Neurol., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OR; [5]Transgenic and Genome Editing Core, [6]Div. of Developmental Biol., [7]Dept. of Pediatrics, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: microRNAs are an emerging class of synaptic regulators. These small noncoding RNAs post-transcriptionally regulate gene expression, thereby altering neuronal pathways and shaping cell-to-cell communication. Though several miRNAs have been identified that regulate the synapse, the full range of synaptic miRNA regulators has not been identified. Here, we demonstrate that miRNA-324-5p regulates dendritic spines, small protrusions along the dendrite that comprise the majority of excitatory synapses in the brain. We demonstrate that both acute and long-term loss of miR-324-5p alter the density, morphology, and channel composition of dendritic spines in the hippocampus. To assess the effect of acute loss of miR-324-5p function, we intracerebroventricularly (ICV) administered a miR-324-5p-specific antagomir (inhibitor) to Thy1-eGFP^{hemi} mice, which exhibit sparse labeling of neurons throughout the brain. Confocal imaging of hydrogel-cleared brain sections revealed reduced dendritic spine density and altered spine morphology with antagomir treatment. To assess the effect of long-term, complete miR-324-5p loss, we generated CRISPR-Cas9-mediated *Mir324* knockout (miR324 KO) mouse model. Characterization of this model reveals no gross morphological or behavioral changes. Interestingly, analysis of Golgi-stained hippocampal dendrites revealed a similar reduction in spine density in miR324 KO mice to that seen in antagomir-treated mice. RNA-sequencing identified altered biological pathways in the miR-324 KO hippocampus that may contribute to the mechanism of miR-324-5p-mediated spine regulation, including cytoskeletal organization. Western-blot and quantitative Real-Time PCR also revealed changes in protein and mRNA levels for potassium channels, cytoskeletal components, and synaptic markers. We used both male and female mice in these studies and did not detect sex-specific differences. Experimenters and analyzers were blind to conditions, and studies were fully powered (power≥0.8) or indicated

as preliminary. Our findings suggest that miR-324-5p is an important and essential regulator of dendritic spines, as loss of miR-324-5p function or expression leads to significant changes in dendritic spine density, morphology, and channel composition. Future work will assess brain functional consequences of the effects of miR-324-5p loss on neuronal morphology.

Title: Dopamine D1R and cAMP/PKA signaling stimulates Brd4 recruitment to chromatin to regulate gene expression in striatal neurons

Authors: *J. JONES-TABAH, R. D. MARTIN, J. J. CHEN, J. C. TANNY, P. B. S. CLARKE, T. E. HÉBERT;
McGill Univ., Montreal, QC, Canada

Abstract: The dopamine D1 receptor (D1R) is a $G\alpha_{s/olf}$-coupled receptor expressed throughput the forebrain, where it regulates motor behavior, reward, motivational states and cognitive performance. D1R is most abundant in the striatum where it couples primarily to $G\alpha_{olf}$ and activates a cAMP/PKA/DARPP-32 signalling cascade that increases neuronal excitability and facilitates structural and synaptic plasticity. Many dopamine dependent striatal functions, such as goal-directed learning and motor learning, depend on transcription and *de novo* protein synthesis. Transcription can be regulated by D1R effectors including PKA and ERK1/2 which can translocate to the nucleus to phosphorylate transcription factors including CREB. Dysregulated transcription linked to D1R hyperactivation contributes to therapy-associated motor disorders such as L-DOPA-induced dyskinesia and to behaviors associated with addiction to drugs of abuse. However, our understanding of the mechanisms by which D1R regulates gene expression downstream of PKA and ERK1/2 activation remain incomplete. In this regard, the chromatin reader Brd4 has previously been found to regulate striatal gene expression in response to drugs of abuse. Brd4 is activated by phosphorylation upon which it interacts with acetylated histones and recruits transcriptional activators including P-TEFb. Here we demonstrate that D1R activation of cAMP/PKA signalling increases Brd4 recruitment to dopamine-induced immediate early genes, and that knockdown or inhibition of Brd4 bi-directionally modulates D1R-induced gene expression. Hence, our findings identify Brd4 as a novel regulator of D1R-dependent transcription and highlight the potential for disrupted striatal function as an adverse effect in the clinical use of Brd4 inhibitors.

Title: Cis and trans features of dendritically localized transcripts in the Hippocampus

Authors: *J. PARK, S. FARRIS;
Fralin Biomed. Res. Inst., Virginia Tech., Roanoke, VA

Abstract: Local translation is required for the synaptic changes underlying learning and memory in the hippocampus. This process relies on the efficient localization of RNAs to their target synapses, which is mediated by RNA binding proteins (RBP). However, the precise mechanisms regulating the trafficking, processing, and translation of appropriate transcripts at hippocampal synapses remains unclear. In order to elucidate how hippocampal neurons regulate the subcellular localization of RNAs, we performed both *in silico* and *in vivo* analyses to uncover cis and trans factors involved in RNA localization at synapses. Among the hippocampal subregions (CA1, CA2, CA3, Dentate Gyrus), we focused on CA2 for its unique synapse-specific plasticity-resistant phenotype. An understudied subregion, CA2 has been reported to have both long-term potentiation (LTP)-competent and LTP-resistant synapses, making it an ideal neuronal population to study local translation factors involved in learning at individual synapses. A previous study utilized laser capture microdissection and RNAseq to identify dendritically localized transcripts in each subregion of the mouse hippocampus. Since sequence elements within the untranslated regions (UTRs), have been shown to mediate RNA trafficking and translational regulation via trans-acting RBPs, we used this dataset to identify enriched sequence motifs in the 5' and 3' UTRs of dendritically localized transcripts in the CA2. We also identified RNA binding proteins that are predicted to bind these transcripts. Referencing the expression levels of these RBPs in the CA2 subregion led to the identification of high-probability candidates for regulating CA2 transcript localization. Furthermore, we focused on alternatively spliced transcripts that show compartment- and/or subregion-specific splice variant expression. SHANK2, a synaptic scaffolding protein, has two splice variants with alternate 5' UTRs. Using splice variant-specific smFISH, we show subregion and compartment specific enrichment of the longer *Shank2* variant in CA2 compared with neighboring hippocampal subregions. Currently, we are using single molecule fluorescence in situ hybridization combined with immunohistochemistry (smFISH-IHC) to confirm candidate RNA-RBP interactions and identify behavior-induced changes in these interactions at hippocampal synapses in vivo. Results from these studies will provide mechanistic insight to how localized RNAs are regulated to support the synaptic changes required for encoding hippocampal-dependent memories.

Title: Investigating potential interactions between Kismet and Amyloid precursor protein-like at the Drosophila neuromuscular junction

Authors: *B. PRATES DE OLIVEIRA ALBANEZ;
Southern Illinois Univ. Edwardsville.

Abstract: Investigating potential interactions between Kismet and Amyloid precursor protein-like at the *Drosophila* neuromuscular junctionKismet (Kis) is the *Drosophila* ortholog of the mammalian chromatin remodeling proteins CHD7 and CHD8. Mutations in *CHD7* and *CHD8* are causative for CHARGE syndrome and implicated in autism spectrum disorders, respectively. Interestingly, *kis* mutants exhibit similar phenotypes as are found in animal models of Alzheimer's Disease (AD) suggesting Kis may influence synaptic mechanisms that underlie AD pathology. AD is characterized by accumulation of neurotoxic Aβ fragments from amyloid precursor protein (APP or APPL in *Drosophila*) cleavage, resulting in loss of neuronal synapses and cognitive decline. Similar to *kis* loss-of-function mutants, overexpression of human APP and BACE (β-site APP cleaving enzyme) at the *Drosophila* neuromuscular junction impaired endocytosis, larval locomotion, and increases the transcript levels of *Neuroligin 2*, which encodes a cell adhesion molecule that stabilizes synaptic connections. The pathway by which Kis influences APPL remains unclear. We discovered that Kis represses *appl* expression in motor neurons. Therefore, Kis could affect APPL three ways, including upstream by direct control, in cooperation with AICD (a fragment generated during APP cleavage), or by acting as a cofactor to promote AICD transcriptional activity. To better characterize APPL synaptic function, first we will examine the expression and localization of the cell adhesion molecule, FasII, and the glutamate receptor subunit, GluRIIC, in animals overexpressing APP and BACE, expressing full-length APPL, constitutively secreted APPL, and a secretion-deficient APPL. Then we will construct double mutants and overexpress Kis in *Drosophila* lacking *appl* to examine endocytosis. In conjunction, these experimental results will contribute to better understand how chromatin remodeling protein Kis influences APPL at the synapse.Authors: Bruna Prates and Faith Liebl, PhD.

Title: Isoflurane Anesthesia Induced Sex-Related Differences in Cortical EEG Dynamics and Gene Expression

Authors: R. TADAVARTY[1], T. MARIAM[1], X. DONG[1], S. SINHA[1], S. KHAN[1], S. LIU[2], T. CHEUNG[2], G. GIAEVER[1], C. NISLOW[1], *P. J. SOJA[1];

Abstract: Exposure to inhalational anesthesia (IA) adversely affects cognition and increases the risk of dementia, leading to post-operative cognitive dysfunction (POCD). Interestingly, POCD may preferentially last in males from several months to years. We recently found that following prolonged exposure to surgical levels of isoflurane anesthesia (ISO), long-term depression (LTD) of hippocampal pEPSPs, once established, can be reversed in female rats but not males. A failure of LTD reversal in males might contribute to cognitive "inflexibility" following ISO exposure. The mechanisms behind this observation are not known. The expression of synaptic plasticity (long-term potentiation; LTP and LTD) and its maintenance critically depends on gene expression. Given that exposure to IA can alter gene expression in the brain, we hypothesized that a prolonged exposure to ISO induces selective changes in gene expression in male vs female rats which underlie sex-differences in de-depression following LTD. Accordingly, adult male or female SD rats were initially anesthetized in an induction chamber, their trachea intubated and head mounted in a stereotaxic frame. Cortical EEG was recorded using stainless steel screw electrodes positioned in S1 bilaterally. After 5h exposure to ISO, S1 cortical tissue was dissected and RNA-seq was used to quantify changes in the transcriptome. Differential expression analyses was performed on these datasets to identify cohort-specific changes. We analyzed the expression of over 13,000 genes, of which ~225 were found to be down-regulated selectively in males. Gene ontology of these differentially expressed genes allowed us to functionally group them into clusters potentially affecting aspects of synaptic transmission, protein phosphorylation, calcium signaling, neuronal activity and neurotransmitter release. EEG slow wave activity (SWA) in male rats revealed oscillatory behavior characterized by robust "up"-states and "down"-states that was marginally present in females. Relative power in "up"-states of male rats was confined to the δ band and was ~3-fold greater than "down"-states. Our results disclose for the first time that males and females differ in EEG SWA oscillation dynamics, spectral content and gene expression following exposure to (IA).

Title: Local regulation and function of Importin-β1 during transcription-dependent plasticity

Authors: ***Y. LEE**[1], S. NAVAKKODE[1], C. TAN[1], S. SZE[1], S. SAJIKUMAR[2], T. CHNG[1]; [1]Nanyang Technological Univ., Singapore, Singapore; [2]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Activity-dependent transcription is critical for the encoding of long-term memories. Regulated nuclear entry of soluble proteins is one method to relay synaptic signals to the nucleus to couple neuronal excitation with transcription. To date, the role of importin-β1 in the nuclear shuttling of proteins during activity-dependent transcription has always been inferred but not directly investigated. In this study, we demonstrate the activity-dependent nuclear accumulation of importin-β1 from the soma and the synapto-dendritic compartments. Importantly, inhibition of importin-β1 mediated nuclear import during synaptic stimulation impairs long-term plasticity. We show evidence that importin-β1 mRNA-ribosome complex is distributed throughout the synapto-dendritic compartment and the synaptic stimulation induces importin-β1 local protein synthesis. Finally, we identified candidate proteins that associate with importin-β1 at the synapse and characterize NDRG1 as an importin-β1 interactor that undergoes activity-dependent translocation into the nucleus. Collectively, our results highlight the crucial role of importin-β1 in nuclear import of proteins during long-term plasticity.

Abstract: The post synaptic densities (PSD) of excitatory synapses are key nodes in the regulation of synaptic plasticity and contain thousands of proteins. To gain new mechanistic insight of experience-induced proteome dynamics, we examined the learning-induced changes in PSD proteome and phosphoproteome. Mice were trained using inhibitory avoidance (IA) paradigm and hippocampal PSD fractions were prepared for quantitative proteomic analysis. We used iTRAQ (Isobaric Tags for Relative and Absolute Quantitation) mass spectrometry combined with phosphopeptide enrichment to quantify the protein expression and phosphorylation events in hippocampal PSD following IA training (IA) or unpaired foot shock (Shock) in mice. We detected and analyzed 6,200 proteins and 3,700 phosphoproteins. Strikingly, of the significantly IA or unpaired shock regulated proteins and phosphoproteins, a large fraction showed decreased abundance and phosphorylation. Gene ontology analysis of proteins and phosphoproteins that were regulated by IA were annotated for an involvement in regulation of glutamate receptor functionality, calcium signaling, and synaptic plasticity. We also identified synaptic kinases, phosphatases and their respective autophosphorylation sites regulated by IA training or unpaired foot shock. Together, these results unravel the dynamic remodeling of the PSD upon IA learning or unpaired foot shock and serve as a resource for elucidating the synaptic proteome dynamics induced by experience-dependent plasticity.

Title: Co-agonist Occupancy as a Determinant of Bidirectional Plasticity

Authors: *E. V. BARRAGAN[1,2], J. GRAY[2,3];
[1]Neurosci. Grad. Group, [2]Ctr. for Neurosci., [3]Dept. of Neurol., UC Davis, Davis, CA

Abstract: Synaptic plasticity, or the ability of synapses to undergo bidirectional changes in strength, underlies a vast number of complex cognitive processes. NMDA receptors (NMDARs) are master regulators of synaptic plasticity but it remains unclear how this one receptor is able to

mediate both depression and potentiation of synaptic strength. NMDARs are unique among receptors in that they require co-agonist binding - either glycine or D-serine - to the glycine-site on the GluN1 subunit, in addition to glutamate binding. It has been recently shown that LTD can occur during competitive antagonism of the NMDAR co-agonist site. This can also reverse the direction of plasticity following an LTP-inducing stimulus. Based on these results, we hypothesize that glycine-site occupancy dictates the directionality of synaptic plasticity. To investigate this hypothesis, we pharmacologically manipulated glycine-site occupancy while administering plasticity-inducing stimuli. We show that blocking the glycine-site results in decreased synaptic strength during LTD and LTP-inducing paradigms, shifting the plasticity curve toward synaptic depression. Similarly, increasing extracellular co-agonist concentration results in increased synaptic strength following LTD induction, which would indicate a shift toward favoring synaptic potentiation. These results support our hypothesis that the glycine-site serves to influence the direction of synaptic plasticity, highlighting it as an attractive target for treatment of the vast range of psychiatric and neurologic disorders that arise due to dysfunction in NMDAR function and synaptic plasticity.

Title: In silico analysis of biochemical mechanisms responsible for astrocyte modulation of synaptic plasticity in developing somatosensory cortex

Authors: *T. MANNINEN[1], A. SAUDARGIENE[2], M.-L. LINNE[1];
[1]Tampere Univ., Tampere, Finland; [2]Lithuanian Univ. of Hlth. Sci., Kaunas, Lithuania

Abstract: Astrocytes have critical roles in controlling synapse development, functionality, plasticity, and elimination (Allen and Eroglu, 2017), but the biochemical and biophysical mechanisms responsible for these phenomena are not fully understood. The mechanisms involved seem to depend not only on the developmental stage of an animal but also on the brain area, neural circuitry, as well as on the experimental technique used to characterize the phenomena. In our previous study, we developed a computational model of astrocyte-neuron interactions at a layer 4 to layer 2/3 synapse in somatosensory cortex during postnatal development (Manninen et al., 2020). The model links presynaptic, postsynaptic, and astrocytic mechanisms to the time window of spike-timing-dependent long-term depression (t-LTD) induction (Min and Nevian, 2012; Banerjee et al., 2014). In brief, we showed that postsynaptically released endocannabinoids increase astrocytic calcium signaling which in turn induces exocytosis of glutamate. Glutamate exocytosis from an astrocyte can further activate presynaptic N-methyl-D-aspartate receptors coupled with calcineurin signaling and influence synaptic properties. These complex signaling cascades between the neurons and the adjacent astrocyte can induce t-LTD which is sensitive to temporal difference between post- and presynaptic activity. The work involved using a multitude of data from molecular, biochemical, and electrophysiological experiments in rodent somatosensory cortex during postnatal development. Recent studies have indicated increased motility of fine astrocyte processes during synaptic activation, particularly with long-term plasticity changes (Bernardinelli et al., 2014; Sakert et al., 2017). Structural reorganization of a fine astrocyte process can thus be hypothesized to change the microenvironment around the synapse. It is of interest to analyse the influence of extracellular glutamate in such conditions, using the previously developed *in silico* model. In the present study we explored the amount of glutamate spillover required to induce t-LTD with and without astrocyte activation. The latter condition may occur when fine astrocyte processes retract from the close vicinity of the synapse during the learning process but also during injury. Our results show that during postnatal development astrocytes take part in synaptic computations and facilitate the biochemical processes for plasticity, a precondition for learning and memory. Computational studies of synaptic functions promote development of new hypotheses that can be tested experimentally.

Title: Input-selective adenosine a_1 receptor-mediated synaptic depression of excitatory transmission in dorsal striatum

Authors: *B. M. FRITZ[1], F. YIN[3], B. K. ATWOOD[2];
[2]Dept. of Psychiatry, [1]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Indiana Univ., Indianapolis, IN

Abstract: The medial (DMS) and lateral (DLS) dorsal striatum differentially drive goal-directed and habitual/compulsive behaviors, respectively, and are implicated in a variety of neuropsychiatric disorders. These subregions receive distinct inputs from cortical and thalamic regions which uniquely determine dorsal striatal activity and function. Adenosine A_1 receptors (A1Rs) are prolific within striatum and regulate excitatory glutamate transmission. Thus, A1Rs may have regionally-specific effects on neuroadaptive processes which may ultimately influence striatally-mediated behaviors. The occurrence of A1R-driven plasticity at specific excitatory inputs to dorsal striatum is currently unknown. To better understand how A1Rs may influence these behaviors, we first sought to understand how A1Rs modulate these distinct inputs. We evaluated A1R-mediated inhibition of cortico- and thalamostriatal transmission using *in vitro* whole-cell, patch clamp slice electrophysiology recordings in medium spiny neurons from both the DLS and DMS of C57BL/6J mice in conjunction with optogenetic approaches. In addition, conditional A1R KO mice lacking A1Rs at specific striatal inputs to DMS and DLS were generated to directly determine the role of these presynaptic A1Rs on the measured electrophysiological responses. Activation of presynaptic A1Rs produced significant long-term synaptic depression (A1R-LTD) of excitatory transmission in the both the DLS and DMS of male and female animals. Our findings indicate that A1R-LTD at corticostriatal and thalamostriatal inputs to DLS can be additive and that A1R-LTD in DMS occurs primarily at thalamostriatal inputs. These findings advance the field's understanding of the functional roles of A1Rs in striatum and implicate their potential contribution to neuropsychiatric diseases.

Title: Clustered synaptic plasticity in a dendrite CA1 compartmental model

Authors: *Z. WU[1], D. B. POLL[4], D. A. DOMBECK[2], W. L. KATH[3];
[2]Neurobio., [3]Applied Mathematics, [1]Northwestern Univ., Evanston, IL; [4]Mathematics, Col. of Charleston, Charleston, SC

Abstract: A hippocampal CA1 place cell is a pyramidal neuron that fires at specific locations in an environment. Recent experimental studies have shown that in novel environments place

activity appears to begin first in dendrites, followed by full somatic place cell firing. Such experiments raise questions concerning how dendritic inputs lead to the formation of CA1 place cells.We have created a compartmental model of a CA1 place cell dendrite and soma with a simplified version of a biophysically-motivated, calcium-based synaptic plasticity model (Rubin et al., J. Neurophysiol., 2005, 93, 2600-2613). First, we verified that the simplified model is capable of reproducing the spike-timing-dependent plasticity rules exhibited by the full model when a single synapse is stimulated. Then, we introduced two spatially-separated synaptic inputs, and paired their stimulations with a somatic action potential. When the distance between the synapses is varied, the synaptic potentiation increases when the synapses are in close proximity with one another, i.e., clustered synaptic potentiation is produced.We also performed simulations to confirm that calcium diffusion is responsible for these spatially-dependent plasticity changes. If we increased the rate of the calcium pump in a compartment between the two stimulated synapses, the distance-dependent effect upon synaptic plasticity was significantly reduced. Moreover, the effect of artificially changing the calcium diffusion coefficient showed a positive correlation with the length scale over which the synaptic potentiation is increased. These two simulations demonstrate that the diffusion of calcium signals from nearby synapses was the primary reason for the distance dependence of the synaptic plasticity.We constructed this model with the formation of place cells in mind, but it is fairly general and so could be relevant for other neurons with extensive dendritic arbors with many synaptic inputs, such as those investigated by Makino and Malinow (Neuron, 2011, 72:1001-1011).

Title: The role of Kv2 and Nav1.6 in Adaptive Firing in Place Fields within the CA1 region of the Hippocampus: A Computational and Experimental Approach

Authors: *C. M. UPCHURCH[1], C. L. COMBE[2], C. J. KNOWLTON[3], S. GASPARINI[4], C. C. CANAVIER[5];
[1]Louisiana State Univ. Hlth. Sci. Center-, New Orleans, LA; [2]Neurosci. Ctr., [3]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [4]Neurosci. Ctr. of Excellence, LSU Hlth. - New Orleans, New Orleans, LA; [5]Cell Biol. and Anat., LSU Hlth., New Orleans, LA

Abstract: CA1 place cells in the hippocampus receive synaptic input from the CA3 region and the entorhinal cortex. *In vivo* this synaptic input has been shown to depolarize the cell as the animal enters a place field and return to baseline as the animal leaves. Our experimental collaborators (see Combe et al. poster) replicate this *in vitro* (slice electrophysiology) through

triangular current ramps of varying durations (1-10 s), delivered either to the soma or dendrites. From their experimental data, we have found that under control conditions, CA1 neurons fire more on the up ramp than the down ramp, and this is accentuated in the dendrites compared to the soma. We have also found spike height decreases in the dendrites during repetitive firing. We believe this to be the result of slow cumulative inactivation of the Nav1.6 voltage gated Na+ channel, which has been shown to increase in dendrites with distance from the soma. In the presence of cholinergic agonists, these CA1 neurons fire more on the down ramp than the up ramp, a possible consequence of the activation of the Ca2+- activated nonspecific current ICAN mediated by TRP channels. We calibrated a five state Markov model of Nav1.6 to fit time, voltage and spatial dependences of slow inactivation according to the literature, and inserted it into our previously published, morphologically realistic, multicompartment model of a CA1 pyramidal cell implemented in NEURON. We simulated triangular current ramps delivered either to the soma or proximal dendrites (~200 um from the soma) to reproduce the in vitro experiments.
With the calibrated Markov model of Nav1.6, our previously published model produced a burst in response to the application of triangular current ramps. In vitro experiments showed the same burst response when triangular ramps were delivered in the presence of Guangxitoxin-1E, a Kv2.1 specific blocker. After the insertion of a model of Kv2, we restored repetitive single spiking during the ramp and replicated the adaptation in the soma, increased adaptation in the dendrites and decrease in spike height. From our modeling results, we find the Kv2 channel is active during afterhyperpolarization and suggest it may be necessary to prevent burst firing in these neurons. The addition of a phenomenological model of TRPM4 shifted the rate response to cause more firing on the down ramp than the up ramp.
Our results suggest 1) the slow inactivation of Nav1.6 contributes to the adaptation seen in CA1 pyramidal cells under control conditions, 2) the afterhyperpolarization mediated by Kv2 is necessary to prevent burst firing in these neurons, 3) TRPM channels contribute to the acceleration seen in these cells in the presence of acetylcholine.

Title: When should, and how can, a dendrite provide sharp thresholding, despite natural input variability?

Authors: *T. RAMDAS[1], B. W. MEL[2];
[1]Neurosci., [2]Biomed. Engin., USC, Los Angeles, CA

Abstract: Experimental and modeling studies over the past 25 years inform us that dendrites can function as separately thresholded learning and signaling units, potentially affording neurons with greater computational power and increased storage capacity. In previous studies that explored the role that dendritic compartmentalization may play in memory formation, we found that storage capacity is maximized when dendrites are sharply thresholded, with cleanly separated sub- and suprathreshold response ranges. From a biophysical perspective, configuring a dendrite to produce effectively binary-valued outputs given natural input variability is non-trivial. Even in the simple case of focal excitation at different dendritic shaft locations, the amplitudes of dendritically-evoked NMDA spikes measured at the soma vary essentially continuously. We carried out compartmental modeling studies of a canonical spiny basal dendrite in search of biophysical conditions that maximize the dendrite's propensity to generate sharply thresholded, rather than continuously varying, voltage responses at the soma despite fluctuations in the patterning of activated synapses. Spines were outfitted with synapses consisting of NMDA and AMPA conductances whose activations (with a burst of 3 inputs at 200 Hz) were modeled as independent Bernoulli random variables. We studied the effects of peak synaptic conductance, spine neck resistance, and spine density, all potentially varying with dendritic shaft location, on the distribution of somatic responses. Our main new finding is that a decaying spine density moving outward along a dendrite leads to a strikingly bimodal NMDA-dependent somatic voltage distribution as compared to either uniform or increasing spine density, which led to more graded responses. To quantify bistability, we measured the widest "gap" along the voltage axis separating sub- and suprathreshold ranges containing no more than 2% of total cases. The peri-threshold voltage gap for the decreasing density case (15 mV) is significantly wider than that for the constant density case (3 mV) and the increasing density case (1 mV). Interestingly, data from a recent EM study indicates that spine density does indeed fall off moving distally along dendrites in hippocampal pyramidal neurons, which the authors showed was consistent with a 2-layer integration scheme in these cells. Our finding adds a normative account for the observed spine density gradient and provides further insight into the brain's subtle biophysical strategies for optimizing the computing capabilities of neural tissue.

Title: Physiologically and anatomically distinct projection neurons connect mediodorsal thalamus to medial prefrontal cortex

Authors: P. LYUBOSLAVSKY, A. KIZIMENKO, *A. C. BRUMBACK;
Neurol., The Univ. of Texas at Austin, Austin, TX

Abstract: At the heart of the prefrontal executive and limbic networks is the mediodorsal thalamus (MD). Despite the importance of MD in a broad range of behaviors and neuropsychiatric disorders, virtually nothing is known about the physiology of the different populations of neurons in MD. Here, we injected the retrograde tracer cholera toxin subunit B (CTB) into the medial prefrontal cortex (mPFC) of adult (8-12 week old) male and female wildtype mice. We prepared acute brain slices and used whole cell electrophysiology to measure and compare the intrinsic properties of the neurons in ipsilateral MD that project to mPFC (MD→mPFC neurons). MD→mPFC neurons are located predominantly in the medial (MD-M) and lateral (MD-L) subnuclei of MD. We found that that MD-M→mPFC neurons have longer membrane time constants, higher membrane resistance, less Hyperpolarization and Cyclic Nucleotide gated (HCN) channel activity, and more readily generate action potentials compared to MD-L→mPFC neurons. Additionally, MD-M→mPFC neurons have larger and more complex dendritic arbors compared to MD-L→mPFC neurons. These data demonstrating that the two populations of MD→mPFC neurons have distinct physiologies and morphologies suggests a differential role in thalamocortical information processing and potentially behavior.

Title: Activity labeling in vivo using CaMPARI2 reveals cell type-specific intrinsic and synaptic differences between neurons with high and low firing rate set points

Authors: *N. TROJANOWSKI, G. TURRIGIANO;
Dept of Biol., Brandeis Univ., Waltham, MA

Abstract: To enable robust network stability in the face of dynamic perturbations, rodent neocortical pyramidal neurons actively maintain their mean firing rates within a target range, termed their firing rate set point (FRSP). Remarkably, while these set points can span several orders of magnitude within a transcriptional cell type, individual pyramidal neurons reliably return to their own specific FRSP during prolonged activity perturbations, demonstrating that these individual set points are actively maintained. High and low FR neurons in rodent frontal

cortex and hippocampus are differentially modulated by sleep states, suggesting that they are functionally distinct and may play unique roles in information storage and transmission. However, little is known about the factors that generate this broad distribution of FRSPs in different cell types *in vivo*.
To investigate the differences between high and low activity neurons within single cell types, we developed an approach for permanently labeling pyramidal neurons according to their *in vivo* mean firing rates before *ex vivo* analysis of their synaptic and intrinsic properties. To permanently label neurons in monocular visual cortex of freely behaving mice *in vivo* based on their mean firing rate, we used the permanent green-to red Ca^{2+}- and UV-dependent photoconversion of CaMPARI2 as a proxy for mean neuronal activity. Red/green ratios following 30-minute *in vivo* photoconversion were lognormally distributed, mirroring *in vivo* firing rates, and neurons with greater *in vivo* photoconversion had higher firing rates *ex vivo*. During *ex vivo* photoconversion, neurons with higher firing rates underwent greater changes in CaMPARI2 red/green ratio. These data show that CaMPARI2 labeling is sensitive enough to detect differences in mean firing rates, and to differentiate between neurons with low and high FRSPs.
We went on to characterize the properties that differentiate high from low FR neurons in different cell types. We found that high activity layer 4 (L4) pyramidal neurons had greater intrinsic excitability and received stronger inputs from other L4 pyramidal neurons, although there were no consistent differences in total E/I ratio between these neurons. In contrast, we then found that in L5 TLX-3-positive neurons (a subset of thin-tufted, regular spiking pyramidal neurons), high activity neurons received greater excitatory input but had no increase in intrinsic excitability. Thus, both intrinsic excitability and intralaminar excitatory synaptic strength can be important contributors to the broad range of FRSPs observed within single cell types *in vivo*, though their relative importance varies across cell types.

Title: Probing Fidelity of High-Frequency Firing in Midbrain Dopaminergic Neuron Axons

Authors: *A. SUKHAREV, P. F. KRAMER, R. ZHANG, Z. KHALIQ;
NINDS, NIH, Bethesda, MD

Abstract: Dopamine release in the striatum is key for motor execution and reinforcement learning. Striatal dopamine that is released following stimulation of dopaminergic neuron axons undergoes dramatic short-term depression at physiological rates (5-40 Hz) through mechanisms

that are incompletely understood. Past studies examining evoked dopamine have focused on calcium coupling and vesicular release mechanisms, while others have posited that the highly branching axonal architecture could increase the likelihood of failure during action potential propagation. However, whether intrinsic axonal firing mechanisms contribute to the observed depression has not been directly tested. Here, we obtain axonal recordings using a combination of cell-attached, whole-cell, and perforated-patch configurations to test the frequency dependence of action potential firing in both the unbranched dopaminergic axons of the medial fiber bundle and the profusely branching terminal processes within the dorsal striatum of adult mice. Trains of action potentials were tested over a range of stimulation frequencies. Axonal action potentials were evoked by either using brief current pulses applied directly through the recording electrode or by placement of a bipolar stimulation electrode within the striatal tissue slices to stimulate propagated spikes. In the main dopaminergic axons, we found action potential firing was completely reliable with no failures observed during 5-pulse trains at 100 Hz (current injected, 8 out of 9 axons; stimulated, 11 of 13 axons). The high maximal firing rates that we observed in dopaminergic axons contrasts with the relatively low maximal firing rates of 30 Hz and below that have been consistently reported in studies of somatic dopaminergic neuron firing. In separate experiments, we tested evoked firing in the thin, highly branching striatal dopaminergic axons. We found that striatal dopaminergic axons could reliably fire action potentials above 100 Hz. Thus, this data demonstrates that action potential firing in axons can follow at rates that are significantly higher than those observed in the soma. We are currently testing whether propagation throughout the branching axonal arbor in striatum occurs reliably during firing rates that are seen during physiologically relevant tonic and phasic firing patterns.

Title: Sex-specific electrophysiological and morphological characterization of regular-firing and burst-firing pyramidal neurons within layer 5 of the mouse prefrontal cortex

Authors: ***A. PATEL**, A. NGUYEN, C. D. BAILEY;
Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: The medial prefrontal cortex (mPFC) plays an important role to support cognitive functioning. Pyramidal neurons within cortical layer 5 form the primary signalling output from this region. These neurons may be categorized as either regular-firing or initial burst-firing, based on threshold responses to positive current injection. These distinct firing patterns are believed to provide distinct contributions toward information transmission between brain

regions. The electrophysiological and morphological properties of these mPFC neurons have not been compared within developing male and female mice. We completed this comparison using whole-cell electrophysiology and biocytin neuron labelling in young postnatal mice (age 15-20 days) of both sexes. We first observed a striking sex difference, in that the proportion of regular-firing neurons was greater in males than in females. Within each sex, regular-firing neurons were generally more excitable than burst-firing neurons. They had a greater membrane resistance, spike adaptation ratio, and input-output firing response, in addition to a lower-magnitude afterhyperpolarization potential. Regular-firing neurons also exhibited a lower frequency of excitatory postsynaptic potentials (EPSCs). Detailed morphological analysis revealed a difference between neuron types in male mice only, such that regular-firing neurons had a greater amount of apical dendrite matter distal to the soma and a greater amount of basal dendrite matter proximal to the soma. Between the sexes, we found that burst-firing neurons had a greater amount of apical and basal dendrite matter in females than in males. Ongoing experiments aim to determine the projection targets for each type of pyramidal neuron within each sex. These novel findings demonstrate sex-differences in the proportion and morphology of regular-firing and burst-firing pyramidal neurons within mPFC layer 5, which may impact the development of cognitive circuits involving this brain region.

Title: Mild head trauma-induced impairment of functional efficacy of both L5 basket cells and chandelier cells

Authors: ***A. C. HARRIS, Jr.**, K. M. JACOBS, M. AFRIFA;
Virginia Commonwealth Univ., Richmond, VA

Abstract: Alterations in the balance of excitation and inhibition within neocortical networks are consistent features of mild traumatic brain injury (TBI). Diffuse axonal injury is borne by neocortical parvalbumin+ interneurons (PV) at the same rate (~10%) as pyramidal neurons. PV interneurons contain both basket (BCs) and chandelier cells (ChCs), and the disruption of ChCs might catalyze the emergence of excitatory-inhibitory imbalance secondary to the release from inhibition of large numbers of pyramidal neurons at the axon initial segment. We labeled ChCs, by crossing Nkx2.1Cre^{ER} with Ai32 mice and administered 0.25 mg tamoxifen at P0. In a separate cohort Ai32 were crossed with PV-Cre mice to target BCs. Mice of each cohort were randomized to receive a sham or mild central fluid percussion injury (1.6-1.7 atm, righting time: 5-7 min). Results reported as mean ±SEM; t-tests were used to compare TBI with sham, with

$p<0.05$ considered significant. Neurons of each cohort were targeted for patch clamp recordings. Despite sharing classification as fast-spiking interneurons, the intrinsic membrane properties of BCs and ChCs differed on many metrics. The input resistance, the ratio of the height of the first to the second action potential (AP), the AP half-width, the total adaptation, and the after-hyperpolarization amplitude were significantly higher in ChCs compared to BCs, while the maximum AP frequency and rheobase were significantly lower in ChCs compared to BCs. In BCs, the AP half-width was significantly longer in TBI compared to sham (0.57 ±0.03 msec TBI; 0.44 ±0.02 msec sham, n = 9 TBI and 18 sham neurons), while the maximum firing frequency was significantly lower (188 ± 9.0 Hz TBI; 234 ±9.4 Hz sham). ChCs of L5 had a significantly lower maximum frequency in the TBI group compared to sham (119.5 ±12.0 Hz TBI; 164.2 ±10.6 Hz, sham, n= 5 TBI and 9 sham neurons). Furthermore, the relative decrement in AP amplitude throughout a train of APs was significantly larger in TBI compared to sham. There were no differences in the intrinsic properties of L2/3 ChCs in TBI compared to sham. These results suggest trauma-induced reduction of the functional efficacy of both L5 BCs and ChCs, which might favor a shift toward excessive excitatory tone within neocortical networks.

Title: Single-neuron models explain role of A-type potassium channels in response diversity of human supragranular pyramidal cells

Authors: ***T. CHARTRAND**, B. E. KALMBACH, A. NANDI, A. BUCHIN, J. BERG, S. A. SORENSEN, J. A. MILLER, J. T. TING, C. KOCH, E. S. LEIN, C. A. ANASTASSIOU; Allen Inst. for Brain Sci., Seattle, WA

Abstract: The study of human single neurons from surgically resected tissue has advanced dramatically in recent years, showing that human cortical neurons exhibit many unique physiological properties compared to their rodent counterparts. Because these findings are of potentially high relevance in understanding human brain circuits as well as the treatment of disease, linking observed differences to the underlying ion channel properties and gene expression is critical for understanding mechanisms and predicting effects of pharmacological interventions. Data-driven biophysical models are a valuable tool in the study of ion channel function, as detailed simultaneous recordings of distinct ion channels are possible only in silico. To fully realize this potential, neuronal models based on multi-modal single-cell data with accompanying gene expression are necessary. Based on recently published patch-seq data from human supragranular pyramidal cells, we developed detailed biophysical models of human single

neurons using a computational optimization pipeline with single-neuron electrophysiology and morphology as input.
We present evidence that the unique bursting or fast spike frequency adaptation dynamics observed at response onset in a subtype of deep layer 3 pyramidal cells in primate may be determined by A-type potassium channels. We provide support from both simulations of detailed biophysical models and data mining for correlations between ion channel genes and electrophysiology features. The correlation analysis points to a role for the K-channel subunit gene KCNAB1, which confers A-type fast inactivation to the composite channel . Fine-tuning the A-type conductance parameter in our models produces a close match to the experimental bursting dynamics. Recording and decomposition of the ion channel currents involved in these spike train simulations show that the faster A-type currents reduce the total K-current during spike repolarization, minimizing the size of the post-spike AHP and thus permitting faster reactivation of sodium channels early in the spike train. This adaptation permits rapid amplification at the onset of synaptic input, possibly reflecting a specialization of deep layer 3 cells to their predominantly feedforward connections in the cortical circuit.

Title: An experimental test for the ectopic origin of the 4-AP-induced burst of hippocampal mossy fibers

Authors: *H. KAMIYA;
Hokkaido Univ. Grad. Sch. of Med..

Abstract: The application of a potassium channel blocker 4-aminopyridine (4-AP) to the hippocampal slice preparation causes hyperexcitability and elicits robust burst discharges in the CA3 region. However, it remains to be determined how a blockade of voltage-dependent potassium channels by 4-AP leads to the generation of burst discharges. A previous study demonstrated that the blockade of potassium channels at the distal axons is sufficient for the generation of the burst discharges, and it suggested the ectopic origin of the burst discharges from the distal portions of the mossy fibers. To test for the burst generation of the mossy fibers from the distal axons, an attempt was made to disconnect the distal axons from the soma and the proximal axons. For this purpose, a surgical cut was made between the dentate gyrus and the CA3 region in the mouse hippocampal slices. The mossy fiber boutons discharged spontaneous

action potentials at low frequency in the control condition, possibly reflecting spontaneous discharges of the granule cells, while they were almost abolished after the surgical cut. The focal application of 100 μM 4-AP to the CA3 region elicited robust burst discharges of the mossy fiber boutons. After the surgical cut, on the other hand, the focal application of 4-AP did not evoke the burst firings of the mossy fiber boutons. These findings suggest that the 4-AP-induced bursts are generated from the distal axons of the mossy fibers, while the invasion of the propagating spontaneous action potentials from the soma is required for triggering the burst discharges from distal axons.

Title: Cholinergic modulation of responses to depolarizing current ramps in CA1 hippocampal pyramidal neurons

Authors: *C. L. COMBE, C. C. CANAVIER, S. GASPARINI;
Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: *In vivo* measurements show that CA1 place cell firing rates within the place field are influenced by novelty and previous exposure to the environment. Although synaptic plasticity likely contributes to modulation, the intrinsic properties of CA1 pyramidal neurons, such as adaptation, also influence the firing rate. To isolate these intrinsic contributions, we injected triangular depolarizing current ramps of various durations (1-10 s) to approximate the spatially-tuned, temporally-diffuse depolarizing synaptic input received by these neurons while traversing a place field. These ramps were applied to CA1 pyramidal neurons *in vitro* (slice electrophysiology, male rats, 7-10 weeks old) and *in silico* (multicompartmental model, see companion poster Upchurch et al). We found that under control conditions, CA1 neurons responded with more action potentials and at higher frequencies on the ascending phase than the descending phase of the depolarizing ramps. The cholinergic agonist carbachol (2 μM) caused the rate responses to shift, with more action potentials fired on the descending phase of the ramps. In order to tease out which aspects of cholinergic activation are responsible for this shift, we investigated the involvement of several currents associated with rate adaptation and known to be modulated by cholinergic activity. Pharmacological blockers of SK, M-type, A-type, and ERG currents did not shift the response, nor did blocking SK and M-type together. Flufenamic acid (FFA) is a wide-spectrum antagonist for the Ca2+-activated nonselective cationic current (ICAN) carried by TRP channels. When applied after carbachol, FFA was effective in reversing the effect of cholinergic activation. Further experiments with blockers specific for TRPC and

TRPM channels suggest that currents mediated by these channels are responsible for the increase in the firing rate on the down ramp in the presence of carbachol. In order to investigate cholinergic modulation in a more nuanced fashion, we looked at dose response effects of acetylcholine (ACh), the endogenous neuromodulator, on the spike ratio (spikes on the up-ramp/spikes on the down-ramp). We found a significant effect of ACh dose on the spike ratio (control 2.5 ± 0.4; 2 μM ACh 1.4 ± 0.1; 10 μM ACh 1.1 ± 0.1; 15 μM ACh 1.1 ± 0.1; $P<0.001$, n = 11). These results suggest that the extracellular concentration of ACh may be important in the modulation of firing rate responses within a cell's place field. Our results suggest that modulation of intrinsic ion channels by experience and novelty-related fluctuations in cholinergic activity may contribute to the shifts observed *in vivo* in peak firing rate as the place field is traversed.

Title: Ethanol decreases excitability of orbitofrontal cortex neurons via dopamine D1-like receptor activation of astrocytic glycine release

Authors: S. NIMITVILAI-ROBERTS, D. GIOIA, *J. J. WOODWARD;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Alcohol addiction is associated with dysfunction of brain circuitry including areas of the orbitofrontal cortex (OFC). Recent findings from this laboratory demonstrate that ethanol reduces the intrinsic excitability of OFC neurons in naïve mice via activation of strychnine-sensitive glycine receptors. Withdrawal from chronic intermittent ethanol exposure enhances current-evoked OFC firing, and diminishes acute ethanol inhibition of spiking by blunting its activation of a glycine receptor-dependent tonic current. Although the mechanism linking ethanol to the release of glycine is currently unknown, several studies have identified astrocytes as a source of neurotransmitters including glycine. Furthermore, dopamine has been reported to cause a functional reversal of the astrocytic glycine transporter 1 (GlyT1) via Gq-coupled receptor activation of PLC/PKC pathway resulting in elevated extracellular glycine levels. We reported previously that like ethanol, dopamine increased a glycine-mediated tonic current in lOFC neurons. In this study, we used whole-cell patch-clamp electrophysiology to examine whether ethanol inhibition of OFC spiking involves the release of glycine from astrocytes and whether this release is dopamine receptor dependent. Ethanol, applied acutely, decreased spiking of lOFC neurons and this inhibition was blocked by a non-transportable GlyT1 blocker,

monoamine transporter inhibitors and a D1 but not D2 receptor blocker. Ethanol enhanced a tonic current in lOFC neurons with no further increase following subsequent exposure to dopamine suggesting that ethanol and dopamine may share a common pathway. Altering astrocyte function by inhibiting glial metabolism or by suppressing intracellular astrocytic calcium signaling decreased, but did not fully eliminate ethanol inhibition of lOFC neuron firing. Likewise, blocking the astrocyte-specific Kir4.1 channel, known to induce depolarization of astrocytes and reversal of GlyT1, reduced but did not abolish ethanol inhibition of OFC firing. However, when both astrocytic calcium signaling and Kir4.1 channels were suppressed, ethanol no longer inhibited lOFC neuron firing. Ethanol inhibition of lOFC neuron firing was also prevented in slices treated with inhibitors that target phospholipase C or conventional isoforms of protein kinase C. Finally, using sharp electrodes to record from astrocytes, we found that bath application of a Kir4.1 blocker, D1 agonist or ethanol depolarized OFC astrocytes. We propose that acute ethanol induces a GlyT1-dependent release of astrocytic glycine via activation of D1-like receptors and subsequent inhibition of Kir4.1 channels.

Title: Qualitative Examination Of Temporal Interference Mechanisms For Cortical Neurons

Authors: *S. C. MARTINEZ[1], P. GROVER[1], A. L. BARTH[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Carnegie Mellon U., Pittsburgh, PA

Abstract: Motivation: Temporal Interference (TI) stimulation has been proposed as a neuromodulation technique for the non-invasive stimulation of deep brain regions, without causing shallow stimulation. This technique consists of an interplay between two high-frequency sinusoidal waves with a small difference in frequencies. Localized wave summation of these sinusoids can drive neural activity, where a single sinusoid application is insufficient. The mechanisms underlying TI stimulation phenomenon are still not well understood and more experimental studies, hand-in-hand with modelling, are needed. Methods/approach: In this experimental study, we qualitatively evaluate the efficacy of TI stimulation for cortical neurons. We performed whole-cell current-clamp recordings in acute brain slices from the mouse cortex (postnatal day (P18)). Waveforms were applied in kHz frequency range using a bipolar probe, maintaining a distance of approximately 100 um from the patched neuron. A cell was said to exhibit TI stimulation if it was stimulated by the summation of two sinusoids of slightly different kHz frequency and equal amplitude, but not by a pure sinusoid of equal kHz carrier frequency and twice the amplitude. Results: We observe that cortical neurons can exhibit TI stimulation

Fig.1. Furthermore, consistent with recent predictions in [Cao et al.,'20], our exploratory results suggest that a) higher current amplitudes are required to observe TI stimulation when the sinusoidal carrier frequencies are increased. b) an increase of the carrier frequency provides more reliable TI stimulation. Early results on effects of modulation frequency are also reported. Conclusions: We provide TI experimental validation in cortical neurons and provide some insights in the amplitudes and frequencies required to produce such results. Further exploration of cell-types would be insightful to gain a better understanding of how TI stimulation could affect different brain regions.

Title: Tacs induces neural entrainment in neocortical neurons models

Authors: *H. TRAN, S. SHIRINPOUR, A. OPITZ;
Univ. of Minnesota, Minneapolis, MN

Abstract: Transcranial alternating current stimulation (tACS) is a non-invasive neuromodulation method which can directly modulate the ongoing activity through neural entrainment, i.e. the firing activity of neurons is synchronized with the external oscillations. tACS thus holds promise as a new treatment option for neuropsychiatric disorders characterized by pathological brain oscillations. However, neural responses to oscillating electric fields depend on the intrinsic

properties of cells and have to be carefully characterized. Here, we perform a computational study to investigate the relationship between electric field strength and neural entrainment in morphologically realistic neocortical neurons. For this, we use cable theory together with proper biophysics to model morphologically realistic models of neurons with synaptic input to create ongoing spiking activity. We explored the effect of different tACS electric field strengths (10Hz) by investigating the subthreshold neuron depolarization - we computed the polarization length - for each cell type and then quantifying the neural entrainment by computing the phase-locking value (PLV) of spikes times across neurons and field strengths. Due to their morphology, pyramidal cells tend to have a larger polarization length resulting in higher phase-locked spiking to the applied oscillation. Both pyramidal cells and interneurons did not show a significant increase in their firing rate for tACS amplitudes achievable in humans. Our results are consistent with experimental literature and can further help to distinguish the effects of oscillating electric fields on single neurons and their spiking activity. Future steps will include to model the effect of tACS on neuronal populations. Modifying the dynamics of the network will allow us to reproduce specific spiking pattern and to better understand how tACS can affect them.

Title: Regional phase amplitude coupling modulation in response to localized subcutaneous alternating current stimulation

Authors: *M. BELL VILA[1], P. BAZIGALUPPI[2], M. KOLETAR[2], B. STEFANOVIC[2,1];
[1]Univ. of Toronto, Toronto, ON, Canada; [2]Sunnybrook Res. Inst., Toronto, ON, Canada

Abstract: Subcutaneous alternating current stimulation (sACS) is a method of electrical stimulation in which the current is applied as a wave, oscillating in amplitude at a given frequency. It has been shown to have the potential to entrain cortical networks, and be localized via targeted placement of stimulating electrodes. Further, previous studies indicate low frequency to high frequency phase amplitude coupling (LF-HF PAC) is correlated with neurological disability in numerous diseases and has been linked to the degree of motor dysfunction in Parkinson's disease (Devergnas et al., 2019). We here investigated the potential of LF-HF PAC as a reporter of disability in stroke and its amenability to modulation via sACS. To determine the feasibility of localized sACS modulating LF-HF PAC, we delivered stimulation through 3-electrode arrays positioned on the skulls over the sensorimotor cortex of 5 naive six-month old Sprague-Dawley rats, while simultaneously recording electrophysiological responses via an intracerebral electrode array. sACS was delivered at high (120Hz) and low (1Hz) frequencies at a 20µA amplitude. Stimulation was administered for a duration of 1 minute. LF-HF PAC was evaluated using an algorithm by Tort et al. (2010). We observed an LF-HF PAC response between pairs of stimulating electrodes while leaving distal regions unaffected. High frequency stimulation resulted in a suppression of neuronal power and LF-HF PAC, with opposite observed effects for low frequency stimulation. These findings demonstrate the possibility of delivering localized sACS while measuring regional LF-HF PAC responses, as well as a frequency dependent attenuation or potentiation effect on neuronal activity.

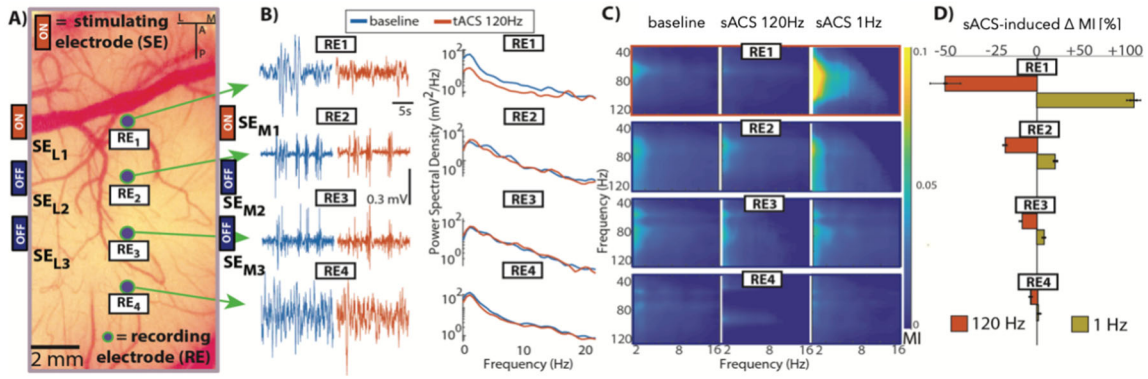

Fig 1. sACS induces frequency-dependent modulation of LF-HF PAC and neuronal power (120-Hz eliciting attenuation and 1-Hz, potentiation), measured from recording electrodes (RE). The use of a stimulating electrode (SE) array permits localization of sACS effects in naive rats.

Title: Er81 transcription factor fine-tunes striatal cholinergic interneuron activity and drives habit formation

Authors: Y. RANJBAR-SLAMLOO, ***N. Y. AHMED**, A. S. AL ABED, L. GAO, Y. SONTANI, A. RCOM-H'CHEO-GAUTHIER, E. ARABZADEH, N. DEHORTER;
Eccles Inst. of Neurosci., John Curtin Sch. of Med. Research, Australian Natl. Univ., Canberra, Australia

Abstract: The molecular mechanisms tuning cholinergic interneuron (CIN) activity, although crucial for striatal function and behaviour, remain largely unexplored. Previous studies report that the Etv1/Er81 transcription factor is vital for regulating neuronal maturation and activity. Whilst Er81 is known to be expressed in the striatum during development, its specific role in defining CIN properties and the resulting consequences on striatal function is unknown. We report here that Er81 is expressed in CINs and its specific ablation leads to prominent changes in their molecular, morphological and electrophysiological features. In particular, the lack of Er81 amplifies intrinsic delayed-rectifier and hyperpolarization-activated currents, which subsequently alters the tonic and phasic activity of CINs. We further reveal that Er81 expression is required for normal CIN pause and time-locked responses to sensorimotor inputs in awake mice. Overall, this study uncovers a new cell-type specific control of CIN function in the striatum which drives habit formation in adult male mice.

Title: Kcnj6 gene variants associated with alcohol use disorder increase excitability in a human ipsc-derived neuron model.

Authors: *D. POPOVA[1], M. YOUSSEF[2], P. ZALAMEA[2], J. A. TISCHFIELD[1], P. A. SLESINGER[3], Z. PANG[4], R. P. HART[2];
[1]Human Genet. Inst. Rutgers Univ., Piscataway, NJ; [2]Rutgers Univ., Piscataway, NJ; [3]Professor, Dept. of Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [4]Child Hlth. Inst., New Brunswick, NJ

Abstract: Alcohol use disorders (AUDs) are leading contributors to preventable mortality and morbidity worldwide. A family study identified genome-wide association of theta event-related oscillations, observed in alcoholics and in their offspring, with single nucleotide polymorphisms (SNPs) in *KCNJ6*, which encodes the inwardly-rectifying potassium channel GIRK2. We hypothesize that alcoholism-associated *KCNJ6* SNPs affect excitability of neurons, altering their response to alcohol. To test this hypothesis we prepared 8 human iPSC lines (4 affected/alcoholics/major allele and 4 unaffected/non-alcoholics/minor allele, sex balanced) from the Collaborative Study on the Genetics of Alcoholism repository collection and generated glutamatergic neurons using Ngn2 induction. Morphological and electrophysiological properties of neurons were examined in parallel with cytochemical detection of GIRK2 expression. We found that basal morphology (soma size, solidity and circularity) and electrophysiological properties (capacitance, resistance, release of glutamate, resting membrane potential and basal firing) of neurons generated from major and minor allele carriers were unchanged. However, affected minor allele carriers show a reduction in punctate GIRK2 expression, detected in presynaptic compartments of neurons, which was paralleled by increased excitability of the neurons measured in action potential induction protocol. Furthermore, even though chronic alcohol treatment affects excitability of the neurons, the treatment eliminates most differences between affected and unaffected groups/individuals. Single-cell RNAseq also identifies that *KCNJ6* minor allele neurons exhibit decreased expression of pathways associated with neuronal and synaptic function. The original KCNJ6 minor allele-associated phenotype, higher theta power in a monetary gambling task, predicts that affected subjects may exhibit increased neural excitability and reward processing, with modulation by alcohol. We conclude that there are physiological differences between neurons from affected and unaffected subjects associated with excitability, possibly due to altered GIRK2 expression, and that alcohol “rescues” excess excitability.

Title: Mathematical simulation predicts regulation of neuronal excitability by changes in the membrane capacitance

Authors: *E. PETROFF, V. SNITSAREV;
Montclair State Univ., Montclair, NJ

Abstract: Mathematical modeling of experimentally obtained action potentials (APs) provides a powerful tool for understanding the intrinsic mechanisms of AP generation and regulation of excitability, as well as helps to formulate further hypotheses to be tested experimentally. In our model of an A-type neuron [https://www.mathworks.com/matlabcentral/fileexchange/18812-nodose-neuron-action-potential-firing], the resting membrane potential (MP) settles to -56 mV. In response to progressively increasing current injections from 0.025 to 0.045 nA with 0.005 nA increments, the model responds with generating 0, 1, 2, 4, and 6 APs, and adapts within 1 second to MPs of -48, -46.4, -44.6, -42.6, and -40.5 mV, respectively. The model behaves similar to an A-type neuron. For example, eliminating the fast tetrodotoxin-sensitive voltage-gated Na^+ channel leads to elimination of APs. *In situ*, membrane capacitance (Cm) increases upon caveolae or synaptic vesicle opening. Changes in Cm can potentially affect excitability. We tested how changes in Cm affect excitability in this model. An increase in Cm by 10% from its default value of 32.5 pF results in 0, 1, 2, 2, and 3 APs and following adaptation to -48, -46.4, -44.6, -42.6, and -40.3 mV in response to 0.025, 0.03, 0.035, 0.04 and 0.045 nA current injections, respectively. A decrease in Cm by 10% from its default value of 32.5 pF results in 0, 1, 4, 10 APs and adaptation to -48, -46.4, -44.6, and -42.8 mV in response to 0.025, 0.03, 0.035, and 0.04 nA current injection, respectively; while in response to 0.045 nA a non-adapting train of APs at 25 Hz was elicited. At 0.4 nA current injection, a minimum decrease in Cm by 2.5% was required to add one AP to the adapting train of four APs, and a minimum increase by 2% was required to eliminate one AP from the adapting train of four APs. Notably, these changes in excitability were not directly related to the changes in the level of depolarization. Based on this simulation, we hypothesize the following. First, fusion of synaptic vesicles increases Cm in the presynaptic terminal and could decrease AP firing to provide the local negative-feedback regulation of the synaptic release. Then, upon synaptic vesicle internalization that decreases Cm, the local excitability could increase to potentiate the following synaptic release. Second, a decrease in Cm due to a decrease in the neuronal surface area increases neuronal excitability to the point of making a neuron spontaneously active at the resting membrane potential (model of epilepsy). Conversely, an increase in Cm due to an increase in the neuronal surface area, makes a neuron less excitable (depression). We are currently testing these hypotheses experimentally.

Title: Envelope analysis of the human alpha rhythm

Authors: *V. M. HIDALGO[1], J. DIAZ[2], J. MPODOZIS[1], J. C. LETELIER[1];
[1]Biol. of Cognition Lab., Univ. of Chile, Santiago, Chile; [2]Intl. Inst. for Integrative Sleep Med., Univ. of Tsukuba, Tsukuba, Japan

Abstract: The origin of human alpha rhythm has been a matter of debate since Lord Adrian attributed it to synchronous neural populations. Although some authors reported Gaussian characteristics for the alpha band, their EEG Gaussianity results were disregarded in favor of Adrian's explanation. We revisit this problem using the EEG envelope analysis (envEEG) − a method relying on the fact that the coefficient of variation of the envelope (CVE) for continuous-time zero-mean Gaussian white noise (as well as for any filtered sub-band) is equal to $\sqrt{((4-\pi)/\pi)} \approx 0.523$, thus making the CVE a fingerprint for Gaussianity (Diaz et al. 2018, DOI:10.1016/j.neuroimage.2018.01.063). The CVE of sampled and finite zero-mean Gaussian white noise, however, is a random variable whose probability distribution must be estimated by numerical simulations and three CVE classes are established: low (CVE<1%), mid (1%≤CVE≤99%), and high (99%<CVE). Low CVE values denote rhythmic signals, consistent with synchronization of coupled oscillators, while medium CVE values represent Gaussian noise. High CVE values represent pulsating activity, consistent with concurrent neuronal activity. We analyzed the "Leipzig Study for Mind-Body-Emotion Interactions" dataset, containing EEG data from 203 subjects with envEEG. Each subject's continuous recording consists of 16 blocks of 60[s], 8 with eyes-closed (EC) and 8 with eyes-open (EO) interleaved. We filtered the data in the alpha band (8-13[Hz]) and segmented it in 24[s] epochs with 50% overlap. For each epoch, we calculated a) the envelope using the Hilbert Transform b) the CVE and c) the mean of the envelope (ME) as a measure of total energy. We analyzed 22893 EC and 22634 EO epochs and found 44% of EC epochs were in the Gaussian class, while 9% and 46% presented low and high CVE values, respectively. For EO epochs, 55% were Gaussian, 43% showed high CVE values and only 0.6% presented low CVE values. When ME values from each individual recording were log-transformed and normalized, the overall positive change in energy from EO to EC was about 2 standard deviations regardless of initial CVE values thus recuperating, within the perspective of envEEG, the classic result about alpha power and visual attention. Fourier analysis showed that epochs from all three CVE classes have the canonical spectral peak at ≈10[Hz] demonstrating that this same peak could be produced by rhythms, pulsating ripples or Gaussian noise. This technique opens a new facet for neural signal analysis relating temporal modulations (CVE) to signal energy.

Title: Effect of repeated exposure to Sevoflurane on physiologic and electroencephalographic features in pediatric patients undergoing radiation therapy

Authors: S. MADARIAGA[1,2], *C. DEVIA[6,1], V. LUCERO[7], S. RAMIREZ[7], M. GANGA[7], N. VALLS[7], R. TORRES[7], N. VILLABLANCA[7], J. EGAÑA[3,4], F. MALDONADO[3], A. PENNA[3,5], R. GUTIERREZ[3,5];

Abstract: Repeated exposure to drugs, such as opioids or benzodiazepines, leads to pharmacological tolerance. However, it has not been established whether the repeated exposure to sevoflurane, an inhalational anesthetic used especially in children, induces pharmacological tolerance. Here, we conducted an observational study in infants (n=11) requiring general anesthesia for radiotherapy treatment under a standardized protocol. Only sevoflurane was administered for Induction (8%) and Maintenance (2.5%) throughout all radiotherapy sessions. We record the "Induction time", defined as the time between the beginning of the anesthetic administration and the insertion of the laryngeal mask once the unconsciousness is established. Every third session we recorded electroencephalographic signals with 4 frontal electrodes. We performed power spectral analysis over cleaned electroencephalographic windows recorded during Maintenance. To compare spectral power through radiotherapy sessions we used a multitaper frequency-domain bootstrap method. Based on this statistical we performed a pot-hoc paired t-test. Throughout sessions, we found no differences in the Induction time. Our preliminary results show an attenuation in alpha-band activity through sessions. Further paired comparison showed a significant decrement in alpha-band power between the first and the last recorded session. Overall, our results suggest that repetitive exposure to sevoflurane does not induce tolerance. (Funds: FONDEF ID19I10345, ICN09_015)

Title: Remifentanil enhances propofol hypnotic clinical and electroencephalographic effect in humans during loss of consciousness

Authors: B. ABURTO[1], C. F. NAVARRO[1], *J. I. EGANA[2], F. MALDONADO[2], C. DEVIA[1], R. GUTIERREZ[2], A. PENNA[2];
[1]Dept. de Neurociencias, [2]Dept. de Anestesiología y Medicina Perioperatoria, Univ. de Chile, Santiago, Chile

Abstract: Introduction:
General anesthesia is a reversible pharmacological state in which patients are unconscious making surgery possible. As part of balanced general anesthesia, it is common to use the synergy between the hypnotic (propofol) and the opioid (remifentanil) to achieve the desired clinical effect. However, the electroencephalographic correlate of this synergy has not been fully studied.
Methods:
Here, we registered patients during anesthesia induction with a 4-frontal electrodes EEG monitor using two protocols. 1) PROPO (n=10): propofol infusion until Loss of Consciousness (LOC). 2) REMI-PROPO (n=10): remifentanil and propofol infusion until LOC. The EEG spectrum was obtained for both protocols during all induction until after LOC. We compared the spectra from both groups using bootstrapping analysis.
Results:
•PROPO patients required higher propofol dose to achieve LOC compared to REMI-PROPO.
•REMI-PROPO patients have lower spectral alpha power before LOC, and lower delta power after LOC than patients in PROPO protocol.
•When PROPO had the same propofol concentration of REMI-PROPO after LOC onset, PROPO had lower alpha power compared to REMI-PROPO.
Discussion:
•Remifentanil enhances propofol hypnotic clinical effect, which is correlated with electroencephalographic activity.
•Electroencephalographic synergy persists once the LOC is reached, evidenced by a higher delta power in those patients who only reach LOC with propofol, which is consistent with the higher concentration of propofol required to reach LOC.

•Lower alpha power in PROPO at the same dose of propofol in REMI-PROPO is consistent with the fact that PROPO patients have not reached the LOC at this dose.

Title: Electrophysiological correlates of acute psilocybin in mice

Authors: *Z. W. SULTAN[1], S. M. GRADY[1], H. A. BASTIEN[1], Z. ZAHID[2], C. J. WENTHUR[3], M. I. BANKS[1];
[1]Anesthesiol., [2]Neurosci. Training Program, [3]Sch. of Pharm., Univ. of Wisconsin, Madison, WI

Abstract: Introduction: Emerging evidence indicates that a single dose of the classical psychedelic psilocybin (PSIL) is effective as rapid and prolonged treatment for multiple psychiatric disorders, including depression, anxiety, and substance use disorder, but the neural mechanisms underlying these therapeutic effects are unclear. In human subjects, PSIL's therapeutic effects correlate with the intensity of the psychedelic experience. Effects on brain oscillations and signal complexity also correlate with psychedelic phenomenology, and are blocked by the serotonin 5-HT2A receptor antagonist ketanserin (KTN). Studies in rodents suggest a role as well for 5-HT1A receptors, though results have been inconsistent. We seek to link neural signatures of PSIL to effects on depression-like and anxiety-like phenotypes in mouse models. As a first step, we measured the effects of PSIL, in combination with 5-HT receptor antagonists, on resting-state brain activity in healthy mice.
Methods: We recorded skull-screw EEG, movement, and head-twitch responses in C57BL/6 mice (male & female, aged 2-8 months old) at baseline and up to 4 hours after intraperitoneal injections of vehicle (VEH; n=8 animals), 3mg/kg PSIL (n=13), PSIL + 1mg/kg KTN (n=9), and PSIL + 0.5mg/kg 5-HT1A receptor antagonist WAY100635 (WAY; n=6). EEG band power and Lempel-Ziv complexity (LZcn) were calculated at baseline and treatment. To avoid confounds due to drug-induced changes in movement, which alter EEG power spectra, propensity score matching was used to match distributions of movement magnitude between baseline and treatment periods. Band power was then compared for comparable movement distributions.
Results: PSIL increased delta (0.5-4Hz) and decreased alpha (13-20Hz) band power during the first hour post-injection. After accounting for spectral changes, increased LZcn was observed at 15-30 minutes after PSIL injection. Pretreatment with KTN decreased the peak effects of PSIL on delta, alpha, and LZcn, while WAY shortened the duration of PSIL's effects without altering peak response.

Conclusions: Our analysis of brain activity in mice on PSIL recapitulates previous observations in humans, and suggests contributions of multiple 5-HT receptors. Future work will explore neural effects in models of depression and anxiety.

Title: Changing characteristics of infant sleep spindles at 9 months contribute to spectral power in a sex dependent manner

Authors: *S. E. PETERS, A. A. BENASICH;
Neurosci., Rutgers Univ. - Newark, Newark, NJ

Abstract: Sleep spindles (SS) are neurophysiologic components of brain maturation thought to be associated with neuroplasticity, network development and refinement, and information processing. In adults, there is increasing evidence for sexually dimorphic characteristics of sleep spindles, which may correlate with cognitive function. SS are thought to be a better correlate of cognition in women, given that spindle amplitude correlates strongly with white matter tracts, and white matter is a better correlate of intellectual performance in women than in men. SS undergo characteristic changes across the lifespan but at the fastest rate during infancy, a time when rapid myelination is occurring and thus may serve as early biomarkers for neurodevelopmental disorders, which are more prevalent in males. To explore the potential role of SS as cognitive biomarkers and examine possible sex differences, we conducted a dEEG study of daytime naps in typically developing infants, concurrent with behavioral measures. The participants were part of a larger study, covering infants across the first year of life, including both cross-sectional and longitudinal groups. The current dataset includes both groups, at the 9-10 month age point. We extracted SS using a Matlab toolbox, allowing us to look at spindle characteristics including spectral power, peak frequency, globality, spindle length (i.e. duration), and spindle incidence (i.e. density). While controlling for age in days, we found strong correlations between some of these characteristics, which differed in a sex dependent manner. In our sample of 9-10 month-olds (n=42, f=26) spindle spectral power is correlated with globality, and spindle length. Spectral power is also correlated with peak frequency, but only in males. Globality is correlated with peak frequency in the combined group. Spindle length is strongly

correlated with peak frequency and globality across groups, with males having higher peak frequency (t=-2.378, p=.027) and longer duration (t=-2.329, p=.025). Hormonal influence, myelination patterns, and maturational spindle topography are all factors that may contribute to these sex differences. In summary, sleep spindles that occur more globally have a higher peak frequency and higher spectral power. Spectral power and frequency are correlated in males at 9 months, but not in females. Spindle duration is a strong correlate of globality, peak frequency, and spectral power at 9 months, with males having higher peak frequency and longer duration spindles. These characteristics may prove to be biomarkers for maturational patterns of myelination and thalamocortical and cortico-cortical networks.

Title: Propagation of Slow Wave Activity across the Primate Cortex under Propofol-Induced Unconsciousness

Authors: *T. XIE[1,3,4], Z. WU[5], X. ZHU[3], X. SHENG[3], L. CHEN[5], P. BRUNNER[4,6,2]; [2]Dept. of Neurosurg., [1]Washington Univ. Sch. of Med., St. Louis, MO; [3]State Key Lab. of Mechanical Syst. and Vibration, Shanghai Jiao Tong Univ., Shanghai, China; [4]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [5]Dept. of Neurosurg., Huashan Hospital, Fudan Univ., Shanghai, China; [6]Dept. of Neurol., Albany Med. Col., Albany, NY

Abstract: Slow waves are large-scale electrophysiological signals observed throughout the brain during loss of consciousness (LOC) in the course of anesthesia, non-REM sleep, and coma. These waves arise from the synchronization of slow oscillations in the membrane potentials of millions of neurons and have been suggested as the default emergent activity of the underlying networks. The characteristics of slow wave activity can be shaped by variations of physiological parameters and thus provide information about the underlying neural network. Studies suggest that slow wave activity travels across the cortex. However, these studies were limited to single oscillation cycles, i.e., the transition from the downstate to the upstate, and did not consider the

entire oscillation period. Consequently, the spatiotemporal dynamics with which slow waves propagate across the cortex are not fully understood. Our study aims to obtain this understanding by analyzing slow wave activity throughout the transition period between awake and LOC.To achieve this, we analyzed electrocorticographic (ECoG) signals from the lateral surface of two resting monkeys that underwent Propofol-induced LOC. In our analysis, we were interested in determining the spatiotemporal dynamics of the slow wave activity throughout the different stages of the Propofol-induced LOC. To extract the slow wave activity, we calculated the cross-frequency modulation coupling between slow wave oscillations (0.5-4 Hz) and broadband gamma activity (55-145 Hz). Our results show that the slow wave activity exhibits two distinct stages as it travels through the entire hemisphere throughout the Propofol-induced anesthesia. The first stage (STAGE-I) encompasses an approximately one-minute-long period following the Propofol injection. The spatial dynamics of this period resemble those of previously reported default networks, which are known to have vast anatomical connections through the brain, and are considered to relate to higher-order functions. The second stage (STAGE-II) encompasses the approximate 5-20 minutes after Propofol injection. In this period, the spatiotemporal dynamics of the slow wave activity exhibit the propagation of the Propofol's effect on individual brain regions. In this, the slow wave preferentially originated from the lateral sulci and anterior cingulate gyrus, and propagated along the anterior-posterior direction. In summary, these results shed some light on the propagation of slow wave activity throughout the cortex. This understanding could lead to new diagnostic methods that characterize pathologies directly from the brain's slow wave activity.

Title: Eeg phenotyping as a tool to characterize preclinical rodent models of brain disorders

Authors: *V. DUVEAU, C. RUGGIERO, A. EVRARD, H. GHARBI, C. ROUCARD, Y. ROCHE;
Synapcell SAS, Saint Ismier, France

Abstract: The development of new neurotherapeutics has been facing a tremendous challenge for over a decade. Several promising drug candidates for brain disorders indeed fail too late in the drug development process, most of the time for lacking effectiveness. Finding the most relevant pathological model as well as translational read-outs very early on, count among the biggest hurdles to overcome in CNS drug development. In addition, behavior, or imaging assays remain preferred techniques to investigate drug candidates' efficacy on preclinical animal models, despite limitations for translational validity assessment. In this work, we took advantage

of electroencephalography (EEG) to give a direct access to brain function with high time resolution and a great sensitivity. Indeed, neuronal network oscillations are highly conserved across mammals, which makes EEG a translational brain monitoring technique that bridges the gap between preclinical research and clinical outcomes when it comes to the development of new neurotherapeutics. The aim of this communication is to show how EEG and its related methodologies can be used to reveal or at least improve the translational value of rodent models of brain disorders. We have identified and validated translational EEG biomarkers for several brain disorders in relevant rodent models with the help of our proprietary Cue® platform. These biomarkers are being routinely used to support our predictive drug discovery programs. Epilepsies : Based on the detection of epileptic discharges by EEG, we have characterized non-convulsive models of mesio-temporal lobe and general absence epilepsies and developed solutions ranging from the screening of small libraries of compounds to the selection and validation of lead compounds. Essential tremor: In a pharmacological induced mouse model of essential tremor, we have identified a specific EEG biomarker that relates to the tremor and shows a pharmacosensitivity to drug of reference and useful for drug development. Parkinson's disease (PD): We have identified specific EEG signatures in two models of Parkinson's disease, mimicking either the evolution of the disease, or the late stage of PD and dyskinesia. These new biomarkers allowed the development of drug discovery programs designed for evaluating new neurotherapeutics and neuroprotective agents against PD. Conclusion: When "augmented" by EEG Biomarkers, rodent models of brain disorders can improve the predictivity of preclinical research, accelerating therefore the discovery of new innovative treatments for patients.

Title: Bidirectional effects of cholinergic signaling on amygdala network oscillations

Authors: *J. X. BRATSCH-PRINCE, J. W. WARREN, III, G. C. JONES, A. J. MCDONALD, D. D. MOTT;
Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: In the brain, the neurotransmitter acetylcholine (ACh) is implicated in a wide variety of functions including emotional and social behaviors. Alterations or deficiencies in these

behaviors are major features of anxiety disorders. Individuals with anxiety disorders show deficits in cholinergic receptors and basal forebrain cholinergic signaling, and in rodent models lesions of cholinergic cells in the brain can induce anxiety-related behaviors. The amygdala receives some of the densest cholinergic projections in the brain, is important for emotional and social behaviors, and shows aberrant activity in anxiety disorders. How ACh modulates network activity, measured in network oscillations, in the amygdala is not clear but can offer insight into how ACh deficits may alter emotional and social behaviors. This study explores the effects of ACh signaling on amygdala network oscillations. Brain slice recordings of the local field potential (LFP) in the basolateral nucleus of the amygdala (BL) show a bidirectional effect in response to optogenetically released ACh: an early onset desynchronization followed by a robust theta frequency synchronization. At the single cell level, the same released ACh in pyramidal neuron recordings showed a similar biphasic response that matched in time with changes in the LFP: an early onset hyperpolarization followed by a depolarizing response and theta membrane potential oscillation. Recording inhibitory currents in these same neurons in response to ACh showed an early barrage of events followed by large theta frequency inhibition, which could synchronize pyramidal neuron firing. These early and late events were mediated by nicotinic and muscarinic ACh receptors, respectively. This indicates combined ACh action on pyramidal and interneurons in the BL drives changes in the LFP. Interestingly, while low amounts of ACh stimulation could produce the early nicotinic network events underlying LFP desynchronization, increasing amounts of ACh were required for the later muscarinic-mediated theta oscillations. Collectively, these studies indicate that differing levels of cholinergic stimulation have profoundly different effects on amygdala network oscillations. Thus, deficits in cholinergic functioning in anxiety disorders could result in aberrant amygdalar activity and contribute to deficits in emotional and social behaviors in these individuals.

Title: Not all unconscious states are equal - differences in response to electrical stimulation during sleep and under general anesthesia in humans

Authors: ***R. ZELMANN**[1], P. KAHALI[2], A. C. PAULK[1], F. TIAN[2], B. CROCKER[1], G. COSGROVE[4], Z. WILLIAMS[3], P. L. PURDON[2], S. S. CASH[1];

[1]Neurol., [2]Anesthesia, [3]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [4]Neurosurg., Brigham and Women's Hosp., Boston, MA

Abstract: Even though being asleep or under general anesthesia are considered states of unconsciousness, they are separable physiological conditions. Under the assumption that the brain's response to perturbations is different during sleep or general anesthesia in contrast to a conscious state, we used multi-region single-pulse direct electrical stimulation (SPES) to probe the human brain in each of these states.
Twelve patients with semi-chronic depth-electrodes implanted for clinical reasons to localize the focus of their seizures voluntarily participated in this study after fully informed consent. We performed SPES (biphasic pulse: 7uA, inter-stimulation interval 2+/-0.25s) sequentially across 4-5 brain regions while simultaneously recording intracranial EEG (iEEG) in the epilepsy monitoring unit (EMU) during wakeful periods and sleep (N=8) and in the operating room (OR) while awake and under propofol induced general anesthesia (N=9).
Focusing on the cortico-cortical evoke potentials (CCEP) in response to SPES, the iEEG was normalized per trial and low-passed filter below 10Hz, after removal of stimulation artifact. We computed the percentage of recorded channels responsive to SPES. We compared anterior (frontal and anterior cingulate cortex) vs. temporal and posterior cortex. We also measured complexity with the perturbational complexity index (PCI) in the first 600ms in the raw iEEG. Wilcoxon test was used for paired comparisons.
We found that the percentage of responsive channels in the brain was significantly smaller under anesthesia than during wakeful periods ($p<0.01$; N=44 channels). When dividing per region, this difference held when stimulation occurred in anterior channels ($p<0.01$; N=24), but not in temporal/posterior channels. In contrast, wake vs. sleep were statistically different only when considering the percentage of responsive channels with stimulation in temporal/posterior regions ($p=0.04$; N=13). Importantly the number of responsive channels was not significantly different between wake in the EMU vs. wake in the OR. Even after removing channels considered epileptogenic (as indicated by the clinical considerations), all these comparisons prevailed.
Complexity was smaller during anesthesia ($p<0.01$; median PCI= 52.3) compared to wake OR (PCI= 107.3) and during sleep ($p<0.01$; PCI=45.8) compared to wake EMU (PCI=86.4).
The brain's distinct response to stimulation during different states not only improves our understanding of the mechanisms of unconsciousness, but has also therapeutic implications for disorders of consciousness, and could inform assessment tools to ensure loss of consciousness during general anesthesia.

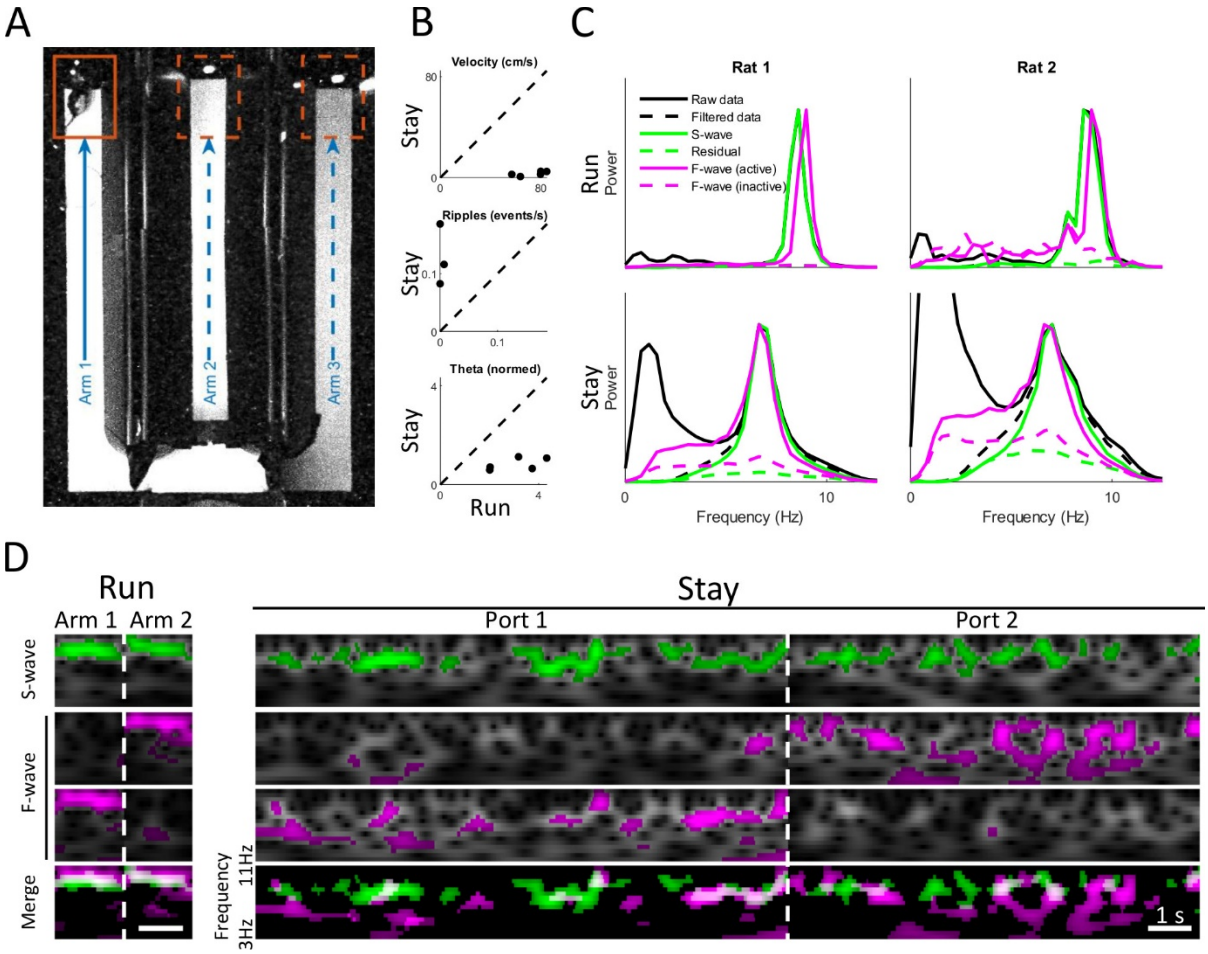
Title: The hippocampal theta rhythm is present and informative during stillness

Authors: *G. AGARWAL[1], B. R. LUSTIG[2], E. PASTALKOVA[2], A. LEE[2], F. SOMMER[1];
[1]UC Berkeley, Berkeley, CA; [2]Janelia Res. Campus, Ashburn, VA

Abstract: Oscillations in the local field potential reflect the synchronized activity of large neuronal populations. Among the most studied is the ~8 Hz theta rhythm, found in the hippocampus during locomotion. The theta rhythm is thought to group temporal sequences during navigation. However, it is unclear whether this rhythm is present or functional during periods of immobility. We use two complementary signal extraction approaches to directly compare theta during movement and stillness in rats navigating a maze. The first is structural: PCA reveals a single oscillatory component ("S-wave") that dominates the multi-electrode signal for the duration of the recording. The second is functional: we developed a novel supervised learning method to isolate oscillatory features ("F-waves") that activate selectively depending on the animal's position. During running, both S- and F-waves are narrow-band and high-amplitude. However, F-waves consistently oscillate at a higher frequency than the S-wave. This frequency shift is a hallmark of the phenomenon of hippocampal phase precession and suggests that S- and F-waves respectively correspond to pacemaker inputs and place cells, as proposed by O'Keefe and Recce's dual-oscillator interference model. We find that during immobility, both oscillations are weaker but clearly present, exhibiting substantial and independent fluctuations in their amplitudes and frequency. Unlike during running, the relative phase of the S- and F-waves is unlikely to carry useful information during stillness, since they are uncoupled in both time and frequency. Our work challenges the common view in the literature that the theta rhythm is absent during stillness, showing that not only is theta present, it also carries information about the animal's position.



A) Alternating maze task used to compare theta during run (blue) and stay (red). B) Stay periods contain biomarkers associated with quiet immobility. C) Power spectra comparing raw LFP, F-, and S-waves. D) Spectrograms show F- and S- waves are uncoupled during stillness. Significant increases in power are colored.

Title: What makes a neuron fire? Spike-LFP relationship in human medial temporal lobe

Authors: *D. J. COLLINS[1], L. KOLIBIUS[2], G. PARISH[3], R. CHELVARAJAH[4], D. ROLLINGS[4], V. SAWLANI[4], H. HAMER[5], S. GOLLWITZER[5], J. LANG[5], G. KREISELMEYER[5], B. STARESINA[3], M. WIMBER[2], S. HANSLMAYR[2];

Abstract: What makes a neuron fire? Previous studies have identified single neurons in the human medial temporal lobe (MTL) that selectively fire to complex, high-level stimuli such as faces and landmarks. These studies have primarily focused on characterising the response profiles of these neurons, for example, the latency of spiking onset and selectivity of spiking response and sensory modality. However, apart from the investigations of Rey et al. (2014), the role of intrinsic oscillatory dynamics in temporally coordinating the firing of such human single neurons has largely been neglected. In the present study, we investigate the role of the local field potential (LFP) in orchestrating single unit activity. To achieve this, 11 patients with intractable epilepsy were implanted bilaterally with microwire hybrid (Behnke-Fried) electrodes in the MTL. We took recordings as patients viewed images presented on a screen. Images were of famous people, landmarks and family relations. A single unit was said to be 'tuned' to an image if its post-stimulus firing rate increased significantly relative to its baseline firing rate, computed across all stimuli. Units could be tuned to one image or several, and each image could have multiple units tuned to it. For analysis, trials were separated into tuning trials where a tuned unit responded and non-tuning trials where there was no response. We found an increase in theta/alpha (4-14Hz) induced power on tuning trials relative to a pre-stimulus baseline, beginning ~100ms after stimulus onset. We also found a broad increase in pairwise phase-consistency of the LFP (1-8Hz) on all trials relative to pre-stimulus baseline, beginning ~200ms after stimulus onset. Both oscillatory measures preceded the average response latency of tuned units, which was ~300ms after stimulus presentation. Our results show that a modulation of oscillatory power in the MTL is concomitant with a spiking rate increase in selectively tuned units. Our results also reveal that phase reorganisation in the MTL following stimulus presentation is a global phenomena that occurs regardless of the presence of selectively spiking tuned units. Further work will involve investigating the spike-LFP relationship through spike-field coupling and multivariate pattern analysis.

Title: Theta-associated nonspatial sequence coding in hippocampus

Authors: *K. W. COOPER[1], L. LI[2], F. AGOSTINELLI[3], M. SARAF[1], G. A. ELIAS[1], P. BALDI[3], A. BORNSTEIN[4], B. SHAHBABA[2], N. FORTIN[1];

Abstract: The hippocampus is critical for our memory of sequential experiences. While this capacity is conserved across species and modalities, the underlying neural mechanisms remain unclear. Although considerable evidence indicates hippocampal activity provides strong temporal coding within task events, it remains to be determined how it supports the integration of events in a sequence. Of particular interest here is the finding that theta oscillations capture information about sequences of past, present, and future locations within a single theta cycle. To determine whether this function of theta extends to the processing of nonspatial information, we recorded hippocampal activity as rats performed an odor sequence memory task. Using novel statistical methods, we focused on decoding the information contained in the activity of simultaneously recorded hippocampal ensembles during odor presentations (when strong theta oscillations are observed). We discovered that, within individual odor presentations, hippocampal ensembles exhibited theta-associated replay of the sequential relationships among stimuli. In addition, when focusing the decoding on a specific theta cycle during each odor presentation, we found that ensembles represented information about past, present and future stimuli within individual theta cycles. These findings suggest theta oscillations play a key role in supporting the hippocampus's ability to encode, preserve, and predict the order of nonspatial experiences.

Title: Changes in cortical functional geometry across states of awareness under anesthesia

Authors: *D. I. CAMPBELL[1], K. V. NOURSKI[2], *H. KAWASAKI[2], M. I. BANKS[1];
[1]Dept. of Anesthesiol., Univ. of Wisconsin Sch. of Med. and Publ. Hlth., Madison, WI; [2]Dept. of Neurosurg., The Univ. of Iowa, Iowa City, IA

Abstract: Intro: Leading theories of consciousness predict that loss of consciousness (LOC) under anesthesia is marked by decreased functional integration and differentiation in the brain. Previous work has demonstrated disrupted global integration across several canonical resting-state networks as well as loss of differentiation of brain responses to external stimuli, but how specific networks reorganize upon LOC is unclear. Diffusion Map Embedding (DME) maps data into a space whose geometry represents the functional connectivity structure of the underlying networks. DME can elucidate hierarchical structure in high dimensional cortical networks and how this structure changes with aging and in psychiatric disorders. We applied DME to test the hypothesis that integration between and differentiation of sensory and higher-order networks is disrupted upon LOC.
Methods: Resting-state intracranial recordings were obtained during induction of propofol anesthesia from neurosurgical patients implanted with electrodes in temporal, parietal, and frontal cortex to identify epileptic foci. Three brain states were compared: pre-drug wake (W), sedated/responsive (S) and unresponsive (U). Channel x channel adjacency matrices were computed as pairwise, thresholded, gamma (30-70Hz) power envelope correlations; affinity matrices derived by cosine similarity were subjected to DME analysis focused on cortical regions of interest (ROIs): primary sensorimotor, auditory core, higher-order auditory, and prefrontal cortex (PFC). Integration was assessed as the Euclidean distance between ROI centroids in the embedding space, and differentiation assessed via the silhouette score of each ROI. Centroid distances and silhouette scores were then compared across all states.
Results: Distance between ROI centroids systematically increases from W to U, suggesting that cortical regions become less functionally integrated upon LOC. Shifts from W to U are especially pronounced between auditory core and PFC and between sensorimotor and PFC (n=9/10 subjects). Furthermore, silhouette scores of PFC clusters increase following LOC in PFC (n=9/10), suggesting an increase in intra-ROI functional differentiation in higher-order cortex.
Conclusions: The observation that the functional integration between PFC and sensory ROIs is disrupted upon LOC is consistent with predictions made by both information integration and global neuronal workspace theories. The increased silhouette score in PFC reflects increased homogeneity in functional connectivity which decreases the repertoire of the PFC network overall.

Title: Basal Forebrain GABAergic Projections to the Amygdala and the BNST in Wistar Rats: A Retrograde Tract-Tracing Study

Authors: T. TUNA, *G. UNAL;
Bogazici Univ., Istanbul, Turkey

Abstract: Basal forebrain (BF) GABAergic neurons from the medial septum selectively target GABAergic interneurons of the hippocampus, forming a disinhibitory circuit that indirectly contributes to the excitation of principal cells. This GABAergic projection is key for the generation of hippocampal theta oscillations (4-12 Hz), which correlate with hippocampal forms of learning and memory including spatial navigation. We test if BF GABAergic projections carry out a similar modulatory function in all the limbic system structures they target. The basolateral amygdala complex and the bed nucleus of the stria terminalis (BNST), also known as the extended amygdala, respectively underlie phasic and sustained fear. BF GABAergic projections innervating these structures may form a similar disinhibitory circuit contributing to local network activity underlying fear and anxiety. We revealed BF GABAergic projections to the amygdala and the BNST by using retrograde tract-tracing and fluorescence immunohistochemistry in adult Wistar rats. In stereotaxic surgeries, red and green Retrobeads were injected unilaterally to different subnuclei of the amygdala and the BNST. The brains were obtained and sliced following 3 days of survival for axonal transport of the tracer. Immunohistochemistry was done for different molecules that may be cell-type or sub-group specific biomarkers. Retrogradely-labeled neurons in different basal forebrain nuclei were counted and mapped. Local connections of the BNST were also examined, as this structure is itself located within the basal forebrain. Injections confined to the lateral and basolateral nuclei of the amygdala revealed the largest number of labeled neurons in the ventral pallidum (VP) and substantia innominata (SI). Fewer labeled neurons were observed in the horizontal limb of the diagonal band of Broca. Remaining BF nuclei were mostly spared, occasionally containing a few labeled neurons. We identified a group of labeled calbindin (CB)-immunopositive putative GABAergic neuron in the VP and SI. Another potential GABAergic subgroup contains fewer neurons that were parvalbumin (PV)-immunopositive. Injections confined to the medial division of the BNST revealed relatively few labeled neurons in the aforementioned BF nuclei. The majority of the labeled neurons were located in the preoptic nuclei of the hypothalamus, especially the medial preoptic nucleus. Several labeled cells were located in other BNST nuclei, some of which were CB- or PV-immunopositive. Current efforts aim to differentiate GABAergic interneurons and long-range GABAergic cells that resemble septo-hippocampal neurons within these populations.

Title: Imaging subthreshold voltage oscillation with cellular resolution in the inferior olive in vitro

Authors: *K. DORGANS[1], B. KUHN[2], M. UUSISAARI[1];
[1]Neuronal Rythms in Movment, [2]Optical Neuroimaging Unit, Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: Imaging neuronal activity from inferior olivary nuclei is still considered as a challenge. Despite its crucial role within motor learning, and key role inside the cerebellar system, physiology and function of inferior olive (IO) are poorly understood. Because of the atypical properties of IO neurons as well as the localization of IO itself (on the ventral part of brainstem) already-existing tools for imaging neuronal activity are barely applicable and require proper refinement. Subthreshold activity of IO neurons is a central phenomenon emerging from electrical coupling among IO neurons and give a tempo for network suprathreshold (firing) synchronicity. Here, we developed a method for delivering voltage sensitive dye ANNINE6-plus (A6+) in IO for imaging subthreshold activity of IO with higher signal-to-noise ratio (SNR) than conventional bath application methods. Using stereotactic surgery, we delivered a non-fully dissolved form of ANNINE6-plus that progressively and durably stains stained IO neuron membranes 7 days after injection. After such an extended incubation period, A6+ labelling is homogenized and spreads within IO allowing wide-field imaging *in-vitro* with an excellent coverage of the structure. Also, we performed high-magnification voltage imaging with CMOS camera (1.2x1.2 um^2 resolution) and could monitor subcellular oscillations of membrane voltage on single cell level. Importantly, A6+ is an ultrafast, pure and electrochromic sensor that offers an alternative to genetically-encoded sensors. A6+ is an excellent tool for visualizing subthreshold oscillations (STO) of IO neurons that allowed identifying clusters of neuronal activity from spontaneously oscillating neurons without trial averaging, deconvolution or any machine learning-based image processing. Also, we could study IO network properties by triggering STO resonance after electrical activation of excitatory inputs. The long-lasting staining demonstrated here could be combined with deep brain imaging using implantable GRIN lenses.

Title: Alternating sources of inhibition during behavior: complementary recruitment of hippocampal cholecystokinin- and parvalbumin-expressing perisomatic interneurons on the time scale of seconds

Authors: *B. DUDOK[1], P. M. KLEIN[1], E. HWAUN[1], B. LEE[2], Z. YAO[2], O. FONG[2], J. C. BOWLER[3], S. TERADA[3], F. T. SPARKS[3], G. G. SZABO[1], J. S. FARRELL[1], J. BERG[2], T. L. DAIGLE[2], B. TASIC[2], J. DIMIDSCHSTEIN[4], G. FISHELL[4], A. LOSONCZY[3], H. ZENG[2], I. SOLTESZ[1];

Abstract: Basket cells (BCs) are perisomatic GABAergic interneurons (INs) targeting the somata and proximal dendrites of pyramidal cells (PCs), efficiently controlling the spiking output of the network. Two types of basket cells are identified by the expression of either parvalbumin (PV) or cholecystokinin (CCK). PV- and CCK BCs display a striking complementarity in their physiological properties. While fast-spiking PV BCs receive strong glutamatergic input and evoke fast and temporally precise postsynaptic responses, regular spiking CCK BCs receive fewer glutamatergic inputs and their postsynaptic responses are more variable in timing and amplitude. The role of PV BCs in regulating the precise timing of PC firing during synchronous network states (such as theta, gamma and ripple oscillations) is well established. However, the circuit function of CCK BCs remains poorly understood. We have used single cell RNA sequencing, *in vitro* and *in vivo* electrophysiology, as well as *in vivo* calcium imaging and optogenetics to characterize a transgenic mouse line (Sncg-Flp) that labels CCK BCs with high specificity in the CA1 region of the hippocampus in both sexes. In head-fixed mice running voluntarily on a linear treadmill, we found that CCK BC activity is suppressed during the on-line brain state associated with locomotion and theta oscillations, as well as during sharp wave-ripple (SWR) episodes, associated with immobility and the off-line replay neuronal sequences. In contrast, CCK BCs were maximally recruited during a brain state characterized by immobility, a lack of synchronous network oscillations, and suppressed PC

activity. By simultaneous calcium imaging from CCK and PV INs during spontaneous behavior, we found a striking negative correlation between their activities on the time scale of seconds. Optogenetic driving of PV INs triggered strong suppression of CCK IN activity compared to no-opsin and no-light controls *in vivo*, suggesting a disinhibitory push-pull mechanism contributing to the temporal segregation of PV and CCK IN activity. Simultaneous large-scale calcium imaging from hundreds of PCs and either PV- or CCK INs revealed that while PV IN activity is strongly and positively correlated to average network activity on the time scale of seconds, CCK IN activity scales negatively with network activity. Taken together, efficient inhibition of CCK by PV INs inversely couples the activity of two complementary perisomatic inhibitory systems on the behaviorally relevant time scale of seconds, resulting in a "hand-off" of inhibition during brain state transitions.

Title: Using fast visual rhythmic stimulation to control inter-hemispheric phase offsets in visual areas

Authors: *Q. CHEN[1], D. WANG[2], K. SHAPIRO[1], S. HANSLMAYR[2];
[1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Spike timing dependent plasticity (STDP) is believed to be important for neural communication and plasticity in human episodic memory, but causal evidence is lacking due to technical challenges. Rhythmic sensory stimulation that has been used to investigate causal relations between oscillations and cognition may be able to address this question. The challenge, however, is that the frequency corresponding to the critical time window for STDP is gamma (~40 Hz), yet the application of rhythmic sensory stimulation has been limited primarily to lower frequencies (<30 Hz). It remains unknown whether this method can be applied to precisely control the activation time delay between distant groups of neurons at the millisecond scale. To answer this question and examine the role of STDP in human episodic memory, we simulated the STDP function by controlling the activation time delay between the left and right visual cortices during memory encoding. This was achieved by presenting flickering (37.5 Hz) movie pairs in

the left and right visual fields with a phase lag of either 0, 90, 180 or 270 degrees. Participants were asked to memorize the two movies within each pair and the association was later tested. Behavioral results revealed no significant difference in memory performance across conditions with different degrees of gamma phase synchrony. Yet importantly, our study showed for the first time, that oscillatory activity can be driven with a precision of 6.67 ms delay between neuronal groups. Our method hereby provides an approach to investigate relations between precise neuronal timing and cognitive functions.

Title: Robust alternative to the righting reflex to assess arousal in rodents

Authors: *S. GAO[1], D. CALDERON[2];
[1]Weill Cornell Med., New York, NY; [2]Weill Cornell Med., NYC, NY

Abstract: Abstract: The righting reflex (RR) is frequently used to assess level of arousal in animal models across multiple neurological disorders. RR produces a single binary result to infer awakening, often without further behavioral corroboration. We found that RR is an unreliable metric for arousal/recovery of consciousness. We hypothesized that the combined analysis of cortical activity and motor behavior that accompany RR is a superior criterion to properly calibrate and establish level of arousal in rodents. To test our hypothesis, we simultaneously recorded local field potentials (LFPs) and movement in mice while decreasing anesthetic concentrations. We delineated cortical dynamics during emergence from anesthesia by applying a smoothed-Z score to extract dominant frequencies from spectrogram. Then, we implemented KMeans to obtain cortical sub-states. Finally, we used density estimation and an abrupt change detection algorithm to segment cortical activity into periods together with examining motor behavior in videos. We established a cortico-motor regimen that calibrated levels of arousal that consisted of five cortical periods with progressive restored motor behavior during emergence from isoflurane anesthetic. Results were further validated in sevoflurane and the hypoglycemic coma model. Our data demonstrated that initial spontaneous RR events occur at a low arousal state, and that a single RR does not predict recovery stage. We also observed multiple RR events and they are clearly distinguishable depending on cortical activity and motor behavior context. We demonstrated that RR alone is an imprecise measurement of arousal level.

Title: Local synapses alter spike responses in models of globus pallidus pars externa

Authors: *E. OLIVARES[1], M. H. HIGGS[2], C. J. WILSON[3];
[1]Univ. of Texas At San Antonio, San Antonio, TX; [2]Univ. of Texas at San Antonio, San Antonio, TX; [3]Univ. Texas San Antonio, San Antonio, TX

Abstract: The globus pallidus pars externa (GPe) is usually considered a relay nucleus that inverts the inhibitory signal arriving from the striatum and passes it to the basal ganglia output neurons. GPe neurons are also interconnected by inhibitory interconnections, but their function is unknown. GPe neurons are fast autonomous oscillators whose local axon collaterals create an active local inhibitory network, but spike timing correlations among GPe neurons have been elusive. To determine how local connectivity might affect GPe steady-state firing and responses to stimuli, we constructed network models of GPe. As GPe neurons are intrinsic oscillators, we simulated them using phase models that allow us to predict the time of the next spike considering all the synaptic inputs arriving during the inter-spike interval (ISI). We experimentally measured the firing rates, and phase resetting curves of a sample of GPe neurons (n=19) in mouse brain slices. Using the experimental dataset, we generated artificial neurons with a diversity similar to that of the recorded neurons. As the connectivity pattern in GPe is unknown, we placed the cells in two different neural architectures (small-world and random). Each network was created using the same set of 1000 neurons and the same total number of connections (10000). Both networks reduced the GPe neurons' firing rates and caused substantial variation of ISIs. The local networks did not generate global synchrony, and strong pairwise correlations were mostly limited to monosynaptically connected pairs. When stimulated by a shared input, the post-stimulus time histogram (PSTH) in both networks shown larger peaks and shortened responses when compared to disconnected neurons. The increase in the transient response was associated with the perturbation in the stationary density of phases generated by the local inhibitory synaptic barrage which induce the neurons to spent more time at late phases, i.e. near spiking. Our results were robust across the network architectures and show that in sparsely coupled networks of autonomous oscillator neurons like GPe, the local inhibitory activity does not generate global synchrony, however, it increases the network sensitivity to external inputs by changing the steady-state phase distribution.

Title: Kinetics and spatial profile of fast-firing-based inhibition in layer 2/3 medial entorhinal cortex and its implications for theta-nested gamma oscillations

Authors: *F. R. FERNANDEZ[1], G. R. VIA[2], C. C. CANAVIER[2], J. A. WHITE[1];
[1]Biomed. Engin., Boston Univ., Boston, MA; [2]Cell Biol. and Anat., LSU Hlth., New Orleans, LA

Abstract: Medial entorhinal cortex (mEC) contains spatially tuned grid cells that may play a significant role in spatial navigation. mEC also generates theta-nested gamma oscillations that synchronize grid cell spike activity to specific phases of network-wide theta oscillations. The mechanisms underlying network activity in mEC are often accounted for with a canonical cortical circuit model that includes negative feedback from inhibitory cells that is crucial to both theta-nested gamma oscillations and the spatial tuning of grid cells. In mEC, inhibitory interneurons provide the sole synaptic communication path between stellate cells that constitute a substantial fraction of the grid cell population. Key to all these roles are the synaptic kinetics and spatial profile of inhibition originating from fast-firing interneurons. To address the nature of inhibition in mEC, we carried out intracellular paired recordings of layer 2/3 PV-PV and stellate-PV cells at distances between 20 to 400 μm in horizontal brain slices from mice. The likelihood of synaptic connection from PV cells dropped off precipitously at intercellular distances greater than 150 μm. Further, the inhibitory decay time constant between PV cells was much smaller (~2.3 ms) than that between PV and stellate cells (~9.8 ms). PV-PV synapses also depressed more rapidly and recovered more slowly than those targeting stellate cells. Finally, gap junctions between PV cells were somewhat rare, with only 33 out of 122 pairs expressing a gap junction connection. These connections, however, were more likely in mutually connected (~0.53) pairs. Using the above data, we implemented an interneuronal network model with sparse inhibitory connections and a network-wide sinusoidal theta drive. We used the interneuron model of Golomb et al. (2007) to match the type II excitability we have previously demonstrated in the PV+ interneurons. In the presence of heterogeneity and noise, nested gamma was not evoked by the theta drive. However, an excitatory pulse delivered to the population midway through the rising phase of theta, when the stellate cells preferentially fire experimentally, did evoke theta-nested gamma oscillations. Unlike classic PING mechanisms of gamma generation in which the excitatory population fires on every gamma cycle, theta-nested gamma was initiated by excitation with subsequent gamma cycles maintained by mutual connections within the inhibitory population. Since these interneurons require excitatory input for nested gamma, but stellate cells do not to fire throughout the peak of theta drive, our proposed mechanism is consistent with experimental observations.

Title: Effective tuning of inter-regional coupling strength and latency through changes in local oscillatory dynamics

Authors: ***S. BENITEZ STULZ**[1], G. DUMONT[2], B. S. GUTKIN[2], D. BATTAGLIA[1];
[1]INS, Univ. Aix-Marseille, Marseille, France; [2]Group For Neural Theory, LNC INSERM U960, Ecole Normale Superieure, Paris, France

Abstract: Neuronal populations within local regions frequently undergo oscillatory modulations of their activity. The oscillations of distant populations coupled by long-range connections can phase lock at different stable phase differences and the flexible change of the phase locking patterns between different brain regions has been hypothesized to modulate communication and functional interactions between them. It is therefore important to understand which factors can affect and control the established inter-regional phase relations.A tool which has proved useful to model and predict the behavior of coupled oscillating populations is the phase response curve (PRC). The PRC is a local transformation function that determines the phase-dependent response of an oscillator to any given input, provided by external stimulation or by other oscillating regions. For this reason, the PRC plays an instrumental role in determining how coupled regions can form robust phase-locked modes.Importantly, the PRC strongly depends on parameters of the local regional microcircuit such as the relative strengths of recurrent excitation and inhibition. It is on the contrary not affected by parameters of the distal couplings, such as the coupling strength or delay of propagation. Here we investigate how equivalent changes in phase-locking between regions can be induced by either modifying local connectivity parameters and thereby the PRC, or by modifying features of the long-range inter-regional connectivity. In particular, we show that modifying the strength of connectivity between excitatory and inhibitory neurons within populations can emulate the effects of varying the strength of inter-regional tracts. Or analogously, that modulating the strength of recurrent inhibition within a region can emulate the effects of varying the delay of propagation along inter-regional tracts. These are all examples of what we may call an “effective tuning” of long-range coupling, obtained via the reshaping of local PRCs and oscillations.We thus propose that modifications of oscillatory dynamics within regions may lead to distributed changes in the functional connectivity between regions which are mediated by phase-locking. Such changes would be achieved without the need for plastic changes in long-range structural tracts but just through modulations of local

connectivity efficacy, as the ones that could be induced by neuro-modulation or by the recruitment of alternative types of inhibitory interneurons.

Abstract: The prefrontal cortex (PFC) plays an important role in the representation and execution of goal-directed action. The PFC forms a structured recurrent network of excitatory (E) and inhibitory (I) cells whose dynamical interactions remain poorly understood. Recent studies are outlining inhibitory-excitatory dynamics that do not naturally emerge from common connectivity motifs of E/I connectivity. Theoretical work has attempted to explain these emergent dynamics with generic implementations of inhibition-stabilized networks (ISNs) that are characterized by strong recurrent excitation balanced by strong inhibition. Current implementations of ISNs do not, however, capture the diversity and connectivity patterns of interneuron cell types found in cortex. To begin examining the contribution of different interneuron subtypes to cortical dynamics, we employed in vitro recordings of PFC circuits and computational modeling of ISN networks with a diversity of cell types. We recorded and stimulated spiking activity in acute slices of PFC by combining electrophysiological and optogenetic methods on high-density multi-electrode arrays containing 4,096 closely spaced electrodes. To parse out the contribution of distinct cell types, we developed a spike sorting technique with spline interpolation and principal components analysis to distinguish putative regular-spiking excitatory neurons from fast-spiking inhibitory interneurons. Our sorting algorithm was validated using a targeted combination of viral and optogenetic strategies to activate parvalbumin (PV) interneurons. When probing different subsamples of cortical ensembles, we found that optogenetically activating PV neurons led to a paradoxical increase in excitatory pyramidal activity and a decrease in overall inhibition. We developed an integrate-and-fire model of somatostatin, parvalbumin and pyramidal cell populations with balanced E/I

that captured these effects. Crucially, the model relied on a strong tonic activation of PV cells. With lower tonic PV activation, the paradoxical effect was reversed: excitatory cells reduced their activation upon PV stimulation. The model also relied on precise balanced E/I inputs to individual excitatory cells, whereby the sum of incoming E/I contributions to subthreshold membrane potential cancelled out within a rapid time window. These results offer evidence for ISN regimes, and support the role of balanced E/I activity and strong tonic PV firing rates to generate paradoxical effects of excitatory activation and inhibitory deactivation upon optogenetic stimulation of prefrontal PV neurons.

Title: Differential spontaneous synaptic transmission in resected brain specimens obtained from patients with cortical dysplasia (CD) and non-CD drug resistant epilepsy pathologies.

Authors: ***J. BANERJEE**[1], S. DEY[2], A. B. DIXIT[3], M. TRIPATHI[2], M. C. SHARMA[2], S. P. CHANDRA[2];
[1]All India Inst. of Med. Sci. (AIIMS), N, New Delhi, India; [2]All India Inst. of Med. Sci., New Delhi, India; [3]Univ. of Delhi, New Delhi, India

Abstract: Altered synaptic transmission was associated with drug-resistant epilepsy (DRE) pathologies like cortical dysplasia (CD) and non-CD pathologies like mesial temporal lobe epilepsy (MTLE). Here we have analyzed the spontaneous glutamatergic and GABAergic activity from resected brain samples obtained from patients with CD and MTLE. CD is a developmental malformation of the cerebral cortex and clinical manifestations in CD varies with age at epilepsy onset. In this study brain specimens were obtained from the maximal spiking region (MAX) and minimal spiking region (MIN) of the epileptic foci of early onset (EO) and late onset (LO) patients undergoing electrocorticography (ECoG) guided surgery. Whole-cell patch clamp technique was used to record spontaneous glutamatergic and GABAergic currents from normal-looking pyramidal neurons in slice preparations of resected brain samples. We detect increased frequency and amplitude of GABAergic events in high and low spiking region samples of EO patients, but only in high spiking region samples in LO patients. We did not observe any alteration in the glutamatergic synaptic transmission in the pyramidal neurons of resected samples obtained from patients with CD. Similar experiments were also carried out on resected hippocampal tissues obtained from patients with MTLE. We observed that frequency of

spontaneous glutamatergic activity was higher in the hippocampal samples obtained from patients with MTLE compared to that in case of non-epileptic controls. Further we observed that glutamatergic activity in the hippocampal samples obtained from patients with MTLE were suppressed by α7 nAChR antagonist, methyllycaconitine, suggesting α7 nAChRs may regulate excitatory transmission in MTLE. We did not observe any alteration in the GABAergic activity on to the pyramidal neurons of resected hippocampal samples obtained from patients with MTLE. Our findings indicate that in patients with CD GABAergic activity was altered and in LO patients with CD, $GABA_A$ receptor-mediated epileptogenicity is confined only to the high spiking area, but in EO patients with CD affects low spiking regions as well. In case of hippocampal samples obtained from patients with MTLE increased glutamatergic activity was observed without affecting the GABAergic synaptic transmission. These findings altogether support the concept that mechanism of hyper excitability varies in patients with CD and non-CD DRE pathologies.

Title: Dendritic morphology in the Scn1b knockout mouse model of Dravet syndrome

Authors: A. A. AHMED, J. CHANCEY, *M. A. HOWARD;
Neurosci., UNIVERSITY OF TEXAS AT AUSTIN, Austin, TX

Abstract: Dravet syndrome (DS) is a genetic epileptic encephalopathy characterized by prolonged seizures and severe cognitive and developmental deficits. Mutations in *SCN1B*, which encodes the β1 protein, have been linked to DS. *Scn1b* knockout (KO) mice model DS, exhibiting spontaneous seizures, ataxia, developmental delays, and early death. β1 is critical in regulating neurite outgrowth and various ion channels important for neuronal excitability. Previous work in an *Scn1b* DS model found subicular pyramidal neurons exhibit increased excitability and decreased dendritic arborization. Our goal is to determine how loss of β1 affects one of the primary neuron types involved in learning and memory: hippocampal CA1 pyramidal neurons (PNs). We have found that CA1 KO PNs have enhanced intrinsic excitability and increased synaptic temporal integration, leading to higher firing rates in response to physiological synaptic stimuli. Here, we examined dendritic structure of CA1 PNs from *Scn1b* KO mice to investigate if changes in morphology have a role in the physiological underpinnings

of DS. Because we found hyperexcitability and reduced capacitance in *Scn1b* KO PNs, we hypothesized that CA1 KO PNs would exhibit reduced dendritic arborization. PNs from KO mice and wild-type (WT) littermates, age p15-20, were filled with Neurobiotin during whole cell recordings, stained using Vectastain ABC-HRP and DAB kits (Vector Labs), and reconstructed using Neurolucida. Dendrite length and arborization of dendrites were quantified with Sholl analyses. Both WT and KO PNs exhibited a large amount of heterogeneity in their dendritic morphology. Unlike previous reports in subiculum, we found no overall differences in dendritic arborization or length between WT and KO CA1 PNs. Our synaptic physiology experiments also show changes in synaptic integration in KO PNs. We quantified spine density of proximal and distal apical dendrites of PNs by filling neurons with fluorescent dye via the whole cell recording pipette and using two-photon imaging. Our preliminary data suggest that spine density is unchanged in KO PNs, reducing the likelihood that changes in synapse number underlie altered synaptic integration from loss of β1. Our findings illustrate that dendritic structure is unexpectedly preserved in *Scn1b* KO PNs in CA1 compared to WT PNs, despite changes in excitability and synaptic function. This suggests that dendritic structure does not underlie the hyperexcitability of CA1 KO PNs, nor does the hyperexcitability inherent in this epileptic model induce marked structural plasticity.

Title: Impaired GABAergic interneuron migration and reduced actin remodeling in Trio-associated epilepsy and autism

Authors: *L. EID[1,2], L. LOKMANE[3], P. K. RAJU[1,2], S. TENE-TADOUM[1,2], X. JIANG[1], A. TOUMI[1,2], K. TOULOUSE[1,2], E. DOUET[1], M. LACHANCE[1], J.-C. LACAILLE[2], E. BLOCH-GALLEGO[3], E. ROSSIGNOL[1,2];

Abstract: Mutations in the *TRIO* gene are associated with intellectual disability, autism spectrum disorder (ASD) and/or epileptic encephalopathies (EE). TRIO is a dual guanine nucleotide exchange factor (GEF) that activates Rac1 and RhoA, two Rho-GTPases that regulate actin remodeling. In mice, *Trio* is known to regulate the dendritic development of excitatory neurons, the pathfinding of thalamocortical and spinal cord axons as well as the migration and morphogenesis of developing cerebellar granule cells. However, its roles in the development of GABAergic interneurons (INs) are unknown. Given the central role of Rac1 and RhoA in cytoskeletal remodeling during neuronal migration and the implication of IN pathologies in specific forms of ASD and EE, we hypothesized that *Trio* might be a central regulator of IN migration. In $Trio^{-/-}$ mice, we observed a reduction of tangentially migrating INs. To bypass the embryonic lethality of $Trio^{-/-}$ mice and to further study the underlying mechanisms, we generated $Dlx5/6^{Cre};Trio^{c/c}$ mice, carrying a targeted deletion of *Trio* in INs. These mutant mice display cognitive deficits and reduced anxiety, as well as spontaneous tonic-clonic seizures. Further, patch-clamp recordings reveal a reduction in IPSC frequency, consistent with a reduction of cortical inhibition. Cell imaging reveals a delay in IN migration at e13.5 and e15.5, along with an increase in neurite complexity and length at e13.5. Live-imaging of e13.5 acute organotypic slice cultures reveals slower and less frequent nucleokinesis along with impaired orientation, resulting in reduced net displacement. Live-imaging of medial ganglionic eminence (MGE) explants electroporated with *Lifeact* reveals a more diffuse distribution of F-actin in the soma of migrating INs, with a decreased compaction at the rear of the soma, compared to controls. Further, we observe an increase in the G-actin to F-actin ratio in the soma of mutant INs, together with an overall decrease in G-actin and F-actin, suggesting that the migration deficits induced by *Trio* deletion in INs reflect a reduction in actin turnover. Finally, the electroporation of a mutated version of *Trio* cDNA, lacking either the GEFD1 or the GEFD2 domain, in *Trio* mutant MGE explants reveals the requirement of the GEFD2-RhoA pathway in the morphological development and the migration dynamics of GABAergic INs, with some contributions from the GEFD1-Rac1 pathway. Altogether, our data suggest that *TRIO* loss-of-function mutations impact the migration of cortical INs through impaired actin remodeling resulting from imbalanced RhoA and Rac1 activity, disrupting cortical inhibitory networks and leading to EE/ASD.

Abstract: Epilepsy is a common neurological disorder that affects 1% of the world population. Advanced genome sequencing has identified over 1300 mutations in the human SCN1A, a gene that encodes the alpha subunit of a sodium ion channel Nav1.1. About 20% of SCN1A missense mutations result in an epilepsy disorder, Genetic Epilepsy with Febrile Seizures Plus (GEFS+). GEFS+ is a childhood onset disorder, characterized by febrile (or fever associated) seizures, which can persist beyond 6-7 years of age. A fundamental challenge in understanding the etiology and developing treatments for genetic epilepsies is the heterogeneity of the phenotypes. Previous studies in the lab have shown that the K1270T ("KT") mutation, linked to GEFS+ in humans, causes heat-induced seizure activity associated with a temperature-dependent decrease in GABAergic neuron excitability in a Drosophila knock-in model and impaired inhibitory neuronal firing in patient-derived human-iPSC cell lines. To examine the behavioral and cellular effects of this mutation in mammalian circuits, we introduced the equivalent KT mutation into the mouse Scn1a gene using CRISPR/Cas9. Mutant mouse lines were generated in two widely used genetic backgrounds: C57BL6NJ and 129X1SvJ. In both backgrounds, mice homozygous for the KT mutation had spontaneous seizures and died by postnatal day 23. There was no difference in mortality of heterozygous KT mice compared to wild-type littermates, monitored up to 6 months. Heterozygous mutants exhibited heat-induced seizures at about 42ºC, a temperature that did not induce seizures in wild-type littermates. In acute brain slices at permissive temperatures, current-clamp recordings revealed a significantly depolarized shift in action potential threshold and reduced action potential amplitude in hippocampal parvalbumin-expressing inhibitory interneurons in heterozygous mice. There was no change in the firing properties of excitatory CA1 pyramidal neurons. These results suggest that a constitutive decrease in inhibitory interneuron excitability contributes to the seizure phenotype in the mouse model- lending support to the 'Interneuron disinhibition' hypothesis for seizure generation. The SCN1A KT mouse model represents an important tool for identifying mechanisms of seizure generation in relation to other epilepsy models, and for development of mutation-specific therapies.

Title: B-arrestin recruitment correlated with delta opioid receptor agonist seizure severity

Authors: *A. T. BLAINE, S. PALANT, R. VAN RIJN;
Purdue Univ., West Lafayette, IN

Abstract: The δ-opioid receptor (DOR), is a promising target for the treatment of a variety of neurological disorders, including chronic pain disorders, alcohol use disorder and mood disorders. However, a major side effect that occurs when activating the DOR is the induction of seizures. The arrestin proteins, a family of proteins involved in regulation of DOR signaling as well as other G-protein coupled receptors (GPCRs), have been heavily implicated in this mechanism. Within the arrestin family, the β-arrestin 1 (β-arr1) and β-arrestin 2 (βarr2) isoforms are ubiquitously expressed throughout the body, including the central nervous system, and function by uncoupling phosphorylated GPCRs from their corresponding G-protein, terminating GPCR signaling in a process known as desensitization. Notably, mice with a genetic knockout of β-arr 1 (β-arr 1 KO) show a markedly increased sensitivity to DOR agonist induced convulsions compared to wild type or β-arr 2 knockout (β-arr 2 KO) mice. This observation generated several research questions. 1) What is the cellular mechanism of action for β-arr's involvement in the seizurogenic effects of DOR activation? 2) Are DOR agonists with lower β-arr recruitment efficacy less seizurogenic? 3) Are β-arr 1 KO mice a novel model of status epilepticus? To address these questions, we measured seizure activity (assessed by Racine score), in male and female wild-type, β-arr 1 KO and β-arr 2 KO C57BL/6 mice ($n \geq 6$ per treatment). We utilized three different DOR agonists, which we determined differed in their β-arr recruitment efficacy using cellular signaling assays. When we injected these three agonists, SNC80, ADL5859 and ARM390 at equianalgesic doses, we noted a strong correlation between β-arr 2 recruitment efficacy and seizure intensity. We did not observe any sex differences. In the hippocampus of our mice we also noted a strong increase in pERK following DOR activation. The ERK activation was more pronounced when mice were treated with a DOR agonist with strong β-arr recruitment efficacy, and also was more pronounced in β-arr 1 KO mice. Blocking ERK activation, with the MEK inhibitor SL327, however, did not reduce DOR induced seizure, suggesting that the ERK activation comes as a result of the seizure and is not part of the mechanism of action of DOR-induced seizures. Thus far, our results suggest that the likelihood of seizures induced by DOR activation can be mitigated using a DOR agonist with low β-arr 2 recruitment efficacy. The β-arr 1 KO mice provide an interesting and new model system in which to study seizures and status epilepticus. This work was supported by NIH (R01AA025368, R03DA045897) and the Purdue Drug Institute for Drug Discovery.

Title: Localized elevation of excitation over inhibition is specific to regions of initiation but not propagation in a larval zebrafish seizure model

Authors: *J. NIEMEYER[1], P. GADAMSETTY[1], C. CHUN[2], S. SYLVESTER[2], J. LUCAS[1], H. MA[1], T. SCHWARTZ[1], E. AKSAY[2];

Abstract: Epilepsy is a debilitating neurological disorder afflicting more than 1% of the US population, characterized by recurring seizures and associated cognitive and memory disturbances. Seizures are believed to be caused by an imbalance in coordinated excitatory and inhibitory (E/I) neuronal activity. Previous studies have examined E/I differences but have focused on small subregions of the brain in anesthetized seizure models, yielding seemingly contradictory findings regarding the roles of these cell types. We aimed to reconcile previous findings by measuring excitatory and inhibitory neuron activity during whole-brain imaging to capture seizure initiation and propagation zones simultaneously in a new seizure model: awake larval zebrafish treated with a chemoconvulsant pentylenetetrazol (PTZ). Unlike other models, these small animals permit whole-brain cellular-resolution calcium imaging of multiple cell types. Our specific goals were to 1) thoroughly characterize seizure development in this model and 2) determine the role of E/I balance during seizure initiation and propagation. We find that generalized seizures in this model most often initiate in midbrain and thalamic structures (N= 167 seizures), spreading rapidly to other brain sites. By developing and applying a novel method of detecting initiation and propagation zones we then analyzed E/I balance at these sites, finding significantly higher E/I cell count ratios and activation ratios in initiation vs propagation zones. Further, network analyses of excitatory and inhibitory cell correlations and activity similarity (by PCA) uncovered a prominent role for excitatory cell activity during seizures. Our results suggest that seizure development can be shaped by local E/I cell ratios and biased by excitatory cell population activity. These results imply that E/I activity differs in small regions throughout the brain and that E/I imbalance in specific brain regions may serve as a novel target in epilepsy treatments.

Title: Circumscribing laser cuts attenuate propagation of cortical seizures in a mouse model of focal epilepsy

Authors: *S. LIEBERMAN[1], D. A. RIVERA[2], R. MORTON[2], M. ZHAO[3], N. NISHIMURA[2], T. H. SCHWARTZ[3], C. B. SCHAFFER[2];
[1]Col. of Vet. Med., [2]Biomed Engin., Cornell Univ., Ithaca, NY; [3]Neurolog. Surgery, Weill Cornell Univ., New York, NY

Abstract: One out of twenty-six people will develop epilepsy within their lifetime. Focal epilepsy is characterized by seizures that initiate at one location and propagate through the brain. Medical management fails in about 45% of focal epilepsy cases and resective surgery remains the only alternative, but often leaves patients with severe neurologic deficits. *In-vivo* two-photon imaging of acute seizure propagation has shown that seizures primarily propagate along lateral connection in cortical layers II-III. Therefore, it has been suggested that making minimally invasive incisions to severe lateral connections that seizures propagate along while maintaining vertical connections in the cortex would preserve much of normal brain function while blocking seizure propagation. Tissue ablation by tightly-focused femtosecond laser pulses provides a "laser scalpel" that can make subsurface microincisions in the cortex without damaging the overlying tissue. Previously, we showed that such laser incisions targeted to layers II-IV of the cortex in rats reduced the propagation of acutely-induced seizures. Here we test the long term efficacy of laser cuts in the supragranular layers of the neocortex in interfering with the propagation of seizures in a chronic model of focal epilepsy, and we examine the impact of the cuts on normal cortical function. Chronic focal seizures were induced by microinjection of iron chloride. In mice with laser cuts in layers II-IV of the cortex that encircled the seizure focus, we observed an 80% reduction in the propagation of seizures, as compared with controls. Seizures were also shorter in duration, lower in power, and delayed when they did propagate in animals with cuts. In a preliminary assessment of the impact of these cuts on normal function, we detected no performance difference in a pellet reaching task in mice with a cut centered on the forelimb motor region of the cortex, as compared to control mice. Mice that received not only the encircling, vertical cuts in the cortex, but also a "flat bottom" cut at the bottom of the cylinder showed a reduction in pellet retrieval success that was similar to that seen with a focal stroke. In conclusion, our results suggest cutting lateral connections in the supragranular cortical layers surrounding a seizure focus could be a promising neurosurgical approach that is efficient in blocking seizure propagation while maintaining most normal brain activity.

Title: Variability of Anti-Epileptic Drug Efficacy in the Pentylenetetrazol (PTZ) Zebrafish Behavior Model

Authors: *P. MILDER, T. CUMMINS, *J. MARRS;
Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: In order to evaluate antiepileptic drug (AED) efficacy, pentelyentetrazol (PTZ) has been used to induce seizures within behavioral zebrafish epilepsy models. The PTZ zebrafish epilepsy model has produced conflicting results for the efficacy of three AEDs: Carbamazepine, Lamotrigine, and Topiramate. The goal of our study was to optimize the PTZ assay and then investigate potential causes behind the divergent results across the literature for zebrafish PTZ models. The PTZ assay was optimized using 10 mM PTZ which allowed for consistent seizure activity in 7 days post fertilization (dpf) larvae over a 90-minute period. The 90-minute assay allowed for a broader view of AED efficacy. Seizures were quantified using the large count value and collected in 15-minute time increments using the Zebrabox™ viewpoint software. The data was then examined using the total number of large counts over the 90-minute assay to evaluate the level of seizure activity. We used our optimized assay to test two hypotheses: the efficacy of AEDs will vary based on the circadian effects of light-dark conditions during development and the efficacy of AEDs will depend on whether AEDs are administered acutely with PTZ or whether the zebrafish are pretreated with the AEDs before PTZ exposure. The light exposure during development resulted in differences of AED efficacy in Carbamazepine, Lamotrigine and Topiramate. There were differences in the behavior of pretreated vs acute treated zebrafish in Lamotrigine. Inconsistencies seen within the behavioral assays is due to variability in methodology. The outcomes of our experiments provide a more consistent and effective model that will facilitate comparisons of various drugs for efficacy. We have shown that the zebrafish PTZ behavioral assay can be used to accurately and consistently evaluate AED efficacy.

Title: Mechanisms of neurological protection and death related with transcranial magnetic stimulation using kindled rats.

Authors: *W. MORENO ROMAN[1], P. RODRIGUEZ[1], L. F. HERNANDEZ, Jr.[2], M. RUBIO-OSORNIO[1], C. R. OSORNIO[3];
[1]Inst. Nacional de Neurologia y Neurocirugia, Mexico city, Mexico; [2]INSTITUTO NACIONAL DE NEUROLOGIA Y NEUROLOGIA, Tizayuca, Mexico; [3]INNN MVS, México, D.F., Mexico

Abstract: Mechanisms of neurological protection and death related with transcranial magnetic stimulation using kindled rats. Abstract Epilepsy is an extensively studied neurological disorder, research has been made from animal models to human experimentation, as a result there are several medications and some surgical treatments aim to control this disorder, despite this 30% of patients are hard to control. Transcranial magnetic stimulation (TMS) has been used as an anti-epileptic treatment and neuro-protective barrier, even though this is used as a treatment there is no cellular, molecular or physiological evidence to sustain this. The way we are evaluating cell death is with BCL-2, BAX, citocrom-c and caspase 3 and 8, all of this markers will tell us the pathway of cells death or protection. We are using 25 male Wistar rats, equally divided in five groups, the experimental and sham groups will get an electrode implant by a stereotaxic surgery at the amygdala, the implant will be use for the electrical stimuli using the Kindling model in the experimental group, once the subjects present the conduct associated to Racine 5 they will be randomly included to the TMS or kindling group, TMS group was stimulated before the electrical stimulus, each rat had its own time for the TMS which depended on the time of the last seizure, every EEG was analyzed in both groups, measuring amygdala and cortex response, after ten sessions in Racine 5 the rat will be decapitated immediately after the seizure, the brain will be extracted, dividing it in half, the right hemisphere will be fixated with paraffin for immunohistochemistry, the other half will be dissected for the bulbus olfactorius, motor cerebral cortex, hippocampus, amygdala and cerebellum. So far we have analyzed the EEG and the recordings for both experimental groups, the recording were also examined by a third party to compere the results, showing a difference between groups in a conduct stand of view, the time of seizures decreased as well in the TMS group. Based on the information above our preliminary results shows that there is a behavioral difference during the seizure, with the TMS group having less a lower seizure in time, only with this results we can say that TMS has an effect in epilepsy, the mechanisms in with the effect is made is still unclear, it can either be from the neuro protection created, thus, limiting the recruitment of fibers and structures produced by the recruitment provoked by epilepsy, on the other hand cell death can also be the cause of this behavioral changes, having fewer neurons to work within the structures affected will also reduce the time.

Title: Sleep-seizure EEG associations predictive of severity and death risk in epilepsy

Authors: *A. TYULMENKOVA, D. KEITH, S. NICOLAS, G. GARCIA, C. ISGOR;
Biomed. Sciences, Col. of Med., Florida Atlantic Univ., Boca Raton, FL

Abstract: Mechanisms behind seizure-induced death are not well understood. Sudden Unexpected Death in Epilepsy (SUDEP) seems to rise with seizure severity. Postictal generalized electroencephalography suppression (PGES) is a major risk factor in cardiorespiratory failure, hence an indicator of seizure severity. Findings from EEG monitoring during SUDEP are consistent with a seizure-induced suppression of the brainstem arousal circuits. Majority of SUDEP cases occur during sleep implying that sleep processes may be associated with these fatal effects. In this study, we used a transgenic mouse model of adult-onset spontaneous epilepsy. The mice overexpress brain derived neurotrophic factor (BDNF) in the forebrain under the CaM kinase II alpha promoter (TgBDNF). TgBDNF mice develop convulsive seizures at ~4 months of age which worsen with each seizure episode. Seizures are elicited via tail lifts and cage agitation. We used this model to examine how seizures progress from mild to severe and if this progression is associated with distinct changes in sleep structure. We surgically implanted subdural electrodes on the TgBDNF mice skulls prior to the first seizure episode (3-channel EEG system, Pinnacle Technology, KS) to record seizure and sleep EEG for 12 weeks. We used age- and litter-matched wild-type mice as controls. We hypothesized that as seizure severity progresses, alterations in sleep structure may be used as biomarkers to identify life threatening potential of upcoming seizures. Seizures were recorded once weekly and induced six times at each recording session. We measured duration of total seizure, ictal phase, PGES and post-ictal spiking waves during recovery. Twenty-four hours following seizure induction, mice were connected to EEG apparatus for sleep recording during inactive phase. We analyzed early and late sleep separately to define the dynamic changes in rapid eye movement (REM) and slow-wave sleep (SWS) phases. Data was assessed by simple regression analyses between seizure and sleep parameters. Our data showed a positive association between the amount of time mice spent asleep in early sleep to longer periods of total motor seizure duration. As expected, PGES duration increased as did the seizure episodes. PGES duration showed a positive association with increased time spent sleeping in early sleep. Severe seizures had increased spiking wave discharge abnormalities in the recovery phase of EEG. The duration of these abnormalities showed a positive association with SWS phase during early sleep. Monitoring sleep changes in epileptic patients and finding critical sleep-seizure EEG associations could lead to quicker identification of death risk.

Title: Diverse spiking signatures of excitability mutations emerge from a stereotypic seizure-flight sequence in Drosophila

Authors: *A. IYENGAR, C.-F. WU;
Univ. of Iowa, Iowa City, IA

Abstract: High-frequency electrical stimulation across the brain triggers seizures in humans, mice and flies. In *Drosophila* such stimulation induces stereotypic electroconvulsive seizure (ECS) discharges which manifest across the nervous system and can be monitored through spiking in the large indirect flight muscles (DLMs) in conjunction with microphone recordings of wing beats. During flight, the DLM motor neuron spikes rhythmically (~5 Hz) providing Ca^{2+}influx for stretch-activated myogenic contractions which powers wing beats (~200 Hz). In contrast, during ECS discharges, a distinctive sequence of firing modes have been reported: an initial discharge (ID, ~50 Hz), a quiescent period, and a delayed seizure discharge (~30 Hz peak). Although widely in studies of circuit excitability, most studies employing ECS in *Drosophila* examine the induction threshold, with considerably less attention on alterations in firing patterns during the discharges. Using an isolated stimulation configuration, we discovered that wild-type (WT) flies would reliably display sustained flight activity following DD (DD-flight). Compared to air-puff triggered flight, DLM spiking during DD-flight was higher (~10 - 20 Hz) while the wing-beat frequency was lower (~170 Hz). We observed a similar motor sequence in other WT strains and in other *Drosophila* species. Furthermore, we observed DD-flight after the surgical removal of sensory structures required for air-puff triggered flight, including the halteres, antennae and wings. Across broad ranges of excitability mutants, we found that spiking activity during the DD can serve as a 'signature' of the specific manifestation hyperexcitability. Non-linear dynamical systems analyses revealed clear distinctions between two classes of hyperexcitable mutants: 'leg-shakers'(e.g. *Sh*, *qvr*) that twitch under ether anesthesia, and 'bang-sensitives' (e.g. *eas*, *sda*) which display mechanical shock-induced seizures. In leg-shaker mutants, with disrupted I_AK^+currents, the DD-evoked flight sequence was largely intact, but with a declining wing beat frequency, presumably reflecting alterations direct flight muscle biophysical properties. In contrast, bang-sensitive mutants displayed mutant-specific DLM ECS discharge patterns, with varying duration, firing frequency and regularity. However, a common feature across the bang-sensitive mutants was the complete absence of DD-evoked flight. This work demonstrates that our quantitative treatments of spike patterning can provide succinct signatures for a variety of mutations-specific vulnerabilities in motor circuits.

Title: Expression of the wnt-b catenin pathway in the limbic system in seizure-induced models subjected to caloric restriction

Authors: *R. LUNA, D. ROJAS, E. TADDEI, M. RUBIO OSORNIO, L. F. HERNANDEZ, Jr., M. C. RUBIO OSORNIO*;
Inst. Nacional de Neurologia y Neurocirugia Manuel Velasco Suarez, Ciudad de México, Mexico

Abstract: The Wnt/β-catenin pathway increases glucose absorption at the cortical level, increasing neuronal excitability, translating epileptic seizures. By conditioning caloric restriction in rats with epileptic seizures induced by the kindling model, the intention was to decrease the cerebral metabolic substrate and observe changes in the expression of the Wnt pathway in the hippocampus and amygdala, the most susceptible zones to nutritional changes, as well as to epileptic activity. We quantify the expression of the proteins Wnt3A, β-catenin, P-β-catenin, cyclin D, and c-Myc in the brain tissue of the amygdala and hippocampus of the rat with generalized crisis and caloric restriction. We used male Wistar rats; we implanted electrodes in the basolateral nucleus of the amygdala and underwent stimulation to develop the kindling model. After the experimentation phase, we performed immunohistochemistry and Western blot techniques with specific antibodies of the Wnt / β-catenin pathway. The caloric restriction showed an increase of c-Myc, cyclin D, β-catenin, P-β-catenin in the amygdala and hippocampus comparing with the kindled group; and a decrease in the Wnt/β-catenin pathway in the dentate gyrus, in relation to the animals that only had kindling, resulting in a decrease in the duration of amygdalin epileptic activity in our caloric restriction group. Restrictive diets provide a neuroprotective effect in epilepsy. CR has anticonvulsant effects in murine and other epilepsy models. CR in rats with induced-seizures using the kindling model increased the threshold after a stimulus applied to the amygdala as well as decreased the duration of the convulsive activity.

Title: Participation of the Wnt / β-catenin pathway in the cerebello-thalamo-cortical pathway of rats with epileptic seizures induced by kindling model subjected to caloric restriction.

Authors: *D. A. ROJAS HERNÁNDEZ[1], R. LUNA[1], M. RUBIO OSORNIO[2], L. F. HERNÁNDEZ LÓPEZ[1], E. TADEI[1], J. BRITO[1], M. C. RUBIO OSORNIO[1];
[1]Dept. de Neurofisiología, [2]2Laboratorio Exptl. de Enfermedades Neurodegenerativas, Inst. Nacional de Neurología y Neurocirugía "Manuel Velasco Suarez", Ciudad de México, Mexico

Abstract: The cerebello-thalamo-cortical pathway participates in epileptic activity, this activity can be modified by glucose metabolism and by ketone products derived from glycolytic metabolism and fatty acids; the *Wnt / β-catenin* pathway has shown to induce metabolic changes in neuronal glucose; these changes have shown to have a stabilizing effect on the neuronal membrane with respect to its excitability, producing an anticonvulsant effect. We infer that caloric restriction (CR) generates a decrease in the metabolic substrate, then in rats with epileptic seizures induced by the kindling model, a modification in the expression of the *Wnt* pathway will be observed. We quantified the expression of the *Wnt*3a, β-catenin, Pβ-catenin, c-Myc and cyclin-D proteins in the cerebellum, ventrolateral nucleus of the thalamus (VL) and cortex of rats with generalized seizures and CR; male Wistar rats were used which were divided into 3 groups: a) control group; b) kindled group fed ad libitum; c) kindled group with CR, fed with controlled diets according to their weight. Once the experimentation phase was finished, the rats were sacrificed, the cerebellum, VL and cortex were extracted, immunohistochemistry and Western Blot was performed with specific *Wnt*3a, β-catenin, Pβ-catenin, c-Myc and cyclin-D antibodies. We found that the animals subjected to CR decrease the epileptic activity, in addition to restoring the quantification of the *Wnt* / β-catenin pathway proteins to control values, compared to the group that had epileptic seizures with *ad libitum* food. We conclude that restrictive diets provide a neuroprotective effect in epileptic seizures. According to the immunohistochemical analysis, we showed changes in the amount and location of the Wnt / β-catenin pathway in the cerebello-thalamo-cortical pathway, a structure that has shown its participation in epileptic activity. These results suggest that the changes induced by the kindling epilepsy model generate modifications in the expression and activation of proteins of the *Wnt* / β-catenin pathway and that this is modified depending on CR.

Title: Knockout of canonical STAT3 signaling in excitatory neurons of a temporal lobe epilepsy model attenuates the development of chronic seizures and fear learning deficits and rescues inflammatory and synaptic signaling at a transcriptomic level.

Authors: *A. E. TIPTON[1,2], K. M. HIXSON[1,2], Y. CRUZ DEL ANGEL[3], J. CARLSEN[3], A. BROOKS-KAYAL[3], S. J. RUSSEK[1,2];

Neurosci., Boston Univ., Boston, MA; [3]Dept. of Pediatric Neurol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Epilepsy is a common neurological disorder characterized by presence of unprovoked, spontaneous seizures (SS) on at least two occasions, affecting 65 million people worldwide. Currently available treatments only work in 2/3 of patients, and often exacerbate neuropsychiatric comorbidities commonly seen with epilepsy, including mood disorders and cognitive dysfunction. The design of novel therapeutics, including those with potential for disease modification, requires a deeper understanding of the molecular cascades responsible for generating and maintaining chronic, spontaneous seizures. This process of epileptogenesis can be studied using the intrahippocampal kainic acid (IHKA) model of temporal lobe epilepsy (TLE). Previous work from our labs has identified the JAK2/STAT3 pathway, traditionally associated with inflammatory responses in immune cells, as relevant in the response of neurons to excess stimulation such as elevated BDNF levels, or status epilepticus (SE). *In vitro* studies of primary hippocampal neuronal cultures demonstrated that application of JAK2/STAT3 inhibitors rescues the dysregulated BDNF-induced changes in expression levels of key ion channels and neurotransmitter receptors, as well as genes implicated in neuroinflammation. Moreover, it appears this is a therapeutically relevant target in epilepsy, as rats treated with one dose of the JAK/STAT inhibitor WP1066 developed significantly fewer SS than controls. The current study utilized a tamoxifen-inducible, cell-type specific STAT3 KO mouse driven by a CAMKIIA promoter, such that STAT3 KO is specific to excitatory neurons (NSTAT3KO). Remarkably, NSTAT3KO mice display both decreased frequency of SS as well as rescue of deficits in hippocampal-dependent fear conditioning, suggesting inhibition of STAT3 in excitatory neurons may help address both seizures and epilepsy comorbidities. Analysis of bulk RNA-sequencing data obtained from hippocampi harvested 24 hours post-SE suggests neuronal STAT3 is an important regulator of both neuronal excitability and its inhibition. Moreover, NSTAT3KO leads to reversal in the upregulation of numerous inflammatory pathways activated in epilepsy via microglia and astrocytes. This finding suggests that *neurons themselves may play an important role in the induction and maintenance of inflammation after SE.* Future studies will utilize single nuclei transcriptomic approaches to directly determine how STAT3 impacts gene expression and DNA accessibility across all brain cell types, with the ultimate goal of uncovering the function of JAK2/STAT3 in excitatory neurons and the viability of targeting this novel pathway in epilepsy.

Title: The role PIGB in neurodevelopment and in the pathogenesis of early epileptic encephalopathy

Authors: *P. K. PEDABALIYARASIMHUNI[1,2], K. TOULOUSE[1,2], T. T. M. NGUYEN[1], A. LUPIEN-MEILLEUR[1,2], L. EID[1,2], M. LACHANCE[1], P. CAMPEAU[1,3], E. ROSSIGNOL[1,4]; [1]CHU Ste-Justine Res. Ctr., Montréal, QC, Canada; [2]Dept. of Neurosciences, [3]Dept. of Pediatrics, [4]Departments of Neurosciences and Pediatrics, Univ. de Montréal, Montréal, QC, Canada

Abstract: BACKGROUND. Epileptic encephalopathies (EE) are severe early-onset epilepsies with cognitive deficits and early lethality. We recently identified recessive mutations in the *PIGB* gene, encoding the mannosyltransferase 3 protein, acting in the glycosylphosphatidylinositol (GPI)-anchor biosynthesis pathway, in patients with EE. GPI anchors localize various receptors, ion channels and cell adhesion proteins on cell membranes. However, the mechanisms by which deficits in GPI anchors result in such a striking neurodevelopmental phenotype are unknown. Recent data from our group suggest that impairments in the early development or function of inhibitory GABAergic interneurons (IN) result in epilepsy and cognitive deficits in mice, thus contributing to specific genetic forms of EE. **HYPOTHESIS**. We postulate that GPI anchor deficit results in EE by impairing IN development. **METHODS**. We generated different mouse models carrying targeted *Pigb* mutations in distinct neuronal populations. We combined high-resolution cell imaging, immunohistochemistry, neuronal quantification, and morphological reconstitution, together with video-EEG recordings and behavioral analysis to characterize these models and investigate the underlying mechanisms. **RESULTS**. While constitutive knock-out and conditional mutant mice in cortical excitatory neurons ($Emx1^{Cre}$) are not viable, mice with GPI deficiency carrying a targeted deletion of *Pigb* in MGE-derived INs ($Nkx2.1^{Cre}$) are viable and develop spontaneous seizures as well as behavioral deficits reminiscent of those observed in patients. Furthermore, neuronal quantification at different key developmental stages (e13.5, e15.5, P0) revealed a delay in IN migration, with reduced number of IN at the migratory front embryonically (e13.5 and e15.5) and in the postnatal cortex (P14 and P21). Notably, 3D reconstruction of e13.5 migrating INs revealed striking perturbations in IN morphology, including increased neurite length, number and complexity of leading and trailing processes. Moreover, live imaging of MGE explants suggests perturbations of migration kinetics in INs. **CONCLUSION**. Our results reveal that the loss of GPI anchors, through *Pigb* recessive mutations, impairs IN migration, resulting in epilepsy and cognitive deficits. Subsequent studies will help unveil the specific candidate GPI-anchored proteins required to sustain IN migration, further clarifying the underlying disease mechanisms.

Title: Trpv1 deletion reduced the severity but not the frequency of spontaneous seizures in a Scn1a+/- model of Dravet syndrome.

Authors: *V. S. JANVE, D. BAHCECI, L. ANDERSON, D. MORGAN, J. ARNOLD; Pharmacol., The Univ. of Sydney, Sydney, Australia

Abstract: Rationale: Dravet syndrome (DS) is an early onset epileptic encephalopathy that begins with febrile seizures and progresses to spontaneous afebrile seizures that are poorly managed by anti-seizure drugs. Majority of the DS patients have loss of function *Scn1a* mutations. The Scn1a$^{+/-}$ mouse model recapitulates features of DS with increased sensitivity to febrile seizures and early onset spontaneous seizures. Cannabidiol (CBD) has been FDA-approved for treatment of DS. While the anti-seizure mechanism of CBD is unknown, it activates and rapidly desensitizes transient receptor potential vanilloid type 1 (Trpv1) cation channels. Trpv1 channel inhibition has been anticonvulsant against PTZ, 6-Hz, and MES-induced seizures in mice. Thus, we tested whether heterozygous deletion of *Trpv1* or inhibition of Trpv1 channels is anticonvulsant in the *Scn1a*$^{+/-}$ model of DS. **Methods:** Scn1a$^{+/-}$ mice were generated as in Miller AR, 2014 and bred with *Trpv1*$^{+/-}$ mice to generate *Scn1a*$^{+/-}$*,Trpv1*$^{+/-}$ mice. Hyperthermia was induced in postnatal day (P) 14-16 mice with a heat lamp and measured with a rectal probe. Onset of the 1st generalised tonic-clonic seizure (GTCS) was noted as the seizure threshold temperature. Mice that reached 42.5 °C without a GTCS for 3 min were considered seizure free. To mimic clinical progression, P18 mice were subjected to a single hyperthermia-induced GTCS followed by rapid cooling (priming). After recovery spontaneous seizures were video monitored for 60 hours. *Scn1a*$^{+/-}$ mice were challenged with hyperthermia-induced GTCS 15 minutes (T_{max}) following i.p. injection of 10 and 20 mg/kg of SB-705498. **Results:** *Scn1a*$^{+/-}$*,Trpv1*$^{+/-}$ had similar hyperthermia-induced GTCS threshold compared to that of Scn1a$^{+/-}$ mice at P14-16 (n=13, p=0.15). Survival and frequency of spontaneous seizures were also similar between *Scn1a*$^{+/-}$*,Trpv1*$^{+/-}$ mice and Scn1a$^{+/-}$ mice (n=16-18, p≥0.05). However, severity of spontaneous seizures, i.e. the percent of seizures progressing to full hindlimb extension, was significantly reduced in Scn1a$^{+/-}$,Trpv1$^{+/-}$ mice compared to Scn1a$^{+/-}$ mice (n=16-18, p=0.0003). Interestingly, priming P18 significantly reduced the hyperthermia-induced GTCS threshold in *Scn1a*$^{+/-}$*,Trpv1*$^{+/-}$ compared to Scn1a$^{+/-}$ mice (n=18-20, p=0.007). Further, acute administration of Trpv1 selective antagonist SB-705498 in Scn1a$^{+/-}$ mice did not affect hyperthermia-induced GTCS threshold compared to vehicle-treated mice, and its effects on spontaneous seizures are being tested. While Trpv1 channel inhibition has been anticonvulsant in several seizure models,

genetically or pharmacologically targeting Trpv1 is not anticonvulsant in the *Scn1a*$^{+/-}$ model of DS.

Recurrent seizures are a hallmark of epilepsy. An imbalance of excitation-inhibition is known to promote seizure generation, and molecular determinants of these alterations remain to be elucidated. Experimental evidence suggests that Pannexin1, an ATP release channel, is a candidate for modifying neuronal excitability that underlies seizure activity. Here, genetically modified zebrafish lines and pharmacological inhibition of Panx1 channels with the FDA-approved drug Probenecid was used to evaluate the efficacy of targeting Panx1 for improving seizures. The pentylenetetrazol (PTZ) model was used to chemically induce seizures during *in vivo* electrophysiological recordings from tectal brain regions of zebrafish larvae. We paired these results with behavioral phenotyping in age-matched larvae. Further, molecular biological techniques were used to determine stress responses and to investigate a mechanistic explanation for the involvement of Panx1 in seizures. Results demonstrate that loss-of-function mutations in Panx1 genes, or pharmacologically blocking the channels, significantly reduces ictal-like events during electrophysiological recordings without altering inter-ictal like activity. A decrease in seizure-related locomotor behavior is accompanied by an improvement in survival rates and reduced molecular fingerprints of cellular stress responses. Our research suggests that Panx1 channels contribute to distorting neurons' electrochemical balance, likely via an ATP release mechanism, and aid in propagating or maintaining seizures. With almost 40% of people with epilepsy having recurrent seizures uncontrolled by medication, we propose that Panx1 channel inhibition could open a window of opportunity to treat drug-resistant epilepsies.

Title: Marked Insomnia in a Mouse Model of Medial Temporal Lobe Epilepsy

Authors: ***N. P. PEDERSEN**[1], L. M. AIANI[1], L. ROSENBERG[2];
[1]Neurol., Emory Univ., Atlanta, GA; [2]Neurosci., Georgia Inst. of Technol., Atlanta, GA

Abstract: In many patients with epilepsy, seizures have a predilection for a particular sleep-wake state or sleep-wake state transition. Further suggestive of a strong relationship between sleep-wake and seizures is the commonality of sleep disturbances in epilepsy and the improvement of seizures with the treatment of sleep disorders. While sleep-wake has been studied in patients with epilepsy, there are relatively few animal studies. We sought to examine the sleep effects of developing seizures in a mouse model of medial temporal lobe epilepsy. These studies will form the basis for cell-selective manipulations of sleep-wake networks to develop a mechanistic understanding of how sleep-wake circuits contribute to seizures. Mice were instrumented using a custom-designed head plate to permit reproducible recordings of the bilateral hippocampus, electrocorticogram, and electromyogram of neck muscles, with the later capacity for optogenetics and fiber photometry. Mice were habituated and underwent chronic video-EEG recording with intra-amygdala kainic acid microinjection by cannula one week later, and recording continuing for a further three weeks. Sleep was significantly disrupted: We found increased wake in mice with seizures (~ 15%, ANOVA $P = 0.019$) as well as increased frequency ($P < 0.05$) and duration of seizures (ANOVA $P = 0.03$) during sleep in this model. Seizures were rarely observed in rapid eye movement (REM) sleep. These findings recapitulate observations from patients with MTLE and form a basis of further work that will cell- selectively manipulate components of sleep-wake networks to modify seizure risk and help understand underlying mechanisms.

Title: In vivo wide-field Ca^{2+} imaging of the cortical spontaneous activity in the Cdkl5 mutant mice reveals altered functional connectivity upon the loss-of-function of CDKL5

Authors: *T. TANAKA[1], T. NOMURA[1], T. MURAKAMI[1], K. SAITOU[1], K. OHKI[1,2];
[1]Grad Sch. of Medicine, The Univ. of Tokyo, Tokyo, Japan; [2]Intl. Res. Ctr. for Neurointelligence (IRCN), the Univ. of Tokyo, Tokyo, Japan

Abstract: Loss-of-function (LOF) mutations in the Cyclin-dependent kinase-like 5 (CDKL5) gene cause severe neurodevelopmental disorders accompanied by early-onset intractable epilepsies, i.e. CDKL5 deficiency disorder (CDD). We have previously generated the *Cdkl5* knock-out (KO) mice and demonstrated postsynaptic overaccumulation of GluN2B-containing NMDA receptors in the hippocampus, significantly enhanced anxiety-like behaviors, and impaired acquisition and retention of spatial reference memory. However, mechanisms underlying these phenotypes remain unknown, and identifying the brain-wide, synapse-to-circuit functional alteration upon the LOF of CDKL5 is necessary to understand the mechanisms. In order to determine how the LOF of CDKL5 has an impact on the cortical neurocircuits, we have adopted the high-resolution wide-field Ca^{2+} imaging of the cortical spontaneous activity in the genetically encoded calcium indicator (GECI)-expressing *Cdkl5* mutant mice. We generated the GCaMP6f-expressing *Cdkl5* KO and kinase-dead knock-in (KI) mice in which GCaMP6f was neuronally expressed by the Thy1 promoter. We performed the *in vivo* wide-field Ca^{2+} imaging of GCaMP6f-expressing *Cdkl5* hemizygous mutant and control mice under anesthesia, awake, and with visual stimulation, at postnatal day (P) 21 and P60. We set 18 regions of interest (ROIs) in each hemicortex, and analyzed spontaneous activity patterns by functional correlation analysis and principal component analysis (PCA). We then evaluated differences in the functional connectivity across different genetic groups. We have so far acquired data from four *Cdkl5* KO, four *Cdkl5* kinase-dead KI, and eight control mice at P60. Functional correlations of ROIs between right and left hemispheres (correlation inside the red square) are analyzed by one-way analysis of variance (ANOVA) and multiple comparison test. The average inter-hemispheric correlation was higher in *Cdkl5* KO mice than that in the control mice. There was no statistically significant difference in inter-hemispheric correlation between *Cdkl5* kinase-dead KI mice and control mice, but hypersynchronization appeared in several areas such as V1 and V2 in the KI mice. These data suggest that a loss-of-function of CDKL5 causes the inter-hemispheric hypersynchronization of cortical spontaneous activity. Since the inter-animal variation was still high in the present set of data, we need to acquire more data to reach reliable outcomes. We will compare the altered neurocircuit activity patterns with behavioral endophenotypes of the *Cdkl5* mutant mice and verify the site-specific neurocircuits impaired upon the loss-of-function of CDKL5.

Title: Investigation of retigabine as a potential treatment for nerve agent-induced status epilepticus

Authors: *P. SHEU[1], B. S. BARKER[1], J. SPAMPANATO[2], K. BERGER[1], C. E. JACKSON PIERCY[1], H. S. MCCARREN[1], J. H. MCDONOUGH, Jr[1];
[1]Med. Toxicology: Nerve Agent Countermeasures, USAMRICD, Aberdeen Proving Ground, MD; [2]Dept. of Neurosurg., Univ. of Utah, Salt Lake City, UT

Abstract: Nerve agents can induce seizures that rapidly progress to status epilepticus (SE). These seizures are clinically treated with benzodiazepines. However, studies in delayed treatment models have established that benzodiazepines lose the ability to stop seizures. Retigabine is a K_v7 (KCNQ) potassium channel opener originally used chronically as an adjunctive treatment for partial seizures. Retigabine promotes K^+ efflux, which can counteract Na^+ influx during depolarization. To investigate the effectiveness of retigabine in controlling nerve agent-induced SE, male Sprague Dawley rats were exposed to the nerve agent soman to elicit SE and continuously observed through electroencephalogram recording. Retigabine was administered at 30 mg/kg as an adjunct to midazolam at 20 or 40 min after SE initiation to evaluate its anticonvulsant effects against benzodiazepine-resistant SE. Controls received PEG200. In the 12 subjects that received 30 mg/kg at 20 min post-initiation of SE, SE stopped in 8 and stayed off for 4 hr. Their gamma power and mean spike frequency were significantly lower for these 4 hr compared to controls (n=17). Animals that received retigabine at 30 mg/kg administered 40 min after SE initiation (n=15) showed similar results compared to controls (n=11), where 9 had seizure termination. To evaluate retigabine as a monotherapy, it was administered without midazolam at 30 mg/kg or 60 mg/kg at 20 min after SE initiation. At 30 mg/kg retigabine alone (n=8) showed minimal anticonvulsant effects with only one animal showing seizure termination and no overall significant difference found versus controls. However, when the dose was increased to 60 mg/kg (n=14), 10 animals showed seizure termination, and of those 10, 8 were seizure free for 24 hr. This group showed significant differences in gamma power and mean spike frequency when compared to both controls and the 30 mg/kg retigabine only group. These results indicate retigabine is effective as not only an adjunctive anticonvulsant with midazolam at both time points but also a stand-alone SE treatment when administered at a higher dose. Additionally, these results prompt increased interest in K_v7 channels as possible targets for attenuating benzodiazepine-resistant SE.

Title: Super refractory status epilepticus in rats following multiple therapeutic treatments for nerve agent exposure

Authors: *B. J. TRAVIS, H. M. BELSKI, K. M. BOUNADER, J. M. COPPOLA, E. N. HORNUNG, K. A. HUNDERTMARK, C. E. JACKSON-PIERCY, K. T. PAGARIGAN, S. C. WILSON, J. E. MORGAN, H. S. MCCARREN;
Med. Toxicology- Neurosci., United States Army Med. Res. Inst. of Chem. Def., Aberdeen Proving Ground, MD

Abstract: Organophosphate nerve agent (NA) exposure poses risk to both military and civilians, producing many toxic symptoms including status epilepticus (SE). SE can quickly progress if not treated promptly and can be fatal if left untreated. Emergency treatments for NA poisoning are often ineffective if delayed and provide no lasting seizure control. Thus, in-hospital care would be required to definitively treat NA-induced SE; yet, no standard of care exists. Clinical care for SE of other etiologies utilizes benzodiazepines as first-line treatment, anti-epileptics as second-line, and general anesthetics as third-line. SE is considered established if first-line treatment fails, refractory status epilepticus (RSE) if second-line fails, and super refractory status epilepticus (SRSE) if third-line fails. Given the severity and generalized nature of the cholinergic crisis produced, it's expected NA-induced SE cases would advance to RSE or SRSE; though, progression to SRSE following third-line treatment has not been researched. We demonstrated the presence of NA-induced SRSE after third-line drug administration. Adult male rats were challenged with a seizure-inducing dose of soman. Following seizure onset, determined by electroencephalography, standard medical countermeasures (atropine sulfate, 2-PAM, and midazolam) were administered, and the rat was placed in an oxygen-rich, temperature-controlled chamber. If seizure wasn't controlled, up to 2 boluses of midazolam or lorazepam were administered intravenously, followed by up to 2 boluses of phenobarbital or valproate, and finally repeated bolus administration of propofol or ketamine until seizure termination, with continuous infusion for 18 hr upon termination. If seizure returned, it was considered to be SRSE. All rats that received third-line treatment (n=67) had seizure termination following intravenous administration of propofol (n=31) or ketamine (n=36). Fifty rats died during continuous infusion. The incidence of mortality was the same regardless of treatment (p=0.57). SRSE was observed in 17 rats (propofol n=10; ketamine n=7). One rat was weaned off ketamine without seizure recurrence and showed promising markers of functional recovery, including a return to baseline weight by day 3 post-exposure and absence of brain damage in 5 critical regions with histopathologic scores of 0. Standard treatment protocols and clinical

recommendations failed to prevent SRSE, highlighting both the necessity for a standardized clinical intensive care regimen for treatment of SE and justification for further research into alternative pharmacological agents for effective termination of NA-induced SE.

Abstract: Soman is a highly potent organophosphorus nerve agent that inhibits the activity of acetylcholinesterase. The resulting excess of acetylcholine at neuromuscular junctions, glands, and within central nervous system synapses results in miosis, hypersecretion, fasciculation, respiratory distress, and seizures that rapidly progress to status epilepticus (SE). Currently no clinical protocol exists for the definitive treatment of nerve agent-induced SE. Pre-hospital treatment alone in the form of benzodiazepine auto-injectors likely would not be sufficient to stop SE if treatment were delayed. A severely poisoned casualty is highly likely to need intensive in-hospital care to completely terminate SE. This work investigated the utility of commonly used SE treatment protocols in a simulated hospital setting to assess their efficacy against soman-induced SE.Adult male rats were challenged with soman, and 20 min after SE onset, as confirmed by electroencephalographic recording, they were administered standard pre-hospital medical countermeasures (atropine sulfate, pralidoxime, and midazolam). They were then moved to intensive care units (ICU) containing 100% oxygen and thermal support. Ten minutes after arrival in the ICUs, rats were administered intravenous (IV) first-line treatment of either midazolam or lorazepam. If this treatment failed to control SE they were administered a second-line treatment of either phenobarbital or valproate. Midazolam (n = 72) and lorazepam (n = 64) terminated SE in 10% and 9% of rats respectively, but in all cases SE returned or the rat died. Phenobarbital (n = 78) was significantly better at terminating SE than was valproate (n = 43) (56% vs. 35%, $p > 0.0360$). SE returned within 24 hours for all rats treated with valproate, while 21% of phenobarbital-treated rats had lasting seizure control ($p > 0.0006$). These rats with

definitive SE resolution returned to baseline weight 3-7 days after exposure, while controls that only received pre-hospital countermeasures took at least 8 days to regain weight. There was also a significant reduction in the severity of histopathology, based on H&E staining, for successfully treated rats compared to controls ($p < 0.0001$).In conclusion, while first-line administration of benzodiazepines was ineffective at permanently terminating SE, second-line treatment with phenobarbital was effective in a subset of cases and led to positive indications of recovery. Future work will investigate the effectiveness of first-line treatment with phenobarbital and other less established SE therapies.

Title: Evaluating anti-epileptic drugs in an intensive care setting for the treatment of nerve agent-induced status epilepticus in rats

Authors: J. E. MORGAN, S. C. WILSON, B. J. TRAVIS, K. PAGARIGAN, P. SHEU, K. A. HUNDERTMARK, H. S. MCCARREN;
USAMRICD, Aberdeen Proving Ground, MD

Abstract: Nerve agent (NA) poisoning initiates a catastrophic cholinergic crisis that can induce *status epilepticus* (SE) if left untreated. Survivors of NA exposure will likely require treatment in a hospital intensive care setting. Guidelines currently exist for pre-hospital management of NA-induced SE, which includes up to two doses of a benzodiazepine. However, previous research in rodent models has indicated that doses of diazepam equivalent to 3-12 convulsive antidote for nerve agent (CANA) auto-injectors are insufficient to stop SE. There is currently no standard therapy regimen for definitive termination of NA-induced SE. Recent work in our lab has attempted to determine a treatment strategy to completely resolve NA-induced SE in a hospital setting that is guided by clinical strategies for treating SE of other etiologies. Male Sprague Dawley rats were surgically implanted with jugular vein catheters and tethered EEG headpieces. Twenty minutes after soman exposure they received human equivalent doses of standard pre-hospital countermeasures for NA exposure (atropine, 2-PAM, and midazolam), followed ten minutes later by initiation of in-hospital treatments. The typical first-line treatments midazolam and lorazepam were equally ineffective at terminating SE ($p > 0.999$), with respective seizure termination rates of 10% ($n = 72$) and 9% ($n = 64$). When administered after the failure of first-line benzodiazepines, valproic acid and phenobarbital showed significantly different efficacy (p

= 0.036), with respective seizure termination rates of 34% (n = 43) and 56% (n = 78). However, seizures returned in all of the valproate-treated rats, and only a small subset of phenobarbital-treated rats (n = 16) remained seizure free 24 hours later. We hypothesized that treating with antiepileptic drugs first, rather than waiting until after benzodiazepine refractoriness was established, would lead to greater seizure control. When administered immediately upon arrival in the ICU, phenobarbital (n=17) was more effective at terminating seizures than was valproic acid (n= 10, p = 0.015). While both valproic acid and phenobarbital had good initial seizure termination (80% and 100%, respectively), phenobarbital was more effective at permanently terminating seizures (59%) than was valproic acid (0%). This suggests that benzodiazepines may not be a necessary precedent for termination of NA-induced seizures with anti-epileptic drugs. Additionally, brain tissue of rats that received phenobarbital displayed minimal damage in key areas such as the amygdala, thalamus, and piriform cortex. Evaluation of other anti-epileptic drugs in this model is ongoing.

Title: Intramuscular dose of midazolam in rats producing exposure equivalent to recommended dose of Seizalam® (midazolam injection) in humans

Authors: *A. DHIR, C. YI-WU, M. A. ROGAWSKI;
Neurol., Univ. of California, Davis, Sacramento, CA

Abstract: Seizalam® is a midazolam HCl (MDZ) formulation approved by the FDA as a first-line treatment for status epilepticus (SE) in adults. The recommended dose is 10 mg, administered by intramuscular (IM) injection. According to its label, Seizalam® at the recommended dose yields a Cmax of 113.9 ± 30.9 (SD) ng/ml. Here we sought to estimate the dose of MDZ which when administered intramuscularly in rats would produce a plasma exposure equal to this value. Our objective was to define the appropriate dose of MDZ to be used in studies in rats of novel SE treatments that may be administered in conjunction with Seizalam®. We provide pharmacokinetic (PK) parameters based on noncompartmental analysis (NCA) of plasma level data and we used two-compartment PK modeling to estimate the rat-equivalent dose. Our analysis assumes that Cmax is the appropriate PK parameter to match. Male Sprague-Dawley rats were implanted with a permanent cannula in the right jugular vein. After 7-10 days of post-operative care, animals were injected with a 0.9 mg/kg IM dose of MDZ. Blood was withdrawn at 0, 2, 5, 15, 30, 60, 120, 240, 300, 360, 480 and 1440 min after the MDZ

injection. The plasma was separated and MDZ levels were measured using LC-MS/MS (<LLOQ=50 pg/ml). A NCA was performed on the plasma level data from each animal to estimate the Tmax, Cmax and AUC. The plasma level data was also fit with a 2-compartment PK model to obtain the clearance parameters for each individual and for the entire group. Simulations were performed of 0.5, 0.7, 0.9, 1, 1.1 mg/kg doses using the PK parameters either from group model fitting or mean of individual model fitting to estimate the dose of MDZ. The dose required to achieve the targeted Cmax was interpolated assuming the Cmax is linearly proportional to the input dose. NCA of the plasma level measurements in each animal yielded a mean Cmax value of 187.7 ± 64.5 (SD) with Tmax values in the range of 2-15 min (mean, 7.2 ± 5.6 min). The mean AUC0-480min was 8840.3 ± 1623.2 min*ng/ml. The levels remained greater than 115 ng/ml for at least 15 min after dosing in 10 of 13 animals tested. Using the PK parameters from the group model fitting, the dose of MDZ required to reach the Cmax of 113.9 ng/ml is 0.647 mg/kg (simulated Cmax is 158.5 ng/ml at 0.9 mg/kg dose). When using the mean of the individual PK parameters, a dose of 0.655 mg/kg MDZ is required to reach the targeted Cmax (simulated Cmax is 156.61 ng/ml at 0.9 mg/kg dose). In conclusion, a MDZ dose of 0.65 mg/kg, IM, in rats is estimated to yield the same plasma exposure (Cmax) as obtained with the recommended Seizalam® dose in humans and is proposed as the appropriate dose to be administered in rat models to mimic the human dosing.

Title: Dexmedetomidine is an effective anticonvulsant via intramuscular, intranasal and intravenous routes of administration in a rat model of acute organophosphate intoxication

Authors: *K. T. PAGARIGAN, B. J. TRAVIS, P. SHEU, J. M. COPPOLA, C. E. JACKSON PIERCY, J. E. MORGAN, P. B. DUBEE, H. S. MCCARREN;
USAMRICD, Gunpowder, MD

Abstract: Exposure to nerve agents (NA) induces seizures that can progress to status epilepticus (SE). NA-induced SE is primarily due to the irreversible inhibition of acetylcholinesterase (AChE) and the subsequent overstimulation of central muscarinic acetylcholine receptors. Currently, benzodiazepines such as diazepam, midazolam or lorazepam are the first line of treatment for controlling SE of any etiology. However, NA-induced SE is notoriously difficult to treat due to the time-dependent development of benzodiazepine-refractory SE. As such, effective therapeutics that control SE when benzodiazepines fail need to be identified. One such candidate is the FDA-approved, highly selective α2-adrenoceptor agonist dexmedetomidine (DEX). DEX

provides anxiolytic, analgesic, and sedative effects without causing respiratory depression like other similar drugs. We have previously shown that co-administration of DEX and midazolam 20 or 40 minutes after NA-induced SE terminated seizures and returned electroencephalographic (EEG) measurements to baseline, suggesting that DEX could enhance neuroprotection alongside midazolam auto-injectors in response to acute NA exposure. However, more research is needed to evaluate the effective dosing range and efficient routes of administration of DEX in the context of NA exposure. Here we determined the anticonvulsant ED90 of DEX when delivered intravenously (IV), intranasally (IN) and intramuscularly (IM) in a rat survival model of soman exposure. Male and female Sprague Dawley rats implanted with cortical electrodes were exposed subcutaneously to 150-180 μg/kg of soman to induce SE, as confirmed by EEG. To model pre-hospital DEX use, IM or IN DEX was administered concurrently with IM midazolam, atropine, and 2-PAM at 20 min after SE onset. To model in-hospital DEX use, IM midazolam, atropine, and 2-PAM were administered 20 min after onset, and then animals were transported to a heated, oxygen-enriched chamber and administered DEX IV via a jugular vein catheter 10 minutes later. The ED90 for females (n = 46 per route of administration) given DEX IN was 0.57 mg/kg (95% CI: 0.16, 61.4), 0.44 mg/kg (95% CI: 0.11, 78) for IM and 0.59 mg/kg (95% CI: 0.13, 39) for IV. Work to determine the anticonvulsant ED90 for males and evaluate the degree to which DEX prevents the long-term consequences of NA-induced SE is ongoing.

Title: Adjunctive high dose intramuscular allopregnanolone in the treatment of tetramethylenedisulfotetramine (TETS)-induced status epilepticus in mice

Authors: *D. ZOLKOWSKA[1], R. JUNG[1], A. KIRIAKI[1], D. J. TANCREDI[2], M. A. ROGAWSKI[1];
[1]Dept. of Neurol., Sch. of Med., Univ. of California, Davis, Sacramento, CA; [2]UC Davis Dept. of Pediatrics and Ctr. for Healthcare Policy and Res., Sacramento, CA

Abstract: Benzodiazepines, the standard of care for initial treatment of status epilepticus (SE) in a chemical exposure emergency, are often ineffective in managing SE, especially when therapy is delayed. Intoxication with tetramethylenedisulfotetramine (TETS), a highly lethal GABA-A receptor antagonist, causes convulsive SE that is refractory to treatment. We have previously shown that allopregnanolone (5α,3α-P), a neurosteroid positive modulator of synaptic and

extrasynaptic GABA-A receptors, may provide an effective treatment option in benzodiazepine refractory SE including that caused by TETS. In the present study, we determined whether high dose of intramuscular (IM) 5α,3α-P (24 mg/kg) administered adjunctively to IM midazolam (MDZ, 1.8 mg/kg) was more effective than IM midazolam alone in terminating SE in mice exposed to TETS. To create a model mimicking the SE produced by TETS in humans, mice implanted with EEG electrodes were pretreated with a single dose of riluzole (10 mg/kg, IP) and 10 min later received a lethal dose of TETS (0.2 mg/kg, IP). Riluzole does not inhibit TETS-induced SE but does protect against the rapidly lethal effects of TETS in mice, providing a model of persistent seizure activity. Video EEG recording was carried out for at least 4 h after exposure to TETS. Animals were monitored for survival for 72 h after treatment. MDZ at a dose of 1.8 mg/kg (IM) was administered once at 40 min after the first myoclonic twitch either alone or in combination with 5α,3α-P (24 mg/kg) that was injected at 40 min and 100 min. Separate group of animals received 2 injections of 5α,3α-P alone. 5α,3α-P alone and in combination with midazolam led to rapid termination of the behavioral and electrographic SE as assessed by EEG power. 5α,3α-P combined with MDZ reduced the time of SE termination from 30.84 ± 12.12 min (MDZ alone) to 3.17 ± 0.58 min and increased 72 h survival from 50% (MDZ alone) to 100%. 5α,3α-P alone terminated SE (mean time to termination 3.04 ± 0.4 min) and protected 87.5% (7 of 8) of animals from mortality. Although all animals receiving the dual therapy and 5α,3α-P alone experienced sedation with loss of righting reflex for 5.72 ± 0.54 h and 3.85 ± 0.31 h, respectively, every animal fully recovered. Our results demonstrate that addition of high dose of 5α,3α-P to standard of care MDZ more rapidly and effectively terminates TETS-induced behavioral and EEG seizures than does MDZ alone. Sedation is a risk to the combination therapy but it is encouraging there is full recovery with no apparent untoward long term effects.

Title: Idh-mutated gliomas promote epileptogenesis via d-2-hydroxyglutarate dependent mtor hyperactivation

Authors: *A. MORTAZAVI[1], I. FAYED[2], M. BACHANI[1], A. KSENDZOVSKY[3], D. MARIC[4], T. DOWDY[1], M. LARION[1], C. YANG[1], K. A. ZAGHLOUL[5];
[1]Natl. Inst. of Hlth., Bethesda, MD; [2]Dept. of Neurosurg., Medstar Georgetown Univ. Hosp., Washington, DC; [3]Univ. of Maryland Sch. of Med., Baltimore, MD; [4]NINDS/NIH, Bethesda, MD; [5]Surgical Neurol. Br., Natl. Inst. of Neurolog. Disorders and Stroke, NIH, Bethesda, MD

Abstract: Introduction:Epileptic seizures in patients with low-grade, isocitrate dehydrogenase (IDH) mutated gliomas reach 90%, a major source of morbidity for these patients. Albeit there are multiple features that contribute to tumor related epileptogenesis, IDH mutations are determined to be an independent factor, although the pathogenesis remains poorly understood. We demonstrate IDH-mutated tumors promote epileptogenesis through D-2-hydroxyglutarate (D-2-HG) dependent mTOR hyperactivation and metabolic reprogramming.
Methods:Human epileptic and nonepileptic cortex were identified via subdural electrodes in patients with IDH-mutated gliomas (n=5). An *in vitro* rat cortical neuronal model on microelectrode arrays were utilized to investigate the role of D-2-HG on neuronal excitability. mTOR and lysine demethylase (KDM) modulators were applied to elucidate the epileptogenic mechanism. Tetrodotoxin was utilized to evaluate the contribution of neuronal activity to mTOR signaling and metabolism. mTOR signaling was evaluated through western blot analysis and multiplex immunofluorescence. Metabolic function were analyzed via Seahorse assays and metabolomic analysis.
Results:
D-2-HG increased normalized bursting rate in the neuronal cultures ($p<0.0001$). Inhibition of mTOR with rapamycin corrected bursting levels to control levels. Furthermore, D-2-HG induced mTOR hyperactivation, independent of bursting activity, which correlated with upregulation of mTOR signaling in human epileptic tissue. KDM inhibition resulted in mTOR hyperactivation and neuronal hyperexcitability, which we demonstrated with D-2-HG, succinate, and PFI-90, a small molecule KDM inhibitor. Epileptic cortex and D-2-HG-treated neurons, have distinct metabolisms independent of neuronal activity compared to peritumoral nonepileptic cortex and control, respectively.
Conclusion:We demonstrate IDH-mutated gliomas promote epileptogenesis through a D-2-HG dependent mTOR hyperactivation via KDM inhibition, a putative mechanism and potential therapeutic targets. Furthermore, we argue mTOR hyperactivation results in metabolic reprogramming, independent of neuronal firing, which may contribute to epileptogenesis, a heretofore unrecognized aspect of pathologic mTOR signaling in neurological diseases.

Abstract: A fundamental question that remains unsolved in clinical neuroscience and epilepsy research is how the brain generates unprovoked hypersynchronous electrical discharges. Notably, these spontaneous activities are highly variable across individual seizures and across patients. Specifically, seizures can be classified into different types based on the localization of onset regions and the accompanying behavioral manifestations. However, the underlying mechanisms that give rise to these different seizure types are not understood. The present study hypothesized that the mechanisms inherent to specific seizure types can be observed through graph network features. We analyzed intracranial electroencephalography (iEEG) data recorded from patients with four epilepsy types: 1) simple focal (onset regions in one hemisphere; intact awareness); 2) complex focal (onset regions in one hemisphere; impaired awareness often accompanied by automatisms); 3) secondary generalized (focal seizures that spread to both hemispheres; impaired awareness); and 4) generalized seizures (onset regions in both hemispheres of the brain; various clinical manifestations). Specifically, we modelled each patient's brain as a graph network where each node and edge represent a cortical region under a recording electrode and its connectivity weight to other electrodes, respectively. Graph network features were then computed separately for each seizure type. We found that the neural dynamics associated with different seizure types can be assessed and identified through a combination of graph network features such as degree, synchronizability, clustering coefficient, and spectral radius. Specifically, we showed that generalized seizures can be identified through a significantly higher spectral radius prior to seizure onsets as compared to the other seizures. After the onsets, network behavior of the three focal seizure types become more similar to that of generalized seizures, whereas the distributed nature of secondary generalized seizures can be captured by the increased degree per node and clustering coefficients as compared to the other two focal seizure types. To summarize, the present study illustrates graph network features as a novel biomarker for determining epileptic seizure types, which can subsequentially be used to guide a personalized patient- and type-specific seizure treatment.

Title: Seizure detection and localization using human intracranial electrophysiology via information theoretic methods

Authors: *L. YAMADA[1], T. OSKOTSKY[2,3], P. NUYUJUKIAN[2,3,1,4,5];
[1]Dept. of Electrical Engin., [2]Dept. of Bioengineering, [3]Dept. of Neurosurg., [4]Wu Tsai Neurosciences Inst., [5]Stanford Bio-X, Stanford Univ., Stanford, CA

Abstract: Of the 1% of the world population with epilepsy, one-third have refractory epilepsy, in which their only option to manage seizures is a high-risk surgery to remove seizure onset zones (SOZs, brain regions that are most likely to cause seizures). The current state of epilepsy treatment heavily relies on manual evaluation of EEGs by epileptologists and lacks interventions that leverage their rich information. To combat this limitation, we introduce an information theoretic estimate of joint entropy called the inverse compression ratio (ICR), which utilizes compression algorithms, as a potential quantitative EEG (qEEG) method. With our data repository of continuous, 10kHz intracranial EEGs acquired from clinical neuromonitoring studies of adult and pediatric participants, we study the relationship between ICR and seizure activity. When comparing ICR across time, we observed a sharp peak at seizure onset, followed by a dip, before returning to baseline. Furthermore, when analyzing characteristics of ICR peaks that occurred at seizure onsets (e.g. peak amplitude) across intracranial channels, we observed prominent changes that distinguished channels located in SOZs. When using ICR to perform seizure detection, we found an average sensitivity/specificity (SE/SP) of 81%/98% across 5 participants with a total of 30 seizures. In comparison, the average SE/SP of sample entropy, approximate entropy, and variance were 29%/97%, 36%/97%, and 45%/96%, respectively. Our results demonstrate that our information theoretic measure of ICR performs comparably to - if not better than - other qEEG measures, suggesting their potential in seizure detection and localization. Previous studies on the entropy of epileptic EEGs may not have detected the brief spike in information content at seizure onset due to signal quality or limitations in sampling rate. Implementing robust qEEG techniques to clinical practice may offload labor-intensive tasks from clinicians and uncover EEG features that cannot be detected by eye, broadening our understanding of epilepsy and improving therapy.

Abstract: The importance of astrocytes - non-neuronal glial cells - to cognitive function has been increasingly highlighted in recent work. Indeed, astrocytes have physiological roles ranging from maintaining brain homeostasis to modulating neuronal communication, and much of these functions occur at the endfeet of astrocytes. In this work, we have considered the crucial role of the cytoskeleton, both in fixed and live astrocytes, to understand the functional responses that result from extracellular environmental changes. To accomplish this goal, we culture primary neocortical rat astrocytes on a variety of surfaces, including poly-D-lysine (PDL) coated glass as a control and hydrotalcite nanoparticle films (HTlc), the latter of which causes astrocytes to become stellate.
For imaging cytoskeletal organization, astrocytes are grown on either PDL or HTlc, fixed, and stained with Phalloidin-488. The fixed cells are then imaged using high resolution stimulated emission depletion (STED) microscopy to obtain detailed images of the actin structure. To determine how actin structure differs for astrocytes grown on PDL versus HTlc, we use image processing methods to extract the actin filaments and quantify their relative angle to the cell boundary. We find significant differences in relative angles of astrocytic actin for cells grown on PDL versus HTlc. These results illustrate the importance of actin as a sensor of mechanical influences in the environment.
For imaging cytoskeletal dynamics, astrocytes are transduced with actin-GFP at 48 hr prior to imaging, and we then use live confocal microscopy to capture changes in actin for astrocytes cultured on PDL and HTlc. We also introduce a change to the chemical environment by replacing the standard, control media with saline containing either high potassium (40 mM KCl) or hypotonic challenge (ΔOsm=60 mOsm) to further understand cytoskeletal adaptations. We then employ optical flow to analyze actin dynamics and to study their persistence. We find that the chemophysical environment greatly influences the localization of actin dynamics and propose that these dynamics are a local manifestation of astrocytes' global homeostatic response to changes in the extracellular microenvironment.

Title: Chemogenetic activation of Gi signaling in dorsal hippocampal astrocytes prevents object memory consolidation in ovariectomized female mice

Authors: *L. TAXIER, S. PHILIPPI, K. M. FRICK;
Dept. of Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Astrocytes, despite being the most abundant cell type in the brain, have historically been relegated to a supportive role in the central nervous system. However, recent evidence suggests a more active role for astrocytes in synaptic activity in brain regions like the hippocampus. To test whether dorsal hippocampal (DH) astrocytic activity impacts memory consolidation, we used Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to manipulate Gi signaling in DH astrocytes. Nine week-old ovariectomized female C57BL/6 mice were infused into the DH with control viral construct (AAV-GFAP-eGFP) or hM4Di-containing viral construct (pAAV-GFAP-HAhM4D(Gi)-IRES-mCitrine) (n=10-12/group). Two weeks following viral delivery, mice were trained and tested in the object recognition (OR) and object placement (OP) tasks to assess object recognition and spatial memory consolidation, respectively. Immediately after training in each task, mice received an intraperitoneal (i.p.) injection of the DREADD actuator Clozapine-N-Oxide (CNO), and were then tested 24 h (OR) or 4 h (OP) later. Here, we tested effects of two doses of CNO, 1 and 5 mg/kg. hM4Di-infused mice injected post-training with 5 mg/kg CNO exhibited impaired OR and OP memory relative to mice expressing control virus, suggesting that activation of Gi signaling in DH astrocytes blocks object recognition and spatial memory consolidation. Two weeks later, mice were retrained with novel objects, received a 1 mg/kg post-training i.p. injection of CNO, and were tested at the same delays as before. The 1 mg/kg dose of CNO did not impair OR and OP memory in mice expressing hM4Di virus relative to chance levels of performance or to GFP-expressing controls. This dose will therefore be used in future studies to determine if activation of astocytic Gi signaling interferes with the memory-enhancing effects of neuromodulators. Combined, these data suggest that activating Gi signaling in DH astrocytes with a sufficiently high dose of CNO impairs object memory consolidation.

Title: Brain sub-region-specific gliosis during subcutaneous Group A Streptococcal infection in humanized mice

Authors: *A. SATPATI, S. MUKUNDAN, C. COMBS, S. NOOKALA;
Dept. of Biomed. Sci., Univ. of North Dakota, Sch. of medicine and Hlth. Sci., Grand Forks, ND

Abstract: Group A Streptococcus (GAS, *Streptococcus pyogenes*) is an important human pathogen that can cause mild self-limiting pharyngitis to life-threatening streptococcal toxic shock and necrotizing fasciitis (NF) that manifests as rapidly spreading progressive necrosis of the subcutaneous tissue and deep fascia. Recurrent GAS infections are not uncommon, and GAS mimics of host proteins can prime individuals with HLA-II predilection for increased risk of severity, outcomes, and post-streptococcal sequelae, that include a spectrum of neurological manifestations and neuropsychiatric disorders. However, the pathological changes in the brain that are in tandem with or latently following GAS NF are unknown. To study the concomitant neuroinflammatory changes during subcutaneous GAS infection and study the effect of clindamycin (CLN) treatment, the standard care for invasive GAS infections, we used clinically relevant HLA-II transgenic mice expressing a human HLA-II DQ8 allele as a preclinical model of GAS NF with no apparent lethal systemic toxicity. Mice were subcutaneously infected with a clinical isolate of GAS 5448 and were either untreated or treated with CLN (10mg/kg, initiated at 6 hours post-infection intraperitoneally and continued for 4 days) and monitored for 15 days. Most strikingly, our data showed a GAS burden in the cerebral cortex (CC) and the hippocampus (HC) lysates from infected mice, that was more profound in male compared to female mice. Treatment with CLN was significantly effective in reducing skin lesion areas, GAS burden, and levels of the pro-inflammatory mediators TNF-α, IL-6, IL-17F, and IL-22 in the skin. However, a sex-dependent difference was seen in the effect of clindamycin treatment against GAS that disseminated into the CC or the HC. The existence of a viable GAS reservoir in the brain was concomitant with a high intensity of staining with anti-glial fibrillary acidic protein (GFAP) and anti-Iba-1 antibodies, suggestive of reactive gliosis. In addition, we observed a spatial selective and region-specific gliosis that was significantly higher in the dentate gyrus and CA1 subfields despite CLN treatment. This was in stark contrast to the decreased reactive gliosis seen in the amygdala and CA3 subfields in male and female mice. Western blot analysis of the CC lysates confirmed significant changes in GFAP and Iba-1. Interestingly, CLN treatment increased

protein levels of occludin, a marker of BBB integrity. Our data provide critical information on the neuropathological changes that occur during or latently following subcutaneous GAS infections.

Title: Morphological differences in astrocyte populations of the basolateral amygdala and anterior cingulate cortex

Authors: *J. KOCUR[1], K. JONES[2], A. BETZ[3], M. MIRRIONE[4];
[1]Master's Program - Biomed. Sci., [3]Psychology, [4]Biomed. Sci., [2]Quinnipiac Univ., Hamden, CT

Abstract: Astrocytes are an omnipresent and seemingly omnipotent subset of the glial cell population found in the brain. They perform a variety of functions critical to CNS homeostasis, including the maintenance and formation of the blood brain barrier, migration of developing neurons, metabolic regulation, neurotransmission, and synaptogenesis. Dysregulation of normal astrocyte function has been implicated in the etiology and progression of numerous neurologic and psychiatric disorders. As such, there is a great demand for advancements with respect to better understanding astrocyte development and heterogeneity. Morphological classification of astrocytes has largely stagnated, with the majority of astrocytes broadly classified as protoplasmic or fibrous. In the present study, we aim to compare the astrocyte populations of the basolateral amygdala (BLA) and anterior cingulate cortex (ACC) of the medial prefrontal cortex, regions responsible for the processing of external stimuli and emotional regulation. Five adolescent female Sprague Dawley rats (postnatal day 40) were tested in the elevated plus maze to confirm non-anxious behavior, and two days later, brain tissue was collected and processed for microscopy. Astrocytes expressing glial fibrillary acidic protein (GFAP), an intermediate filament protein found in mature astrocytes, were evaluated using immunofluorescence and confocal microscopy. Astrocytes in two ACC subdivisions, area 1 and area 2, across three Bregma coordinates (2.28 mm, 0.00 mm, -1.44 mm) as well as the BLA (-1.56 mm, -2.40 mm, and -3.24 mm) bilaterally were quantified and analyzed. An open source software ImageJ, along with the plug-in Simple Neurite Tracer, was employed to count and trace astrocytes. A Sholl analysis was used to quantify the complexity of astrocyte process arbors. We found the total number of astrocytes counted per square mm in the BLA was significantly higher compared to the ACC. Furthermore, we found astrocytes in the BLA had significantly more complex process arbors with a significantly higher average number of intersections, as well as longer process

lengths when compared to the astrocytes in the ACC. While our sample is limited, this data supports further investigation into the characteristics of astrocyte populations in cortical and subcortical regions across sex, age, and behavioral state, of both male and female subjects. Further experimentation will examine the functional significance of these differences in morphology and may provide in-roads to modernizing the broad astrocyte classification system.

Title: Astrocytes contribute to motor learning, neuronal correlations and movement encoding by motor cortex neurons

Authors: *C. DELEPINE, K. LI, J. SHIH, P. GAUDEAUX, M. SUR;
Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: While motor cortex is crucial for learning precise and reliable movements, whether and how astrocytes contribute to its plasticity and function during motor learning is unknown. Here we report that primary motor cortex (M1) astrocytes in mice show in vivo plasticity during learning of a lever push task, as revealed by transcriptomic and functional modifications, particularly changes in expression of glutamate transporter genes and increased coincidence of microdomain calcium events. Astrocyte-specific manipulations of M1 are sufficient to alter motor learning and execution, and neuronal population coding, in the same task. Specifically, mice expressing decreased levels of the astrocyte glutamate transporter GLT1 show impaired and variable movement trajectories. Mice with increased astrocyte Gq signaling show decreased performance rates, delayed response times and impaired trajectories, along with abnormally high levels of GLT1. In both groups of mice, M1 neurons have altered inter-neuronal correlations and impaired population representations of task parameters, including response time and movement trajectories. Thus, astrocytes have a specific role in coordinating M1 neuronal activity during motor learning, and control learned movement execution and dexterity through mechanisms that include fine regulation of glutamate transport.

Title: Establishment of an in vitro model for myelination studies using neonate mice dorsal root ganglia explants

Authors: *G. SARDELLA-SILVA, R. A. DE MELO REIS, V. T. RIBEIRO-RESENDE;
Inst. de Biofísica Carlos Chagas Filho, Univ. Federal Do Rio De Janeiro, Rio de Janeiro, Brazil

Abstract: Schwann cells (SC) myelinate neurons in the peripheral nervous system and differentiate to terminal phenotypes in a temporally regulated manner. Some demyelinating diseases compromise in a severe and progressive way the patient's life quality. Therefore, studying myelination in an *in vitro* model that mimics demyelinating pathologies might help important future therapeutic strategies. Our study aims to establish an *in vitro* myelination model using C57BL/6 neonatal mice (P0-P2) dorsal root ganglia (DRG) explants. We evaluated DRG cultures over 4 substrate conditions: poly-L-lysine (control), poly-L-lysine associated with laminin-111 in PBS buffer, poly-laminin (laminin-111, pH 4), and laminin (laminin-111, pH7). Neurite outgrowth was evaluated through phase-contrast and fluorescence microscopy in all DRG explant conditions, while migrating cells were aligned to the neurites and had a SC morphology. The laminin group had the largest neurite extension and migration area, when compared to other substrates. Neuro-glial connections were observed using single cell calcium imaging responses, showing a functional connected system, correlated to the expression of connexin-43. The expression of the transcriptional factors Sox10 and Krox20 was also evaluated through fluorescence microscopy, characterizing the total glial and myelinating cell number, respectively, over the time course of 3-5 days *in vitro* (div). None of the groups showed differences in the percentage of myelinating cells over the observed timepoints, but poly-laminin and laminin groups had an increase in the total number of migrating cells in cultures maintained for 5 div. Immunostaining for myelin basic protein (MBP) confirmed myelin presence, and relative quantification showed that the laminin group had the highest expression of MBP. All results were obtained from at least 3 replication experiments, with individual DRG from different animals as sample. Statistics were performed following a normality test, 1-way ANOVA and Tukey's post hoc. Altogether, our results show that DRG explants from neonatal mice are a suitable model for *in vitro* myelination studies, resulting in functional Schwann cells. Moreover, DRG explants had a better adhesion and stability at polymerized laminin substrate (pH 4), displaying migrated cells with myelinating profile with higher MBP expression. The model stands out for its simplicity, not requiring the addition of many factors and its potential application for many myelination experimental approaches.

Catholique De Louvain, Brussel, Belgium; [8]Hunter James Kelly Res. Inst., State Univ. of New York at Buffalo, Buffalo, NY

Abstract: The mechanisms that govern peripheral myelination are not completely understood. To identify novel candidates involved in axo-glial interactions we used a Schwann cell pseudopod assay with the addition of laminin to generate polarity. The proteomic analysis of subcellular fractions revealed an enrichment of the Planar Cell Polarity protein CELSR2 (for Cadherin EGF LAG Seven-Pass G-Type Receptor 2) in Schwann cell protrusions extended towards neuronal membranes.Thus, we evaluated whether CELSR2 is necessary for Schwann cell myelination in co-cultures with dorsal root ganglia (DRG) neurons. Indeed, knockdown of CELSR2 in Schwann cells impaired myelination in vitro. In vivo, constitutive knockout of CELSR2 delays peripheral myelination. During development (postnatal days P5-20), sciatic nerves of CELSR2 KO mice have an impairment on radial sorting characterized by higher number of bundles of unsorted axons and more axons per bundle compared to WT littermates. Additionally, these animals have more amyelinated axons and their G-ratios are higher indicating thinner myelin. This delay is transient and is resolved by the time myelination is complete at P30. CELSR2 does not have an apparent role in myelin maintenance since KO and WT aged mice have similar numbers of degenerating axons and demyelinated fibers. The internodal length is also normal in adult CELSR2 KO mice. The family of orthologs of *Drosophila's* protein Flamingo also includes CELSR1 and CELSR3. Therefore, one possibility is that these similar proteins have redundant roles with CELSR2. The mRNA expression levels of CELSR2 are higher than the ones of CELSR3 whereas the expression of CELSR1 is almost negligible in mouse sciatic nerves. It is plausible that CELSR3 may compensate for the loss of CELSR2, thus concomitant ablation of the respective genes might worsen the phenotype. Using isolated Schwann cells and neurons we found that CELSR2 is expressed in both cell types, therefore a role for neuronal CELSR2 cannot be ruled out in the constitutive KO mouse. One way to address

these questions is by generating CELSR2 (and CELSR3) in conditional knockout mice in which the gene is only knocked out in Schwann cells. CELSR2 is a promising candidate to evaluate regarding its role in peripheral myelination and the underlying mechanisms are to be elucidated.

Abstract: Identification of the VEGF-C isoform in Muller cells cultures from mice retina. Carranza Jiménez Zoe Pamela[1], Medina Arellano Alan[1], Sánchez-Castillo Hugo[3], Galvan Emilio[3], Ochoa-de la Paz Lenin David[1,2]. Laboratorio de neurobiología molecular y celular de la glia, Departamento de Bioquímica, Facultad de Medicina, UNAM[1]. Unidad de investigación UNAM-APEC Asociacion para prevenir la ceguera en México I.A.P. Hospital "Dr. Luis Sánchez Bulnes"[2], Facultad de Psicología[3], UNAM, CINVESTAV Sur[4].Muller cells (MC) are the main macroglia of the retina. They extend from the ganglion cell layer to the internal segments of photoreceptors, facilitates physical contact with many types of cells in the retina. So it plays an important role in various physiological processes in the retina such as regulating the blood-retinal barrier, releasing growth factors, homeostasis of water and ions (K^+) and regulating innate immunity of retina through microglia interaction, among others. In pathological conditions such as diabetic retinopathy or age-related macular degeneration, MC contribute to neurovascular dysfunction by producing inflammatory and angiogenic factors. In the last years, experimental observations, indicate that MC is an important source of VEGF in the retina under pathological conditions. The VEGF family consists of five members (VEGF-A, B, C, D, and PlGF), all of them, structurally related to three different tyrosine kinase receptors (VEGFR1, VEGFR2, and VEGFR3) and two neuropilin choreographers (NRP1 and NRP2) that improve ligand affinity for VEGFR receptors, thus improving their physiological actions. VEGF-C is a specific growth

factor for lymph vessels in a variety of models, also promotes the growth of and also blood vessels. One of the functions of MC is to regulate the angiogenic factors release, such as VEGF-A, however, it is unknown about the presence of VEGF-C in these glial cells. We aimed to determine if the VEGF-C form is present in the MC. Using immunofluorescence assays we observe that VEGF-C is expressed in MC (Fig 1), also the mRNA, according to the rt-PCR analysis of MC in cultures. These results, shown the presence of VEGF-C in MC, so the presence of this growth factor suggests that MC not only regulate the angiogenic process in the retina, also, could interact with microglia, playing a role in the inflammatory mechanism presents in different retinopathies. Nevertheless, more experiments are necessary to confirm this hypothesis.

Title: An optogenetic approach to understand molecular mechanisms of astrocyte-neuron interactions in the development of neuronal synchrony.

Authors: *T. CLIFFORD[1], M. TEMBURNI[2];
[2]Biol., [1]Delaware State Univ., Dover, DE

Abstract: Neurons must fire together in networks to perform a variety of functions but the mechanisms by which they accomplish this synchronization are not entirely understood. In some cases, this phenomenon does not function as intended, leading to states like epileptic seizures. Existing models of synchronous activity assume that it is intrinsic to neurons. Astrocytes have been shown to modulate oscillatory activity in networks of neurons possibly by releasing gliotransmitters like glutamate and ATP. Using the mitotic inhibitor 5-fluorodeoxyuridine (FUdR) we established pure neuron only cultures from chick embryonic day 7 (E7) optic tectum and recorded neuronal network activity on multielectrode arrays (MEAs). Our preliminary results indicate that astrocytes are necessary for synchronous activity of neurons in culture. Mixed neuron and astrocyte cultures on multi-electrode arrays (MEAs) show random spiking activity which synchronizes over time whereas astrocyte-free neurons only show random activity without synchronization. Our results validated that the physical presence of astrocytes is required to properly establish synchronized activity in neuronal networks. We implicate calcium mobilization within astrocytes via metabotropic g-protein coupled receptor (GPCR) pathways leading to gliotransmitter release as a possible mechanism for neuronal synchronization. To test this hypothesis, we used an optogenetic approach - using a lentiviral vector we expressed the

photopigment melanopsin, a Gaq coupled GPCR with an absorption peak of around 470nm, in chick optic tectum astrocytes. Our preliminary optogenetic activation experiments indicate Ca++ flux in astrocytes upon optogenetic stimulation with 470nm blue light. This powerful tool allows us to combine live calcium imaging with multielectrode array experiments to clearly define the role of astrocytic calcium in the development of network activity of neurons, particularly synchronization.

Title: Microglial calcium signaling is attuned to neuronal activity shifts

Authors: *A. D. UMPIERRE, L.-J. WU;
Neurol., Mayo Clin., Rochester, MN

Abstract: Microglial calcium signaling underlies a number of key physiological and pathological processes in situ, but has not been studied in vivo in awake mice. Using multiple GCaMP6 variants targeted to microglia, we assessed how microglial calcium signaling responds to alterations in neuronal activity across a wide range. We find that only a small subset of microglial somata and processes exhibited spontaneous calcium transients in a chronic window preparation. However, hyperactive shifts in neuronal activity (kainate status epilepticus and CaMKIIa Gq DREADD activation) triggered increased microglial process calcium signaling, often concomitant with process extension. Additionally, hypoactive shifts in neuronal activity (isoflurane anesthesia and CaMKIIa Gi DREADD activation) also increased microglial process calcium signaling. Under hypoactive neuronal conditions, microglia also exhibited process extension and outgrowth with greater calcium signaling. Our work reveals that microglia have highly distinct microdomain signaling, and that processes specifically respond to bi-directional shifts in neuronal activity through increased calcium signaling.

Title: Role of the Astrocytic mGluR Pathway in the Development of Neuronal Synchrony

Authors: V. A. N. TALABATTULA[1], M. MOORE[2], *M. TEMBURNI[1];
[1]Biol. Sci., [2]OSCAR Imaging Ctr., Delaware State Univ., Dover, DE

Abstract: Synchronous oscillations are necessary for establishing functional neuronal networks in normal vertebrate brain development - however, the mechanisms of neuronal synchronization are not fully understood. Existing models of synchronous activity assume that it is intrinsic to neurons. Astrocytes have been shown to modulate oscillatory activity in networks of neurons possibly by releasing gliotransmitters like glutamate and ATP. We have established pure neuron only and mixed (astrocyte and neurons) cultures from the developing chicken brain (optic tectum) and recorded neuronal network on multi-electrode arrays. Our preliminary results indicate that astrocytes are necessary for synchronous activity of neurons in culture. To further dissect the molecular pathways involved, we targeted the metabotropic glutamate receptor (mGluR) pathway within astrocytes as a mechanism by which astrocytes influence synchronous firing. Astrocytes express mGluRs that consist of the same subunits and stoichiometry as those expressed in neurons. Our model predicts that glutamate sensing at tripartite synapses via mGluRs elevates local calcium within astrocyte processes. With sufficient activation, the localized calcium elevation crosses a threshold causing a global calcium release within the astrocyte leading to the exocytosis of glutamate. To test this model we expressed a truncated mGluR subunit (mGluR DN) which acts as a dominant negative to block downstream signaling along with GCaMP6F for assaying Ca^{++}activity in primary chick astrocytes. Our results demonstrated that astrocytes expressing the mGluR DN reduced the calcium elevation upon stimulation with glutamate. Our next steps involve co-culture of the mGluRDN-GCamP6F astrocytes with neurons on MEAs and measure synchrony index, mean firing rates, spike amplitudes and other network parameters.

Title: Role of synaptobrevin in glutamate exocytosis by astrocytes

Authors: *T. I. AMANFO[1], V. A. N. TALABATTULA[1], M. TEMBURNI[2];
[2]Biol. Sci., [1]Delaware State Univ., Dover, DE

Abstract: Synchronous neuronal activity is a hallmark of developing as well as fully developed neuronal networks and is necessary for the functional organization of the brain. However, the mechanisms of the development of these synchronous oscillations are poorly understood. While existing models assume it as a process intrinsic to neurons, recent evidence suggests that astrocytes have an important role in the development of the synchronous activity. We established pure neuron only and mixed (astrocyte and neuron) cultures on multielectrode arrays (MEAs) from the embryonic chick optic tectum. Our preliminary results indicate that astrocytes are necessary for the synchronous activity of neurons in culture. Mixed neuron and astrocyte cultures show random spiking activity which synchronizes over time whereas astrocyte-free neurons only show random activity without synchronization. Our results validated that the physical presence of astrocytes is required to properly establish synchronized activity in neuronal networks. Our model predicts that glutamate sensing at tripartite synapses via mGluRs elevates local calcium within astrocyte processes. With sufficient activation, the localized calcium elevation crosses a threshold causing a global calcium release within the astrocyte leading to glutamate exocytosis. We targeted the SNARE protein Synaptobrevin (Vamp2) within astrocytes as crucial for communication with neurons via the exocytotic release of glutamate. We proposed to test this model by disrupting glutamate exocytosis within astrocytes using a truncated Vamp2 subunit (Vamp2 DN) which acts as a dominant-negative blocking exocytotic release. Astrocytes expressing the Vamp2 DN are expected to not release glutamate causing a problem in the synchronization provided by astrocytes. We have generated astrocyte lines expressing the synaptobrevin dominant-negative (Vamp2 DN) along with the glutamate sensor iGluSnFR. With these tools, a more comprehensive molecular model for astrocyte involvement in the generation of neuronal synchrony can be developed.

Title: Myelin ensheathment and activity-dependence in a developing visual system

Authors: *Z. CHORGHAY[1,3], D. MACFARQUHAR[2], V. J. LI[1,3], S. AUFMKOLK[2], A. SCHOHL[1,3], P. W. WISEMAN[2], R. T. KÁRADÓTTIR[4], E. S. RUTHAZER[1,3];
[2]Dept. of Chem., [1]McGill Univ., Montreal, QC, Canada; [3]Montreal Neurolog. Inst., Montreal, QC, Canada; [4]Cambridge Univ., Cambridge, United Kingdom

Abstract: Myelination is important for the fidelity of information transmission in brain circuits and is increasingly thought to be a substrate of plasticity. The African claw-toed frog, *Xenopus laevis*, is a good model organism for the study of circuit development and function, particularly in response to changes in activity, but a comprehensive characterization of the timecourse of myelin ensheathment during its development has been lacking. Here, we use immunostaining of myelin basic protein (MBP) as a proxy for myelin ensheathment, and cross-validate it with third-harmonic generation microscopy, an emerging label-free technique for imaging myelin in the nervous system that relies on sub-micrometer heterogeneities produced by optical interfaces of neighboring regions. Consistent with other species, we observe a caudal-to-rostral developmental progression of MBP expression. This detailed characterization allowed us to narrow down a developmental window and region in which to systematically study the interplay between myelination and activity. We focus on the visual system at a developmental stage where MBP expression is just beginning to occur, and ask what happens to myelin ensheathment here when we manipulate neuronal activity through visual experience. First, we recorded calcium responses from GCaMP6s animals to systematically characterize the persistent activation and adaptation of the visual system in response to LED flashes ("strobe") presented at different frequencies. Based on these findings, we selected two strobe frequencies: 1/16 Hz to evoke ongoing activity and 1 Hz to habituate the visual response. We reared stage 48 animals at either strobe frequency or under ambient light (control) for 7 days, then collected high-resolution confocal images of the immunostained optic chiasm of each animal. We report a significant difference in the MBP-associated axonal volume at the chiasm between these conditions, with ongoing calcium responses and increased MBP expression elicited by 1/16 Hz stimulation compared to adaptation of calcium responses and correspondingly reduced MBP expression with 1 Hz strobe stimulation. Taken together, we report myelin ensheathment in normal Xenopus development and the effects of sensory experience, highlighting the interaction between neuronal activity and myelination in developing brain circuits.

Title: Systems approach to neuroinflammation - computable biological network model for reactive astrogliosis

Authors: *M. BARKHUIZEN, V. BELCASTRO, M. C. PEITSCH, J. HOENG, M. TALIKKA;
PMI R&D, Philip Morris Products S.A., Neuchâtel, Switzerland

Abstract: Astrocytes play a central role in maintaining normal CNS function and the neuroimmune response. Following a CNS insult, astrocytes respond with diverse molecular and morphological changes in a process commonly referred to as reactive astrogliosis. While traditional approaches have unraveled critical mechanisms, the insights are often limited to the production of inflammatory proteins and changes in key astrocyte markers. To complement traditional endpoints, the changes in thousands of molecules (e.g., RNA) triggered by reactive astrogliosis can be captured using high-throughput technologies and interpreted with computational approaches. Causal biological network models, scripted in the Biological Expression Language, facilitate the assembly of available biological knowledge in a structured computable format that facilitates mechanistic interpretation of molecular data in a well-defined biological context. The network model consists of biological entities (nodes) and relationships between the nodes (edges). Information regarding gene expression regulation by some of the nodes in the network backbone is employed to build a second, scorable layer to the network model. This layer is used to infer the activity of the backbone nodes from transcriptomic data, and the impact on the network as a whole can be assessed using the network perturbation amplitude algorithm. Here, we introduce causal biological network models that describes the molecular pathways underlying reactive astrogliosis. The models captures key signaling pathways involved in i) pan-insult astrocyte reactivity, ii) neurotoxic A1 specific reactivity, iii) neurotrophic A2 specific reactivity, iv) loss of homeostatic functions, and v) glial scar formation pathways. Owing to the second layer, the network models can be scored with transcriptomic data from studies of CNS insults to derive a quantitative measure and mechanistic understanding of key molecules driving astrocyte reactivity. This is the first step to comprehensively model reactive astrogliosis in a computable form.

Abstract: Purpose: Glioblastoma (GB) is one of the most aggressive tumors affecting the central nervous system (CNS) due to its rapid progress and resistance to drugs associated with the presence of ATP-binding cassette (ABC) transporters, such as breast cancer resistant protein (BCRP), a drug efflux transporter. The first-line treatment of the disease is surgery, followed by radiotherapy combined with chemotherapy (temozolomide-TMZ), but the prognosis is poor. Recent studies have shown that albendazole (ALB), and their active metabolite albendazole sulfoxide (ALBSO), have anticancer activity attributed to their tubulin binding capacity, resulting in de-polymerization and cell-cycle arrest; whereas melatonin (MLT) with antioxidant properties, has been associated with the inactivation of signaling pathways for the proliferation and survival of tumor cells. In the search of new treatments, we considered that this drug combination could be an alternative approach. Objective: Evaluate the in vitro effect of the ALB-MLT and ALBSO-MLT combinations against glioblastoma cells.Methods: C6 cells were treated with ALB in the range of 0.16 to 1.25 µM; ALBSO in a range of 2.0 to 64.0 µM; MLT in the range of 0.25 to 8.0 mM and TMZ (positive control) at 100 µM, for 72 hours. Cell viability was evaluated with the MTT technique. The mean effect (Dm) was calculated and then the ALB-MLT combination was evaluated in a 1:1 and 1:4 ratios, and also the ALBSO-MLT combination in a 1:1 ratio. The combination index (CI) and dose reduction index (DRI) were determined using CompuSyn software. To determine the type of the cell death (apoptosis or necrosis) the annexin V / 7AAD test was performed using by flow cytometry. Data were expressed as the mean of the standard error (MSE). All experiments were performed in triplicate. The determination of significant differences in the experiments of cell viability and induction of necrosis and apoptosis was performed with a one-way analysis of variance (ANOVA) and a Tukey post hoc test. In all cases, significance was considered when * $p < 0.05$.Results: The Dm for ALB, ALBSO and MLT were 0.6 µM, 20.0 µM and 1.0 mM, respectively. Most combinations of ALB-MLT and ALBSO-MLT exhibited synergism (CI between 0.1 and 0.85) and favorable dose reduction (DRI between 2.0 and 19.0). Cytometric analysis showed a greater effect of cell death with the combination than with the drugs alone, mainly due to apoptosis.Conclusion: The results are promising, mainly for the favorable dose reduction. Other studies in animal models are needed to determine the advantages of the combination.

Title: The role of astrocytes in SMA motor neuron synaptic defects

Authors: *E. WELBY, A. D. EBERT;
Cell Biology, Neurobiology, and Anat., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Spinal muscular atrophy (SMA) is a neurodegenerative disease primarily characterized by the loss of lower spinal motor neurons. Evidence suggests that survival motor neuron (SMN) protein deficiency in other cell types, including astrocytes, also contributes to SMA pathology. We and others have previously demonstrated that astrocytes derived from patient induced pluripotent stem cells (iPSCs) show SMN-dependent intrinsic defects. In addition to providing neurotrophic support, astrocytes play an important regulatory role in synapse development and function. Motor neuron peripheral and central synaptic defects have been previously described and restoration of SMN expression in motor neurons can improve synaptic integrity, but only to a certain extent. It remains to be fully determined how human glial cells contribute to SMA synapse pathogenesis.
Differential gene expression analysis of our iPSC-derived astrocyte RNA seq data demonstrates a significant down-regulation of genes associated with synaptic transmission and plasma membrane cell projections in patient-derived samples. Using the SurfaceGenie prediction tool, we verified many of these down-regulated genes are likely to encode cell surface proteins. A large number of genes are associated with regulation of ion gradients (K^+ ion channels, Ca^{2+} regulatory channels), neurotransmitter release (glutamate receptors and transporters) and synaptic formation and integrity (ephrins, cell adhesion proteins). We therefore hypothesize that SMA astrocytes may lack important synaptic-related cell surface genes and their encoding proteins, which could contribute towards motor neuron synaptic defects. We will further characterize abnormal cell surface protein expression in SMA astrocytes using cell surface capture mass spectrometry and investigate the downstream molecular and functional implications in our *in vitro* co-culture system using super resolution microscopy and multi-electrode array (MEA) approaches. Preliminary MEA data from SMA iPSC-derived motor neuron cultures already suggests an intrinsic defect in mean firing rate and we will investigate if SMA astrocytes could further compound this intrinsic synaptic deficit.

Title: Cerebral cavernous malformation 3 regulates astrocytic plasticity and neurovascular coupling under excitotoxicity

Authors: Y.-T. LIU[1,3], P.-C. HSU[2], P.-K. YU[2], Y.-C. HSIN[2], J.-F. LIRNG[1,4], *Y.-H. LEE[2]; [1]Fac. of Med., [2]Physiol., Natl. Yang-Ming Univ. Sch. of Med., Taipei, Taiwan; [3]Neurol., [4]Radiology, Taipei Veteran Gen. Hosp., Taipei, Taiwan

Abstract: Cerebral vascular malformations (CVMs) are lesions due to abnormal vasculogenesis in the brain, with arteriovenous malformation (AVM) and cerebral cavernous malformation (CCM) as the two commonest types. CCM is the most frequent epileptic CVM. Familial CCM mutations in the three genes are most frequently identified: *CCM1 (KRIT1), CCM2 (MGC4607)* and *CCM3 (PDCD10). CCM3* mutations are responsible for the most aggressive phenotypes and an earlier age of onset, and is predominantly expressed in glial cells. In this study, we used human cortical astrocytes and human brain microvascular endothelial cells (BMEC) to study the role of CCMs in astrocyte functions. Our data show that reduction of CCM1, 2, and 3 expressions by RNA interference (siCCMs) inhibit the expression of glutamate transporter 1 in astrocytes and VCAM1 in BMEC, but only siCCM3 increase reactive astrocyte marker GFAP. Indeed, we found that siCCM3 in astrocytes not only causes hypertrophy but also increase the vulnerability to high glutamate stimulation. Importantly, CCM3 is predominantly expressed in astrocytes, not brain vascular endothelial layers, in mouse brain hippocampus. Astrocyte conditioned medium from siCCM3- astrocytes show damaging effects on BMEC morphology and tight function protein expression For the immune response of astrocytes, siCCM3, not siCCM1 or siCCM2 in human astrocyte-conditioned medium show common feature in cytokine elevation as in CCM patients' serum. Thus, these results suggest that CCM3 loss of function would cause molecular and structural alterations of astrocytes, which may be causal to the neuronal hyperexcitation and vasculopatholgy in CCM.

Title: Serum levels of glial fibrillar acidic protein as a peripheral biomarker of cognitive dysfunction due to high-fat/high-fructose diet consumption.

Authors: *L. AYALA-GUERRERO[1,2], F. BERMÚDEZ-RATTONI[1], K. R. GUZMAN-RAMOS[3];
[1]Inst. de Fisiologia Celular, Mexico, Mexico; [2]Posgrado en Ciencias Biológicas, Mexico, Mexico; [3]Ciencias de la Salud, Univ. Autónoma Metropolitana, Mexico, Mexico

Abstract: One of the main public health problems in the world is the high prevalence of overweight and obesity. The fundamental cause of these metabolic disorders is an energy imbalance between the expended and the consumed calories, together with the increase of sedentary behaviors from early ages. In consequence, it is evident an increase of the prevalence of cardiovascular problems, dyslipidemias, liver disease, inflammation, metabolic syndrome and type II diabetes mellitus, chronic non-communicable diseases that are expensive for the health sector. Along with the peripheric consequences of such states, there is an increased risk to suffer cognitive impairment, which occurs naturally until advanced ages. Both, aging and metabolic disorders are associated with production of oxidative stress in the brain and neuroinflammation which is considered a main culprit of the development of such cognitive impairment. Astrocytes are the most abundant cells in the brain and respond to any type of brain insult through astrogliosis. One hallmark of astrogliosis is the increase of glial fibrillar acidic protein (GFAP); essential for the growing and proliferation of astrocytes which expression is predominantly in the central nervous system. It has been reported that astrogliosis increase during aging and after exposure to a high-fat diet in young mice, so it is possible that serum GFAP would be a good peripheral biomarker of central injury and aid us to predict the beginning of cognitive impairment. To test this hypothesis, first we analyzed the cognitive performance and astrocyte morphology on dorsal hippocampus (DH) from male and female C57BL/6 mice of 5 (n=17), 10 (n=15), 15 (n=17), and 19 (n=18) months. Then, we analyzed the same parameters from male and female C57BL/6 weaning mice (n=13) exposed during 5 months to a diet composed of 10% fructose and 60% caloric intake from fat. We found a progressive decline of cognitive function in DH dependent memory tasks such as Morris's water maze in normal aging. On the other hand, high fat/fructose diet in adult mice induces increased weight, central adiposity, glucose intolerance and causes cognitive impairment like older mouse. Sholl analysis showed slight morphological changes in DH astrocytes from high fat/fructose group. However, we did not find changes in serum GFAP levels among groups, indicating that, under these conditions, serum GFAP is not a good peripheral biomarker, so we suggest examining serum GFAP levels in advanced stages of central damage.

Title: Determination of histological changes in the brain through the astrocytic response in the calcification process in neurocysticercosis

Authors: *L. E. BAQUEDANO SANTANA[1], N. MIRANDA[2], J. BUSTOS[2], H. H. GARCIA[3], M. FORERO[4];
[1]Univ. Peruana Cayetano Heredia, Lima, Peru; [2]UPCH, Lima, Peru; [3]Inst. Nacional de Ciencias Neurologicas, Lima, Peru; [4]Univ. de Ibague, Ibague, Tolima, Colombia

Abstract: Neurocysticercosis (NCC) is a parasitic disease caused by the Taenia solium larval stage (cyst) in the central nervous system. It is the leading cause of acquired epilepsy in endemic countries. Calcifications produced by this disease are associated with seizures in 20% of patients. This study aimed to characterize and evaluate the neuropathological findings of calcifications in the brain of pigs with NCC. We used 14 pigs naturally infected with T. solium, and they received antiparasitic treatment. Were sacrificed at eight months post-treatment and the brains were perfused, removed, and fixed in paraformaldehyde. Hematoxylin-Eosin and Masson's Trichrome stain were used to describe the response inflammatory. Also, we use Von Kossa and Alizarin red stain to identify and describe the presence of calcium deposits and scanning electron microscopy to quantify calcium phosphate deposits, and the immunostaining studies were evaluated with IBA, and GFAP. We found differences in collagen scarring, microglial reactivity, calcium accumulation, and axonal damage in the classic morphological appearance of traumatic axonal injury in the treated group compared with non-treated group. Our data provide novel insight into the relationship between disrupted blood-brain barrier (BBB), glial reactivity, and the progression of calcification of the neurocysticercosis. Future studies in new drugs on the antiparasitic treatments will be conducted.

Title: Peripheral astrocyte protein level characterization after transcranial magnetic stimulation in treatment resistant depression

Authors: *A. M. FUKUDA[1,2], L. E. HINDLEY[2], J. D. KANG[2], E. TIRRELL[2], A. R. TYRKA[1,3], L. L. CARPENTER[1,2];
[1]Psychiatry and Human Behavior, Brown Univ. Alpert Sch. of Med., Providence, RI;
[2]Neuromodulation Res. Facility, [3]Butler Hosp., Providence, RI

Abstract: Background: Transcranial magnetic stimulation (TMS) therapy is effective for treatment resistant depression (MDD) but the therapeutic mechanism of action is still being elucidated. Astrocytic contributions to the pathophysiology of depression has started garnering attention but has not been explored in TMS in depression. A pilot study examining serum levels of three astrocytic proteins: S100 Calcium Binding Protein B (S100B), Glial Fibrillary Acidic Protein (GFAP), and Vascular endothelial growth factor (VEGF), before and after TMS in MDD was carried out to study their potential roles in the mechanism of TMS. **Methods:** Serum was collected from a naturalistic population of 35 patients (40% male, 60% female) with MDD at two timepoints: prior to receiving first session of TMS and after the 30th session. Protein concentrations were determined via Enzyme-linked Immunosorbent Assay (ELISA) and all samples were run in duplicates. Inventory of Depressive Symptomatology Self Report (IDS-SR) was used as a measure of depression symptom severity, clinical response, and remission. TMS was given at standard 10 Hz delivered to the dorsolateral left prefrontal cortex daily at 120% maximum intensity relative to their motor threshold for a minimum of 3000 pulses. **Results:** There was a positive correlation between %change in IDS-SR and %change in GFAP ($r=.561$, $p<0.05$), and VEGF ($r=.358$, $p<0.05$). Amongst those who remitted, VEGF increased from pre to post TMS (%change +12.30%) whereas VEGF decreased in nonremitters (% change -9.24%) ($p=0.054$). This same pattern was observed when comparing VEGF changes between responders (+9.35%) and non-responders (-12.42%) ($p<0.05$). Similarly, GFAP also increased in responders (+151.18%) but decreased in non-responders (-41.10%) ($p<0.05$). S100B did not correlate with depression severity changes, nor did they differ between those with different clinical outcomes. The protein levels did not differ by sex or with age. **Conclusions:** Patients with a successful treatment with TMS had significantly greater increase in VEGF and GFAP from pre to post treatment compared to non-responders and a larger increase was associated with greater improvement in depressive symptoms after TMS. These patterns were not seen in S100B. The functional implications of the differential changes in these astrocytic proteins are yet to be elucidated, but data from preclinical work hint at neuroinflammation, angiogenesis, synaptic remodeling, and blood brain permeability changes. This pilot study provides promising exploratory data showing that GFAP and VEGF is an important mediator in the mechanism behind TMS' antidepressant effects.

Title: Functional Remodeling of the Tripartite Synapse in Cocaine Abuse and Addiction

Authors: *D. M. GIANGRASSO, J. N. WAGNER, M. M. TIMM, K. S. WILCOX, K. A. KEEFE;
Dept. of Pharmacol. & Toxicology, Univ. of Utah, Salt Lake City, UT

Abstract: Cocaine is a commonly abused psychostimulant. With repeated drug exposure, there is a shift from drug abuse to addiction that is thought to develop via transition from goal-directed to habitual control over behavior. The transition to habitual control over behavior is associated with potentiated corticostriatal glutamate signaling in dorsolateral striatum (DLS); however, the mechanisms underlying such potentiation, particularly in drug addiction, are largely unknown. Astrocytes critically regulate synaptic transmission. In particular, astrocytes express glutamate transporter-1 (GLT-1), which regulates the concentration and time-course of extracellular glutamate. Rats with a history of cocaine self-administration display decreased GLT-1 protein expression in ventral striatum and DLS. However, the functional impact of the decrease in GLT-1 on glutamate clearance in DLS is unknown, as is the relation to development of habitual control over drug-seeking. The objective of this study therefore was to determine if glutamate clearance is reduced in DLS following repeated cocaine self-administration in rats exhibiting habitual control over cocaine-seeking. We expressed the intensity-based glutamate-sensing fluorescent reporter (iGluSnFr) in astrocytes of DLS of male Long-Evans rats before they underwent training on a chained cocaine self-administration paradigm. At the end of training, rats underwent extinction of the taking lever, followed by testing under devalued and then re-valued conditions. The ratio of cocaine-seeking under devalued vs. valued conditions was used to classify rats as being habitual (resistant to outcome devaluation) or goal-directed (sensitive to outcome devaluation) in their cocaine-seeking. Following testing, coronal brain slices were collected and local stimulation (1mA pulses) was used to evoke glutamate release and iGluSnFr signals. Experimenters were blinded to drug condition and classification during imaging and data analysis. The average decay tau of evoked iGluSnFr signals in DLS was significantly slower in rats whose cocaine-seeking was under habitual control relative to rats whose cocaine-seeking was goal-directed ($p<0.003$) and yoked-saline controls ($p<0.006$). There was no difference between rats whose cocaine-seeking was goal-directed and yoked-saline rats ($p=0.56$). These data suggest that glutamate clearance in DLS is slowed in rats exhibiting habitual, but not goal-directed, cocaine-seeking. Studies are ongoing to examine whether these changes are specific to

DLS and are associated with alterations in GLT-1 expression and excitatory transmission onto striatal efferent neurons.

Title: Role of CD38 in Spinal Opioid Antinociception

Authors: *R. E. QUINTANA, A. GUEDES;
Univ. Of Minnesota, Saint Paul, MN

Abstract: The number of deaths by opioid overdose has risen fivefold over the past twenty years, yet opioids remain highly prescribed for the treatment of pain. In addition, opioid therapy is frequently associated with tolerance and addiction. Better understanding of the mechanisms that modulate opioid antinociception and tolerance could lead to the development of better pain treatment alternatives. The transmembrane glycoprotein CD38, which is important for intracellular calcium homeostasis, has been linked to supraspinal opioid anti-nociception and tolerance, but these experiments were only on male mice and failed to provide a pain model to study the role of CD38 in opioid antinociception. There is also a lack of information regarding the cellular expression of CD38 in the spinal cord, a site relevant for opioid actions. Our study aims to understand the role of CD38 in opioid antinociception in chronic neuropathic pain and to explore the cellular expression of CD38 in the spinal cord. To investigate the role of CD38 in neuropathic pain, we used the spared nerve injury (SNI) model in male and female, 6-12-month-old wild type (WT) and CD38 knockout (CD38KO) mice. We determined mechanical withdrawal thresholds using von Frey filaments using the up-and-down method. We found that both mice developed similar magnitudes and significant mechanical hypersensitivity as determined using the von Frey test during a 12-week test period. To determine the role of spinal CD38 in opioid antinociception in the SNI model, CD38KO and WT animals received cumulative doses of the mu-opioid receptor agonist morphine (0, 0.125, 0.25, 0.5, 1 and 2 μmol/5μl, I.T.). We found the anti-nociceptive effect of morphine to be significantly decreased in CD38KO compared to WT mice. Together, these results suggest that CD38 is not involved in the development and maintenance of mechanical hypersensitivity due to peripheral nerve injury, but its presence in the spinal cord is required for the pain-relieving action of mu-opioid receptor agonists. To further understand how CD38 might mediate opioid-induced anti-nociception, we performed in-situ hybridization and immunohistochemistry in spinal cord tissues from WT mice and found that CD38 is localized exclusively in astrocytes. The canonical opioid anti-nociceptive

mechanisms have been thought to be exclusively neuronal, but our results suggest that CD38-expressing astrocytes are critical for effective opioid anti-nociception in the SNI model of neuropathic pain. Further exploration of astrocytic mechanisms in opioid signaling at the spinal level could reveal novel anti-nociceptive targets for neuropathic pain.

Title: Two phenotypically and functionally distinct microglial populations in adult zebrafish

Authors: *S. WU[1], L. T. M. NGUYEN[1], H. PAN[1], S. HASSAN[1], Y. DAI[1], J. XU[2], Z. WEN[1]; [1]Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [2]South China Univ. of Technol., Guang Zhou, China

Abstract: Microglia are the tissue-resident macrophages in the central nervous system and are critically involved in immune defense, neural development and function, and neuroinflammation. The versatility of microglia has long been attributed to heterogeneity. Recent studies revealed possible heterogeneity in human but not in murine microglia, yet a firm demonstration linking microglial heterogeneity to functional phenotypes remains scarce. Here, we identified two distinct microglial populations in adult zebrafish that differ in morphology, distribution, development, and function. The predominant population - phagocytotic microglia, which expresses *ccl34b.1*, is broadly distributed, amoeboid in shape, highly mobile and phagocytotic. The other white matter-enriched *ccl34b.1*$^{-}$ population, regulatory microglia, has ramified protrusions but has limited mobility and phagocytosis capability. Their functional differences are further supported by distinct transcriptomes and responses to bacterial infection, where *ccl34b.1*$^{+}$ microglia function in tissue clearance and *ccl34b.1*$^{-}$ microglia release immune regulators. Our study sheds light on the heterogeneity and functional diversification of microglia.

Title: How Microglia Sense and Regulate Neuronal Activity?

Authors: *L.-J. WU;
Dept. of Neurol., Mayo Clin., ROCHESTER, MN

Abstract: Microglia are innate immune cells of the central nervous system (CNS) and are sensitive to extracellular cues. Brain injuries, inflammation, and pathology evoke dynamic structural responses in microglia, altering their morphology and motility. In addition, microglia respond to and engage in neuronal activity—a facet of their biology that exists alongside their pathological responses. Using in vivo imaging approaches, we found that microglia increase their process dynamics and surveillance in response to either hyperactive or hypoactive network activity in mouse brain. Interestingly, microglia sense neuronal hyperactivity via P2Y12 receptors while they sense hypoactivity via adrenergic β2 receptors. Using microglia calcium imaging and chemogenetic manipulation in awake mice, we further demonstrate that microglia calcium is attuned to neuronal activity. Specifically, microglia increase calcium signaling in response to bi-directional shifts in neuronal activity. Using genetic ablation of microglia, we found that both acute and chronic seizures are increased after microglial depletion. Consistently, in P2Y12 deficiency mice with impaired microglia-neuron interaction, KA-induced seizures are aggravated. Together, these results demonstrate that microglia can dampen neuronal activity in seizures. Therefore, our studies elucidate how microglia sense neuronal activity and later influence neuronal function following their engagement. The dynamic function of microglia in monitoring and dictating neuronal activity is critical for brain hemostasis and repair in health and disease.

Title: Quantification of microglia in the dorsal hippocampus following temporary intra-hippocampal microglia depletion during development

Authors: *N. HABASH, M. B. BIELICKI, N. HAAS, J. M. SCHWARZ;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: Microglia, the resident immune cells of the brain, interact with neurons to shape cognitive development. Microglial activation during the early postnatal period has been linked to long-term effects on cognition and learning in rats. We seek to examine the role of microglia in hippocampal learning by establishing a method to selectively deplete microglia in the dorsal hippocampus during a unique juvenile period development in rats. Liposome-encapsulated clodronate (LEC) is a drug that is selectively ingested by and results in the death of phagocytic cells. We infused 3 microliters LEC bilaterally into the dorsal hippocampus (dHP) of male and female rats (Sprague-Dawley) at P16 to determine whether LEC selectively depletes microglia during a period of hippocampal development. We utilized immunohistochemical (IHC) staining and RT-PCR to examine changes in microglia density and gene expression in the CA1, CA3, and dentate gyrus (DG) subregions of dorsal and ventral hippocampus (vHP) on P21, P24, P27, P30, and P40. Iba1 stain for microglia revealed that LEC significantly decreased the percent area of microglia density and the number of microglia cells per area of microglia in subregions CA1 and DG of dHP from P21-P30. LEC did not significantly deplete microglia in any vHP subregions, nor the CA3 subregion of dHP, which indicate that the spread of LEC does not go beyond the intended target of dHP CA1 and DG subregions. Future research will use this data to establish a timeline of microglial depletion during the juvenile period in order to investigate the role of microglia in hippocampal learning deficits following immune activation.

Abstract: Cell death, axon elimination, and synaptic pruning are major events during development that dramatically rewire cortical projections, eliminating up to 70% of connections. Defects in this process is hypothesized to result in psychiatric diseases like Schizophrenia. Recently this theory received a boost when a genome-wide association study identified copy number variants in the C4 gene as a risk factor for schizophrenia. The proteolytic cascade of Complement signalling factors (C1q, C3, C4, C5) is thought to serve as an opsonization signal to promote microglial phagocytosis of synapses. However, the role of Complement Cascade in the development of cortical structures in unclear. We discovered that mice lacking Complement 3 receptor (*CR3*), a downstream receptor in complement cascade have increased number of axons in the developing optic nerve but not in cortex. These mice do not show any difference in synapse density in cortex. We also find, using resting-state fMRI, that *CR3* knockout mice have defective functional connectivity selectively in the Prefrontal Cortex and Dorsal Thalamus areas implicated in schizophrenia risk in humans. These data suggest a divergent role for Complement cascade in cortical development.

Title: Optogenetic activation of spinal microglia triggers chronic pain in mice

Authors: *M.-H. YI[1], Y. LIU[1], A. UMPIERRE[1], T. CHEN[1], Y. YING[1], A. DHEER[1], D. BOSCO[1], H. DONG[4], L.-J. WU[1,2,3];

Abstract: Spinal microglia are highly responsive to peripheral nerve injury and are known to be a key player in neuropathic pain. However, there has not been any direct evidence showing selective microglial activation in vivo is sufficient to induce chronic pain. Here we used optogenetic approaches in microglia to address this question employing $CX3CR1^{creER/+}$: $R26^{LSL-}$

$^{ReaChR/+}$ transgenic mice, in which red-activated channelrhodopsin (ReaChR) is inducibly and specifically expressed in microglia. We found that activation of ReaChR by red light in spinal microglia evoked reliable inward currents and membrane depolarization. In vivo optogenetic activation of microglial ReaChR in the spinal cord triggered chronic pain hypersensitivity lasting for 5-7 days. In addition, activation of microglial ReaChR upregulated neuronal c-fos expression and enhanced C-fiber responses. Mechanistically, ReaChR activation led to a reactive microglial phenotype with increased IL-1β production. IL-1 receptor antagonist was able to reverse the pain hypersensitivity and neuronal hyperactivity induced by microglial ReaChR activation. Therefore, our work demonstrates that optogenetic activation of spinal microglia is sufficient to trigger chronic pain phenotypes by increasing neuronal activity via IL-1 signaling.

Title: Functional Changes in Microglia in a Neonatal Rabbit Model of Cerebral Palsy

Authors: ***A. SHI**, E. KHOURY, K. LIAW, A. FOWLER, A. SHARMA, R. M. KANNAN, S. KANNAN;
Johns Hopkins Univ., Baltimore, MD

Abstract: Cerebral palsy (CP) is a pediatric neurodevelopmental disorder that manifests in a range of motor and cognitive symptoms with no effective cure. The microglial response to neuroinflammation during fetal and infant brain development is a major contributor to CP pathogenesis; in fact, inducing microglial activation by in utero exposure to lipopolysaccharide in rabbits results in a robust animal model of CP. We have previously demonstrated that microglia of CP rabbits undergo change to a pro-inflammatory phenotype, that these activated microglia uptake dendrimer nanoparticles via endocytosis while healthy microglia do not, and that delivery of anti-inflammatory drugs via dendrimers to activated microglia can reverse motor deficits. However, the functional changes in microglia associated with activation and related mechanisms of dendrimer uptake are not well characterized. We established a method for isolating microglia from rabbit brain and assessed the difference in microglial (1) phagocytic activity and (2) dendrimer uptake from CP and healthy rabbits. Flow cytometry studies showed that surface marker CD11b is reliably expressed and can be used to isolate microglia in rabbit brain tissue. Phagocytic activity was studied by exposing isolated microglia to fluorescent *E. coli*-coated beads and uptake was quantified by flow cytometry. Phagocytic activity was found to be significantly higher in CP animals compared to healthy controls. Another functional measure

studied was difference in microglial dendrimer uptake; to assess this, dendrimer conjugated to fluorescent dye (D-Cy5) was dosed intravenously and microglia were collected 24 hours later. D-Cy5 localized in a subset of microglia but not in CD11b- cells, and to a greater extent in microglia extracted from CP rabbits than from healthy controls. Ongoing studies are focused on further characterization of this subpopulation of microglia. A better understanding of inflammatory microglial function will inform design of microglia-targeted drug delivery platforms for treatment of neuroinflammatory disorders such as CP.

Title: Icv administration of p2x7 antagonist prevents sps-induced ptsd-related behavior

Authors: *O. I. TORRES-RODRÍGUEZ, Y. RIVERA-ESCOBALES, M. COLÓN-ROMERO, A. HERNÁNDEZ, J. T. PORTER;
Ponce Hlth. Sci. Univ., Ponce, Puerto Rico

Abstract: Clinical evidence has linked increased peripheral levels of pro-inflammatory cytokines with the severity of PTSD symptoms. Since microglia are known as a major producer of pro-inflammatory cytokines in the brain, the inflammatory manifestation mediated by microglia may contribute to PTSD-related behaviors. We hypothesized that stress exposure induces a microglial-mediated inflammation that precedes the PTSD behavioral manifestations. To test this, we exposed rats to single prolonged stress (SPS) one week before measuring fear discrimination, extinction, and anxiety-like behaviors. Consistent with the literature, our data show that exposing rats to SPS produces a PTSD-like phenotype of impaired fear extinction and increased anxiety in male and female rats. Additionally, SPS-exposed animals showed increased expression of Iba-1, P2X7R, and CD68 by microglia in the ventral hippocampus (VH), a structure that regulates fear extinction and anxiety. Furthermore, VH microglial cells increased their expression of IL-1β and TNF-α genes three days following SPS suggesting an increased inflammatory-state before behavioral testing. Although our data suggest that SPS induces an inflammatory manifestation mediated by microglia, it is not clear whether inhibition of the inflammation will prevent the SPS-induced PTSD-related behaviors. Since P2X7R leads to inflammation, we hypothesized that inhibition of inflammatory P2X7R signaling would prevent the SPS-induced PTSD-related behaviors. To test this hypothesis, we implanted Intracerebroventricular (ICV) cannulas into the animals 2 weeks before SPS exposure for the administration of the P2X7R antagonist, A-438079. Animals were randomly assigned and received one week of daily infusions of the vehicle or A-438079 starting the day of SPS exposure. Then, animals were subjected to a behavioral paradigm to examine cue-associated fear discrimination, fear extinction, and anxiety. Our results indicate that animals that received A-438079 showed improved extinction and less anxiety-like behaviors. Consistent with our hypothesis, inhibition of the P2X7R prevented the SPS-induced impaired fear extinction and increased anxiety-like behaviors in male and female rats. Altogether, these data suggest that inhibiting inflammatory responses, such as P2X7R signaling in microglia, following trauma exposure might prevent the development of trauma-associated neuropsychiatric disorders such as PTSD.

Title: Analysis of Glucose Metabolism by ^{18}F-FDG-PET Imaging and Glucose Transporter Expression in a Mouse Model of Intracerebral Hemorrhage

Authors: *X. HAN, H. REN, A. NANDI, X. FAN, R. KOEHLER;
Johns Hopkins University, Sch. of Med., Baltimore, MD

Abstract: The relationship between cerebral glucose metabolism and glucose transporter expression after intracerebral hemorrhage (ICH) is unclear. Few studies have used positron emission tomography (PET) to explore cerebral glucose metabolism after ICH in rodents. In this study, we produced ICH in mice with an intrastriatal injection of collagenase to investigate whether glucose metabolic changes in ^{18}F-fluoro-2-deoxy-D-glucose (FDG)-PET images are associated with expression of glucose transporters (GLUTs) over time. On days 1 and 3 after ICH, the ipsilateral striatum exhibited significant hypometabolism. However, by days 7 and 14, glucose metabolism was significantly higher in the ipsilateral striatum than in the contralateral striatum. The contralateral hemisphere did not show hypermetabolism at any time after ICH. Qualitative immunofluorescence and Western blotting indicated that the expression of GLUT1 in ipsilateral striatum decreased on days 1 and 3 after ICH and gradually returned to baseline by day 21. The ^{18}F-FDG uptake after ICH was associated with expression of GLUT1 but not GLUT3 or GLUT5. Our data suggest that ipsilateral cerebral glucose metabolism decreases in the early stage after ICH and increases progressively in the late stage. Changes in ^{18}F-FDG uptake on PET imaging are associated with the expression of GLUT1 in the ipsilateral striatum.

Title: Bpa induced increases in microglia tspo clustering are reduced by emapunil

Authors: *H. N. STRONG, K. I. MCGLOTHEN, R. M. HINES, D. J. HINES;
Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Bisphenol *A* (BPA) is a common environmental pollutant that has been linked to neurodevelopmental and mitochondrial dysfunction. Alterations in the molecular pathways underlying the effects of BPA on the brain remain unclear. The mitochondrial 18kDa translocator protein (TSPO) is a particular protein that changes expression in response to damaging changes in energy demands. Microglia play a major role in brain energy homeostasis and contain the majority of brain derived TSPO. We show that TSPO forms clusters in microglia and acute BPA exposure increases TSPO clustering in the branches of microglia. Treatment with the TSPO agonist Emapunil attenuates BPA induced increases in branch clustering. Using immunofluorescent staining of TSPO and microglia, we labeled TSPO clustering patterns. Mice not treated with BPA or Emapunil showed somatic TSPO clustering in microglia of the prefrontal cortex. BPA exposure increased branch clustering of TSPO, while treatment with Emapunil reduced branch clustering. These results show BPA alters TSPO clustering patterns in microglia and TSPO function is important in regulating clustering patterns. Further research into the variations and role of TSPO clustering patterns will be important for understanding the progression of neurological diseases.

Title: Increased TSPO in microglia endfeet aids cell survival and attenuates gross-motor deficits following a blast induced traumatic brain injury.

Authors: *E. A. AQUINO[1], D. J. HINES[2];
[2]Psychology, [1]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: Traumatic brain injuries (TBIs) are hallmarked by prolonged cognitive and motor deficits. Neuroinflammation is been implicated in promoting secondary injuries yet its role in the neuropathology of secondary injuries is poorly understood. Microglia are the resident immune cells of the central nervous system responsible for the regulation of neuroinflammatory responses, spine development and removal of waste and debris. Microglia undergo a series of dynamic structural changes called *reactive microgliosis,* following injury. Microgliosis is necessary for a proper immune response and is crucial to recovery, but if it persists, dysregulated microgliosis can become detrimental and result in secondary injury. When activated, microglia express an abundance of translocator protein (TSPO). TSPO is an 18kDA outer mitochondrial protein that is upregulated during neuroinflammatory responses and is implicated in regulating pro-inflammatory and anti-inflammatory processes. Despite its involvement in microglia activation, its precise role remains elusive. To relate changes in microglial TSPO expression to gross motor sequela, TSPO levels and motor behavior will be assessed 24, 72, and 120 hours

following a blast induced TBI (bTBI). To determine how modulation of TSPO levels can affect TBI outcomes, mice were treated with electroconvulsive shock (ECS) prior to bTBI. ECS is a neurostimulation that elicits microglia activation. Using immunohistochemistry and multiple behavior tasks, we found a distinct activity zone (β) containing microglia with elevated TSPO levels in their endfeet proceeding behavioral improvements. Assessing changes in microglial TSPO levels in response to TBI at different time points can help determine the ideal therapeutic window to prevent progression of chronic pathologies.

Title: Detecting myelin-dependent plasticity: therapeutic effect of an aerobic exercise intervention on corpus callosum myelination in a rodent model of Fetal Alcohol Spectrum Disorders

Authors: *K. A. MILBOCKER[1], G. L. LEBLANC[1], E. K. BRENGEL[1], S. K. HEKMATYAR[2], P. P. KULKARNI[3], C. F. FERRIS[3], A. Y. KLINTSOVA[1];
[1]Psychological & Brain Sci., [2]Ctr. for Biomed. and Brain Imaging, Univ. of Delaware, Newark, DE; [3]Psychology, Northeastern University, Ctr. for Translational NeuroImaging, Boston, MA

Abstract: 1 in 20 infants born annually in the U.S. has been exposed to alcohol prenatally, sufficient to produce long-term cognitive deficits that disrupt learning and memory and are clinically categorized as Fetal Alcohol Spectrum Disorders (FASD) (May et al., 2015). Higher-order cognitive processing requires exchange of information between hemispheres and cortical and subcortical structures that is largely achieved via myelinated corpus callosum (CC) axons. Abnormalities in CC, including reduced axon myelination, are well-described in adolescent children with prenatal alcohol exposure (AE) (i.e., Wozniak et al., 2019; Jacobson et al., 2017; Gautam et al., 2014). This study employs diffusion tensor imaging (DTI) scanning to investigate the effects of: 1) developmental AE and 2) an adolescent exercise intervention on CC axonal myelination in a rodent model of FASD. Male and female Long-Evans pups were AE via intragastric intubation (5.25 g/kg/day) on postnatal days (PD) 4-9, during the rodent brain growth spurt (BGS), a period of rapid brain growth. Sham-intubated controls received no liquid during intubation. From PD 30-42, half of all rats had free access to a running wheel for aerobic intervention. DTI scans were acquired twice longitudinally (on PD 30 and 42) in all rats using a 9.4T Bruker scanner to assess alterations to CC axonal myelination noninvasively. CC was

divided into two sub-regions for analysis: the interhemispheric region (ICC) and cortically-projecting region (PCC). Preliminary cross-sectional analyses show that AE during the BGS reduces ICC and PCC volume pre-intervention on PD 30 ($F_{1, 35} = 9.4$, $p = .004$; $F_{1, 32} = 14.1$, $p = .001$, respectively) and PCC volume only post-intervention on PD 42 ($F_{3, 32} = 5.0$, $p = .006$). DTI scan analysis shows that fractional anisotropy, the movement of water molecules, in ICC and PCC is decreased in AE rats on PD 30 ($F_{1, 35} = 16.6$, $p < .001$; $F_{1, 32} = 17.7$, $p < .001$). Fractional anisotropy remains reduced in PCC only in AE rats on PD 42 ($F_{3, 32} = 5.5$, $p = .004$). Radial and axial diffusivity were analyzed to interpret whether these neuroanatomical changes could be attributed to decreased myelination or axonal degeneration, respectively. We found that on PD 30, radial but not axial diffusivity is increased in ICC and PCC of AE rats ($F_{1, 35} = 22.9$, $p < .001$; $F_{1, 32} = 14.9$, $p = .001$). On PD 42, both radial and axial diffusivity are unchanged in ICC, while radial diffusivity only is increased in PCC of AE rats ($F_{3, 32} = 3.8$, $p = .020$). These findings suggest that AE during the BGS reduces CC myelination in adolescence. PCC myelination is particularly vulnerable to the teratogenicity of AE likely due to the lateral-medial development of CC myelination during the BGS.

Title: Oligodendrocyte mechanisms in the anterior cingulate cortex are critical for the consolidation of both recent and remote episodic memories

Authors: ***L. P. BARBOZA**[1], B. BESSIÈRES[2], O. NAZARZODA[1], C. M. ALBERINI[1]; [1]NYU, New York, NY; [2]NYU, NYC, NY

Abstract: Oligodendrogenesis and *de novo* myelination have been implicated in motor learning and spatial memory consolidation. Whether these mechanisms play a role in episodic memory consolidation and in which specific brain regions remains unknown. Consolidation is a temporally graded process by which initially labile memories become stabilized across various brain regions including the anterior cingulate cortex (ACC). Studies indicate that the ACC is involved in the storage of remote but not recent memories; however, recent reports suggest that ACC is also critical for recent memory formation. Using RT-qPCR analyses of the ACC at various time points after training, we found significant upregulations of transcripts involved in oligodendrocyte differentiation and myelin biogenesis, including Olig2, Myrf, and Mbp, starting at one hour after training. Western blot and immunohistochemistry analyses confirmed

significant upregulation of corresponding proteins one day after training in the ACC. Furthermore, conditional global and ACC-targeted knockout, as well as ACC-targeted antisense-mediated knockdown of Myrf, a master regulator of myelin expression, impaired memory retention at both recent (1 day) and remote (28 days) time points after training. Thus, oligodendrocyte-specific mechanisms are regulated and required in the ACC for the consolidation of recent and remote episodic memories.

Abstract: Lipid study has traditionally been restricted to the formation of biological membranes, however studies in the last two decades have described new functions in these fatty acids; from energy supply via β-oxidation and protein post-traductional modifications, to intracellular lipid signaling pathways and modulation of ion channels properties. Besides that, recent studies have shown a key role of fatty acids in angiogenic processes, evidencing their importance in different diseases. Palmitic acid (PA), the most abundant saturated fatty acid in blood plasma, increases levels in patients with diabetic retinopathy (DR) or age-related macular degeneration (AMD), pathologies associated with neovascularization in the retina. In this neural tissue, Müller glial cells (MC) regulate a plethora of retinal functions, critical to the homeostasis of this neural tissue, such as potassium ion buffering, neurotransmitter recycling, and angiogenic factors regulation. We aimed to determine if the MC plays a critical role in processes related to PA effects. We use CD1 P5-7 mice MC primary cultures, exposed to 250 μM PA and vehicle (0.008% DMSO). Our results show a significant reduction in cell viability after 72h of incubation with PA and morphological changes associated with the presence of this lipid. We

also detect by immunofluorescence assays a significant increase of VEGF-A in MC cultures exposed to PA. Studies suggest that HIF-1α, a transcriptional factor related to VEGF, participates in the signaling pathway that links fatty acid and alterations in the retinal vasculature. Our preliminary data show that HIF-1α mRNA expression decreases in the MC during PA treatments. These results together suggest that MG plays a pivotal role in the VEGF synthesis, possibly through HIF1α, by an increment in the PA levels, an event associated with DR and AMD pathologies.

Title: Tnfα Promotes oral cancer growth, pain, and schwann cell activation

Authors: *Y. YE, E. SALVO, N. TU, Z. DUBEYKOVSKAYA, S. SHAVAN, N. SCHEFF, B. AOUIZERAT;
Col. of Dent., New York Univ., New York, NY

Abstract: Oral cancer patients rate Pain as the worst symptom, which significantly impairs a patient's ability to eat, talk, and drink. Mediators such as TNFα, secreted from oral cancer and microenvironment, excite primary afferent neurons inducing pain. We aim to investigate whether TNFα can activate Schwann cells, peripheral glia, to further amplify pain signals and to increase cancer progression. We measured pain in patients using a validated University of California Oral Cancer Pain questionnaire. We used human primary cultures of Schwann cells, human oral cancer cell line HSC-3, and human dysplastic oral keratinocytes (DOK). Cell proliferation was measured using a real-time cell analyzer (RTCA) and the CellTiter 96® Aqueous One Solution Cell Proliferation Assay kit. Cell migration was examined using Transwell migration assays. We used two animal models of oral cancer: a tongue carcinogenesis model by feeding mice with 4-Nitroquinoline 1-oxide (4NQO), and a xenograft models by inoculating oral cancer cells (HSC-3) into the mouse right hind paw. Mechanical sensitivity was tested with von Frey filaments. Tumor size was measured using a plethysmometer. Schwann cell activation in the presence of TNFα or oral cancer cells was characterized using proliferation and migration assays and activation markers. To determine whether activated Schwann cells mediate oral cancer pain, we cultured Schwann cells in hypoxic conditions - a known cancer stimulus inducing robust Schwann cell activation. Schwann cell supernatant was then collected and injected into the mouse cheek; nociception in the face was measured using facial von Frey tests. C-87, a small molecule TNFα inhibitor was used to block the effect of TNFα on cancer proliferation, Schwann cell activation, and nociception in cell culture and animal models of oral cancer. We demonstrate that TNFα is overexpressed in human oral cancer tissues and correlates with increased self-reported pain in patients. C-87 reduced oral cancer proliferation, cytokine production, and nociception in animals with oral cancer. Oral cancer or TNFα increases Schwann cell activation, which can be inhibited by neutralizing TNFα. Cancer or TNFα activated Schwann cells release pro-nociceptive mediators such as TNFα and NGF. Activated Schwann cells induce nociceptive behaviors in mice, which is alleviated by blocking TNFα. Our study suggests that TNFα

promotes cancer proliferation, progression, and nociception at least partially by activating Schwann cells.

Title: Refinement of optic nerve function and myelination during postnatal development

Authors: *A. BALRAJ[1], R. H. MILLER[2];
[2]Anat. & Cell Biol., [1]George Washington Univ., Washington, DC

Abstract: Retinal ganglion cells generate a pattern of action potentials to communicate visual information. Myelin, an insulating sheath, facilitates signal propagation by wrapping around axons and, when deficient (as observed in patients with optic neuritis), can cause significant visual deficits. However, the relationship between optic nerve function and the extent of myelination is currently unknown. We tested if myelination patterns are correlated with changes in optic nerve function during postnatal development using extracellular nerve recordings, immunohistochemistry, western blot, and scanning electron microscopy. Comparing compound action potentials from C57Bl6 mice across ages 4-12 wks revealed an increase in the number of functional axons and shifts toward more fast-conducting axon populations at 5 and 8 wks ($p<0.05$, $n=8$). At these ages, nerve assessments suggest increases in myelin and neurofilament protein concentrations ($n=2$) and lower g-ratios ($n>2$). Increased expression of a mature sodium ion channel (Nav 1.6) at nodes of Ranvier was observed at 6 wks ($p<0.05$, $n=3$), while axon diameter, axon density, and nodal density remained unchanged across ages. Changes in the normal optic nerve to favor faster axonal conduction correlate with additional myelin proteins, thicker myelin around axons, and node maturity, suggesting that these properties are critical in the refinement of optic nerve signaling during postnatal maturation.

Title: Yap and taz regulate schwann cell proliferation and differentiation during peripheral nerve regeneration.

Authors: H. JEANETTE[1], L. MARZIALI[2], L. FELTRI[2], ***Y. POITELON**[1], S. BELIN[1]; [1]Albany Med. Col., Albany, NY; [2]Hunter James Kelly Res. Institute, Univ. at Buffalo, Buffalo, NY

Abstract: YAP and TAZ are effectors of the Hippo pathway that controls multicellular development by integrating chemical and mechanical signals. Peripheral nervous system development depends on the Hippo pathway. We previously showed that loss of YAP and TAZ impairs the development of peripheral nerve as well as Schwann cell myelination. The role of the Hippo pathway in peripheral nerve regeneration has just started to be explored. After injury, Schwann cells adopt new identities to promote regeneration by converting to a repair-promoting phenotype. While the re-programming of Schwann cells to repair cells has been well characterized, the maintenance of such repair phenotype cannot be sustained for a very long period, which limits nerve repair in human. First, we show that short or long-term myelin maintenance is not affected by defect in YAP and TAZ expression. Using crush nerve injury and conditional mutagenesis in mice we also show that YAP and TAZ are regulators of repair Schwann cell proliferation and differentiation. We found that YAP and TAZ are required in repair Schwann cells for their re-differentiation into myelinating Schwann cell following crush injury. In this present study, we describe how the Hippo pathway and YAP and TAZ regulate remyelination over time during peripheral nerve regeneration.

Abstract: Neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD) and comorbid conditions, have complex polygenic etiologies. Single gene deletions and mutations identified in patients can help define causative molecular mechanisms. We recently identified patients around the world harboring monogenic deletions of the *ANKS1B* gene with confirmed haploinsufficiency. Affected individuals present with a spectrum of neurodevelopmental phenotypes, including autism and speech and motor deficits. Our findings corroborate previous genome-wide and genetic studies implicating *ANKS1B* in brain disorders and formalize a link between *ANKS1B* haploinsufficiency and a previously undefined syndrome. *ANKS1B* encodes for AIDA-1, a brain-specific protein that we have shown is enriched at neuronal synapses and regulates *N*-methyl-D-aspartate receptors (NMDARs) subunit composition and NMDAR-dependent synaptic plasticity. A transgenic mouse model of Anks1b haploinsufficiency recapitulates a range of phenotypes observed in patients, including social behavior deficits, hyperactivity, and sensorimotor dysfunction. Neurons generated from patient-derived induced pluripotent stem cells (iPSCs) show that the *ANKS1B* microdeletions lead to abnormal NMDAR subunit surface expression, confirming results in mice. Recent findings indicate that AIDA-1 may play a role in oligodendrocyte function and myelination. Loss of AIDA-1 leads to impaired oligodendrocyte maturation and migration throughout development, and following the application of demyelinating agents *in vivo*. Although we find that this novel NDD is rare, identification of the AIDA-1 interactome using isobaric tags and quantitative proteomics shows that AIDA-1 binds to diverse factors causative for NDDs, including Shank and SynGAP1. Moreover, single-nucleotide variants in *ANKS1B* have also been associated with NDDs, suggesting broader relevance for other monogenic or polygenic/complex forms of NDD.

Title: Demyelination derived TGFbeta1 signaling inhibits neural stem cells through the novel regulator Gpnmb

Authors: *D. Z. RADECKI[1], J. SAMANTA[2];
[1]Comparative Biosci., Univ. of Wisconsin, Madison, WI; [2]Comparative Biosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Demyelination in the CNS occurs across a range of neurodegenerative disorders, but the signaling pathways modulating subsequent repair and remyelination are incompletely understood. Specifically, the ability to recruit the multipotent periventricular adult neural stem cells (NSCs) to demyelinated lesions and promote oligodendrocyte generation and remyelination is of current interest. Using the cuprizone toxin model of demyelination, our group has identified glycoprotein non-metastatic melanoma b (*Gpnmb*), as a regulator of lesion derived TGFbeta1 signaling in Gli1 expressing ventral NSCs. GPNMB is a single pass, cleavable transmembrane protein whose function in NSCs is unknown. During cuprizone mediated demyelination, *Tgfbeta1* expression increases at the site of lesion and Gpnmb expression increases in *Gli1* vNSCs in parallel. Using a *Gpnmb-LacZ* reporter mouse, we show that GPNMB is predominantly expressed in periventricular neural stem cells, and oligodendrocyte precursor cells throughout white and gray matter. To determine if loss of *Gpnmb* alone can alter remyelination, cuprizone demyelinated *Gpnmb-Null* mice showed increased oligodendrocyte lineage number in the corpus collosum following remyelination. Reciprocally, *in vitro* overexpression of GPNMB resulted in a significant downregulation of oligodendrocyte genes, and interestingly an increase in TGFbeta receptor subunit 2 (*Tgfbeta-R2*) levels, indicating a potential feedforward mechanism with the TGFbeta1 pathway. First, in order to confirm TGFbeta1 directly activates *Gpnmb*, we treated mouse NSCs *in vitro* and found a significant increase in *Gpnmb* levels, with a corresponding decrease in oligodendrocyte lineage generation. Further evidence of direct regulation was the identification of a putative SMAD3/4 binding site, the downstream mediators of TGFbeta1, in the putative promoter region of *Gpnmb*, and a renilla-luciferase assay showed that TGFbeta1 activated the *Gpnmb* promoter. Finally, we show that knocking out *Tgfbeta-R2* in Gli1 vNSCs increases their recruitment to lesioned white matter following LPC mediated demyelination, indicating that part of the inhibition on endogenous vNSC recruitment is due directly to TGFbeta1 signaling. Our results indicate that lesion derived TGFbeta1 activates *Gpnmb* in Gli1 vNSCs via binding to TGFbeta-R2, and this activation inhibits the recruitment and oligodendrogenic potential of vNSCs to repair the CNS.

Title: Demyelination regulates the circadian transcription factor BMAL1 to signal adult neural stem cells to initiate oligodendrogenesis

Authors: S. HUANG[1], M. CHOI[2], H. HUANG[1], X. WANG[2], Y. CHANG[1], ***J. KIM**[2];

Abstract: Circadian clocks, endogenous oscillators generating cell-autonomous rhythms, are intrinsic inmost cells, including neural cells. Under physiological conditions, they are synchronized tolocal macro- and micro-environments by the action of external cues and regulate variouscellular processes. Demyelination is a common form of central nervous system pathology thathas variable degrees of recovery. Demyelination changes the surrounding microenvironmentvia damaged myelin and activation of glial cells. How these microenvironmental changesaffect circadian clocks in the lesions, and their consequences are mostly unknown. Here, weshow that circadian clocks are altered in demyelinating lesions. This initiates molecularsignals that induce adult neural stem cells (NSCs) in the subventricular zone (SVZ) toproduce oligodendrocyte lineage cells (OLCs) to enhance restoring myelin. Circadian clocksin demyelinating lesions shortened the period to transcribe more clock target genes, includingthe Wnt inhibitors SFRP1 and SFRP5. Unexpectedly, SFRP1 and SFRP5 signaled to the SVZto reduce the circadian transcription factor BMAL1, causing more SVZ NSCs to differentiateinto OLCs. We further found that inhibition of *Bmal1* expression in astrocytes, the signalproducing cells in the lesions, prevented the migration of OLCs from the SVZ todemyelinating lesions. Thus, our findings show that communication between demyelinatinglesions and the SVZ via local circadian clocks enhances the remyelination process bysupplying OLCs from the SVZ to the lesions.

Abstract: Multiple sclerosis (MS) is a complex disease in which the underlying etiology includes loss of myelin, the multi-layered structure that surrounds and insulates neuronal axons, primarily through disordered glial cells. In MS, myelin-forming oligodendrocytes are the targets of an autoimmune inflammatory response that results in damage to myelin sheaths within the brain and spinal cord. While myelin-forming oligodendrocytes have limited innate repair capacity, largely stemming from a robustly cycling and proliferative population of oligodendrocyte precursor cells (OPCs), multiple demyelinating events hinder this response. Understanding the mechanisms underlying this lineage stability in health and MS is imperative to the development of regenerative strategies aimed at remyelination. Numerous lines of evidence suggest that dysregulation of the circadian or 24-hour clock is involved in the pathophysiology of MS. Nevertheless, how the circadian clock modulates myelin-forming cells and myelination remains unstudied, leaving a substantial gap in the field. This project explored the effect of circadian disruption on myelination in white matter development and remyelination in a lysolecithin-induced (L-a-Lysophosphatidylcholine, Sigma L4129 in 1% PBS; 1ul into the cingulum of the corpus callosum) model of demyelinating disease. Specifically, through knockdown of the molecular circadian clock regulator, *Bmal1*, in oligodendrocyte lineage cells (*NG2::Cre;Bmal1^{KO}*) at embryonic development, there was a substantial reduction in OPC and oligodendrocyte density, a ~40% decrease in myelin basic protein (MBP) in the corpus callosum and a significant dysregulation of motor function measured through CatWalk gait analysis. These results were further validated using the tamoxifen-inducible *PDGFRα::CreER^{T2};Bmal1^{KO}*, where *Bmal1* knockdown at postnatal days 18-20 also resulted in reduced OPC density and motor dysregulation. Assessment of remyelination potential between in *PDGFRα::CreER^{T2};Bmal1^{KO}* and *PDGFRα::CreER^{T2};Bmal1^{WT}* remains in progress. Together, this work highlights the novel role of the circadian clock in myelin maintenance and disease, opening new avenues of MS research and potential therapeutics.

Title: CD38 dependent NAD+ depletion contributes to oligodendrocyte loss following high fat diet consumption and impairs myelin regeneration

Authors: *M. R. LANGLEY[1], C. CHOI[1], T. R. PECLAT[2], W. SIMON[1], H. YOON[3], L. KLEPPE[1], C. C. S. CHINI[4], E. N. CHINI[4], I. A. SCARISBRICK[3];

Abstract: Recent work from our laboratory and others demonstrate that Western-style diets cause disruptions in myelinating cells and astrocytes within the mouse central nervous system. CD38 is the main NAD+ depleting enzyme in CNS tissue, and altered NAD+ metabolism has been linked to both high fat consumption and Multiple Sclerosis (MS). We identified increased CD38 expression in the mouse spinal cord following chronic high fat consumption or focal demyelinating injury. We also show that male CD38-catalytically inactive mice are significantly protected from high fat-induced NAD^+ depletion, oligodendrocyte loss, oxidative damage, and astrogliosis. In primary murine glial cultures, 78c, a CD38 inhibitor, increased NAD^+ levels and attenuated neuroinflammatory changes in astrocytes induced by saturated fat. Conditioned media from saturated fat-treated astrocytes impaired oligodendrocyte differentiation, pointing to indirect mechanisms of oligodendrogliopathy. Combined saturated fat and lysolecithin demyelination in cerebellar slice cultures resulted in additional deficits in myelin proteins that were mitigated by concomitant 78c treatment. Importantly, oral 78c increased counts of oligodendrocytes and remyelinated axons after focal lysolecithin-induced demyelination to the adult male mouse spinal cord. Our findings suggest that high fat diet impairs oligodendrocyte survival and differentiation through astrocyte-linked mechanisms mediated by the NAD^+ase CD38, and highlight the use of CD38 inhibitors as potential therapeutic candidates to improve myelin regeneration.

Title: β-endorphin and opioid growth factor as biomarkers of physical ability in multiple sclerosis

Authors: C. PATEL, G. THOMAS, N. ZOMORODI, I. S. ZAGON, *P. J. MCLAUGHLIN; Penn State Univ. Coll Med., Hershey, PA

Abstract: Multiple sclerosis (MS) is an autoimmune mediated degenerative disease of the central nervous system with an estimated prevalence 2.5 million worldwide. Localized neuro-inflammation presents as demyelinating plaques within white matter monitored with magnetic resonance imaging. With the increasing MS-related healthcare costs, the need to validate minimally invasive biomarkers is imperative. In this study, conducted between 2019-2020 at the Penn State Hershey Neurology Clinic, 60 male and female relapsing-remitting MS patients on disease modifying therapies were consented to provide blood samples for analysis of serum cytokines (TNFα, IL6, and IL-17A) and endogenous opioid peptides (OGF and β-endorphin), as well as to complete the MSQOL-54 survey. Vitamin D levels were obtained from patient records. Patient age ranged from 23-78 years, with length of disease ~ 14 years. Mean serum OGF levels in all MS patients were elevated ($p<0.01$) and ranged from 193 -393 pg/ml in comparison to age matched controls (~98 pg/ml). The increased interaction between OGF and its receptor was hypothesized to facilitate a modulation of cytokines TNFα and IL-17A. Elevated OGF levels corresponded to increased levels of TNFα ($r = 0.78$) and IL-17A ($r = 0.81$). Analyses of MS-QOL data showed no significant differences in physical or mental composite scores between treatment groups. However, β-endorphin levels correlated with physical health composite score ($r = 0.70$), physical function score ($r = 0.68$), and social function ($r = 0.68$). Social function scores were indirectly correlated with increases in TNFα ($r = 0.63$) and IL6 ($r = 0.63$). Although the correlations do not demonstrate causality of disease, the data provide strong associations suggesting that serum levels of OGF, β-endorphin, and Vitamin D are potential biomarkers of patient perception of their disease.

Title: Analysis of ELAVL1-dependent transcripts involved in cell fusion and tunneling membrane nanotube formations in gliomas.

Authors: *N. FILIPPOVA, X. YANG, J. A. CALANO, E. N. HAYWARD, H. D. NAMKOONG, L. B. NABORS;
Neurol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Homotypic and heterotypic cell fusions via permanent membrane fusions and temporal tunneling nanotube formations (TNT) in the glioma microenvironment were recently documented in vitro and in vivo and mediate glioma survival, plasticity, and recurrence. Cell fusion is a multistep process, which consists of activation of the cellular stress response, autophagy formation, rearrangement of cytoskeletal architecture in the areas of cell-to-cell contacts, and the expression of proinflammatory cytokines and fusogenic proteins. The mRNA-binding protein of ELAV-family HuR is a critical node, which orchestrates the stress response, autophagy formation, cytoskeletal architecture, and the expression of proinflammatory cytokines and fusogenic proteins. Our work provides analyses of HuR role in the expression of fusogen and TNT-related transcripts in gliomas. Meta-analysis and the data from R2: Genomics Analysis and Visualization Platform confirmed the significant expression of the following known fusogens in the glioma microenvironment: i) the fusogen transcripts from genomes of pathogenic enveloped viruses; ii) the fusogen transcripts encoding endogenous retroviral envelope proteins; iii) the fusogen transcripts encoding proteins essential for sexual reproduction and gamete fusions; iv) the muscle-specific fusogen transcripts at low levels; v) the transcripts of fusogens involved in the intercellular and extracellular vesicle-specific transfers. The type-1 TNT-related transcripts were significantly overexpressed in gliomas compared to normal brain samples. The type 2 TNT-transcripts (GJA1, GAP43), which overlap with gap junction formations, exhibited diverse expression in gliomas (GJA1 transcript was significantly overexpressed; however, GAP43 expression was significantly decreased compared to normal brain samples.We developed transcriptomic data (RNA-seq) of five patient-derived glioma xenograft (PDGx) cell lines of classic, proneural, and mesenchymal subtypes to analyze the expression of the fusogens and the TNT-related transcripts in gliomas of different subtypes alone and in the presence of the newly developed inhibitor of HuR dimerization. The analyses of the transcriptome signatures of five PDGx neurosphere cell lines confirmed the expression of a variety of fusogen and TNT-related transcripts in different glioma subtypes and the modulation of the expression of the key transcripts by inhibitors of HuR dimerization. The clinical outcome of patients with gliomas harboring low or high expression of key HuR-dependent fusogens and the TNT-related transcripts is provided.

Title: Blood glutamate scavengers increased pro-apoptotic signaling and reduced metastatic melanoma growing in-vivo

Authors: Y. GOLDSHMIT[1], E. BANYAS[2], A. YAKOVCHUK[2], ***A. RUBAN**[2];
[1]Fac. of Med., [2]Tel Aviv Univ., Tel Aviv, Israel

Abstract: Blood glutamate scavengers increased pro-apoptotic signaling and reduced metastatic melanoma growing in-vivo In the past few years, an ever-increasing body of data has suggested that glutamate (Glu) plays a crucial role in the growth of glioma cells, their invasiveness and ability to destroy neighboring brain tissue. The ability of glioma to secrete Glu into the tumor microenvironment has prompted the question of whether this feature is common to other types of cancer like melanoma. It has been shown that transgenic mice, which conditionally express mGluR1 in melanocytes, secret Glu and produce melanomas at a frequency of 100% 52 weeks after transgene activation. Furthermore, it is possible that more advanced tumors in stage III and IV metastases have a higher frequency of mGluR1 expression and that ectopic mGluR1 is more frequent in more advanced stages of the disease. In such case, the inhibition or reduction of extracellular brain glutamate could be very effective in the management of brain metastatic melanoma.The overall objective of this study was to evaluate the therapeutic efficacy of an entirely novel approach in which excess Glu is removed from brain into blood as a result of blood Glu scavenging. Materials and methods: mCherry RET melanoma cells were implanted intracranially in C57BL mice and treated with glutamate scavenger (BGS) vs. vehicle-control starting one hour after the implantation and for 7 consecutive days. CSF and blood Glu levels were measured at days 3 and 7 post implantation to confirm a continuous increase in Glu levels following the tumor progression, and to prove the scavenging activity of the treatment. The tumors' growth was examined 2- and 7-days post implantation by bioluminescence imaging. At day 7 mice were sacrificed and the tumors were analyzed for pro-apoptotic and DNA markers by immunohistochemistry. Results: Our results demonstrate that in control mice, Glu levels in the CSF have increased more than 5 folds at 7 days post cell implantation compared to the 3-fold in the BGS treated group. Moreover, BGS 7 days treatment has significantly increased expression of DNA suppressor marker 53BP1, active caspase-3 expression and has mediated CD8+ cells infiltration into the tumors. Importantly, BGS 7 days treatment has significantly decreased the tumor's growth in-vivo.Discussion: We have shown that the administration of blood Glu scavengers is highly effective in reducing the proliferation of RET melanoma cells in brain metastatic mice model. Our results suggest that BGS treatment is mediating DNA damage and apoptotic cell death in brain metastatic melanoma model. This is the first time that this approach is used in metastatic melanoma.

Title: Aminoquinolines impede proliferation of brain cancer cell lines

Authors: ***A. SANGAMI**, E. E. SERRANO;
Biol., New Mexico State Univ., Las Cruces, NM

Abstract: FDA approved drugs Chloroquine and Hydroxychloroquine are alkylated 4-aminoquinolines that can be repurposed to treat brain cancer. Our previous reports have suggested 96-hour chloroquine exposure had significant effects in reducing the proliferation of a glioblastoma cell line (Sangami et al.; 2019; SFN Abstract 557.08.). To further evaluate drug activity, a double-blind experiment was conducted with drug exposure times of 24 hours and 48 hours. Glioblastoma cells (CCF-STTG1; ATCC CRL-1718; RRID: CVCL_1118) were maintained according to vendor guidelines and treated with 50 μM or 400 μM of chloroquine diphosphate (CQ; Sigma12084-10MG-F) or hydroxychloroquine sulphate (HCQ; Sigma H0915-15MG). We evaluated cell viability with Calcein-AM (Invitrogen C3099) and counted cell numbers by labelling nuclei with Hoechst 33342 (Invitrogen H3570). Images captured with the Nikon Eclipse TE 2000-S microscope were analyzed using the open access image analysis tool, ImageJ, by counting nuclei in 2% area of the chamber to determine cell proliferation. Analysis revealed that longer exposure times and higher concentrations of CQ and HCQ were correlated with reduced cell counts as compared with controls. Cells exposed to 50 μM CQ and HCQ showed negligible treatment reduction and low effect sizes (MD, SMD) at 24 and 48 hours. Visible changes and greater effect sizes were observed in cell lines treated with 400 μM chloroquine diphosphate ($p = .048$) and hydroxychloroquine sulphate ($p = .078$) at 24 hours, and this effect was more pronounced at 48 hours. Analysis of controls indicated the process of plating cells introduced technical variation that we aim to minimize. Future experiments will implement a newly acquired Incucyte® S3 Live-Cell Analysis System to capture image data from the entire well in real time. Cells will be treated with multiple concentrations of CQ and HCQ and to evaluate the proliferation and viability of cell lines, reduce technical variation due to plating, and further confirm the validity of results obtained.

Title: Adult language process is influenced by thrombospondin-1 paracrine signaling from glioma-neuron interactions

Authors: *S. KRISHNA[1], A. CHOUDHURY[1], K. SEO[1], L. NI[2], A. LEE[1], A. AABEDI[1], D. BRANG[3], S. HERVEY-JUMPER[1];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Stanford Univ., Stanford, CA; [3]Univ. of Michigan, Ann Arbor, MI

Abstract: The cellular biology of human language processing remains largely unknown given the limited scope of animal models. We now know that a subpopulation of gliomas interacts with neurons via electrochemical synapses. Little is known about the consequences of glioma-neuron interactions on cognitions in humans. We therefore studied the cellular mechanisms underlying network integration of gliomas as a model to study human language processing. We used electrocorticography to measure event related potentials during language task performance in IDH-wild-type glioblastoma (GBM). Site-directed tumor biopsies from high (HFC) and low (LFC)-functional connectivity intratumoral regions identified by magnetoencephalography were analyzed by RNA sequencing, immunohistochemistry (IHC), and patient-derived xenografts. Secreted proteins from patient serum was measured using ELISA. Language evaluation of patients were performed to correlate with functional connectivity measures. We found that speech initiation recruit glioma-language network activity with both tumor-infiltrated and non-tumor regions generating similar 'normal' neural responses. HFC regions showed increased expression of the neurogenic factor, thrombospondin 1 (TSP-1) originating from glioma cells in HFC regions and non-tumor astrocytes in LFC regions. This was further confirmed at protein level by IHC. The number of intratumoral HFC sites positively correlated with the serum TSP-1 of glioma patients. Compared to LFC, primary patient samples from HFC regions showed increased expression of pre- and post-synaptic markers in tissues and cells co-cultured with hippocampal neurons and neuron organoids. Furthermore, the integration of HFC cells with neurons was significantly higher than LFC cells and addition of TSP-1 to the LFC-neuron co-culture rescued the integrative phenotype. Mice bearing HFC xenografts showed increased total number of synapse structures. Importantly, compared to patients without intratumoral high connectivity sites, GBM patients with intratumoral HFC showed worse language task performance. To conclude, we found that glioma infiltrated regions generate task-relevant neural responses, with speech production evoking neuronal activity throughout tumor-involved cortex in the dominant hemisphere. A population of synaptogenic glioma cells within high connectivity intratumoral regions maintains their affinity for neurons through TSP-1 mediated paracrine signaling. Together, these findings indicate that malignant gliomas can functionally remodel

neural circuitry, thereby impairing neurological function and conferring negative cognitive outcomes.

Title: Outcomes of Awake versus Sleep Craniotomy for Brain Tumors in a Developing Country

Authors: ***J. A. GILANI**, K. NATHANI, M. BARAKZAI, H. IFTIKHAR, S. KHAN, S. ENAM, F. SHAFIQ;
Aga Khan Univ., Karachi, Pakistan

Abstract: Objectives: Awake Craniotomy for brain tumors is a neurosurgical procedure in which the patient is intraoperatively assessed for neurological deficits to avoid damage to an eloquent cranial region. Despite being popular in the developed world, it is still a rare technique in the rest of the globe. This study aimed to assess the outcomes of awake craniotomy, which was recently introduced at our facility, and compare it to craniotomy under general anesthesia for intracranial brain tumors in a developing country. **Methods:** A retrospective cohort study was conducted with 43 patients who underwent craniotomy for intracranial tumor resection by a single neurosurgeon between November 2015 and October 2016 at The Aga Khan University Hospital, Pakistan. The patients were assigned to an awake or sleep group based on the type of craniotomy they underwent. Medical records were reviewed for basic demographics, preoperative characteristics and postoperative outcomes, including KPS scores. **Results:** The mean age of the enrolled patients was 43.37 ± 13.24 years. For resection of the tumor, 26 (60.5%) patients underwent awake craniotomy, whereas 17 (39.5%) patients underwent sleep craniotomy. Awake craniotomy was associated with significantly higher discharge KPS score, shorter duration of surgery and lower length of hospital stay. Both groups had similar KPS scores at last follow up, with similar follow up periods. **Conclusion:** Awake craniotomy has proved to be an advantageous neurosurgical technique within the first twelve months of its introduction. It offers better postoperative functional status along with lower treatment cost, which can be valuable in a developing country.

Abstract: Aging is an intricate process that is characterized by multiple hallmarks including stem cell exhaustion, genome instability, epigenome alteration, impaired proteostasis, and cellular senescence. While each of these is detrimental at the cellular level, it remains unclear how they are interconnected to cause systemic organ deterioration. Here we show that abrogating Brap, a BRCA1 associated protein, results in cellular senescence with persistent DNA double-strand breaks and elevation of histone H2A mono- and poly-ubiquitination (H2Aub). The high H2Aub initiates proteasome-dependent histone proteolysis, leading to global epigenetic alteration, ubiquitinated protein accumulation, and senescence reinforcement. When these defects occur in mice carrying Brap deletions in cerebral cortical neural progenitors or postnatal neurons, they accelerate brain aging, induce neurodegeneration, and shorten lifespan. As we show H2Aub is also increased in human brain tissues of Alzheimer's disease, these data together suggest that chromatin aberrations mediated by H2Aub act as a nexus of multiple aging hallmarks.

Title: Examining age-dependent DNA methylation patterns and gene expression in the male and female hippocampus

Authors: *C. CHINN[1], H. REN[2], Q. NIE[2], M. A. WOOD[1], T. L. DOWNING[3];
[1]Neurobio. & Behavior, [2]Mathematics, [3]Biomed. Engin., Univ. of California Irvine, Irvine, CA

Abstract: Epigenetic signatures of biological age have recently been generated based on measurements of cytosine methylation within CpG dinucleotide contexts throughout the genome. Patterns of methylation are highly correlated with chronological age and form the molecular basis for the establishment of epigenetic clocks. However, CpG sites identified from different tissues in mice, such as liver or brain, show that these epigenetic clocks are largely tissue specific and do not share the same DNA methylation patterns across the genome. Current epigenetic

clocks from brain tissue include cortex and cerebellum combined, but a multi-tissue approach creates a signature not comparable to clocks made from other, single tissues. Given their tissue specificity, clocks generated from a brain region that is crucial to learning and memory may reveal key sites in the genome where methylation changes correlate with age. Here, we performed reduced representation bisulfite sequencing (RRBS) from mouse dorsal hippocampus in young (2 months) and old (20 months) mice of both male (n=10 young, 10 old) and female (n=10 young, 10 old) sex to investigate whether baseline tissue specific age-related methylation differences can be observed in a brain region involved in memory formation. After statistical analysis to define differentially methylated regions (DMRs), genomic 3'-UTR regions were found to have the highest bimodal degree of change in methylation levels in aging, displaying hypermethylation in females but hypomethylation in males. Furthermore, motif enrichment analysis revealed the AP-1 complex family of transcription factors, a major regulator of gene expression, as the most commonly associated transcription factor binding sites within hypomethylated regions in aged mice when compared to young. Using RNA sequencing data from the same brain region in young and aging mice, we identified differentially expressed genes with DMRs in their enhancer and/or promoter regions, suggesting that these genes may be important to understanding how methylation markers of epigenetic age correlate with age-related impairments in gene expression and long-term memory formation. Overall, our findings demonstrate that methylation levels within the dorsal hippocampus are divergent between sexes during aging, particularly in regions correlating to mRNA functionality, transcription factor binding sites, and gene regulatory elements. These results provide a foundational analysis for creating an epigenetic clock from a brain region involved in memory and defining age-related changes in the methylome across the lifespan.

Abstract: Aging is one of the most impactful risk factors for the onset and progression of cognitive and neurodegenerative diseases such as Alzheimer disease (AD) and Parkinson disease (PD). Previous researches have showed that the lifespan of the AKR/J mice is significantly shorter than that of the mice from the more common laboratory strain, C57BL/6J (median

lifespan for AKR/J male: 288 days; median lifespan for C57BL6/J male: 901 days). Moreover, age acceleration (AA) was observed in both blood and brain tissues of AKR/J mice compared to C57BL6/J mice measured by DNA methylation-based epigenetic clocks. This proved that AKR/J strain of mice is a valid model organism for AA study using genome-wide NGS methods that was not adequately exploited previously.To elucidate the underlying mechanisms of neurological aging, we used reduced representation bisulfite sequencing (RRBS) and total RNA sequencing (RNA-seq) to profile DNA methylation and whole transcriptome in the cortex and the hippocampus extracted from these two strains of mice at age of 24 weeks, respectively (6 biological replicates per brain region for the AKR/J strain, 4 biological replicates per brain region for the C57BL/6J strain). Distinctive DNA methylation patterns and transcriptome patterns were identified among these two brain regions of the two strains. Specifically, we identified more than 14,000 differentially methylated cytosines (DMCs, Benjamini-Hochberg FDR <0.05; methylation difference ≥0.15), more than 200 differentially methylation regions (DMRs, p-value <0.05; methylation difference ≥0.15), and more than 500 differentially expressed genes (DEGs, adjusted p-value <0.05) from each of the cortex and hippocampus regions, respectively. Interestingly, multiple genes with DMRs were among the DEGs, presenting possible interplays between the levels of DNA methylation and gene expression. These genes were further identified to participate in several biological pathways for metabolism, immune response, development and beyond. In conclusion, this study leveraged NGS profiling of DNA methylation and transcriptome of the cortex and hippocampus regions between the AKR/J and the C57BL/6J mice to reveal the genes and pathways playing roles in the neurological aging process. This may in turn help uncover the mechanisms connecting lifespans and neurological aging, and shed light on the understanding of the pathogenesis of related neurological diseases. Future work should continue probing for the interactions between genetic and epigenetic factors contributing to neurological aging, as well as capturing the transcriptomic consequences of such interplay.

Title: Ultrastructural alterations in the upper motor neurons of rats after systemic delivery of genes encoding TDP-43 via viral vectors

Authors: *E. POLAT CORUMLU[1], H. A. KAPKAC[3], M. ARSLANYOLU[3], E. ULUPINAR[2]; [1]Interdisciplinary Neuroscience Department, [2]Interdisciplinary Neuroscience And Anatomy

Departments, Eskisehir Osmangazi University, Eskisehir, Turkey; [3]Department Of Molecular Biology, Eskisehir Technical University, Eskisehir, Turkey

Abstract: TDP-proteinopathies include cytoplasmic mislocalization, formation of toxic TDP-43(TarDNA-binding protein-43) fragments and aggregates, deposition of ubiquitinated and hyper-phosphorylated TDP-43 into inclusion bodies in the cortical and spinal motor neurons. In an effort to generate a novel rat model with TDP-43 pathology, we used AAV-mediated gene transfer method and aimed to investigate ultrastructural changes in the upper motor neurons. AAV9 was used in the design of construction cassette for expression of gene encoding TDP-43 with eGFP under the control of a cell-type specific promoter (UCHL1). The tail vein of 30-day old Sprague-Dawley rats was used for systemic injection of vectors at the dose of $1.77X10^{12}$vg/kg. Animals were sacrificed by intracardiac perfusion under ketamine and xylazine anesthesia on postnatal day 80. Ultra-thin sections obtained from the layer V of motor cortex were treated with 2% osmium tetroxide and then counterstained with 1% uranyl acetate and 0.2% lead citrate. Electron microscopic examination of motor neurons revealed disorganization in the cristae and the mitochondrial matrix. Various shapes and sizes of vacuoles were observed in the soma as an early stage symptom in the process of neurodegeneration. The most prominent alterations were observed in the nuclear envelope of Betz cells which displayed ondulations, large defects, notches and indentations. Membrane integrity of the endoplasmic reticulum was disrupted and broken pieces of membranes were detectable in autophagosomes and/or were engulfed by lysosomes. Taken together, these observations suggest that TDP-43 proteinopathy might cause defects in the nucleocytoplasmic transport by disrupting nuclear membrane and nuclear por complexes of the upper motor neurons. Therefore, better understanding of the role of TDP-43 in nucleostoplasmic transport is necessary in developing novel strategies for both neurodegeneration and physiological aging.

Title: Metabolic labeling of newly synthesized myelin in the rhesus monkey brain

Authors: *K. R. BOTTENFIELD, T. L. MOORE, F. MORTAZAVI, D. L. ROSENE; Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: Pathology in primate brains often involves damage to myelin and impacts normal function as myelin constitutes 40% or more of the forebrain. Myelin can be assessed by electron microscopy, histological stains (e.g. Luxol Fast Blue), immunohistochemistry (e.g. for myelin basic protein), and a label free confocal method (SCoRe). Each has advantages but none offer a reliable, validated method to assess microscopic synthesis or repair of myelin across the entire primate forebrain. Interestingly, newly synthesized myelin can be labeled by in vivo administration of a choline analog, propargylcholine (P-Cho). It is readily incorporated into phosphatidylcholine and sphingomyelin which are major components of the myelin sheath. Importantly, P-Cho contains an alkyne moiety that can be labelled by conjugation with a fluoro-labeled azide using click chemistry and visualized with confocal microscopy. Since previous research had only demonstrated the use of P-Cho to assess remyelination in mice, we decided to explore the efficacy and safety in non-human primates by administering P-Cho by intraperitoneal injection (IP) daily for 6 days (3.5 - 4.0 mg/kg) to 6 young adult and 2 older adult monkeys at different time points before euthanasia (1, 2, 4 and 6 weeks). After fixation and cryoprotection, frozen brain sections were cut, labeled with a fluorescent azide using Click-iT technology, and the sections evaluated for the presence and specificity of P-Cho in white and gray matter regions throughout the brain by co-labeling the tissue with antibodies for axons, oligodendrocytes, and myelin basic protein using immunohistochemistry. In addition, we co-localized P-Cho labeling with spectral confocal reflectance microscopy (SCoRe), a label free method to visualize myelinated axons. Analyses show effective incorporation of P-Cho into newly synthesized myelin within 1 week of dosing and sustained presence beyond 6 weeks. These results validate P-Cho as a promising new method for investigating myelin plasticity and white matter pathologies related to aging, neurodegeneration, brain injury, and neurological disease in an animal model that is highly translatable to humans. This method can also be instrumental for assessing pharmacotherapies for inducing remyelination and myelin synthesis (Supported by NINDS grants R21-NS111174, U01 NS076474 and RF1 AG043640).

Title: Imaging the age-related decline of neuronal function in C. elegans

Authors: *G. S. WIRAK, C. W. CONNOR, C. V. GABEL;
Physiol. and Biophysics, Boston Univ. Sch. of Med., Boston, MA

Abstract: Title: Imaging the age-related decline of neuronal function in *C. elegans*
Neuronal function declines with age resulting in behavioral deficits. How this age-related decline is related to changes in neuronal connectivity and circuit function on the cellular level is largely

unknown. Here we employ pan-neuronal fluorescence imaging in the nematode worm *C. elegans* to measure changes in neuronal activity and connectivity with age across the animal's nervous system. Prior research into the aging *C. elegans* nervous system has largely focused on the cell biology and accompanying morphological and ultrastructural changes. Employing transgenic expression of the fluorescent calcium indicator GCaMP6s in specific neurons, we identify changes in activity of individual neurons and circuits linked to the locomotory behaviors that are modulated by age. We further perform pan-neuronal imaging, employing light sheet microscopy to capture neuronal activity at single-cell resolution across the organism's entire head region. We identify substantial age-related alterations in the activity dynamics of neurons as well as changes in connectivity and functional organization across the entire nervous system. These age-related effects are recapitulated in young animals bearing a gain-of-function mutation within the *unc-2* gene, encoding a pre-synaptic voltage-gated calcium channel. Conversely, a loss-of-function mutation diminishes such effects. As the technologies enabling functional neuronal imaging rapidly advance, the simple and highly tractable nematode *C. elegans* might be employed to further our understanding of the breakdown of nervous system function with age.

Title: The effect of oxidative stress on proNGF transport in basal forebrain cholinergic neurons

Authors: A. SHEKARI[1], C. WU[3], *M. FAHNESTOCK[2];
[1]Grad. Program in Neurosci., [2]Psychiatry & Behavioural Neurosciences, McMaster Univ., Hamilton, ON, Canada; [3]Neurosciences MC0624, UCSD, La Jolla, CA

Abstract: Profound and early basal forebrain cholinergic neuron (BFCN) degeneration is a hallmark of Alzheimer's disease. BFCNs depend for survival and function on neurotrophins like nerve growth factor (NGF) which are retrogradely transported from BFCN target tissue. We have recently shown that the retrograde axonal transport of proNGF, the only detectable form of NGF in the brain, is reduced with age in cultured BFCNs and coincides with the loss of proNGF receptor tropomyosin-related kinase A (TrkA). We sought to determine whether mechanisms related to oxidative stress, a longstanding hypothesized contributor to Alzheimer's disease, account for these reductions. We found that elevation of intracellular oxidative stress via antioxidant deprivation significantly reduced both TrkA immunoreactivity and proNGF retrograde transport in rat BFCNs cultured in microfluidic chambers. TrkA levels are partially regulated by protein tyrosine phosphatase 1B (PTP1B), an enzyme whose activity is reduced by

the oxidation of a cysteine residue within its active site. siRNA knockdown of PTP1B and pharmacological PTP1B antagonism via selective inhibitor TCS401 significantly reduced TrkA levels in BFCNs. Furthermore, TCS401 treatment reduced proNGF retrograde axonal transport in BFCNs and reduced axonal uptake of proNGF-KKE, a mutant form of proNGF that only binds TrkA. Finally, treatment of BFCNs with thioredoxin-1, an antioxidant responsible for the reactivation of oxidized PTP1B, significantly increased TrkA levels in BFCNs following antioxidant deprivation. Our results suggest that, during aging and in Alzheimer's disease, increased oxidative stress reduces TrkA levels and proNGF transport through a PTP1B-dependent mechanism. Impaired proNGF retrograde transport due to TrkA loss may contribute to BFCN degeneration in Alzheimer's disease.

Title: The cross-talk of energy sensing and mitochondrial anchoring sustains synaptic efficacy by maintaining presynaptic metabolism.

Authors: ***S. LI**, G.-J. XIONG, N. HUANG, Z.-H. SHENG;
NIH, Bethesda, MD

Abstract: Mitochondria supply ATP essential for synaptic transmission. Neurons face exceptional challenges in maintaining energy homoeostasis at synapses. Regulation of mitochondrial trafficking and anchoring is critical for neurons to meet increased energy consumption during sustained synaptic activity. However, mechanisms recruiting and retaining presynaptic mitochondria in sensing synaptic ATP levels remain elusive. Here we reveal an energy signalling axis that controls presynaptic mitochondrial maintenance. Activity-induced presynaptic energy deficits can be rescued by recruiting mitochondria through the AMP-activated protein kinase (AMPK)-p21-activated kinase (PAK) energy signalling pathway. Synaptic activity induces AMPK activation within axonal compartments and AMPK-PAK signalling triggers phosphorylation of myosin VI, which drives mitochondrial recruitment and syntaphilin-mediated anchoring on presynaptic filamentous actin. This pathway maintains presynaptic energy supply and calcium clearance during intensive synaptic activity. Disrupting this signalling cross-talk triggers local energy deficits and intracellular calcium build-up, leading to impaired synaptic efficacy during trains of stimulation and reduced recovery from synaptic depression after prolonged synaptic activity. Our study reveals a mechanistic cross-talk between

energy sensing and mitochondria anchoring to maintain presynaptic metabolism, thus fine-tuning short-term synaptic plasticity and prolonged synaptic efficacy.

Title: Differential effects of ketamine and fluoxetine on the mitochondrial respiratory chain of brain regions involved in depression

Authors: A. ELEXPE[1], J. AURREKOETXEA[1], N. AZKARGORTA[1], E. ASTIGARRAGA[1], C. BRUZOS-CIDÓN[2], M. TORRECILLA[2], ***G. BARREDA-GÓMEZ**[1];
[1]IMG Pharma Biotech, Derio, Spain; [2]Univ. of the Basque Country UPV/EHU, Leioa, Spain

Abstract: Depression is the most disabling illness worldwide that highly strikes life quality of the patients. Although antidepressant drugs relieve clinical depression symptoms after 2-4 weeks of treatment an important group of patients presents incomplete or lack of response after two or more trials of monoaminergic antidepressants and they are considered to have treatment-resistant depression. In current clinical practice, a new line of research suggests that mitochondrial dysfunction may be involved in the late antidepressant response. Recently, ketamine has been reported as a rapidly acting antidepressant that is effective in patients with treatment-resistant depression. Its mechanism of action involves activation of the mTOR signaling which affects mitochondrial energy metabolism. However, its action on mitochondrial respiratory chain needs further investigation.
To study the action of fluoxetine and ketamine on the activity of mitochondrial respiratory chain in multiple brain areas simultaneously, we developed microarrays using cell membranes isolated from mouse cerebral tissues. Subsequently, the superoxide formation capacity of each cerebral region was determined on the cell membrane microarrays using complexes I and II substrates and the specific inhibitors rotenone and azide as standards. Rotenone induced a similar reduction of the superoxide production rate in all the brain areas studied, according to the blockage of the mitochondrial complex I. However, the inhibition of the cytochrome c oxidase evoked by azide enhanced the superoxide production depending on the brain area, showing specific differences in the potency and in the maximal effect. While ketamine did not alter the activity of the respiratory chain at physiological concentrations, fluoxetine inhibited the complex I activity in the same range as rotenone in all brain areas studied. This inhibition was attenuated by decylubiquinone, suggesting that fluoxetine exerts a competitive action on the binding site of the electron transporter.
In conclusion, these data indicate that unlike ketamine, fluoxetine reduces mitochondrial

respiration of central neurons, compromising their energetic state. This restriction may contribute to delay the fluoxetine antidepressant response.

Title: The role of microglia in blood-brain barrier cholesterol synthesis and uptake

Authors: *C. P. PROFACI, T. Z. ZHANG, R. DANEMAN;
UC San Diego, La Jolla, CA

Abstract: The blood-brain barrier (BBB) is a set of properties unique to central nervous system (CNS) vasculature that enables tight control of the brain microenvironment. Approximately 10-30% of microglia closely associate with CNS blood vessels and can reach their processes in between astrocyte endfeet to touch the endothelial basement membrane. Despite this intimate interaction, it is unknown whether microglia play a functional role at the healthy BBB. To answer this question, we used the colony-stimulating factor 1 inhibitor PLX5622 to deplete microglia and assessed the structural, functional, and transcriptomic effects on brain endothelial cells. Microglial depletion did not alter the ultrastructure of the BBB, its permeability to hydrophilic or hydrophobic molecules, or its expression of genes associated with classic BBB properties. However, to our surprise, PLX5622 treatment significantly increased the expression of cholesterol synthesis enzymes and uptake receptors in brain endothelial cells. This effect was extremely stable throughout time; the increased expression was still evident in mice on the PLX5622 diet for over a year. As cellular cholesterol levels can influence processing of amyloid precursor protein (APP), this result has particularly important implications for the role of microglial dysfunction in cerebral amyloid angiopathy (CAA) - the accumulation of vascular Aβ plaques that can cause stroke, dementia, inflammation, cortical microbleeds, and hemorrhage. It has long been thought that blood cholesterol and brain cholesterol are two separate pools, with glial cells making brain cholesterol *de novo*. Our results instead suggest that cholesterol synthesis and uptake at the BBB can be dynamically regulated by the brain microenvironment. We further investigated the effect of brain microenvironment on endothelial cholesterol metabolism and found that endothelial expression of cholesterol synthesis enzymes and uptake inhibitors is directly correlated to levels of neural activity. We are now performing further experiments to understand how microglia and neural activity interact in the context of endothelial cholesterol metabolism. We are also investigating the functional consequences of increased cholesterol uptake by injecting microglia-deficient and control mice with labeled low density lipoprotein.

Together, these experiments will shed light on the role of microglia in regulating brain and BBB cholesterol metabolism and uptake with potential implications for vascular diseases such as CAA and atherosclerosis.

Title: Imperfect regeneration in the perfect aging model: functional recovery impaired by cellular senescence?

Authors: *S. VANHUNSEL[1], S. BERGMANS[1], A. BECKERS[1], J. VAN HOUCKE[2], L. MOONS[1];
[1]Neural Circuit Develop. and Regeneration, [2]Neuroplasticity and Neuroproteomics, KU Leuven, Leuven, Belgium

Abstract: Purpose: As the number of elderly in our society is growing, more and more age-associated neuropathies affect our world population. Research efforts therefore focus on stimulating repair in the (degenerating) central nervous system (CNS). Inducing neuroregeneration, however, remains challenging, especially in an aging environment. As the African turquoise killifish has a remarkable regenerative potential in its adult CNS and displays aging features similar to humans, this fast-aging teleost is very well-suited to investigate the underlying mechanisms that underlie successful restoration in an aging environment.
Methods and results: An in-depth evaluation of the aging hallmarks in the visual system of young, middle-aged, old and very old killifish, using techniques such as qPCR, (immuno)histochemistry ((I)HC) and the optokinetic response (OKR) test, revealed several age-associated manifestations in old fish, including decreased visual acuity, declined neurogenesis, cellular senescence, inflammaging and gliosis. To unravel the effect of these aging processes on CNS repair, and more specifically on axonal regrowth, we compared optic nerve regeneration in the 4 age groups subjected to optic nerve crush (ONC) injury. Strikingly, biocytin tracing experiments show that both the number of regenerating retinal ganglion cells and the level of tectal reinnervation are reduced in old fish. As a consequence, old fish do not recover their vision, as evaluated by OKR and dorsal light reflex tests. To investigate why there is no functional recovery and where in the regenerative process old fish are failing, we are currently performing experiments in which neurodegeneration, synaptic repair and the role of the innate immune system upon ONC are being examined.
Conclusion: Our current results point towards the presence of several aging hallmarks in the killifish visual system, which seem to impact the regenerative capacities in these old fish. These

findings urge further investigations into the underlying cellular aging processes affecting the regenerative potential, thereby contributing to the search for effective neuroregenerative therapies.

Title: Expression of the Immediate-early Genes Arc and Narp during Cognitive Multitasking is Attenuated in Aged Rats

Authors: *C. N. LOGAN, K. LUBKE, S. N. BURKE;
Univ. of Florida, Gainesville, FL

Abstract: Aged humans (Clapp et al., 2011), monkeys (Gray et al., 2017) and rats are impaired at cognitive multitasking (Hernandez et al., 2015; Hernandez et al., 2019). The working memory/biconditional association task (WM/BAT), which requires the perirhinal cortex (Hernandez et al., 2017), has been used in rats to examine the neurobiological basis of these decificits. For this task, an animal must simultaneously perform and spatial alternation task that while also performing an object discrimination task in which the correct choice updates based on the animal's position in the maze. A previous study has shown that the expression of the immediate-early gene Arc is altered in the perirhinal cortex (PER) of aged rats. The expression patterns of other immediate-early genes that may be critical for updating PER cortical circuits in response to behavior, however, have not been examined. The PER is hypothesized to function as a wall of inhibition between the entorhinal cortex and the hippocampus since PER cortical interneurons project to layer II entorhinal cells that synapse in the hippocampus (de Curtis & Pare, 2004; Pinto et al., 2006). Aged rats have reduced monosynaptic coupling between excitatory principal cells and interneurons in the PER (Maurer, Burke, et al., 2017). Reduced afferent drive onto PER interneurons may manifest as increased activation in the lateral entorhinal cortical neurons that project to the hippocampus and hyperactivity in CA3 of the hippocampus (Maurer, Johnson, et al., 2017). Together these data suggest that a disruption in the balance between inhibition and excitation within the PER may aggregate across the medial temporal lobe circuit. A candidate gene that could be critical for regulating PER excitatory balance is neuronal activity-regulated pentraxin (Narp). Narp is up-regulated following behavior and encodes an effector protein that is released from the axons of excitatory neurons to cluster AMPA receptors on parvalbumin-positive interneurons (Chang et al., 2010; O'Brien et al., 1999).

The current work quantified the co-expression of Arc and Narp in young and aged rats that performed the WM/BAT and a control alternation task. The proportion of cells that were positive for Narp mRNA and co-expression of Arc and Narp were decreased in aged compared to young rats. These data provide additional evidence that a dysregulation of the balance between inhibition and excitation within the PER contributes to the interruption in feedforward inhibition necessary for cognitive multitasking. Future studies will continue to examine the relationship between the hyperactivation and hypoactivation in cognitive deficits in aging.

Title: Higher body mass is associated with smaller select hippocampal subfields in older African Americans at increased genetic risk for Alzheimer's disease

Authors: *B. A. FAUSTO, Z. OSIECKA, N. SINHA, M. A. GLUCK;
Ctr. for Mol. & Behavioral Neurosci., Rutgers University–Newark, Newark, NJ

Abstract: Obesity disproportionately affects African Americans and has been inconsistently associated with Alzheimer's disease (AD) risk in later-life. Examining the influence of the strongest genetic risk factor for AD, the APOE ε4 allele, may provide additional insight into the complex relationship between late-life obesity and AD. The purpose of this study was to: (1) compare hippocampal-dependent cognitive performance among older African Americans in the normal, overweight, and obese ranges of body mass index (BMI); and (2) explore the independent and interactive effects of BMI and genetic risk for AD on medial temporal lobe (MTL) cortical region and hippocampal subfield structure. Analyses included 70 cognitively normal older African Americans (ages 60-90, 86% female, mean education level = 14 years, 47% BMI >= 30 kg/m^2, 39% APOE ε4 allele carriers) who completed cognitive testing, saliva sampling for genotyping, and structural neuroimaging. Separate ANCOVAs were used to compare the three BMI groups on the following cognitive outcome measures of generalization, feedback-based learning, and verbal episodic memory, respectively: Concurrent Discrimination and Transfer Task, Acquired Equivalence Task, Rey Auditory Verbal Learning Test. Moderated hierarchical linear regressions were performed to determine the independent association between BMI, APOE ε4 status, and MTL cortical region/hippocampal subfield volume and surface area

and whether APOE ε4 status moderates the BMI-structure relationship while controlling for age, sex, education, literacy, and depressive symptomology. There was a statistically significant difference between BMI groups on Concurrent Discrimination and Transfer Task errors, $F(2, 60) = 3.60$, $p = .03$, partial eta-squared = .11. The normal BMI group committed significantly greater errors (17.22 +/- 2.88) than the overweight group (7.87 +/- 2.08), $p_{corrected} = .03$. BMI and APOE ε4 status were independently but inconsistently associated with MTL cortical regions and hippocampal subfield structure. APOE ε4 status moderated the relationship between BMI and hippocampal subfield structures. With increasing BMI levels, the following hippocampal subfield volumes and surface areas decreased but *only* in the APOE ε4 allele carriers: right and left dentate gyrus/CA3, left CA1, $ps < .05$. These results suggest being overweight may confer some neuroprotection in older African Americans. However, higher BMI is associated with smaller hippocampal subfields in APOE ε4 allele carriers. Future studies should investigate the potential overlap between the metabolic sequelae of late-life obesity and genetic mechanisms underlying AD.

Abstract: Abstract
Dalton Patterson, Constanza J. Cortes
Department of Cell, Development and Integrative BiologyUniversity of Alabama at Birmingham
Exercise is a powerful behavioral intervention against central nervous system aging and Alzheimer's Disease, and plays an essential role in maintaining healthy neurocognitive function and immune metabolism in the aging brain. Physical activity is a positive regulator of hippocampal plasticity, stimulating adult neurogenesis, increasing levels of BDNF and ultimately preserving neurocognitive function in the aging CNS. Moreover, physical activity decreases the risk of developing Alzheimer's Disease, is associated with better Alzheimer's Disease prognosis, and positively affects cognitive function in Alzheimer's patients. Mechanistic studies in murine

Alzheimer's Disease models show that exercise rescues impaired neurogenesis, enhances synaptic plasticity, and attenuates the accumulation of tau tangles and Aβ-plaques, the two histopathological hallmarks of Alzheimer's Disease. Multiple epidemiological studies have suggested that skeletal muscle aging is a risk factor for the development of age-associated disease, including those of the CNS. By observing the effects of exercise, we saw that the effects of this opposes the local deleterious effects of aging on skeletal muscle, reversing age-associated transcriptional and metabolic dysregulation. We hypothesize that the differential expression and secretion of exerkines may underlie responsiveness to the CNS-targeting effects of exercise. We have identified differential expression of cytokines in circulation of exercised and exercise-mimetic transgenic mice with CNS targeting effects. We are currently investigating the role of these cytokines in neuronal survival using in vivo and in vitro approaches, measuring neuroinflammation, neurogenesis and AD-associated phenotypes, with the ultimate goal of developing novel CNS-targeting therapeutics that mimic the neuroprotective effects of exercise.

Title: Characterizing lifespan changes in the expression of SARS-CoV-2 receptors and co-receptors in the human brain

Authors: N. HALABIAN, B. KUMAGAI, K. NAEEM, D. AHUJA, E. JEYANESAN, *K. M. MURPHY;
McMaster Univ., Hamilton, ON, Canada

Abstract: Many individuals infected with the SARS-CoV-2 virus will experience neurological symptoms ranging from headaches to more serious events such as delirium and ischemic stroke. The symptoms tend to differ across age groups. For example, younger adults with COVID-19 are vulnerable to stroke, while older adults also experience delirium. Even children may be affected, with distinct neurological symptoms in children with severe systemic inflammatory response to SARS-CoV-2 infection. Some of these neurological complications could be secondary to the infection. However, others may result from the direct effects of the SARS-CoV-2 virus on the brain. At present, there is little information about lifespan changes in expression of the virus receptor, ACE2, in the human brain that might help to understand the age-related impacts of COVID-19. We used transcriptomic data from postmortem tissue samples to determine the

lifespan trajectories (n=83 samples, age range: 2nd trimester - 80 years) for a network of 37 SARS-CoV-2-related genes in 16 areas of the human brain. The genes included coronavirus receptors, ACE2, DPP2, ANPEP, ENPEP, CD209, CLEC4G, CLEC4M, CECAM1, CECAM2, and the proteases (e.g.TMPRSS2) and integrins (e.g. ITGB3) that act as co-receptors for SARS-CoV-2. First, we characterized the lifespan changes for ACE2 and TMPRSS2. We found that most subcortical and 3 cortical (VFC, IPC, V1) areas followed undulating trajectories where those genes increased into young childhood, declined into teens then increase through younger and older adults. In 4 cortical areas (OFC, M1, S1, ITC), ACE2 and TMPRSS2 expression did not undulate but instead increased to a peak in young childhood and then declined across the rest of the lifespan. Thus, there is more than one lifespan trajectory for the expression of ACE2 and TMPRSS2 in the human brain. Next, we used high dimensional analyses to identify 4 clusters of brain areas with common developmental trajectories. The clusters represent anatomical regions: frontal cortex, parietal cortex, occipital/temporal cortex, and subcortical areas. Finally, we used a new analysis and visualization technique (PHATE) to compare the 16 brain areas' development using all 37 SARS-CoV-2-related genes. The high dimensional analyses identified regional and age-related differences in the expression of SARS-CoV-2-related genes in the human brain. The long-term neurological consequences of COVID-19 have the potential to be debilitating. So this new information about lifespan changes in the expression of SARS-CoV-2 receptors and co-receptors may help understand the neurological symptoms suffered by COVID-19 patients.

Title: Agora, an open platform for the exploration of alzheimer's disease evidence

Authors: *A. K. GREENWOOD, J. GOCKLEY, J. WILEY, K. LEAL, D. ALUTHGAMAGE, K. WOO, S. SIEBERTS, S. SIMON, Z. LEANZA, A. GENDEL, E. MILLS, T. THYER, K. DO, M. PETERS, L. OMBERG, L. MANGRAVITE;
Sage Bionetworks, Seattle, WA

Abstract: There is an urgent need for new therapies for the treatment of Alzheimer’s Disease. Discovery-based research studies have identified a suite of promising new AD targets across a spectrum of therapeutic hypotheses. However, validation of targets and development of new experimental reagents and therapeutics requires efforts broader than the focus of any single

research group. We developed the Agora site as a public resource to openly share information about new AD targets in order to support evaluation by the broader AD research community. Agora is freely available at https://agora.adknowledgeportal.org. Agora aggregates information and experimental resources in support of emerging AD targets and hypotheses. Agora presents a list of nominated targets stemming from the Accelerating Medicines Partnership in AD (AMP-AD) consortium and the broader AD research community. Agora also hosts interactive visualizations designed to support non-bioinformaticians in the evaluation of data from RNAseq, proteomic, and metabolomic studies. We are expanding Agora to catalog evidence and experimental reagents being generated by the TaRget Enablement to Accelerate Therapy Development for AD Centers (TREAT-AD). Updates to Agora in support of TREAT-AD will include individual scorecards for nominated targets based on multiple lines of evidence. In summary, Agora is a platform aimed at enabling the AD research community to evaluate promising target hypotheses.

Title: In silico gene expression analysis of Dek in the human brain across the lifespan

Authors: ***A. GREENE**[1], L. PRIVETTE VINNEDGE[2], M. SOLOMON[1];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: DEK, a chromatin-associated phosphoprotein, mainly studied in the periphery, is known for its role in DNA repair, cellular proliferation and apoptosis inhibition. Our group is the first to associate DEK loss with central nervous system diseases, including Alzheimer’s disease. Consistent with this, we determined that DEK is prominently expressed in the murine brain in learning and memory-relevant brain regions, such as the hippocampus, prefrontal cortex, and amygdala. However, Dek expression has not yet been characterized in the human brain. Therefore, we leveraged data from the BrainCloud and Human Brain Transcriptome databases to assess Dek mRNA expression in human brain across the lifespan. Specifically, we examined the impact of age and biological sex on Dek expression in the dorsolateral prefrontal cortex (dlPFC; BrainCloud and Human Brain Transcriptome) and hippocampus (Human Brain Transcriptome). Given its role in cellular proliferation, DNA repair, and chromatin remodeling, we hypothesized that DEK expression would be highest in fetal development relative to other developmental

stages (e.g., adulthood) because this period is associated with cellular proliferation and synaptic growth. We also hypothesized that women would have higher Dek expression than men because it is an ER-alpha target gene. Consistent with our hypothesis, Dek expression in the hippocampus and dlPFC is highest during fetal development and decreases with aging in both sexes, which is consistent across databases. Contrary to our hypothesis, we observed elevated Dek expression in males over females across the lifespan in the dlPFC (BrainCloud). Given the prominent expression of Dek in the fetal brain and its subsequent decline in aging, the data suggest a role of DEK in brain development. This assertion is consistent with our previous findings whereby DEK loss *in vitro* and in mouse models induces impaired neurite length, DNA damage, and apoptosis. Further analyses will include correlations of Dek expression with expression of genes associated with proliferation and brain development. Assessing Dek mRNA expression patterns in human brain across lifespan not only informs us of the possible roles of DEK in normal brain development, but may also hint at its potential role in age-related brain diseases.

Title: Validation of late-onset Alzheimer's disease risk variants in mouse models

Authors: ***M. SASNER**[1], A. OBLAK[2], D. GARCEAU[1], K. KOTREDES[1], P. LIN[2], D. SONI[2], R. PANDEY[1], A. UYAR[1], C. PREUSS[1], A. GREENWOOD[3], G. CARTER[1], G. HOWELL[1], B. T. LAMB[2];
[1]The Jackson Lab., Bar Harbor, ME; [2]STARK Neurosci. Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Sage Bionetworks, Seattle, WA

Abstract: Alzheimer’s disease (AD) is the most common form of dementia, and has a significant genetic component. While rare familial causative mutations have been known for decades, the genetic etiology of the common (>95%) late-onset AD (LOAD) is still unknown. Numerous AD risk loci and variants have been identified by large-scale genetic studies, but few have been functionally verified and models to study their mechanism of action are lacking. The Model Organism Development and Evaluation for Late-onset AD (MODEL-AD) Center was created to develop, characterize, and distribute more precise preclinical models for late-onset AD by engineering disease-associated variants into mouse models, and characterizing the phenotypes using clinically relevant assays. Criteria to prioritize risk variants include replication in multiple studies, predicted pathogenicity of variant, sequence conservation between human and mouse, and expression in relevant cell types. We have created coding variants in the *Abca7, Clasp2, Mthfr, Mtmr4, Picalm, Plcg2, Shc2, Slc6a17, Snx1, Sorl1* and other loci. Knockouts of *Abca7*,

Ceacam1, *Il1rap*, and *Plcg2* have been created to model human loss-of-function variants. Because a large percentage of AD risk variants occur in non-coding regions, we have most recently created 6 alleles in promoter or enhancer regions in the murine *Adamts4, Bin1, Cd2ap, Epha1, Ptk2b, and Scimp* loci.These variants have been engineered into a mouse model that expresses the AD risk variants APOE4 and Trem2*R47H as well as a humanized Abeta allele. Primary screening was completed by transcriptomic analysis using the nanoString Mouse AD Panel at 4 and 12 months, which demonstrated that the *Abca7*A1527G*, *Mthfr*C677T*, and *Plcg2*M28L* models exhibited age-dependent similarities to transcriptomic changes observed in post-mortem human samples from the AMP-AD cohort. These are now being aged for comprehensive phenotyping at 12, 18 and 24 months of age to include biomarker analysis, transcriptomics, proteomics, metabolomics, *in vivo* neuroimaging of glucose utilization and amyloid deposition, neuropathology and cognitive assays. Additional models will be added as primary screening is completed. All models are made available for both academic and for-profit use from The Jackson Laboratory, and all validation protocols and data will be shared via the AD knowledge portal (https://adknowledgeportal.synapse.org/). For more information see www.model-ad.org.

Title: Novel whole-transcriptome RNA-Seq protocol reveals major perturbations in microglial function in a transgenic mouse model of Alzheimer's Disease.

Authors: ***N. POTEMKIN**[1], S. M. CAWOOD[1], B. MOCKETT[2], J.-A. L. STANTON[1], J. M. WILLIAMS[1];
[1]Dept. of Anat., [2]Dept. of Psychology, Univ. of Otago, Dunedin, New Zealand

Abstract: RNA sequencing (RNA-Seq) can offer unique insights into the pathology of disease. In particular, simultaneous identification and quantification of both coding and non-coding RNA bypasses many shortcomings of more traditional RNA-Seq protocols. In Alzheimer's Disease, non-coding RNA species such as microRNA, long-non-coding RNA, small nuclear RNA, and small nucleolar RNA, are increasingly being implicated in the pathogenesis of the disease. Here we implement a novel method of ribosomal RNA depleted RNA-Seq that encompasses coding- and non-coding RNA, to investigate changes in the transcriptome of APPswe/PSEN1dE9 transgenic mice and wild-type controls at 15 months (n=4). We identified >30,000 transcripts

corresponding to messenger RNA and numerous species of non-coding RNA. Differential expression analysis using edgeR found in total 615 differentially-expressed genes including 336 protein-coding genes, 26 miRNA and 15 pseudogenes (Exact Test; $p<0.05$). Bioinformatics and functional enrichment analysis of these differentially-expressed transcripts (coding *and* non-coding) reveals significant changes in microglial function. One major enriched pathway is the Complement Cascade activation pathway. This is an immune pathway responsible for microglial phagocytosis of damaged neurons and cellular debris, which has been implicated in the later stages of Alzheimer's Disease pathogenesis involving clearance of Amyloid-ß. Our results show that this protocol allows deep simultaneous sequencing of coding and non-coding RNA, and reveals some of the extensive changes to biological processes that underpin Alzheimer's Disease-like pathology in this mouse model.

Title: In Silico analysis of differential expression genes in databases of Alzheimer´s disease patient's vs controls, to identify potential biomarkers of the disease

Authors: *M. SILVA-LUCERO[1], J. RIVERA-OSORIO[2,1], Y. MULEY VIJAYKUMAR[2], G. LOPEZ-TOLEDO[3,1], C. SANCHEZ-HERNANDEZ[4], M. CARDENAS-AGUAYO[1]; [1]Physiol. Dept., Med. School, UNAM, Mexico city, Mexico; [2]Inst. de Neurobiología, UNAM, Mexico city, Mexico; [3]Physiology, Biophysics and Neurosciences, CINVESTAV-IPN, Mexico city, Mexico; [4]HMG Hosp. Coyoacán, Mexico city, Mexico

Abstract: Introduction. Alzheimer's disease (AD) is the most common cause of dementia. Symptoms begin with mild memory difficulties and evolve towards cognitive impairment. The discovery of biomarkers for AD diagnosis is a valuable tool to study the etiology of the disease, to find risk factors, and to discover new treatments. Bioinformatics has become a relevant research tool in which computational models of biological processes and expression analysis have lead to the identification of a number of pathways whose relationship with the diseases was still unknown. Methods. RNA seq databases or RNA microarrays of tissue from the medial temporal lobe and peripheral blood of patients with AD, which were processed by TrueSeq RNA-seq. Values were normalized with the Limma program of the statistical R programming language. We performed a computational analysis of the genetic differential expression using t-statistic-Limma. Data were corrected with the Benjamini and Hochberg approach and the genes with *p* values equal to or less than 0.05 were considered significant. The direction of the change

in gene expression was determined by its variation in the "log2-fold change" between controls and patients. We performed a functional enrichment analysis of GO was performed using goana and topGO-Limma (Smyth et al., 2016). Results were compared with clusterProfilerR. Results. With brain tissue database of medial temporal lobe (EMEXP 2280) we obtained 359 down regulated genes (DR) and 324 up regulated genes (UR), the UR pathways were: transcription, mitochondrial function and hydrolase activity, while DR were: gene expression and regulation of cell proliferation, nuclear alterations, transmembrane receptor signaling. Analysis with KEGGp showed that metabolic pathways were UR and cytokine pathways and their receptors were DR. The blood samples analysis (PBMC, E-GEOD-18309) showed 383 genes DR and 257 genes UR. UR: negative regulation of Wnt signaling, hormonal metabolism processes, and DR: in subcellular components and homeostatic processes, cytosol and extracellular space alterations. KEGGp analysis showed UR: alteration in the Retinol and Cytochrome P450 and DR of the actin cytoskeleton. Finally, the intersection of the differentially expressed genes in the two databases showed 34 genes shared between the brain and blood arrangements: UR: SCG2, CA14, AHSP, HAPLN2, RALY-AS1, PLEKHG4, PRSS35, LINC01116; DR: DBH, NME8, CXCL6, SERPINA7, OR10H3, NYNRIN, MOS, C3, IL10RB-DT, CDKN2A-DT, CCDC60, CPB2, RBPMS6 CRST, T4ENT5D, DGKG. TRIM58 matched in both databases. Conclusion. *In silico* search for altered gene expression in AD will allow us to identify new biomarkers for AD.

Title: Circadian clock is a central regulator of genes disrupted in early Alzheimer's disease pathology

Authors: *L. AKHMETOVA[1], J. MOTT[1], D. WHITTAKER[1,2], P. DESPLATS[1];
[1]UCSD, La Jolla, CA; [2]UCLA, Los Angeles, CA

Abstract: Background: Circadian disruptions are experienced by more than 80% of Alzheimer's disease (AD) patients, and emerging data strongly supports a causal role for circadian abnormalities in AD pathophysiology including exacerbation of inflammation and Amyloid-β accumulation, cognitive impairment and oxidative stress. Circadian rhythms are generated by oscillation of clock genes and regulate up to 30% of genome. Studying the nature of circadian alterations in the brain early in disease progression is therefore fundamental to our understanding of AD pathology development.
Methods: APP23 transgenic mice, overexpressing human APP_{Swe} (n = 26), and non-transgenic

littermates (NTG; n = 28) were housed in individual cages under 12:12 LD cycle. Cage activity was monitored and analyzed with ClockLab. Mice were sacrificed at 10-months old, at six-hour intervals and brains were collected for neuropathology. RNA-Seq was used to analyze gene expression in hippocampus (HIPP) and frontal cortex (FC). MetaCycle package and Ingenuity Pathway Analysis (IPA) software were used to detect rhythmic signals in the data and for transcriptomics analysis, respectively.
Results: APP23 mice were at early stages of pathology at the time of sacrifice, with mild behavioral abnormalities and low levels of amyloid plaque accumulation. Global transcriptional changes between TG and NTG mice were modest: 22 and 157 genes with higher than 30% expression level changes in FC and HIPP respectively. We identified a large number of genes with circadian rhythmicity in HIPP and FC of NTG mice: 868 and 1190 respectively. According to IPA analysis, many of them are associated with neurological disease pathways, including AD, as well as senescence pathway. Crucially, we observed significant changes in the expression profile of oscillating genes between NTG and APP23 mice. We identified 257 genes in the HIPP samples that lost their 24-hour periodicity, exhibited more than two-fold change in amplitude, or more than 3-hour phase shift. Importantly, more than 15% of these genes are involved in the immune system development and response. In FC, 294 genes exhibited similar loss/changes of circadian rhythmicty in APP23 TG mice, with more than 70% of these associated with neurological disease.
Conclusions: Transcriptomic analysis in this AD mouse model suggests that early gene expression changes are highly associated with abnormalities in circadian rhythmicity. In NTG mouse brains, a large number of AD-related genes exhibit circadian oscillations, which are lost or severely disrupted early in disease progression in APP23 mice, potentially driving later neuropathological changes.

Title: Determining the mechanisms by which APOE$^{\varepsilon 3/\varepsilon 4}$ modifies risk for AD and related dementias

Authors: *K. FOLEY[1,2], D. GARCEAU[1], K. KOTREDES[1], G. CARTER[1,2], M. SASNER[1], G. HOWELL[1,2];
[1]The Jackson Lab., Bar Harbor, ME; [2]Sch. of Biomed. Sci., Tufts Univ., Boston, MA

Abstract: Background: Human and murine studies have parsed out mechanisms by which *APOE*$^{\varepsilon4}$ differs from *APOE*$^{\varepsilon3}$ to increase risk for Alzheimer's disease (AD). However, little is known about the ways *APOE*$^{\varepsilon3}$ and *APOE*$^{\varepsilon4}$ interact to affect risk for AD. This is due in part to legal restrictions of existing humanized *APOE* strains – including breeding of *APOE*$^{\varepsilon4/\varepsilon4}$ to *APOE*$^{\varepsilon3/\varepsilon3}$ mice to create the commonly understudied risk genotype in human AD cases - *APOE*$^{\varepsilon3/\varepsilon4}$. To overcome these limitations, here we describe the creation of a new set of humanized *APOE* alleles and test our hypothesis that *APOE*$^{\varepsilon3/\varepsilon4}$ modifies risk for AD and related dementias in ways distinct from *APOE*$^{\varepsilon4/\varepsilon4}$.
Methods: A new allelic series of humanized *APOE* mice that includes *APOE*$^{\varepsilon4/\varepsilon4}$, *APOE*$^{\varepsilon3/\varepsilon3}$, and *APOE*$^{\varepsilon2/\varepsilon2}$ mice were generated by MODEL-AD using homologous directed repair followed by CRISPR, and validated using PCR, sanger sequencing, RNA sequencing and western blotting. Female and male *APOE*$^{\varepsilon3/\varepsilon3}$, *APOE*$^{\varepsilon3/\varepsilon4}$ and *APOE*$^{\varepsilon4/\varepsilon4}$ mice were then established and characterized at 2 mos, 4 mos and 12 mos of age. Two voluntary running cohorts (1-4 mo and 1-12 mos) were included to determine whether the effects of *APOE*$^{\varepsilon4}$ genotype are modified by exercise. Our extensive assays included blood lipid/cholesterol profiles, novel spatial memory, advanced metabolic assessment, immunofluorescence and cortical transcriptional profiling. Linear modeling and weighted gene co-expression network analysis (WGCNA) were used to identify effects of sex, genotype, and running in gene expression data.
Results: At both 2 and 4 mos, linear modeling revealed more significant genes unique to either *APOE*$^{\varepsilon3/\varepsilon4}$ or *APOE*$^{\varepsilon4/\varepsilon4}$ when compared back to *APOE*$^{\varepsilon3/\varepsilon3}$, than in the intersection of these two comparisons. We also show that genes unique to *APOE*$^{\varepsilon3/\varepsilon4}$ at 4 mo enriched for extracullar matrix (ECM) and coagulation related terms. Further, WGCNA identified gliogenesis and myelination terms affected by exercise regardless of *APOE* genotype. Additionally, we show an increased in collagen deposition in *APOE*$^{\varepsilon4/\varepsilon4}$ mice compared to *APOE*$^{\varepsilon3/\varepsilon3}$ mice at 12 mos.
Conclusions: Our study predicts important differences between *APOE*$^{\varepsilon3/\varepsilon4}$ and *APOE*$^{\varepsilon4/\varepsilon4}$ genotypes on AD-relevant cerebrovascular transcriptional profiles.This work challenges the well hypothesized notion that *APOE*$^{\varepsilon3/\varepsilon4}$ shows an intermediate dose response between *APOE*$^{\varepsilon3/\varepsilon3}$ and *APOE*$^{\varepsilon4/\varepsilon4}$. Specifically, our results suggest that cerebrovascular health through ECM homeostasis is altered at a young age by *APOE*$^{\varepsilon4}$ allele dosage, and remains affected at one year. This work suggests that therapies aimed at modifying APOE biology to treat dementias may need to be targeted to specific *APOE* genotypes.

Title: Long-read RNA-seq and microRNA-seq analysis of the 5xFAD transcriptome

Authors: *G. BALDERRAMA-GUTIERREZ[1], E. REBBOAH[1], C. MCGILL[2], D. WYMAN[1], F. REESE[1], A. MORTAZAVI[1], C. MODEL-AD[1];
[1]Univ. of California At Irvine, Irvine, CA; [2]Univ. of California at Irvine, Irvine, CA

Abstract: Alzheimer's disease (AD) is a neurodegenerative pathology characterized by loss of memory and cognitive impairment due to cell loss in the cortex and hippocampus, which are the first affected regions. The cells in our brain, like in any other tissue, are under constant transcriptional regulation to respond to environmental stimuli. Alternative splicing is a process where a gene can have multiple protein products by choosing different combinations of exons. Some genes involved in AD have shown changes at isoform level as a contributor for the pathology, Mapt (Tau) being a known example. The 5xFAD mouse model has 5 familial mutations associated with AD and presents aggressive pathology since early age. As one of the most popular AD mouse models, it has been widely characterized using short-read sequencing, but as long-read technologies improve their yield and accuracy full-length transcriptomes promise a different insight at an isoform level. To complement already available short-read data deposited in Synapse, MODEL-AD has matching cortex and hippocampus samples characterized using PacBio (Sequel II platform) and microRNA sequencing from 8-month-old 5xFAD mice. In this poster, we will explore the full-length transcriptome using TALON for long-read annotation and quantification and Swan for differential transcript analysis and transcript visualization. Additionally, characterization and differential analysis will be done for the microRNA data.

Title: Bulk and single-nucleus analysis of the 3xTG cortex and hippocampus transcriptome

Authors: *N. REZAIE, G. BALDERRAMA-GUTIERREZ, H. LIANG, C. MCGILL, A. MORTAZAVI, C. MODEL-AD;
Univ. of California, Irvine, Irvine, CA

Abstract: Clinical trials for potential Alzheimer disease (AD) drugs have a high failure rate due to the fact that most drugs are successful in mouse models but are not translatable to humans. Mouse models fail to fully recapitulate the pathology, specially presenting plaques and tangles at the same time.
The 3xTg mouse model contains three mutations associated with familial AD (APP Swedish, MAPT P301L, and PSEN1 M146V), and it presents both plaques and tangles accumulation at later stages of development. Cognitive impairments happen by 4 months, but there is no data that

indicates neuronal loss.
Responses to the accumulation of plaques and tangles will involve all cell diversity in the brain. In particular, activation of glial cells such as microglia will start and promote neurodegeneration by eliminating debris from cells of protein aggregates around them. Model-AD has collected cortex and hippocampus of 3xTg mice at different time points (4,12,18 and 24 months) to be characterized with RNA-seq. We generated matching single-cell and single-nucleus from 12, 18 and 24-month 3xTg mice using the ddSeq platform. The scRNA-seq datasets were produced exclusively from isolated microglia. As an alternative to performing separate experiments for nuclei and cells, we have generated microglia + nuclei datasets from a 24-month female 3xTg mouse using the SplitBio barcoding kit.
In this poster, we will explore brain cell diversity as well as microglial subpopulations in the 3xTg mouse models to generate additional insights about the cell response to AD.

Title: Tip60 HAT/HDAC2 subcellular localization is critical for neuroprotection

Authors: *E. ARMOUR, J. PERHACS, F. KHOA, H. ZHANG, F. ELEFANT;
Drexel Univ., Philadelphia, PA

Abstract: Neurodegenerative diseases such as Alzheimer’s disease (AD), Parkinson’s disease (PD), and Amyotrophic Lateral Sclerosis (ALS) that involve cognitive defects are becoming increasingly common in our aging population. Epigenetic mechanisms, such as histone acetylation, have proven to reinstate cognition and are critical for proper neuronal function, although the exact mechanisms are yet to be elucidated. Previous work in our lab has shown the imbalance of Tip60 histone acetyltransferase (HAT) and histone deacetylase 2 (HDAC2) in a well characterized *Drosophila* AD model results in epigenetic repression of synaptic plasticity genes and functional cognitive defects. Remarkably, Tip60 overexpression restores AD-induced neuropathology, emphasizing Tip60’s neuroprotective role. Recent work in our lab has identified Tip60 as having shuttling capabilities between the nucleus and the cytoplasm. Moreover, we have shown that in the human AD hippocampus, Tip60 is largely excluded from the nucleus, suggesting that disruption of Tip60 subcellular localization may contribute to AD. To further elucidate the importance of localization and the HAT/HDAC balance, we examined the subcellular localization of Tip60 and HDAC2 in the *Drosophila* brain. Under normal conditions, Tip60 is localized mainly in the cytoplasm, while HDAC2 is localized mainly in the nucleus. By

elucidating Tip60 HAT/HDAC2 shuttling mechanisms, we can better understand the interaction between these two epigenetic modulators in an attempt to develop more specific therapeutic targets for neurodegenerative diseases.

Title: Transcriptomic cell type analysis of human middle temporal gyrus in the context of Alzheimer's disease

Authors: *A. BUCHIN[1], R. D. HODGE[1], K. A. SMITH[1], J. GOLDY[1], A. TORKELSON[1], E. S. KAPLAN[1], E. J. MELIEF[2], M. J. HAWRYLYCZ[1], D. C. KEEN[2], E. S. LEIN[1], J. A. MILLER[1]; [1]Allen Inst. For Brain Sci., Seattle, WA; [2]Univ. of Washington, Seattle, WA

Abstract: Dementia affects nearly ~11% of the U.S. population over the age of 65, with the incidence doubling every 5 years up to 40-60% after the age of 90. Around 2/3 of these cases are correlated with Alzheimer's disease. Even though Alzheimer's disease has been studied intensively for decades there is still no clear understanding of its underlying cellular mechanisms. Recent advances in single cell or single nucleus transcriptomics have provided a new strategy to understand cellular diversity in normal brain and cell type specific changes in disease. Indeed, recent work has begun to identify selective cell type vulnerability in AD using these techniques [Mathys et al. 2019]. One key strategy to identify AD-related changes in cell type proportions and properties is to generate a well-annotated reference cell type classification of the neurotypical brain, and then map AD data to that reference to discern pathological changes in specific cell types during disease progression. Here we present a workflow for constructing a neurotypical brain reference classification and strategies for mapping disease datasets for middle temporal gyrus (MTG) based on 10x Genomics single nucleus RNA sequencing data. Non-linear dimensionality reduction and clustering of nearly 90 thousand nuclei from 3 patients identified 29 glutamatergic neuron, 41 GABAergic neuron and 10 non-neuronal types, very similar to recently published results using SMART-seq methodologies [Hodge et al. 2019]. To identify known cell types, we applied neural network and random forest classifiers to the tissue from aged and Alzheimer's patients. We found that that the new reference dataset based on 10X Genomics MTG data could be successfully used to identify known cell types in AD tissues based on patterns of gene expression. This novel reference dataset could enable high resolution tracking of cell type-specific changes associated with Alzheimer's disease and normal aging.

Title: Using brain-wide spatial analysis to identify region-specific changes in cell composition and define the nature of cognitive resilience to Alzheimer's Disease in a model mouse population

Authors: *B. GURDON[1], N. HADAD[1], *M. TELPOUKHOVSKAIA[1], S. YATES[2], M. AMEDJKOUH-PUCHADES[2], J. G. BJAALIE[2], C. KACZOROWSKI[1];

Abstract: Age is currently the greatest risk factor for developing Alzheimer's disease (AD); however, it is increasingly evident that there is also a strong genetic component to AD. Identifying neuroanatomical correlates of cognitive resilience and their underlying genetic modifiers can potentially elucidate why there is significant variation in the progression of AD. Recent advances in large-scale immunohistochemistry (IHC), now make it feasible to assess brain-wide regional and cell-type-specific hallmarks of AD progression in terms of pathology and clinically relevant traits in well-characterized cohorts of AD model mice that include extensive behavior and omics data. To identify differences in such traits, hemibrains of 34 male and female, adult(6m) and middle-aged(14m), C57BL/6J(B6) and B6/D2 F1 (D2) mice harboring five causal human familial AD mutations (5XFAD) and their non-transgenic (Ntg) littermates were stained to evaluate neurodegeneration (NeuN), gliosis (Iba1&GFAP), and amyloid pathology (AB1-42) using IHC. The QUINT workflow was implemented to measure individual differences in cellular composition. This workflow allowed for experimental slices to be systematically segmented and registered to the Allen Brain Atlas to gain a global perspective of % coverage of each stain across brain regions. Compositional differences between the B6 and F1-D2 strains became apparent when evaluating potential neurodegeneration, as measured by reduced NeuN coverage across regions. Despite comparable levels of amyloid, the B6-5XFAD strain exhibited a greater decrease in % neuron coverage than the D2-5XFADs by 14m in the hippocampus and cortex. Surprisingly this smaller cell coverage did not relate to deficits in short or long-term memory. Thus, although the B6-5XFAD mice were not resilient to AD-induced

neurodegeneration, on average the B6-5XFAD mice were more cognitively resilient and performed better than their D2-5XFAD counterparts on memory tasks at both 6m and 14m. A significant interaction between background strain and 5XFAD mutation was also revealed by the analysis of Iba1 coverage specifically in the cortex and striatum. Interestingly, our results suggest that B6-5XFAD Iba1-positive microglia were reduced relative to Ntg counterparts, and the opposite was observed in the D2-5XFAD mice. In summary, performing brain-wide spatial mapping fostered an unbiased approach to identifying cell types and regions vulnerable to AD among two commonly used mouse strains. Future studies will investigate how genetics affect regional and cell-type composition and employ genetic mapping to identify loci associated with these endophenotypes of resilience.

Title: Learning and memory is differentially affected in middle aged wild type and McGill-R-Thy1-APP rats according to sex

Authors: M. HABIF[1], N. COLETTIS[1], F. FILIPPIN[1], S. DO CARMO[2], C. SISTER[1], V. BERKOWICZ[1], M. CERCATO[1], A. CUELLO[2], *D. A. JERUSALINSKY[1];

Abstract: Recent studies have shown a sex difference in neuropathology and cognition in mouse models of Alzheimer’s disease (AD). In this study, we investigated the influence of sex on short-term (STM) and long-term memory (LTM) in middle-aged McGill-R-Thy1-APP transgenic (Tg) rats, a model of AD-like brain amyloidosis. In heterozygous (+/-) McGill Tg rats the amyloid pathology is mainly intraneuronal with extracellular plaques developing at advanced age, offering an opportunity for testing cognitive deficits at preplaque stages. 12-13 month old McGill +/- male and female rats and their wild-type (wt) littermates were left to explore an open field for 5min and tested 24hr later. Horizontal (traveled distance) and vertical (rearings) exploration as well as grooming and time spent in the center of the arena vs periphery, were quantified. Most of the exploratory parameters were significantly lower along a session, as well as in the 2nd vs. the 1st exposure, denoting habituation in the 4 groups, without significant differences between them. However, the number of rearings appeared lower in males than in females. Rats were then

trained in 2-novel object recognition (NOR) and location (NOL) tasks. Both wt and Tg rats discriminated well a new vs. a familiar object 1hr later (short-term memory, STM). However, 24h later (long-term memory, LTM), Tg rats either female or male, did not reach the discrimination criteria. In the NOL task, only wt females performed well to discriminate a new location for a familiar object. For inhibitory avoidance (IA), rats were left in an enlighten compartment, receiving a mild foot shock when entering a dark compartment, and latency to enter was recorded. 24h later test latencies were significantly higher for both wt and Tg females, and for wt males, though not for Tg males. Furthermore, 14 days later only wt females reached the criteria. In conclusion, both 12-13 month-old wt and Tg+/- rats showed sex-dependent impairments in some cognitive functions: wt males and Tg (both female and male) rats exhibited selective LTM and persistence deficits in associative memories involving spatial reference and/or aversive stimulus compared to wt females. This highlights the importance of including sex as a variable when interpreting cognitive behavior data.

Title: N-terminal phosphorylation of fused in sarcoma (FUS) linked to DNA damage leads to distinct changes in the FUS proteome

Authors: *M. A. JOHNSON[1], T. A. NUCKOLS[1], S. NANDY[1], G. TAYLOR[1], J. ROOT[1], T. KUKAR[1,2,3];
[1]Dept. of Pharmacol. and Chem. Biol., [2]Ctr. for Neurodegenerative Dis., [3]Dept. of Neurol., Emory Univ., Atlanta, GA

Abstract: Frontotemporal dementia (FTD) and amyotrophic lateral sclerosis (ALS) are two neurodegenerative disorders that exhibit overlapping clinical symptoms and pathological markers. One such neuropathological marker is the abnormal cytoplasmic aggregation of fused in sarcoma (FUS). FUS is an RNA/DNA binding protein involved in gene transcription, mRNA splicing, DNA-repair pathways, and mRNA transport. While FUS is primarily a nuclear protein, FUS must shuttle between various cellular compartments to function properly. When shuttling is disrupted, FUS accumulates into cytoplasmic aggregates leading to the loss of FUS nuclear functions and a toxic gain of cytoplasmic functions. FUS shuttling can be disrupted through genetic mutations, but most of these cases have been linked to either ALS or mixed ALS/FTD.

Therefore, non-genetic factors such as post-translational modifications may drive pure FTLD-FUS pathology. Our lab discovered that double-strand DNA damage induces phosphorylation of FUS (p-FUS) at multiple N-terminal sites leading to an accumulation of p-FUS in the cytoplasm, yet the consequence of this cytoplasmic p-FUS remain unknown. To investigate this, we used an unbiased proximity labeling approach termed APEX2 to interrogate how phosphorylation may change the FUS proteome. We and others have mapped the major N-terminal phosphorylation sites, enabling the creation of a phosphomimic variant of FUS (PM FUS) that mimics the phosphorylation of FUS caused by double-stranded DNA damage. We then linked WT FUS, PM FUS, or the ALS-linked mutant P525L FUS to the engineered peroxidase, APEX2, and used proximity-dependent biotin tagging to enrich for all possible interacting partners. Biotin-tagged proteins were identified and quantified using label-free quantitative proteomics. We identified a total of 3,313 differentially expressed proteins within our three groups. From this, we identified 228 proteins significantly enriched in PM FUS over WT FUS and 1,332 proteins significantly enriched in PM FUS over P525L FUS. Overall, we found PM FUS enriched for cytoplasmic proteins involved in mRNA catabolic process, translation initiation, and stress granule assembly over WT FUS. In contrast, PM FUS enriched for nuclear proteins involved in functions such as spliceosome, ribonucleoprotein complex biogenesis, and covalent chromatin modification over P525L FUS. Taken together, these data suggest that phosphorylation results in a novel FUS interaction state that exists between the toxic P525L and the homeostatic WT functions. Findings from these studies will help to inform whether FUS phosphorylation status is important to FTLD-FUS pathology.

Title: Interactions Between Autophagy, Herpesvirus and Neurodegeneration in Alzheimer's Disease

Authors: ***A. NAFCHI**[1], M. ANANI[2], T. OPREA[3], B. READHEAD[4], E. BEARER[2]; [1]Pathalogy, [2]Pathology, [3]Sch. of Med., Univ. of New Mexico, Albuquerque, NM; [4]Arizona State Univ., Tempe, AZ

Abstract: Introduction: Various microbes and viruses have been associated with the pathogenesis of Alzheimer’s Diseases (AD), with many studies dating back to the 1950s. There are challenges in establishing direct links between the microbes and AD pathology. Since microbes and viruses have been observed to be dormant and reactivate in aging brains, it is not

clear if the microbes are a byproduct of AD pathology or a direct cause of it. Recently, various publications considered the link between several herpes simplex viruses and neurodegeneration in AD. For example, Readhead et al. utilized multiomics data from post-mortem brain samples meeting the neuropathological criteria for AD to construct biological networks and look for associations between viral genome, transcription and AD. This study established associations between human herpesviruses HHV-6A and HHV-7 and various aspects of AD. The herpes simplex viruses (HSV1 & 2) interact with intracellular membranes during egress. After viral replication and exit from the cell's nucleus, a secondary envelopment process, by which HSV acquires its envelope, structurally resembles the process of autophagy. Thus, autophagy might have significant interactions with HSV. In this study, we are interested in investigating whether autophagy-related genes are regulated by herpesviruses to determine molecular relationships between autophagy, herpesviruses, and AD.**Methods:** We have downloaded the R codes and datasets published by Readhead et al. available on synapse.org. We were able to run the code and reproduce the figures in their paper. We've also compiled a list of 180 autophagy-related genes. We plan to mine viral quantitative trait loci (vQTL) to correlate host genomic and RNA-seq to viral load in preclinical and clinical AD; and Quantitative trait of host genes (eQTL) to identify genes associated those host sites that also correlate with cognition and Braak stage. This produces 91,000 sites which we will mine for autophagy genes to construct a network of autophagy, viral activity, and AD traits. **Results:** We hypothesize that there exists a correlation between autophagy related genes and the reactivation of the dormant viruses and the progression of AD pathology.**Conclusions:** The integration of autophagy related genes in this project will potentially clarify the role microbes and viruses play in the progression and onset of AD pathology and how they interact with viral products in the brain.

Title: Ptprd phosphatase positive allosteric modulation and flavanol benefits for reducing alzheimers disease incidence

Authors: *G. R. UHL[1,2], I. M. HENDERSON[2], M. MARTINEZ[2], K. DOKLADNY[3], D. JOHNSON[4];
[1]Univ. of New Mexico and NMVAHCS, Albuquerque, NM; [2]Biomed. Res. Inst. of New Mexico, Albuquerque, NM; [3]Med., Univ. of New Mexico, Albuquerque, NM; [4]Univ. of Kansas, Lawrence, KS

Abstract: Alzheimers disease (AD) and the key elements of AD neuropathology receive contributions from genetics and environmental influences that include diet. Variants in intron 10 of the gene encoding the receptor type protein tyrosine phosphatase PTPRD are associated with individual differences in densities of neurofibrillary tangles, the AD pathological element that is rich in hyperphosphrylated tau. Serine threonine kinases most associated with tau phosphorylation include the glycogen synthase kinases GSK3 alpha and beta and the cyclin dependent kinase CDK5. Activity of each of these kinases is enhanced by phosphorylation of their own tyrosines. We now report that a phosphopeptide that has a phosphotyrosine in sequences that are identical between GSK3 alpha and GSK3 beta and a CDK5 phosphopeptide (pYGSK3 and pYCDK5) are avidly dephosphorylated by recombinant human PTPRD phosphatase with several lines of evidence for specificity, including effects of varying sequence and comparisons with activities of the related phosphatases PTPRS and PTPRF. We report that PTPRRD activities on the pYGSK3 phosphopeptide are almost doubled by addition of quercetin and related flavanols, but not by flavones or flavanones. This structure-activity relationship is similar to that for dietary flavanol intake in preventing AD incidence in studies of aging. PTPRD is well positioned to contribute to both genetic and environmental influences on Alzheimer's pathophysiology. Improved PTPRD positive allosteric modulators should come from testing our in silico models for PTPRD phosphatase interactions with phosphopeptides and flavanols.

Title: APOE genotype-dependent secretion and expression of apoE in astrocytes and microglia after inflammation

Authors: ***M. LANFRANCO**[1], J. SEPULVEDA[2], G. KOPETSKY[1], G. W. REBECK[1]; [1]Neurosci., [2]Pharmacol., Georgetown Univ., Washington, DC

Abstract: Neuroinflammation is a common feature in neurodegenerative diseases, characterized by activated glial cells and increased levels of cytokines and chemokines. Apolipoprotein E (apoE) is a protein with immunomodulatory properties, but the effect of inflammation on apoE production and processing is poorly understood. In the brain, apoE is synthesized by astrocytes

and microglia. We isolated both astrocytes and microglia from human *APOE (E2, E3* and *E4)* targeted-replacement mice, collected cells and conditioned media, and analyzed levels and forms of apoE. We found that astrocytes secrete two species of apoE, and that cellular apoE consists only of one of those species. In contrast to cellular apoE, both forms of secreted astrocytic apoE were glycosylated evidenced by glycoprotein isolation, and by a convergence to a single form after enzymatic removal of the glycans. Microglia release only a single species of apoE, and cellular apoE consists of two forms. Secreted apoE and only one of the two forms of cellular apoE were glycosylated. We tested whether the levels of forms of apoE were affected by inflammation, using either endogenous (TNFα) or exogenous (LPS) pro-inflammatory stimuli. While LPS had no effect on astrocytic apoE, *APOE2* and *APOE3* microglia increased the release of apoE; *APOE4* microglia showed no effect. *APOE4* microglia showed higher baseline secretion of TNFα compared to *APOE2* and *APOE3* microglia. Treatment with TNFα reduced the secretion and cellular expression of apoE only in *APOE4* astrocytes. The patterns of apoE species produced by astrocytes and microglia were not affected by inflammation. No detectable changes in *APOE* mRNA was observed in astrocytes after both treatments. Together, our data support a model by which astrocytic and microglial apoE secretion and expression are affected by inflammation in an *APOE* genotype-dependent manner, such that *APOE4* astrocytes and microglia are deficient in immunomodulation compared to *APOE2* and *APOE3*, leading to excessive inflammation in response to stimuli.

Title: Generation of iPSC-derived TREM2 R47H and isogenic TREM2 Loss of Function (LOF) microglia to investigate Alzheimer’s disease risk

Authors: C. MUNN, S. BURTON, I. GUREVICH, M. GOEDLAND, M. MCLACHLAN, M. XONG, D. RAJESH, S. HILCOVE, ***W. W. POON**;
FUJIFILM Cell. Dynamics, Inc., Madison, WI

Abstract: Recent Genome-wide association studies (GWAS) in Alzheimer’s disease (AD) have uncovered a number of single nucleotide polymorphisms (SNPs) or genetic variants within genes predominantly expressed in microglia in the CNS (TREM2, CD33, TYROBP, PLCG2). Microglia are the resident immune cell of the brain, and numerous studies have linked genetic variants of triggering receptor expressed on myeloid cells 2 (TREM2), including the R47H variant, with impairment of microglia function affecting ligand binding/sensing, phagocytosis, metabolism, and inflammatory responses. Since primary human microglia from living donors are not accessible for research, we generated microglia from episomally reprogrammed human

induced pluripotent stem cells (iPSCs) from donors harboring either WT TREM2 or the R47H mutation. In addition, end-stage microglia were generated from both heterozygous (TREM2 HT) and homozygous (TREM2 HO) TREM2 KO gene edited isogenic iPSCs derived from an apparently healthy normal (AHN) donor. To generate a large batch of cryopreserved end-stage microglia, iPSCs were first differentiated to hematopoietic progenitor cells (HPCs) and purified by MACS of $CD34^+$ cells (>90%) along with CD43, CD45, and CD235/CD31 coexpression. Next, HPCs were differentiated to pure end-stage microglia and cryopreserved. Upon thaw, the microglia (i) retained a high purity based on CD45, CD11b, CD33, P2RY12, TREM2, CX3CR1, and IBA-1 expression, (ii) retained the ability to be polarized towards an inflammatory or anti-inflammatory subtype by specific stimuli, and (iii) are indistinguishable from freshly differentiated microglia. This panel of iPSC-derived microglia expressing WT TREM2, TREM2 R47H, TREM2 HT, TREM2 HO was used to understand the role of TREM2 R47H or loss of function (LOF) of TREM2 in isogenic microglia on phagocytic function, cytokine response and whole transcriptome gene expression for predictive *in vitro* disease modeling applications. This unique tool set of microglia is useful for interrogating the role of TREM2 function and for identification of compounds that restore TREM2 function in high throughput screening assays. Thus, both patient-derived TREM2 R47H and isogenic variants of TREM2 LOF microglia are valuable platforms for investigating TREM2's role in AD pathogenesis.

Title: Cultured Microglia from Cognitive SuperAgers Show High Rates of Proliferation

Authors: ***E. TAEFI**[1], I. AYALA[1], T. GEFEN[1], M. E. FLANAGAN[2], E. ROGALSKI[1], M. M. MESULAM[1], C. GEULA[1];

[1]Mesulam Ctr. for Cognitive Neurol. and Alzheimer's Dis., [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Cognitive SuperAgers are individuals 80 years of age or older, with episodic memory performance that is equal or better than those of individuals 20-30 years their junior. The Northwestern University SuperAging project was established to identify cognitive, behavioral, anatomic, pathologic, molecular, cellular and neurochemical factors that contribute to the SuperAging phenotype and distinguish these individuals from their cognitively normal peers. Accordingly, studies of SuperAgers have identified a number of signatures that distinguish them from cognitively normal elderly, including thicker cerebral cortices, lower Alzheimer's disease pathology, increased density of von Economo neurons in the anterior cingulate cortex, and greater preservation of cortical cholinergic innervation. Given the recent surge of evidence indicating a central role for microglia function in the pathobiology of cognitive decline, we sought to determine if microglia cultured from brains of SuperAgers display different characteristics when compared with those from cognitively normal elderly. Fresh autopsied prefrontal cortical tissue from 9 SuperAgers and 10 cognitively normal elderly were used in these experiments. Microglia cultures were prepared from whole cell suspensions in the presence of microglia medium (SienCell, Inc), supplemented with 5% fetal bovine serum, 100 U/ml penicillin, 100 µg/ml streptomycin, 1 ml/500ml primocin, 1%microglia growth supplement (ScienCell), and 10 ng/ml GM-CSF (Sigma-Aldrich). Cultures were passaged after they were 70% confluent and until growth had significantly slowed or stopped. Cultured microglia from all participants were viable and continued proliferation at least up to passage 7-10. The average time, in days, to reach confluence was considerably shorter in microglia cultures from SuperAgers when compared with cognitively normal controls (7.1 ± 1.7 days in SuperAgers vs 12.3 ± 0.76 days in cognitively normal controls; $p<0.03$). Moreover, the highest passage reached among all participants was passage 21, which was achieved in the SuperAger group. These observations point to significant enhancement of the proliferative capacity of microglia in SuperAgers, which may relate to the protective functions of these cells in the brain. The precise mechanisms that contribute to differences in microglia proliferation in SuperAgers remain to be elucidated.

Title: Characterized Adult Primary Human Microglia Cells for Research

Authors: *C. GEULA, E. SABETI, A. BAHRAMI, I. AYALA;
Mesulam Ctr. for Cognitive Neurol. and Alzheimer's Dis., Northwestern Univ. Med. Sch., Chicago, IL

Abstract: Microglia have diverse functions in the healthy and diseased brain. Much of what has been learned regarding microglia biology is based on *in vitro* studies the overwhelming majority of which used cells isolated from the rodent brain. However, higher anatomical and functional complexity of the human brain and species differences in microglia response and function make imperative the use of human microglia to ascertain that the results are applicable to man. Investigation of microglia function in the adult brain, in which many inflammatory and protective microglia responses occur, requires use of human microglia from adult brains. Microglia cultured from embryonic human brain show substantial proliferative capacity. However, while methods for isolation of microglia from adult postmortem human brains had been described, they allowed only use of a limited quantity of microglia isolated and cultured from each case due to low levels of proliferation. We have developed a method that allows culturing microglia from adult postmortem human brains to high passage and have found that such cells maintain their phenotype in high passage cultures. Briefly, microglia cultures were prepared from whole cell suspensions in the presence of microglia medium (SienCell, Inc), supplemented with 5% fetal bovine serum, 100 U/ml penicillin, 100 µg/ml streptomycin, 1 ml/500ml primocin, 1%microglia growth supplement (ScienCell), and 10 ng/ml GM-CSF (Sigma-Aldrich). Microglia maintained their phenotype in culture as evidenced by uptake of acetylated low density lipoprotein, a marker of scavenger receptors, presence of CD68 immunoreactivity, and production of reactive oxygen species in response to fibrillary amyloid-β peptide. We have built a library of primary adult human microglia cells of various passages from young and aged postmortem brains and from brains of individuals with various neurodegenerative disorders. The goal of the current project is to continue to culture and characterize adult primary human microglia cells of various passages from normal and diseased human brains and to share them with researchers nationally and internationally. High yield and well characterized adult human microglia cultures from our library will allow mechanistic *in vitro* studies with cells from the same case used in different experimental conditions. Availability of large numbers of cells would also allow initial testing of drugs that can regulate microglial functions and permit isolation of large amounts of RNA and/or protein for transcriptomic or proteomic studies. To obtain primary adult human microglia for your research, please contact Changiz Geula at c-geula@northwestern.edu.

Title: Novel neuroprotective Elovanoids (ELVs) modulate Tau hyperphosphorylation (Tau-HP), microtubule-associated protein tau (MAPT) missorting, and neuronal integrity in a cellular model of Alzheimer's disease.

Authors: S. BHATTACHARJEE[1], P. K. MUKHERJEE[1], A. J. LEDET[1], C. POLK[1], N. DESAI[1], N. A. PETASIS[2], N. G. BAZAN[1];
[1]Neurosci. Ctr. of Excellence, LSU Hlth., New Orleans, LA; [2]Loker Hydrocarbon Res. Inst., USC, Los Angeles, CA

Abstract: *Rationale:* AD involves accumulation of amyloid-β, Tau hyperphosphorylation (Tau-HP), neuroinflammation and homeostasis perturbations. In this project, we tested a new conceptual framework to understand early events in the pathophysiology of AD. It focuses on the novel pro-homeostatic, neuroprotective lipid mediators (LMs) - elovanoids (ELVs) and its targeting of events that counteract neuroinflammation, in human neuronal cells in primary culture as well as a rodent cellular model of AD. Our lab in 2017 reported the finding that ELVs are novel LMs endogenously produced in the CNS and derived from 32:6n3 and 34:6n3. In the 5XFAD model, we recently demonstrated altered pro-homeostatic lipid signalling, including downregulation of Neuroprotectin D1 (NPD1) and ELVs early in the retina, preceding photoreceptor cell loss. This project brings novel LMs as key in the initiation and early progression of AD, senescence gene programming (SASP) and microtubule associated protein Tau (MAPT). Hyperphosphorylated forms of MAPT are constituent of neurofibrillary tangles (NFT), a histopathological hallmark of AD and appear in dendrites, “somatodendritic missorting.” *Methods:* Primary hippocampal cultures were exposed to Oaβ (10μM) and treated with ELVs or other LMs. Tau-HP, missorting was assessed by confocal microscopy. Images were acquired using Olympus Fluoview 3000 confocal microscope at a size 512x512 pixels. Z section images were taken, with focal plane +/- 20 micrometers captured. Images were captured from random sites in a well. Using Olympus Multi-Area Time Lapse (MATL) function, wells were duplicated, resulting in identical locations imaged in each well of a standard 12 well cell culture plate (Corning). Images were quantified in an unbiassed manner using Bitplane Imaris software 9.5.1. The Intensity Mean function of Imaris software was used to assess the signal intensity of captured images using surfaces parameter. Signal intensity data was statistically analyzed using GraphPad Prism software 8.4.3. Protein abundance of phosphorylated tau residues p-Tau-Thr181, p-Tau-Thr217, p-Tau-Thr231 and (pSer202/pThr205) (AT8) was checked by Western Blotting (WB). *Results/Conclusions:* Confocal imaging demonstrates a significant difference ($p<0.0001$) in signal intensity of AT8, Thr231 from wells exposed to Oaβ in comparison to Oaβ+ELVs/NPD1 at 250 nM - 1μM. WB results show significant upregulation of Tau-HP at AT8, p-Tau-Thr181, p-Tau-Thr217, p-Tau-Thr231 which is abrogated by LMs. ELVs arrest senescence gene programming expression, including SASP secretome. ELVs and NPD1 reduce Oaβ-induced MAPT hyperphosphorylation.

Title: Metabolic syndrome effect on olfactory function, memory and neurodegeneration

Authors: P. I. CLAVEL PÉREZ[1,2], K. G. CARVAJAL AGUILERA[2], *B. PHILLIPS-FARFAN[3];
[1]Univ. Nacional Autónoma de México, Mexico City, Mexico; [2]Inst. Nacional de Pediatría, Mexico City, Mexico; [3]Inst. Nacional Pediatría, Mexico City, Mexico

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder distinguished by an advancing cognitive decline. Although memory loss is evident, olfactory dysfunction can arise years before any cognitive symptoms. Metabolic syndrome (MS) is a significant risk factor for AD development. Insulin resistance and oxidative stress, two core MS dysfunctions, promote the development of neuritic plaques that characterize AD. However, whether these alterations participate in early olfactory dysfunction remains unknown. We investigated cerebral insulin resistance and oxidative stress induced by a model of metabolic syndrome without alterations in glucose metabolism. For this we used Wistar rats, with 250-300 g body weight on arrival. They were randomly divided in two groups: 1. a control group (n=3-4) that received standard chow plus water and 2. the MS group (n=4-5) that received standard chow plus 30 % sucrose in their drinking water. Both groups were kept on their respective diet for 23 weeks and 3 independent replications were done (30 rats in total). Olfactory and memory function were evaluated using behavioral tests. Insulin pathway activation and amyloid precursor protein (APP) expression were assessed with western blots. Lipid peroxidation was evaluated by the determination of malondialdehyde levels. Neurodegeneration was assessed by measuring the fluorescence intensity of Fluro-Jade-C. All these techniques were performed in the olfactory bulb and hippocampus. Rats receiving the high-carbohydrate diet had olfactory dysfunction, but interestingly memory appeared to be better. Systemic hyperinsulinemia hyper-activated the insulin pathway and APP expression was reduced in the hippocampus. These effects were not present in the olfactory bulb, insulin activation and APP expression were similar in both groups. Malondialdehyde, a lipid peroxidation marker, was reduced in the hippocampus but remained unchanged in the olfactory bulb. We did not find signs of neurodegeneration in these tissues. Insulin cascade stimulation, reduced APP expression and malondialdehyde levels suggest that compensatory mechanisms likely occurr in the hippocampus. We propose that the olfactory bulb has early insulin resistance, accounting for the olfactory impairment. We provide novel information about olfactory dysfunction in a model of MS induced by high carbohydrate. Insulin pathway impairment and accumulation of amyloid beta in the olfactory bulb merit further research.

Abstract: Neurogenesis, the conversion of neural stem cells to neurons, declines in Alzheimer's disease (AD), and the mechanisms are unknown. In cancer cells and in other cell types, mitochondria and metabolism change dramatically with differentiation. Indeed, differentiation can be modulated by manipulating mitochondria. Since reduced metabolism always accompanies AD, we hypothesize that the decline in neurogenesis with AD is caused by diminished metabolism and altered mitochondrial function. Differentiation from neural stem cells to neurons is accompanied by a "glycolytic switch," and the cell's energy production shifts the cells from depending primarily on glycolysis to utilizing oxidative phosphorylation. This shift has downstream effects on the differentiation of stem cells to neurons. The link between metabolism and neurogenesis is unknown. We have focused on the key mitochondrial enzyme complex, the alpha-ketoglutarate dehydrogenase complex (KGDHC), which is often rate limiting in the regulation of the tricarboxylic acid cycle. The reduction of KGDHC has a surprisingly large number of consequences, and we postulate that many of its actions are related to KGDHC mediated post-translational modifications. The second enzyme of the KGDHC is a succinyl-transferase (DLST). We have shown that altered metabolism changes the subcellular distribution of DLST, and DLST regulates the lysine succinylation of hundreds of proteins in the mitochondria and cytosol. We have not yet studied nuclear succinylation. To determine the role of KGDHC and succinylation in neurogenesis, we established a model of *in vitro* neurogenesis using cells derived from induced pluripotent stem cells (iPSC), which were derived from fibroblasts. To verify this model, we quantified the temporal pattern of protein and RNA markers that change during normal neurogenesis (SOX1, Nestin, ASCL1, Doublecortin, and Calbindin). Exploratory experiments examined changes in the levels and subcellular localization of succinylation and DLST during early neurogenesis. When compared to neural stem cells, immature neurons show a decrease in nuclear succinylation and an increase in mitochondrial succinylation. There is also a slight, not statistically significant increase in DLST staining in the

mitochondria and nuclei of immature neurons, as compared to neural stem cells, which agrees with the well-established increase in KGDHC in brain with maturation. The experiments demonstrate that iPSC derived neural stem cells and neurons are a valid model to explore the interaction of succinylation, mitochondria and differentiation.

Title: Type2 diabetes-induced cognitive deterioration in AD is associated with IRS modifications but not with amyloid beta accumulation

Authors: D. TANOKASHIRA[1], W. WANG[1], M. MARUYAMA[1], C. KUROIWA[1], T. SAITO[2], T. SAIDO[3], ***A. TAGUCHI**[1];

Abstract: Type2 diabetes (T2DM) is associated with an increased risk for Alzheimer's disease (AD), suggesting that insulin signaling that regulates glucose metabolism may be involved in the development of AD. Our recent studies show that alterations in the hippocampal insulin receptor substrates (IRSs) signaling are associated with cognitive decline in T2DM model mice and middle-aged APP knockin (APP KI) mice for AD model. However, the effect of T2DM on APP KI mice and the changes of hippocampal IRSs signaling in T2DM-induced APPKI mice remain unknown. We found that T2DM deteriorates memory impairment, decline in neurogenesis, and modification in IRSs in middle-aged APP KI mice, while T2DM has no effect on amyloid β(Aβ) accumulation and microglial activation. On the other hand, T2DM-induced glucose intolerance is suppressed in middle-aged APP KI mice. These results suggest that specific modifications in IRSs maybe related to the development and progression of memory impairment caused by AD with/without T2DM and T2DM-induced cognitive dysfunction may occur independent of Aβ accumulation and impaired systemic glucose metabolism.

Title: Splicing landscape of ApoER2 in Alzheimer's disease, mapped by single molecule, long read RNA sequencing

Authors: *C. M. GALLO[1,3], A. T. LABADORF[2,4], U. BEFFERT[3], A. HO[3,1];
[1]Pharmacol., [2]Neurol., Boston Univ. Sch. of Med., Boston, MA; [3]Biol., [4]Bioinformatics Program, Boston Univ., Boston, MA

Abstract: Age and the ε4 allele of apolipoprotein E (apoE) are the two greatest risk factors for developing Late Onset Alzheimer's Disease (LOAD). As there is no known cure for or cause of LOAD, understanding the mechanism underlying known risk factors is paramount for moving therapeutic research forward. ApoE mediates its physiological effects in the brain by binding to cognate receptors like apoER2. Using long read single molecule RNA sequencing, we have identified over 40 isoforms of apoER2 in the human cerebral cortex indicating vast diversity at the level of apoE receptors. This diversity is reflected at the protein level, as multiple apoER2 isoforms have already been shown to have distinct functions in the brain and majority of splicing events remove or add unique functional domains. Recent studies have discovered a novel link between aging, neurodegeneration and alternative splicing. Interestingly, alternative splicing of the apoE receptor apoER2 is altered in Alzheimer's disease (AD). Therefore, abnormal alternative splicing in aging and neurodegeneration may alter the interactome of the key AD risk factor APOE through apoER2, influencing APOE physiological function and highlighting a new scientific paradigm through which to investigate the role of APOE in LOAD. Based on this rationale, we hypothesize that apoER2 isoform balance is progressively perturbed in AD contributing to synaptic dysfunction. To characterize apoER2 isoform distribution in the AD hippocampus, we have utilized long read single molecule RNA sequencing to generate novel apoER2 transcript maps from three female control patients and three female Braak Stage IV LOAD patients. Our data indicates common isoforms amongst control and AD patients and highlights several isoforms of interest for quantitative follow-up including a potentially novel 3' splicing event. To ensure experimental rigor and analyze apoER2 splicing trends quantitatively, we plan to interrogate apoER2 splicing patterns using qPCR across over 200 control and AD tissue samples in the hippocampus, as well as the prefrontal cortex, parietal cortex and control region cerebellum. Our findings suggest a novel scientific model through which to view conferred APOE risk in AD: altered splicing of the cognate receptor apoER2.

Title: Tissue inhibitor of matrix metalloproteinase-1 modulates Akt phosphorylation in promoting neuronal survival and in ameliorating cognitive functions in 5xFAD mouse

Authors: S. SARKAR, *R. PAIDI, ***S. C. BISWAS**;
CSIR-IICB, Kolkata, India

Abstract: Alzheimer's disease (AD), a progressive neurological disorder develops over several decades with reactive astrocytes displaying major functional dichotomy across disease stages. Reactive astrocytes are characterized by dramatic transcriptional, morphological and biochemical changes and secrete several cytokines dictating their role in regulating neuronal health in neurological diseases including AD. Recently, we have shown that tissue inhibitor of matrix metalloproteinase-1 (TIMP-1) is rapidly secreted by reactive astrocytes as early as 6 hours in response to synthetic oligomeric $A\beta_{1-42}$ (Aβ) treatment in primary culture and promotes neuronal survival in primary rat cortical neurons. Moreover, intracerebroventricular TIMP-1 infusion in Aβ-injected rat arrests apoptotic cell death, reduces Aβ load and ameliorates cognitive functions. However, the underlying signaling pathway/s responsible for TIMP-1's neuroprotective functions or how TIMP-1 binds to neuron was unclear, especially in a more biologically relevant AD model. In our present work we show that TIMP-1 can activate the serine-threonine kinase, Akt by phosphorylating at serine 473, a major regulator of both autophagic and apoptotic pathways in 5xFAD mice model of AD and downregulates the apoptotic pathway while upregulating autophagy flux, in cortex and hippocampus as seen by western blot and immunofluorescence analyses. Intracerebroventricular TIMP-1 infusion ameliorated cognitive behaviours assessed by fear conditioning, passive avoidance, elevated plus maze tests etc. in 6-month old 5xFAD mice. Improvement in cognition may be attributed to the underlying recovery in their synaptic deficits. Indeed, recombinant TIMP-1 treatment improved synaptic health by inducing expression of pre- and post-synaptic proteins SNAP-25 and PSD-95 in hippocampus and cortex of 5xFAD mice assessed by western blotting and immunohistochemistry. However, we noted that TIMP-1 mediated phosphorylation of Akt at threonine 308, different from the earlier site, which further inactivates the apoptogenic protein glycogen synthase kinase-3β playing a pivotal role in regulating synaptic plasticity. Importantly, we emphasize that TIMP-1 mediates its neuroprotective role in a matrix metalloproteinase-9 independent manner by binding through CD63 receptor on neuronal surface. Thus, TIMP-1 binds to CD63 on neurons activating Akt by phosphorylating it at distinct sites and driving TIMP-1's neuroprotective role in models of AD. TIMP-1's ability to induce recovery in major cognitive deficits in an advanced AD transgenic model projects it as a major candidate in cytokine-mediated therapy of AD.

Title: A Novel Inducible Complement C3 Conditional Global Knockout Mouse Model to Investigate Neurodegeneration in Alzheimer's disease

Authors: ***A. F. BATISTA**[1], M. SCHROEDER[2], K. KHAN[2], J. PRESUMEY[3], E. YALCIN[3], M. CARROLL[4], C. A. LEMERE[5];
[1]Brigham and Women's Hosp. and Harvard Med. Sch., Boston, MA; [2]Brigham and Women's Hosp., Boston, MA; [3]Boston Children's Hosp. and Harvard Med. Sch., Boston, MA; [4]Boston Children's Hosp. and Harvard Med. Sch., Boston, MA; [5]Ann Romney Ctr. Neurol Dis, Brigham & Women's Hosp; Harvard Med. Sch., Boston, MA

Abstract: The complement pathway, part of the innate immune system, is involved in the elimination of dead cells, and pathogens, and as well as brain wiring during development. Complement protein C3, a central component of the complement pathway, participates in eliminating synapses and is elevated with aging and neurodegenerative diseases, including Alzheimer's Disease. Although we previously showed that lifelong, germline C3-deficiency protected aged male wild-type and APPswe/PS1dE9 mice against hippocampal neuronal dysfunction and cognitive decline, despite increasing the Aβ plaque load, it remains unknown whether suppressing complement C3 signaling during early stages of AD pathogenesis, when relevant therapeutic interventions might be considered, can confer neuroprotection. Therefore, we generated a C3 floxed (C3fl/fl) mouse line, and crossed it to an inducible, global Cre line (Rosa26-Cre-ERT2+/-) for 2 generations to generate novel inducible C3 conditional knockout C3fl/fl; Rosa26-Cre-ERT2+/- (C3iKO) mice on a C57BL/6J background. Mice aged 2-3 months received intraperitoneal injections of either corn oil or tamoxifen (75 mg/kg) once a day for 5 consecutive days. We analyzed the C3 serum levels at 7, 14, 30, 60, 90, 120, 150, 180 and 210 days post-tamoxifen treatment. We also analyzed the mRNA expression of complement proteins and receptors in the brain and liver 60 days and 150 days following tamoxifen treatment. C3iKO mice had a significant 85-90% reduction in serum C3 levels compared to controls, which was consistent at all timepoints analyzed. C3 mRNA expression in the liver, the main source of complement proteins, as well as in the brain was significantly reduced, demonstrating effective recombinase activity in these organs. We confirmed in the brain that C3 protein levels remain suppressed at 60 and 150 days after tamoxifen treatment. Surprisingly, C1q mRNA expression was increased in the brain and liver at 60 days but not at 150 days following tamoxifen treatment. None of the other complement component/receptor mRNAs were altered. Some brain homeostatic genes which include TMEM-119, P2ry12; Cx3cr1 and TGFβR1 were not altered.

Interestingly, we observed a significant reduction in TGF-β mRNA expression only on day 150. Further studies are underway. In conclusion, we present a novel mouse model, C3iKO, in which tamoxifen treatment resulted in sustained lowering of C3 in the serum, liver, and brain. We will next cross this model with AD-like mouse models of amyloidosis and tau pathology to evaluate whether global C3 lowering in early stages AD pathogenesis is protective and if so, our data would support targeting complement as a therapy for AD.

Nancy E. and Peter C. Meinig School of Biomedical Engineering, Cornell University, Ithaca, New York, USA
We recently found that increased obstructions in capillaries caused by adhesion of leucocytes in the cortical microvascular leads to a ~20% reduction of cerebral blood flow (CBF) in mouse models of Alzheimer's disease. Here, we explore the contribution of peripheral Vascular Endothelial Growth Factor (VEGF-A) signaling at the luminal side of the brain microvasculature as a driver of capillary stalling and blood-brain barrier (BBB) integrity in the APP/PS1 mouse model of AD. The number of stalled cortical capillaries and blood flow speeds were measured in cortical capillaries using high resolution in vivo two-photon imaging, before and after one hour

and two weeks of i.p. anti-VEGF-A164 antibody injection. Capillary stalls were measured using the citizen science platform Stall Catchers. The blood-brain barrier integrity was analyzed using immunohistochemistry. We found that inhibition of VEGF-A signaling in APP/PS1 mice reduces capillary stalling by ~75% and improves average capillary speed by ~50%. In contrast, no such effects were seen in wild-type saline-injected controls. The anti-VEGF164 injection also reduced overall eNOS protein concentrations and increased the tight junction protein levels of occludin. Intriguingly, the few APP/PS1 capillaries that were still prone to obstructions after anti-VEGF-A treatment had lower occludin concentrations between their endothelial cells than flowing capillaries. We further demonstrate that capillary stalling reductions and capillary speed improvements occur within an hour of intraperitoneal anti-mouseVEGF164 injection. At the same time scale, anti-VEGF-A treatment reduced Evan's blue diffusion across the BBB.This data demonstrates that peripheral inhibition of VEGF-A signaling in APP/PS1 mice restores aberrant eNOS/occludin-associated BBB permeability, and is associated with decreased capillary stalls and increased CBF.

Abstract: Cerebral blood flow (CBF) is decreased by ~30% in both patients and animal models of Alzheimer's disease (AD). Previously, we identified that about 2% of cortical capillaries in the APP/PS1 mouse model of AD had stalled blood flow due to white blood cell arrest in the capillary segment. In comparison, only 0.4% of capillaries were stalled in wild type controls. Antibodies against the neutrophil surface protein Ly6G reduced the incidence of capillary stalls, leading to increased CBF and improved short-term memory. Here, we report on the upstream molecular mechanisms contributing to increased neutrophil arrest, focusing on oxidative stress pathways that have previously been implicated in endothelial dysfunction in mouse models of

AD, including loss of neurovascular regulation. We inhibited NOX2-containing NADPH-oxidase, a reactive oxygen species producing enzyme shown to be activated in AD, in 10-11 month old APP/PS1 mice for two weeks. We found that, in APP/PS1 mice, the fraction of capillaries with stalled blood flow was decreased by 67%, CBF was increased by 29%, and performance on short-term memory tasks was improved. Enzyme-linked immunosorbent assays showed no significant changes in amyloid-beta monomeric species, and the overall plaque load was not affected. NOX2 inhibition was also associated with a decrease in blood brain barrier dysfunction and neurovascular inflammation. This study implicates the NOX2 pathway as a molecular mechanism contributing to capillary stalling and CBF reductions in a mouse model of AD and could represent a molecular pathway with therapeutic potential for AD.

Title: Hm15211 can reduce spatial memory deficits, reverse neuroinflammation and restore insulin signaling pathway in aged triple transgenic mouse model of alzheimer's disease.

Authors: *L. PALADUGU, P. MAITI, Z. BOWERS, J. ROSSIGNOL, G. DUNBAR; Neurosci., Central Michigan Univ., Mount Pleasant, MI

Abstract: Despite extensive research on potential treatments for Alzheimer’s disease (AD), no effective therapy has emerged. Previous studies have shown a strong link between AD and type 2 diabetes mellitus (T2DM) to an extent that AD has been called type 3 diabetes mellitus. In this context, a promising approach is to repurpose anti-diabetic drugs as a potential way to treat the pathological hallmarks of the disease and restore cognitive function. Apart from the traditional anti-diabetic drugs, like metformin and insulin, incretin analogues, like liraglutide, a glucagon-like peptide-1 (GLP-1) and peptides that have anti-diabetic effects, like gastric inhibitory peptide (GIP), have shown potential for reversing the cognitive dysfunction and ameliorating the effects of AD. In the present study we tested the efficacy of a triple receptor agonist (TA), in aged triple transgenic (3xTg) mice, that carry transgenes for AD. TA activates GLP-1, GIP and glucagon (Gcg) receptors at the same time in the brain. Fourteen-month old 3xTg mice and their WT counterparts were treated with 10- and 25- nM of TA or saline vehicle with daily intra-peritoneal injections (i.p) for thirty days. Following a battery of behavioral tests including open field, novel object recognition, and Morris water maze, several neuropathological parameters, including

markers for neurodegeneration, neuroinflammation, insulin signaling, tau, and amyloid beta (Aβ) were studied in both cortical and hippocampal regions of the brain via immunohistochemical and Western Blot studies. Our results indicated that treatment with TA significantly reversed memory deficits in the Morris water maze task. Western Blot analysis indicated that the drug reduced the levels of type 1 and type 2 macrophages in the brain and normalized the expression of proteins associated with insulin signaling pathway in the brain. Moreover, TA also reduced the expression of phosphorylated tau in both cortical and hippocampal regions of the brain. Collectively, our results suggest that TA can be a promising drug to restore the disrupted insulin signaling pathway and reduce memory deficits and reduce neuroinflammation in AD.

A transient blockade of the PD-1/PD-L1 immune checkpoint pathway was shown to improve cognitive performance, and to reduce pathology in Alzheimer's disease (AD) in the mouse. Based on our previous studies, we hypothesized that such a treatment leads to systemic elevation of IFN-γ producing T cells, and thereby to an increase of availability of IFN-γ signaling at the choroid plexus (CP) that needed for supporting trafficking of repairing immune cells to the brain. Here we challenged this hypothesis using a mouse model of 5xFAD bred with IFN-γ-Receptor loxP/loxP mice. At the age of 5.5 months old these mice received a bilaterally

intracerebroventricularly (i.c.v.) TAT-CRE recombinase injection to locally downregulate IFN-γ-Receptor within the CP. Following a 2-week recovery period, mice were given a single injection (i.p.) of either anti-PD-L1 antibody or vehicle. Multi-parameter immune profiling using flow cytometry was performed on spleen, blood and brains 1, 3 or 7 days following anti-PD-L1 injection, while cognitive performance and AD-related neuropathologies were assessed 4-5 weeks following the anti-PD-L1 injection. Our results show that 4 weeks following anti-PD-L1 injection, INF-γ-Receptor flox/flox mice that received vehicle i.c.v. injection showed a robust improvement in cognitive performance as well as a reduction in hippocampal soluble and insoluble β-amyloid levels relative to a matched IgG2b-treated group. TAT-CRE i.c.v. injected mice showed a significant reduction in the response to anti-PD-L1 treatment with respect to cognitive improvement and a complete loss of the beneficial effect on hippocampal β-amyloid levels. Importantly, i.c.v. TAT-CRE injection had no effect on the systemic response to anti-PD-L1 measured by the levels of splenocyte T cells and FOXP3+ regulatory CD4+ T cells in the blood. Downregulation of IFN-γ-Receptor at the CP following TAT-CRE injection was verified using Real-Time PCR. We conclude that these results strengthen our suggested mechanism that the therapeutic effect of immune checkpoint pathway blockade on AD-related pathology involves IFN-γ-dependent signaling at the brain's CP epithelium.

Title: Sex differences in the impact of prediabetes on multi-etiology dementia

Authors: ***O. J. GANNON**[1], L. ROBISON[2], A. SALINERO[1], F. MANSOUR[1], D. RICCIO[1], A. TYAGI[1], M. THOMAS[1], K. ZULOAGA[1];

Abstract: It is estimated that 60-80% of Alzheimer's disease (AD) cases also have underlying vascular contributions to cognitive impairment and dementia (VCID). This overlap of vascular and Alzheimer's pathology is termed multi-etiology dementia (MED). AD and VCID have many mutual risk factors; however, men are more likely to develop VCID and women are more likely

to develop AD. When diabetes is present, this sex difference reverses, with women having a higher risk of VCID (19% greater risk compared to men). The effects of prediabetes, which is three times more common than diabetes, on this sex difference and on MED are unknown. We hypothesize that prediabetes will exacerbate cognitive deficits and pathology in MED, with females having greater deficits. We used a triple transgenic (3xTg-AD) model of AD in which mice develop amyloid and tau pathology and wild type mice (B6129SF1/J; WT) as controls. To model MED, we performed a unilateral common carotid artery occlusion surgery on 3xTg-AD mice, which produces chronic cerebral hypoperfusion. Prediabetes was modeled using a high fat (HF) diet. We have previously shown that 3xTg-AD females suffer greater metabolic consequences of a HF diet than WT females. This did not occur in 3xTg-AD males. To assess cognitive function, we performed Morris water maze (spatial learning and memory), novel object recognition (episodic memory), and nest building (activities of daily living) tests. Episodic memory was impaired by the HF diet in control females but not males, and all dementia groups were impaired by a HF diet regardless of sex. Spatial memory was impaired by HF diet in male and female AD and MED mice. HF diet caused deficits in spatial learning in female dementia groups only. AD and MED females, regardless of diet, had deficits in activities of daily living while the males were unaffected. Using immunohistochemistry and Western blot, we are assessing sex differences in the effects of dementia and HF diet on AD pathology, including amyloid pathology, cerebral microbleeds, and tau/p-tau levels. In conclusion, HF diet resulted in a wider array of adverse cognitive effects in AD and MED females compared to males. These results support the role of prediabetes as a potentially greater dementia risk factor for women.

Title: Neuroinflammatory signals correlate with age related cognitive decline in 5XFAD (B6SJL) mouse model of Alzheimer’s disease

Authors: *A. BANIK, T. GANESH;
Dept. of Pharmacol. and Chem. Biol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Alzheimer’s disease (AD) is the third leading cause of death, and the leading cause of dementia in the USA. AD is also associated with substantial medical and societal burden with currently no approved therapy that can clearly alter the disease progression. Decades of research on amyloid and tau pathological markers helped us to elucidate the pathophysiological features

of AD, but they have not yet culminated into disease modifying therapies. Recent findings implicate that neuroinflammatory pathways play a key role in exacerbating AD pathology and ensuing cognitive and behavioral deficits in patients. However, it is not clearly investigated the relative induction of neuroinflammatory markers during the ageing of AD transgenic animal models to design an effective anti-inflammatory therapy. To answer this question, we investigated 5XFAD mouse model, which carries five AD-linked mutations for human APP and PSEN1 genes. 5XFAD line has been maintained on both genetic backgrounds (hybrid B6SJL and congenic C57BL6). Our previous studies using 5XFAD mouse on C57BL6 background indicated that they do not display a robust neuroinflammatory signaling until 5 months, and no behavioral deficits until 9 months of age. Therefore, we investigated the neuroinflammatory and cognitive profiles of 5XFAD mice in B6SJL background longitudinally from 5-9 months. 5XFAD transgenic and non-transgenic littermates in both sexes were tested in Y-maze and Morris water maze (MWM) and then perfused at 5, 7 and 9 months of their age to harvest the brains. A series of neuroinflammatory cytokines, chemokines and astrocytic and microglial markers were analyzed in the brain regions. The Y-maze data showed little difference in working memory in 9 months old mice compared to their younger counterparts while their performance in MWM showed an age dependent decline in spatial memory with maximum impairment at 9 months of their age. mRNA levels of several neuroinflammatory markers indicated that significant changes in the level of proinflammatory cytokines, IL1β, IL6, CCL3, CCL4, immunomodulatory markers including chemokines such as EP2, TREM2, NOX2 and CXCL10, and astrocytic and microglial markers such as GFAP, CD68, IBA1 and CD11b. These data suggest the role of neuroinflammation in associated cognitive decline in AD brains and further downstream molecular pathway analysis will help us to find prudent anti-inflammatory targets for future therapies.

Title: Il-33 promotes a stepwise functional state transition of microglia to alleviate alzheimer's disease pathology

Abstract: Impaired clearance activity of microglia results in the accumulation of beta-amyloid (Aβ) deposition and contributes to Alzheimer disease (AD) pathogenesis. While previous studies have demonstrated that modulating cytokine milieus enhances microglial clearance activity in AD, it remains unclear how microglia response to cytokine and regulate their clearance capacity. Here, we demonstrate that interleukin (IL)-33 enhances microglial clearance activity through stimulating a stepwise state transition in AD. Upon IL-33 treatment, microglia undergo stepwise transcriptome programming and lead to the induction of IL-33-responsive microglia (IL-33RM). These IL-33RM exhibit enhanced Aβ phagocytic and clearance activity. Furthermore, our epigenetic profiling reveal that IL-33RM induction is controlled by the remodeling of chromatin accessibility and PU.1 transcription factor binding. Inhibiting PU.1-DNA interaction abolishes the IL-33-induced microglial state transition and Aβ clearance. Thus, we define a IL-33-induced functional state transition in microglia that drives their beneficial functions in AD.

Title: Splenectomy reduces Aβ plaque load ameliorating the Alzheimer's pathology potentially by increasing beneficial neuro-inflammatory cycle

Authors: *B. SAHU, M. SOHRABI, A. M. FLODEN, G. D. MANOCHA, S. NOOKALA, C. K. COMBS;
Univ. of North Dakota, Grand Forks, ND

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by the accumulation of amyloid-β (Aβ) plaques, neuroinflammation, and neuronal death affecting nearly 5 million individuals in the United States. Unfortunately, current therapeutic options are limited in efficacy requiring additional understanding for disease intervention. Numerous studies support the idea that peripheral immune dysfunction likely influences immune cell phenotype in the brain. As the secondary lymphoid organ for the circulatory system, the spleen is constantly monitoring antigens to modulate both innate and adaptive immune responses. Since splenic control of immune cell phenotype is associated with both pro and anti-inflammatory effects in the brain in paradigms such as stroke and traumatic brain injury, we hypothesized that a similar spleen to brain communication was relevant in AD. To test this idea, splenocytes from 12-14 months old male and female C57BL/6 wild type, APP/PS1, and App^{NL-G-F} mice were analyzed by flow cytometry. Male but not female APP/PS1 and App^{NL-G-F} mice had altered spleen immune cell numbers and phenotype compared to C57BL/6 mice indicating sex selective peripheral immune dysfunction as a consequence of disease. To better understand the contribution of these splenic changes to the brain we removed the spleen in male C57BL/6 wild type, APP/PS1 and App^{NL-G-F} mice. The mice were divided into 3 groups: control, sham surgery, and splenectomy. Mice were sacrificed 2 weeks post-surgery for analysis of brains. Splenectomy led to elevated brain CD68 but not GFAP immunoreactivity and increased concentrations of proinflammatory cytokines, TNF-α, IL-1β, and IL-6. Interestingly, splenectomy also significantly reduced Aβ levels and plaque load in comparison to controls. Overall, our data suggest that splenocyte phenotype directly influences immune status and Aβ levels in the brain.

Abstract: Research objective and rationale. The Western diet, which combines high saturated fat, sugar, and salt (HFSS), is negatively linked to human health disorders, including brain dysfunctions that are amplified during aging and likely involved in the onset of age-related neurodegeneration. Our objective is to explore the specific behavioral (muscular and sensory), cellular, and molecular consequences of the HFSS diet on the aged brain using mice in aging. **Methods and results.** Aged male C57BL/6 mice were fed with HFSS, and tested for their muscular and sensory functions. Our study then followed glial activation and associated inflammatory reactions, neurodegeneration, and accumulation of amyloid β (Aβ) and phosphorylated tau (pTau) in brain, using immunohistochemistry and cellular quantification. Significant reductions were observed in the motor-muscle grip strength and sensory behaviors of mice fed a HFSS diet, concomitant with an increase in inflammatory $iNOs^+$ microglia and a decrease in inflammation-resolving reparative $Arg\text{-}1^+$ microglia in the motor and sensory cortex, with simultaneous signs of neurodegeneration. The HFSS diet promotes the deposition of pTau and Aβ around the neurons and blood vessels, respectively, in both the motor and sensory cortexes, indicating the early onset of AD. Metformin (1,1-dimethylbuguanide hydrochloride) administration resulted in neuroprotection in both aging and HFSS-fed mice. **Conclusions.** A HFSS diet damages the brain and behavior of aging mice by promoting the progression of neurodegeneration, whereas metformin counteracts the majority of these effects. The appearance of Alzheimer's disease (AD) pathology following HFSS consumption and the related motor and sensory behavioral alterations disclosed here provide an effective window into the mechanisms involved, while targeting potential new therapeutic avenues. The new animal model described here is valuable for these endeavors. The ameliorating neuroprotective effects of Metformin in aging and HFSS-diet related dysregulation at different ages also require additional approaches and further exploration to better understand the neuroprotective therapeutic effects of Metformin.

Title: Effect of continuous treatment of 5α-androstane-3α,17β-diol on ERK signalling and inflammatory protein markers in the 3xTg mouse model of Alzheimer's Disease

Authors: *S. BHULLAR[1], N. KUWAHARA[1], K. NICHOLSON[1], L. ISAACS[1], N. J. MACLUSKY[1], B. D. WINTERS[2];
[1]Biomed. Sci., [2]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Decreased circulating levels of free testosterone have been associated with a significant increase in the risk of developing neurodegenerative diseases such as Alzheimer's Disease (AD). Treatment with testosterone, however, has shown mixed results regarding improvement in age-related cognitive dysfunction. Recent *in vitro* studies have shown that the major neurosteroid metabolite of testosterone - 5α-androstane-3α,17β-diol (3α-diol) significantly reduces extracellular signal-regulated kinase (ERK) phosphorylation associated with a reduction in programmed cell death. The role of 3α diol *in vivo* however, remains unclear. The current study tests the hypothesis that continuous long-term treatment with 3α-diol will reduce the expression of protein markers associated with AD progression in a transgenic mouse model of AD (3xTg). 3-month-old wild-type and 3xTg mice of both sexes were implanted subcutaneously with either a 1 cm long empty silastic capsule as a control, or silastic capsule releasing 3α-diol dipropionate. Brains were collected 3 months later from a subset of animals to analyze for changes in expression of hippocampal levels of phospho-ERK, phospho-tau and glial fibrillary acidic protein (GFAP) by western blotting (n=6). Three-way ANOVA was performed to test for between sex, genotype and treatment effects. Initial results from 6-month-old animals indicate sex-based differences in ERK phosphorylation with males exhibiting greater ERK 1/2 phosphorylation compared to females. No effect of 3α-diol treatment was observed. Analysis of phospho-tau (Ser 202) levels revealed a significant interaction between sex and genotype. Although no treatment effect was observed in levels of GFAP expression, transgenic mice had higher levels of GFAP compared to wild types. Transgenic males implanted with 3α-diol tended to have decreased levels of GFAP compared to sham-implanted controls; but this trend was not statistically significant. Changes in protein expression may become more apparent as the animals reach 1 year of age, when the neuropathology in the 3xTg animals fully develops.

Title: Axonal Aβ stress induces tau mislocalization and retrograde synaptic defects within a compartmentalized in vitro model system.

Authors: *T. NAGENDRAN[1], J.-H. TSENG[2,3], T. J. COHEN[2,3], A. M. TAYLOR[1];
[1]Xona Microfluidics, Inc., Durham, NC; [2]UNC Neurosci. Ctr., [3]Neurol., Univ. of North Carolina, Chapel Hill, NC

Abstract: Tau protein tangles and brain atrophy are hallmarks of Alzheimer's Disease (AD). An early cellular event in the progression of AD is the mislocalization of pathological tau from the axon to the somatodendritic compartment of affected neurons. Following this mislocalization, pathological tau is released and taken up by adjacent neurons and cells. However, the molecular mechanisms that regulate tau mislocalization and how neuronal function is affected, remains unclear. To test whether exposure of axons to Aβ challenge regulates tau relocalization and leads to synaptic defects, we used microfluidic chambers to isolate hippocampal axons and treated them with Aβ conditioned media (Aβ- CM). Aβ CM is collected from Aβ oligomer-challenged microglia and contains neuroinflammatory factors that induce neuritic tau beading with exposure to non-compartmentalized neurons. Restricted exposure of Aβ CM to axons within compartmentalized chips for 24 h caused a redistribution of tau to the somatodendritic compartment in the absence of neuritic beading. In addition to tau relocalization, we found that exposure of axons to Aβ CM for 24 h was sufficient to cause a significant increase in synaptic vesicle release rate. We quantified synaptic vesicle release rate by using an FM dye based optical method in conjunction with electrical stimulation. Further we found that application of a local activity blockade (tetrodotoxin and low calcium) at the time of treatment largely inhibited the relocalization of tau puncta and synaptic vesicle release rate. These results indicate that tau mislocalization correlates with synaptic defects and these defects are ameliorated by pharmacological activity blockade. Together, our results provide confirmation that tau redistribution can be quantified in our *in vitro* model in advance of cell death, mirroring AD phenotype *in vivo* and providing a unique platform to identify therapeutic targets that may reduce the spread of AD pathology in the brain.

Title: The effects of amyloid beta protein on excitatory transmission in layer II of the entorhinal cortex

Authors: *M. E. SUVANTO[1], J. SARAGOSA[2], O. OLAJIDE[2], A. CHAPMAN[1];
[1]Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montréal, QC, Canada; [2]Ctr. for Studies in Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: In Alzheimer's Disease (AD), neurodegeneration is first found in layer II of the entorhinal cortex (EC; Guo et al. 2010). Neuronal degeneration in the EC likely contributes to memory deficits and cognitive impairments that occur early in AD (Braak & Braak, 1991, 1998; Jahn, 2013; Kocahan & Doğan, 2017). Current hypotheses regarding the early stages of AD suggest this neurodegeneration begins as a result of toxic accumulation of soluble amyloid beta peptides (Aβ; Selkoe and Hardy, 2016). Elevated Aβ levels interfere with typical excitatory synaptic transmission in the hippocampus by facilitating postsynaptic calcium influx into the neurons via NMDA glutamate receptors (Findley et al., 2019; Rudy et al., 2015; Li et al., 2009; Kamenetz et al. 2003; Mucke et al., 2000). Chronically elevated calcium ion levels are thought to be a major factor that contributes to excitotoxicity and eventual cell death in both the EC and hippocampus (Findley et al., 2019; Rudy et al., 2015). Aβ mediated excitotoxicity and the effects of Aβ on excitatory transmission have been studied extensively in the hippocampus. However much less is known about the effects of Aβ on excitatory synaptic transmission in the first site of neurodegeneration, layer II of the EC. We studied the effects of incubating 400 μm horizontal slices of rat EC in 100 nM $A\beta_{(1-42)}$ (n=24) or a dimethylsulfoxide control (n=25) for 45 minutes to 3 hours on excitatory synaptic transmission in layer II EC using field excitatory postsynaptic potentials (fEPSPs) recorded in vitro. We then examined the effects of incubating slices with the addition of 50 μM of D-AP5 to the Aβ incubation (n=13) and the control (n=12). All experiments were blinded. The amplitudes of fEPSPs were increased in slices incubated in Aβ relative to control slices. The facilitation of synaptic responses induced by Aβ was blocked by constant bath application of the NMDA receptor blocker D-AP5, indicating that the activation of NMDA receptors is required for the facilitation of synaptic excitability. The facilitation of synaptic responses induced by Aβ likely results primarily from activation of postsynaptic NMDA receptors that enhance calcium influx, but activation of presynaptic NMDA receptors that enhance transmitter release in the EC may also contribute. These effects of exposure to Aβ may contribute to mechanisms of excitotoxicity that contribute to cognitive decline observed early during the progression of Alzheimer's Disease.

Title: Amyloid-beta peptide induces rapid NMDA receptor-dependent alterations at glutamatergic synapses in the entorhinal cortex.

Authors: O. J. OLAJIDE[1], D. BUTLER[2], *C. A. CHAPMAN[3];
[1]Dept. of Anat., Univ. of Ilorin, Ilorin, Nigeria; [2]Dept. of Pharm. and Pharmacol., Univ. of Bath, Bath, United Kingdom; [3]Concordia Univ., Montreal, QC, Canada

Abstract: Medial temporal lobe structures including the hippocampus and entorhinal cortex (EC) show early accumulation of amyloid beta peptides (Aβ) and neurofibrillary tangles that are thought to drive synaptic degeneration in Alzheimer's disease (AD). The mechanisms of Aβ-mediated synaptic degeneration have been extensively explored in the hippocampus, but surprisingly little is known about their effects in the EC. We therefore investigated the acute effects of soluble $A\beta_{1-42}$ on the molecular expression of presynaptic and postsynaptic components modulating mechanisms of glutamatergic neurotransmission in the medial and lateral EC (MEC and LEC). Acute EC slices obtained from male Long-Evans rats were exposed to solubilized $A\beta_{1-42}$ peptides (500 nM) or control solution for 3 hours. The dependence of $A\beta_{1-42}$ mediated effects on activation of NMDA glutamate receptors was tested using selective antagonists for GluN2B (Ro25-6981), GluN2A (TCN201), or the broad-spectrum NMDA receptor antagonist APV. Presynaptic effects of $A\beta_{1-42}$ in both MEC and LEC were found to include marked reduction of synaptophysin and increased VGluT2 protein expression. $A\beta_{1-42}$ also induced downregulation of synapsin-2a mRNA, which was accompanied by upregulation of Ca^{2+}-activated channel KCa2.2 mRNA levels, suggesting that dysregulation of Ca^{2+} signaling may play a role in presynaptic degeneration. Protein immunoblots further showed that $A\beta_{1-42}$ induced degeneration of postsynaptic elements PSD95 and GluN2B, although the mRNA expression of postsynaptic scaffolding elements SAP-97 and PICK-1 were unperturbed by $A\beta_{1-42}$-treatment. Also, the protein expression of astrocytes (GFAP) and microglia (IBA1) were not altered in $A\beta_{1-42}$-treated EC slices. However, we found that $A\beta_{1-42}$ induced downregulation of GluN2A and GluN2B mRNA in the EC, while GluN1 mRNA expression was unaffected. Whereas mGluR3 and mGluR5 mRNA expressions were altered by $A\beta_{1-42}$ treatment, the genetic expression of mGluR1 and mGluR8 were unchanged in slices exposed to $A\beta_{1-42}$. Interestingly, selectively blocking either GluN2A or GluN2B -containing subunits of NMDA receptors did not significantly reduce $A\beta_{1-42}$-mediated synaptic degeneration. However, coincubation of slices with both GluN2A and GluN2B blockers blocked $A\beta_{1-42}$-related degeneration of presynaptic and postsynaptic elements, consistent with our results obtained with APV. In summary, our findings indicate that $A\beta_{1-42}$ rapidly modulates synaptic components that mediate glutamatergic synaptic transmission in both the MEC and LEC through mechanisms that may involve simultaneous activation GluN2A and GluN2B containing subunits of NMDA receptors.

Title: Role of human cytomegalovirus infection in Alzheimer's Disease pathology

Authors: *J. W. ADELMAN[1], M. SCHUMACHER[2], B. O'BRIEN[1], R. MOKRY[2], I. LUECKE[1], S. TERHUNE[2], A. EBERT[1];

Abstract: Alzheimer's Disease (AD) is a common, debilitating form of dementia typically characterized by a progressive decline in neuronal function that ultimately results in memory loss, unpredictable behavior, and death. To date, much remains unknown about the underlying mechanisms and potentiating factors of AD. A growing body of literature describes the potential for viral infection to play a role in AD pathogenesis and progression. Specifically, members of the viral family *Herpesviridae* have been found to induce phenotypes like those of AD, such as altered calcium signaling and amyloid beta accumulation. However, studies to investigate the direct role of viral infection in human AD pathology are lacking. Here, we capitalize on the use of human induced pluripotent stem cell (iPSC)-derived organoids generated from AD patients to directly test whether infection with human cytomegalovirus (HCMV) can worsen AD pathology. Cortical organoids are generated from a familial AD patient harboring a Presenilin-2 (PSEN2) mutation. Simultaneously, control organoids are produced from an iPSC line with no apparent AD-related mutations. We either infect organoids with the clinical HCMV strain (TB40/E-eGFP variant) or mock treat at day 30 (D30) of differentiation, with subsequent collection at D60. Samples are then processed for RNA sequencing, protein analysis, and RT-qPCR. Early data demonstrate that AD organoids exhibit increased soluble amyloid beta burden compared to control organoids, which we hypothesize will increase with HCMV infection. Also, RNA sequencing data from control organoids infected with HCMV show alterations in calcium signaling. Specifically, HCMV infected organoids exhibit upregulated expression of NMDA receptor subunit GRIN2C, a component found to confer lower ion conductance for calcium. Moreover, AMPA receptor subunits GRIA1, GRIA3, and GRIA4 show a clear downward trend in expression in infected organoids compared to mock. Alterations to these ionotropic glutamate receptors potentially indicate a detrimental impact on long-term potentiation, a key cellular mechanism underlying memory. We predict that these gene changes will be amplified in AD organoids, with the AD + HCMV infection condition demonstrating the most disruption. Interestingly, calmodulins (CALM1-3) are among the most down-regulated transcripts in control HCMV infected organoids, further highlighting the impact of HCMV on calcium signaling pathways. In sum, these experiments will directly test the role HCMV plays in AD pathology, which has important implications for viral pathogens in neurodegenerative disease.

Title: Mutations in microtubule associated protein UNC-33 lead to defects in autophagosome maturation in C. elegans, connecting autophagy and neurodegeneration

Authors: *I. I. BAZALDUA, J. HOLECHEK, M. LOPEZ, E. CARRILLO, R. JAUREGUI, A. HOLGADO;
St. Edward's Univ., Austin, TX

Abstract: The accumulation of misfolded proteins is a shared pathology among neurodegenerative disorders such as Parkinson's and Alzheimer's. These defective proteins are degraded in a multi-step process known as autophagy. During this process, the defective proteins are first sequestered within an autophagosome. The autophagosome is then transported along microtubules from the synapses to the cell body. Microtubules and their microtubule-associated proteins (MAPs) such as CRMP2/UNC-33 are key elements supporting the transport of autophagosomes. Studies indicate that the accumulation of these autophagic vacuoles could contribute to the development of neurodegenerative diseases. Based on this information and considering that autophagy is dependent on the trafficking of autophagosomes to the cell body through motor proteins, our lab hypothesizes that trafficking of synaptic autophagosomes may be defective in unc-33 mutants. To test this hypothesis, we monitored the trafficking of double fluorescently tagged autophagosomes (dFP) in the AIY neuron using confocal microscopy. Autophagy flux was also quantified under autophagy-inducing conditions through western blotting techniques. To further understand the mechanisms by which CRMP-2/UNC-33 regulates autophagy, we analyzed autophagosome maturation during trafficking to the cell body. Images of 25 animals per strain, per condition, were obtained and quantified after randomization. Preliminary data of dFP in autophagic vacuoles shows a statistically significant build up of autophagosomes in the neurite of unc-33 mutants when compared to the control strain DCR5074. Analysis of autophagy flux through western blotting also shows the accumulation of cleaved dFP in unc-33 mutants subjected to autophagy inducing conditions. This suggests that autophagy flux is dependent upon the proper functioning of UNC-33. Taken together, this is the first report that analyzes the potential role of UNC-33 in neuronal autophagy and provides insight on its role in neurodegeneration.

Title: The CHD protein, Kismet, may regulate gamma-secretase proteolysis of amyloid precursor protein-like at the Drosophila neuromuscular junction

Authors: *E. L. HENDRICKS, F. L. W. LIEBL;
Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Group III chromodomain helicase DNA-binding (CHD) proteins and their *Drosophila* ortholog, Kismet (Kis), catalyze nucleosome remodeling to regulate genes important for several aspects of synaptic function including morphology, vesicle endocytosis, and receptor localization. Specifically, we find that Kis negatively regulates transcription of *Appl*, the *Drosophila* amyloid precursor protein (APP) homolog. Amyloidogenic processing of APP by beta- and gamma-secretases leads to the production of toxic, insoluble Abeta fragments implicated in Alzheimer's disease (AD) progression. However, aberrant synaptic organization could leave APPL inaccessible to proteolytic processing by secretases leading to an accumulation of APPL in the central nervous system. Of the many different proteins regulating synaptic organization, Kis binds to the regulatory regions of two tetraspanins, *tsp42Ee* and *tsp42Eg*, which are expressed in motor neurons and muscle, respectively. Tetraspanins form self-organizing clusters, known as tetraspanin-enriched microdomains, and regulate the spatiotemporal distribution of proteins at the synapse. CD63, the mammalian homolog of Tsp42Ee and Tsp42Eg, binds to gamma-secretase and may represent a mechanism by which tetraspanins regulate synaptic levels of APP/APPL. Notably, both *kis* and *tsp42Ee* mutants show an increase in synaptic levels of Endophilin A (EndoA) and Dynamin (Dyn), a decrease in both *rab11* transcripts and synaptic localization, and locomotor impairments, suggesting that Kis may exert its synaptic organizational effects through regulation of tetraspanins, specifically *tsp42Ee*. Furthermore, loss of either APPL function or pharmacologic inhibition of APPL processing restores synaptic levels of Rab11, EndoA, and Dyn. While the specific cellular processes underlying Alzheimer's disease are still not well understood, these data suggest a role for Kis in the regulation of tetraspanins and promote our understanding of the cellular mechanisms underlying AD pathology.

Title: Investigating a potential interaction between the chromatin remodeling protein Kismet and APP in a Drosophila model of Alzheimer's disease

Authors: N. LINSKEY, E. HENDRICKS, ***F. L. LIEBL**;
Southern Illinois Univ. Edwardsville, EDWARDSVILLE, IL

Abstract: Alzheimer's disease is characterized by an abundance of plaques formed from amyloid β (Aβ) peptides. These plaques result in a loss of neurons and synaptic connections, which leads to impaired memory and places Alzheimer's disease as a leading cause of dementia in geriatric patients. The cell adhesion molecule amyloid precursor protein (APP) can be processed by β-site APP-cleaving enzyme (BACE). BACE cleaves APP and, through a series of other enzymatic functions, ultimately causes Aβ to be released from the plasma membrane to aggregate and form plaques. Overexpression of human APP and BACE1 in *Drosophila* larval motor neurons is used as a synaptic model for late onset Alzheimer's disease. Kismet (Kis), which is the *Drosophila* ortholog of the mammalian chromatin remodeling enzymes CHD7 and CHD8, positively regulates the localization of synaptic cell adhesion molecules and BMP signaling. Expression of human *APP* and *BACE1* in motor neurons produces similar phenotypes as are observed in *kismet* loss of function mutants including impaired neurotransmission and larval locomotion, deficient endocytosis, increased synaptic levels of the BMP signaling protein pMad, and increased *neuroligin2* transcripts. In addition, *app-like* transcripts are increased in *kismet* mutant motor neurons. To further investigate a potential connection between Kis and APP, we will examine expression of *kismet* in *app-like* mutants and neuronal APPL in *kismet* mutants. These data will clarify whether interactions between Kismet and APPL may regulate synaptic function.

Title: Ps1 familial alzheimer disease mutants inactivate factor-dependent protection against neurotoxicity by affecting neuroprotective complexes of nmda receptor.

Authors: *N. K. ROBAKIS[1], M. A. RAHIM[1], Y. YOON[1], C. DIMOVASILI[1], N. KEZUNOVIC[2], L. CHEN[1], A. SCHAFFNER[3], G. W. HUNTLEY[2], I. UBARRETXENA-BELANDIA[3], A. GEORGAKOPOULOS[1];

Abstract: Excitotoxicity is known to play key roles in brain neurodegeneration and stroke. We obtained data that neuroprotection by trophic factors such as ephrinB1(EFNB1) and brain-derived neurotrophic factor (BDNF) (called Factors) depends on presenilin1 (PS1; Barthet et al., Neurobiol Aging. 34: 499–510, 2013) and requires *de novo* formation of "survival complexes" that are Factor-stimulated complexes of *N*-methyl-d-aspartate receptor (NMDAR) with Factor receptor (FR) and PS1 (Rahim et al., https://doi.org/10.1093/braincomms/fcaa100). Using coimmunoprecipitation, western blot and *in vitro* cell survival assay we found that absence of PS1 reduces formation of survival complexes and abolishes neuroprotection. Peptides designed to disrupt formation of survival complexes also decrease the Factor-stimulated neuroprotection. Strikingly, Factor-dependent neuroprotection and levels of *de novo* Factor-stimulated survival complexes decrease dramatically in neurons expressing PS1 familial Alzheimer disease (FAD) mutants. Mouse neurons and brains expressing humanized knockin (KI) PS1FAD mutants contain increased amounts of constitutive non-functional PS1-NMDAR complexes unresponsive to Factors. In addition, the stability of the FAD PS1-NMDAR complexes differs from that of wild type (WT) complexes and using Middle Cerebral Artery Occlusion (MCAO) and immunohistochemistry of brain sections we found that brain neurons expressing heterozygous FAD mutants are more vulnerable to cerebral ischemia than neurons of WT brains. Furthermore, NMDAR-mediated excitatory postsynaptic currents (EPSCs) at CA1 synapses are altered by PS1 FAD mutants in cortical neurons in *in vitro* electrophysiology experiments. Importantly, high levels of PS1-NMDAR complexes are also found in postmortem Alzheimer disease (AD) brains expressing PS1 FAD mutants. Together, our data identify a novel PS1-dependent neuroprotective mechanism and reveal a pathway by which PS1 FAD mutants increase toxicity-induced neuronal death in the absence of AD neuropathological hallmarks. These findings have implications for the pathogenic effects of FAD mutants and therapeutic strategies.

Inst., Shenzhen, China

Abstract: Alzheimer's disease (AD), the most common form of dementia, is characterized by irreversible memory loss with no effective treatment to date. The accumulation of amyloid-beta (Aβ) is believed to be an important pathological contributor in AD, which leads to synaptic failure. Emerging evidence along with our previous findings have demonstrated that dysregulated erythropoietin-producing hepatocellular A4 (EphA4) signaling is involved in abnormal hippocampal synaptic function and impaired cognition in AD progression. However, the underlying mechanisms remain unclear. Here, we inhibited EphA4 activity using KYL peptide in an APP/PS1 transgenic AD mouse model, and examined its effect on hippocampal synaptic function. We found that blockade of EphA4 signaling by KYL treatment rescued the loss of excitatory synapses in the hippocampus of APP/PS1 mice. Moreover, KYL administration restored the impairment in hippocampal synaptic plasticity. To further delineate the downstream mechanisms by which EphA4 inhibition rescues hippocampal synaptic dysfunction in AD, we conducted single-nuclei RNA sequencing analysis. The expression of several genes and pathways associated with excitatory synapse formation and maintenance were identified to be restored in the hippocampus of APP/PS1 mice after KYL treatment. Collectively, our findings suggest that modulation of EphA4 signaling can restore excitatory synaptic functions in the hippocampus in AD.

Title: Olfactory decline during aging predicts gray matter volume loss in key AD brain regions

Authors: *R. R. PACYNA[1], D. HAN[2], K. E. WROBLEWSKI[3], M. K. MCCLINTOCK[4], J. M. PINTO[5];
[1]Univ. of Chicago Pritzker Sch. of Med., Chicago, IL; [2]Departments of Family Medicine, Neurology, Psychology, and Gerontology, USC, Los Angeles, CA; [3]Dept. of Publ. Hlth. Sci., [4]Dept. of Comparative Human Develop. and The Inst. for Mind and Biol., [5]Section of Otolaryngology-Head and Neck Surgery, Dept. of Surgery, Univ. of Chicago, Chicago, IL

Abstract: Objective: To examine whether olfactory decline is associated with structural neuroimaging findings in brain regions specific to Alzheimer's dementia (AD). Rationale: Olfactory dysfunction signals increased AD risk, but whether olfactory decline predicts gray matter loss in specific brain regions is unclear. Methods: 121 older adults (mean age=77.7, SD=7.1 at baseline; 69% women) with normal cognition (NC; n=104) and mild cognitive impairment (MCI; n=17) completed a median of 4 Brief Smell Identification Tests (BSIT) over a median of 6 years prior to MRI and final cognitive diagnosis (NC, MCI, or AD) as part of the Rush Memory and Aging Project, a prospective, longitudinal study exploring the origins of dementia. Linear regression of annual BSIT scores and age for each participant yielded individual trajectories of smell function categorized as: severe decline, decreased, unchanged, or improved. Gray matter volumes (GMV) in the primary olfactory (PO), secondary olfactory (SO), temporal (T), fronto-parietal (FP), sensorimotor (SM), and visual (VS) brain regions were estimated (% of intracranial volume) using standard methods (FreeSurfer v6, gyral-based and sub-cortical segmentation) from available 3T MRI. Relationships between olfactory trajectories and regional GMVs were evaluated, along with AD risk factors (e.g. APOE status), using trend tests and multivariable linear regression. Results: The mean trajectory (slope) of olfactory change was -0.2, SD +/- 0.5. Participants with MCI (n=25) and AD (n=23) had smaller GMV in the PO, SO, and T regions ($p<0.01$, all) compared to those with NC (n=73) but not in the FP, SM, and VS regions. Confirming our main hypothesis, those with more severe olfactory decline had smaller GMV in the PO, SO, T, and FP areas ($p<0.05$, all) but not in the SM or VS. After adjustment for known AD risk factors (e.g., age, sex, education, global cognition at MRI, APOE genotype), more severe olfactory decline (β= -0.11, 95% CI -0.21, -0.00) predicted smaller GMV only in the PO region, with an effect size comparable to carrying APOE-ε4 (β= -0.36, 95% CI -0.64, -0.09). Older age was significantly associated with smaller GMV across all brain regions. Conclusion: Increasing severity of olfactory decline leads to specific GMV loss in the PO, SO, and T regions beyond that seen with increasing age and mirroring patterns seen in MCI and AD. Both severity of olfactory decline and APOE-ε4 genotype independently predict neurodegenerative changes in the PO cortex, suggesting that primary olfactory brain regions play a key role in AD pathogenesis.

Title: Free water increases in cholinergic regions and along brainstem tracts with cognitive impairment severity

Authors: *W. T. CHU[1], W.-E. WANG[2], S. COOMBES[2], D. VAILLANCOURT[2];
[1]Biomed. Engin., [2]Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: The purpose of this study was to determine the anatomical progression of neurodegeneration in the early stages of Alzheimer's disease severity as measured by clinical diagnosis, clinical measures, and Neurofilament-light chain (NfL). To accomplish this aim, free water, a diffusion MRI metric, was calculated in the hippocampus, basal forebrain, entorhinal cortex, and a locus coeruleus (LC) to transentorhinal cortex (TEC) tract in four patient groups: cognitively normal (CN; n=31), early mild cognitive impairment (EMCI; n=77), late mild cognitive impairment (LMCI; n=24), and Alzheimer's disease (AD; n=23). Blood samples were collected for quantification of NfL levels and all patients received a battery of cognitive assessments. Our results show that free water increases with disease severity in all of the examined regions but only a subset of these regions (hippocampus, nucleus basalis of Meynert, and LC to TEC) are significantly different in EMCI compared to CN. Furthermore, free water in all of the examined regions significantly correlated with patient performance on clinical measures (Montreal Cognitive Assessment, Clinical Dementia Rating scale Sum of Boxes, Mini Mental State Exam, and Loewenstein-Acevedo Scale for Semantic Interference and Learning) and neurofilament-light chain. Together, these results suggest that neurodegeneration may occur in the hippocampus, nucleus basalis of Meynert, and LC to TEC tract in the early stages of Alzheimer's disease while other basal forebrain regions, the entorhinal cortex, and the substantia nigra are not affected until a later stage. These findings also show that free water imaging is a clinically-relevant and non-invasive marker that is sensitive to changes in cognitive impairment severity.

Title: Multimodal characterization of hippocampal integrity in mild cognitive impairment: combining volumetry, diffusion, perfusion, and viscoelasticity from magnetic resonance imaging

Authors: *E. M. TINNEY, L. HISCOX, P. DELGORIO, C. MARTENS, C. JOHNSON;
Univ. of Delaware, Newark, DE

Abstract: Novel neuroimaging biomarkers are urgently being sought to characterize early changes to the brain in mild cognitive impairment (MCI), which is typically a precursor to Alzheimer's disease (AD). As the hippocampus is a critical site of AD pathogenesis that underlies principal symptoms of memory impairment, numerous studies have utilized multiple imaging modalities to characterize hippocampal integrity. Here we additionally include magnetic resonance elastography (MRE)[1], which has recently emerged as a sensitive measure of microstructural tissue health[2-4]. For the first time, we adopt a multimodal neuroimaging approach consisting of measures of hippocampal viscoelasticity, volume, perfusion, and diffusion - including neurite orientation and dispersion density imaging (NODDI) metrics - resulting in a total of twelve separate measures of hippocampal health. The purpose of this study was to determine which MRI measures were most sensitive in detecting differences in hippocampal integrity between cognitively healthy older adults (OA) and those with amnestic MCI. We recruited 23 OA and 7 MCI participants (demographics in Table 1). A binomial logistical regression was performed to establish the effect of the 12 hippocampal measures on the likelihood of an MCI diagnosis. Hippocampal integrity metrics for both OA and MCI groups are presented in Table 1. The full model correctly classified 72% of cases. Viscoelastic damping ratio (DR) from MRE was 32% higher in the MCI group and was the only significant predictor in differentiating between OA and MCI (p=0.013). The significant relationship between MCI status and DR (B=0.796, S.E.=0.321, after adjusting for age and sex) suggests that for every 0.01 increase in DR, the likelihood of having MCI is 2.22 times higher. No other hippocampal measures were significant predictors in the model, although hippocampal volume was close to approaching significance (p=0.090). Our results suggest that MRE measures of viscoelasticity may provide a unique and highly sensitive biophysical signature of hippocampal health relevant to microstructural changes that are expected to occur in MCI.

Title: In vivo molecular imaging of the mouse cholinergic projection system

Authors: *K. M. ONUSKA[1], H. R. C. SHANKS[1], M. FOX[2], J. HICKS[2], J. THIESSEN[2], V. F. PRADO[3], M. A. M. PRADO[4], T. W. SCHMITZ[4];
[1]Neurosci., [2]Med. Biophysics, [3]Anat. and Cell Biol., [4]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

Abstract: The cholinergic neurons of the basal forebrain (BF) are among the first cells to become damaged in Alzheimer's disease (AD). Structural magnetic resonance imaging (sMRI) studies have shown that this damage occurs prior to cortical degeneration and memory loss. Although sMRI is sensitive to early volumetric losses within the BF, it cannot specifically assay degeneration of distal BF cholinergic axons, which is thought to occur earlier than degeneration

of the cell bodies within the BF. Positron emission tomography (PET) with the [^{18}F] FEOBV radiotracer overcomes this problem. [^{18}F] FEOBV binds to the vesicular acetylcholine transporter (VAChT), a protein found solely in cholinergic nerve terminals, thereby providing a cell-type specific measurement of the cholinergic projectome. However, the sensitivity and specificity of *in vivo* [^{18}F] FEOBV-PET to the endogenous expression of VAChT is unknown. This has created a major obstacle for assessing the utility of [^{18}F] FEOBV-PET as a biomarker for preclinical stages of AD. The goal of this study is therefore to calibrate the sensitivity and specificity of [^{18}F] FEOBV-PET for measuring preclinical changes in the cholinergic cortical projectome. To do this, we used mouse lines in which endogenous VAChT expression is held under genetic control. We evaluated binding intensity patterns and uptake profiles of [^{18}F] FEOBV in a wild type (WT) mouse and a knockdown (KD) mouse with 60% global reductions in VAChT expression (VAChT^{HOM} KD). First, we demonstrated that [^{18}F] FEOBV-PET binding patterns reflect the underlying anatomy of the mouse cholinergic projectome in both WT and VAChT^{HOM} KD mice (Results, *left*). Next, we observed that decreases in [^{18}F] FEOBV uptake occur in regions that receive cholinergic input in the VAChT^{HOM} KD mouse when compared to the WT mouse, consistent with the 60% global reduction of VAChT present in this mouse. (Results, *right*). Overall, these preliminary results support [^{18}F] FEOBV-PET as a sensitive *in vivo* cell-type specific tool for measuring cholinergic integrity.

Title: An anatomically and biochemically specific relationship between phosphatidylcholine and basal forebrain degeneration in Alzheimer's disease

Authors: ***H. R. C. SHANKS**[1], K. M. ONUSKA[1,2], D. K. BARUPAL[3], T. W. SCHMITZ[1,2]; [1]Schulich Med. and Dent., Univ. of Western Ontario, London, ON, Canada; [2]Lawson Hlth. Res. Inst., London, ON, Canada; [3]Icahn Sch. of Med. at Mount Sinai Hosp., New York, NY

Abstract: Basal forebrain cholinergic neurons degenerate before other cell types in Alzheimer's disease (AD). The factors which contribute to cholinergic selective vulnerability are poorly understood. We hypothesized that AD-related reductions in the bioavailability of the lipid phosphatidylcholine (PC) may potentiate vulnerability of cholinergic basal forebrain neurons. All neurons use PC to maintain their cell membrane. Cholinergic neurons also use PC to make acetylcholine. Moreover, cholinergic neurons are highly plastic in adulthood which may increase demand for PC to support axonal remodeling. An AD-related bottleneck on PC may therefore selectively impact cholinergic neuronal functions earlier and more severely than other cell types. To test our hypothesis, we leveraged data from the Alzheimer's Disease Neuroimaging Initiative. Participants were divided into a normal cerebrospinal fluid (nCSF; n = 62) group and an abnormal cerebrospinal fluid (aCSF; n = 161) group based on their CSF ratios of phosphorylated tau and amyloid beta. Groups were age matched ($t = 0.59$, $p = 0.55$). Longitudinal structural magnetic resonance imaging data were used to calculate grey matter annual percent change for each participant. Partial least squares analyses assessed the multivariate relationship between serum lipids, including PC, and neuroimaging data. Of all serum lipids, PC ($p = 0.002$ on 5000 permutations) and acylcarnitine ($p = 0.003$ on 5000 permutations) were the only lipid types to exhibit a relationship with grey matter degeneration which was modified by CSF-confirmed AD pathology. In addition to biochemical specificity, the relationship between PC and longitudinal grey matter degeneration revealed a spatial pattern (Figure; blue) with high anatomical specificity to brain regions known to be cholinergic, such as the basal forebrain and striatum. Overall, this study provides *in vivo* evidence for a selective relationship between PC and basal forebrain degeneration in human AD.

Title: Declines in cognitive-motor integration performance are correlated with lower white matter integrity in older adults with genetic risk for Alzheimer's disease

Authors: ***A. ROGOJIN**, D. J. GORBET, K. M. HAWKINS, L. E. SERGIO;
Kinesiology and Hlth. Sci., York Univ., Toronto, ON, Canada

Abstract: *Introduction:* Cognitive-motor integration (CMI) involves concurrent thought and action, which requires the interaction of large networks in the brain [1]. Previous findings have shown that CMI performance is impaired in individuals with specific dementia risk factors (family history of dementia and presence of the APOE e4 allele) [2]. These findings suggest that CMI impairments are associated with early dementia-related brain changes. The objectives of the current research study are 1) to examine changes in white-matter integrity associated with dementia family history, sex, and APOE status, and 2) to assess the relationship between white matter integrity and cognitive-motor performance. *Methods:* Participants included right-handed older adults with a high-risk (n=25, 12 female) and a low-risk (n=24, 12 female) for dementia. Participants were tested on four visuomotor tasks where reach and gaze were increasingly spatially dissociated using two linked touchscreens. These tasks included a standard condition requiring direct interaction with visual targets, and three dissociated non-standard conditions requiring CMI (visual feedback reversal, plane-change, and plane-change + feedback reversal). APOE genotyping was determined from salivary measures, and diffusion-weighted magnetic resonance images (dw-MRI) were collected to look at white matter integrity. Automated fiber quantification (AFQ) was used to characterize white matter properties in healthy aging compared to increased dementia risk. *Results:* Preliminary analysis of these data has revealed significant correlations between the mean fractional anisotropy in several major white matter tracts and CMI task performance in individuals with the APOE e4 allele. These data support our hypothesis that disruptions in CMI performance are associated with identifiable brain alterations early in disease progression. *Conclusion:* The preliminary findings provide insight into the impact of AD pathology on neural networks underlying complex visuomotor transformations, and demonstrate that the CMI paradigm discussed in this study may be used as a non-invasive, easily accessible assessment tool for dementia risk.

Title: Optimization of relaxation times to provide the best signal intensity and resolution in MR images following exposure of Gadolinium-based Contrast Agents

Authors: *A. A. SOTELO[1], N. HUANG[2], K. S. STEED[4,5], J. A. HAMILTON[2], J. WISCO[3,5]; [1]Dept of Physiol. and Biophysics & Dept. of Anat. and Neurobio., [2]Dept of Physiol. and Biophysics, [3]Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [4]Biomed. Educ., California Hlth. Sci. Univ., Fresno, CA; [5]Brigham Young Univ., Provo, UT

Abstract: Previous studies have indicated that Gadolinium-based Contrast Agent (GBCA) immersion of post mortem animal brains can enhance their MRI signal. We examined the utility of a GBCA for the enhancement of murine brains in our ongoing study of hippocampal pathophysiological differences in transgenic Alzheimer's disease (AD). Ex-vivo Presenilin-1 (PSEN1), Tau, and wild-type (WT) mice [12 (6M, 6F) in each cohort] were sacrificed at 6 months of age. One brain hemisphere was immersed in, then imaged with fomblin, then imaged again after being immersed for one week in gadolinium (Gd). We wanted to know the extent of signal gain from the Gd using ex-vivo imaging in a 11.7T MRI Bruker 500 MHz magnet. We assessed signal gain between cohorts. We acquired T1, T2, and T2* images at 11.7T throughout the volume of the hemisphere and compared the signal intensity of the body of the hippocampus between the image contrasts. We hypothesized that the T2* relaxation time, derived from the rapid acquisition with relaxation enhancement (RARE) sequence, to be the most effective due to its multiple 180 degree echos. Measurements were acquired from one axial slice at a level where both the anterior and posterior horns of the lateral ventricles were visible using the analysis software Horos (https://horosproject.org/). We did paired t-tests for Gd for each of T1, T2 and T2*. T2 normal images displayed a significant difference in the scores for Gd absence (M= 7.9, SD=4.8) and the addition of Gd (M=16.6, SD=4.4) conditions; $t(35)= -7.556$, $p = 0.000$. Our findings indicated POST-Gd T2 images as the optimal signal intensity for hippocampal clarity.

Additionally, T2* normal image SNR presented a significant difference in the scores for Gd absence (M= 28.2, SD=10.9) and the addition of Gd (M=19.8, SD=7.9) conditions; t(35)= 3.807, p = 0.001. These results suggest that the addition of Gd positively improves 11.7T image SNR. No difference in Gd enhancement was observed between transgene cohorts. An approximate linear difference in T2 and T2* signal in 11.7T following Gd exposure in 11.7T MR field strengths was observed. This study indicates post-mortem imaging following Gd exposure, at high-field strength can be added to our protocol to better assess general high-field visualization effects in human and animal models; while contributing to existing knowledge by providing further analysis and understanding of pathological changes in mice brains.

Title: Applications of volume imaging by 3D electron microscopy and advanced segmentation tools to the reanalysis of legacy biopsy samples from Alzheimer’s

Authors: M. MADANY, E. BUSHONG, S. PELTIER, *M. H. ELLISMAN;
Dept Neurosci, UCSD Sch. Med., La Jolla, CA

Abstract: Senile Dementia of Alzheimer’s Type (SDAT) is perhaps the most intensively studied neurodegenerative disease. Early electron microscopic (EM) studies identified pronounced hallmarks of AD, Paired Helical Filament (PHF) containing tangles and amyloid-bearing plaques. We have re-examined brain biopsy samples taken from human specimens with severe dementia and AD in the 1960s. We experiment with an array of imaging approaches with a focus on throughput and autonomous analysis. Large fields of serial-section electron microscopy (SSEM) samples are taken and registered to reveal enriched 3D scenes of autophagosomal stresses, neurofibrillary tangles, somatic lipofuscin agglomerations, and vascular-adjacent plaques. In order to scale a label-analysis of the tissue, we test deep-learning neural network (DNN) object classifiers and content-aware image restorers. Due to challenges of high-resolution imaging in pathology samples, a high-degree of effort and sophistication is required of the autonomous techniques, regardless we see initial successes by pioneering emerging machine-learning advances. Most EM DNNs classifiers use binary classification with softmax or sigmoid activation functions. We find that using multilabel classification without activation functions creates significant improvements to classifier signal, especially in the context of sparse objects, such as synapses. We also apply generative adversarial network (GAN) DNN approaches, such as to try and artificially preserve the samples, and make them appear more like canonical EM

fixation-and-preservation samples from other organisms for the purposes of enhanced acuities. After apply GAN-drive content-aware image restoration, certain neurite processes become discernable that were otherwise obfuscated by the challenges of the specimen. Resolution deficits are also addressed and boosted using GANs, using an emerging machine-learning method of EM Superresolution. We find that testing these emerging A.I. approaches produces data that bridges the divide between the difficulties of experimentation and analysis of SDAT in model species such as mouse, and directly mining pathologically-relevant quantities and qualitative observations from these clinical samples.

Abstract: Familial Alzheimer’s disease (AD) is caused by autosomal dominant missense mutations in the genes encoding amyloid precursor protein (APP), presenilin 1 (PSEN1) and presenilin 2(PSEN2), which result in excessive production of amyloid-beta peptides. Given that

most patients with familial AD have a heterozygous disease mutation and humans that naturally carry one copy of *APP*, *PSEN1*, or *PSEN2* do not exhibit obvious neurological symptoms, the selective disruption of the disease-causing allele at the adult stage may be a rational and feasible treatment strategy for familial AD. While it has been demonstrated that CRISPR/Cas9-mediated genome editing disrupted familial AD mutations and reduced Aβ production *in vitro*, the inefficient delivery of CRISPR/Cas9 into the brain and limited efficiency of genome editing restrict the potential beneficial effects of allele-specific editing *in vivo*. Here, we show that a CRISPR/Cas9-based strategy can selectively and efficiently edits the *APP* Swedish (*APPswe*) mutation *in vivo* and ameliorate amyloid-associated pathology in two different familial AD transgenic mouse models via an all-in-one AAV-mediated delivery of a small Cas9 and the sgRNA. Of note, this CRISPR-mediated beneficial effect is effective in transgenic mice at an age when amyloid pathology is obvious and can persist for at least 6 months after a single virus administration. Thus, our results provide strong evidence that CRISPR/Cas9-mediated disruption of the allele that carries familial AD mutation can ameliorate amyloid-mediated pathology *in vivo*. Our findings also provide important insights for the development of disease-modifying treatments for familial AD as well as other brain diseases caused by dominant mutations.

Title: Use of deep neural network algorithm on cognitive performances to early identify Alzheimer’s disease: An animal study

Authors: S. SUTOKO[1], A. MASUDA[2], A. KANDORI[1], H. SASAGURI[3], T. SAITO[4], T. C. SAIDO[3], *T. FUNANE[1];
[1]Hitachi, Ltd., Kokubunji, Japan; [2]Organization for Res. Initiatives and Develop., Doshisha Univ., Kyotanabe, Japan; [3]Lab. for Proteolytic Neurosci., RIKEN Ctr. For Brain Sci., Wako, Japan; [4]Dept. of Neurocognitive Sci., Nagoya City Univ. Grad. Sch. of Med. Sci., Nagoya, Japan

Abstract: One of the most common types of dementia is Alzheimer’s disease (AD; 60-70%). The prevalence rate of AD is increasing as the population is getting older; more than 30% of elderly people (> 85 years old) suffered AD. The core AD symptoms associated with declines of memory, speech, linguistic, and executive functions that may lower quality of life and disrupt behaviors. The AD prognosis might take decades; thus, the AD studies are often done in the animal samples to accelerate findings. One of AD-modelled mice is created by using a knock-in (KI) strategy; those mice express preclinical AD symptoms caused by the overproduction of amyloid-β peptide (Aβ) plaques. These AD-modelled mice are suitable for the study of early AD

identification. In this study, we aimed to develop a practical and affordable method for early AD screening based on only the behavioral evaluation rather than the neuroimaging measurement. Wild-type (WT) and KI AD-modelled (*App*$^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$) mice were raised, and their behaviors during cognitive tasks (*e.g.*, learning, impulsivity, attention, compulsivity) were assessed in an automated monitoring system. The behavioral parameters were quantified by correct and error rates as mice were performing tasks at phases 1 (age of 8-12 months) and 2 (age of 13-17 months). The deep neural network (DNN) algorithm was used for classifying *App*$^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$ mice from WT mice. The conventional threshold algorithm was also conducted to confirm the DNN method as a superior classifier. The stepwise feature selection method supported both DNN and conventional threshold algorithms to optimize uses of behavioral parameters. The classification performance was relatively high (88.0-89.3% accuracy) even at the early age (*i.e.*, phase 1) when the AD symptoms were still underdeveloped. The use of DNN algorithm offered a lower performance variability (*i.e.*, low standard deviation across cross-validation; 89.3 ± 9.8% vs. 88.0 ± 17.9% accuracy) and a better practicability (*i.e.*, fewer used parameters and required tasks; 4 vs. 11 parameters) than that of conventional threshold algorithm. The DNN algorithm can be advantageous for any purposes, such as prognostic and therapeutic monitoring. Classifying behavioral parameters were related to compulsive and learning impairments in *App*$^{NL\text{-}G\text{-}F/NL\text{-}G\text{-}F}$ mice; the importance of those behavior evaluations is frequently underestimated in the current diagnostic paradigm. This study unveil the potential of early AD screening based on only behaviors that will significantly improve translatability to human studies.

Abstract: Alzheimer's Disease (AD) is associated with several cognitive deficits that interfere with an individual's lifestyle. The cognitive reserve hypothesis posits that individuals who have a high education, higher occupational attainment, and exercise regularly will be less susceptible to cognitive impairment associated with aging and dementia. Cognitive reserve can be modeled with a standard Environmental enrichment (EE) protocol, which places mice in a large cage with extra cagemates, a running wheel, and objects that can be substituted daily. Unfortunately, the standard EE procedure has a limit on quantifying the enrichment each individual mouse obtains from being in a shared enriched cage. Thus, we developed a novel EE procedure to enable better control and quantification of daily enrichment. In the present study, we used 69 male wildtype (WT) and 63 male Triple Transgenic AD (3xTg-AD) mice to evaluate the potential for modeling cognitive reserve using this procedure. Mice were assigned to each of the four following conditions immediately after weaning at 5 weeks of age: Environmental Enrichment homecage (EH), which is modeled after 'conventional' EE protocols; Enrichment Track (ET), in which mice run laps on an obstacle track 6 days/week with novel obstacles daily; Exercise Control Track (CT), in which mice run laps but are not exposed to complex obstacles; and Standard Housing (SH). Following two months in these conditions, we tested all mice on tasks assessing multisensory integration abilities, an understudied but potentially important aspect of AD cognitive impairment. These tasks were the tactile-visual Cross-Modal Object Recognition (CMOR) task with a 5-min retention delay, and the olfactory-tactile Multisensory Oddity (MSO) task, which removes the mnemonic component. At 3 months of age, only the WT ET, EH, and 3xTG-AD ET groups successfully performed the CMOR task. All mice were re-tested at 6 months, 9 months, and 12 months of age, but the results were nonsignificant and none of the mice could successfully perform the CMOR task, possible due to procedural difficulties and age-related memory impairment. We therefore tested the mice on the olfactory-tactile MSO task at 12 months of age, which also included unimodal tactile and olfactory controls. Results revealed that ET mice (both WT and 3xTg-AD) were the only groups that could perform all three tasks (MSO and unimodal tasks). Thus, our early results suggest that enrichment track training early in life may confer cognitive and perceptual benefits related to multisensory integration and that this effect can reverse deficits on the CMOR and MSO tasks that relate to AD-like pathology.Supported by NSERC.

Title: Spatial memory deficits are observed in young adult and middle-aged TgF344-AD rats

Authors: *M. M. OH, C. LIN, C. SPAENI, N. VILCEK, C. HICHERI, J. F. DISTERHOFT; Physiol., Northwestern Univ., Chicago, IL

Abstract: Early-onset Alzheimer's disease (AD) has been linked to mutations in the amyloid precursor proteins (APP), giving rise to the amyloid cascade hypothesis of AD (Selkoe & Hardy, 2016). The strong hereditary nature of mutations in APP gene with early-onset AD has led to much work and focus on the amyloid hypothesis using transgenic mouse models to understand AD (Myers & McGonigle, 2019). While the mouse models of AD engineered to overexpress just Aβ peptides are extremely useful to examine the effects of Aβ peptides (e.g., 5xFAD, Tg2576, PSAPP), they fail to recapitulate the complex range of human AD pathologies without the addition of human tau mutation (e.g., 3xTg-AD). Namely two critical factors are missing from the Aβ-overproducing transgenic AD mice: (1) lack of neurofibrillary tangles (NFTs) as a measure of robust tauopathy, and (2) lack of consistent and extensive neuronal loss. In addition, these transgenic mouse models generally have amyloid pathology early in life, unlike the majority of human AD cases that show more severe symptoms with aging. Therefore, we have established a colony of a rat model of AD, TgF344-AD, that overexpress Aβ peptides and recapitulates the full range of human AD hallmarks without the introduction of additional human tau mutations (Cohen et al., 2013). Using hippocampus-dependent spatial water maze task, we found that memory of the hidden-platform location is significantly impaired in nearly 50% of young adult (6-8 month old: 11 female, 15 male) and middle-aged (12-13 mo: 6 female, 15 male) TgF344-AD rats, as compared to wild-type young adult F344 rats (6-8 mo: 9 female, 14 male). Preliminary immunohistochemical examination revealed extensive amyloid plaques detected with thioflavin S and 6E10, and increased hyperphosphorylated tau detected with AT8 in the temporal lobe regions (e.g., hippocampus, entorhinal cortex) from middle-aged TgF344-AD rats. Experiments are ongoing to continue behavioral, immunohistochemical, biophysical and proteomic experiments that will include middle-aged and aged wild-type (19-22 mo) F344 and aged TgF344-AD rats. The rats will also be tested in an additional hippocampus-dependent task, trace eyeblink conditioning.

Title: The APP23 mouse model of Alzheimer's disease exhibits early disruption of circadian rhythms that progress with developing pathology

Authors: *D. S. WHITTAKER[1,3], L. AKHMETOVA[1], J. MOTT[1], C. S. COLWELL[3], P. A. DESPLATS[2];
[1]Neurosci., [2]Neurosciences and Pathology, Univ. California San Diego, La Jolla, CA;
[3]Psychiatry and Biobehavioral Sci., Univ. California Los Angeles, Los Angeles, CA

Abstract: Circadian rhythm disturbances impact nearly all Alzheimer's disease (AD) patients. The most common disturbances include daytime sleepiness, sundowning, insomnia and increasing sleep fragmentation. Early, preclinical changes in circadian rhythms and sleep in AD support the role of circadian disfunction as a driver of the disease and suggest that circadian disruption may be an important target for treatment. Therefore, there is a fundamental need to identify research models that recapitulate these key facets of the disease and permit investigation of therapeutic approaches. Notably, circadian disruptions have not been well characterized in AD mouse models. APP23 mice (transgenic mice with the Thy1 promoter driving expression of the human APP gene containing the Swedish mutation) have been reported to exhibit disrupted behavior resembling the sundowning seen in AD patients; however, detailed circadian phenotyping has not been performed. We hypothesized that circadian disruption in APP23 mice manifests early and progresses with advancing neuropathology. To assess circadian rhythms in APP23 mice and littermate controls (n=3-5 per sex and genotype), we measured behavioral sleep and ongoing cage locomotor activity from presymptomatic animals (starting at 7 mo). To assess circadian function, we measured responses to phase shifting of light (6-hr phase advance), and to negative masking (1-hr light pulse in the dark phase) and positive masking (1-hr dark pulse during the light phase). Our analysis showed that APP23 transgenic mice (Tg) exhibit progressive disruptions in sleep and circadian activity patterns, including the emergence of excessive wakefulness and activity in the active phase accompanied by excessive sleep fragmentation. In addition, at 10 mo of age APP23 Tg mice manifest an exceptionally fast entrainment to a 6-hour phase shift when compared to NTg, and display altered behaviors in response to negative and positive light masking. Further, analysis of older Tg mice with full symptomatic neuropathology (>15 mo) reveals that these mice do not present the age-related decline in activity behaviors we observe in age-matched NTg mice; instead, old APP23 Tg continue to manifest disrupted circadian activity patterns, including excessive agitation with elevated activity onset imprecision. Taken together, our findings show that APP23 Tg mice present early circadian disruptions that are progressive and advance with developing neuropathology. This suggests that the APP23 mouse may be a good model in which to study the interaction of circadian disruption and AD neuropathology.

Title: Pre-symptomatic levels of amyloid beta are neuroprotective against stroke

Authors: *A. K. J. BOYCE, L. A. PALMER, A. W. LOHMAN, R. J. THOMPSON;
Cell Biol. & Anat., Univ. of Calgary, Calgary, AB, Canada

Abstract: During Alzheimer's disease (AD) progression, the amyloid β (Aβ) protein is pathologically produced and deposited amongst the brain parenchyma. Only 5% of AD is familial, thus environmental risk factors and co-morbidities play a key role in disease development. For instance, ischemic stroke increases in the risk of developing AD by five-fold. Hypoxia, a product of ischemia, upregulates Aβ production with unknown functional outcome. Due to the link between amyloid burden and AD severity, we hypothesized that Aβ would enhance excitotoxicity during hypoxia. We recently demonstrated that ischemia triggers metabotropic NMDAR-dependent activation of PANX1 channels, contributing to the anoxic depolarization (aDP), a large inward NMDAR-dependent current that occurs in response to reversed glutamate uptake and elevated glutamate release during stroke, and eventually causing cell death. Since NMDAR signaling is known to be modulated by Aβ, we hypothesized that Aβ could modify stroke evoked PANX1 activity, the resultant aDP, and associated neuronal death. To our surprise, we found that low concentrations of Aβ are protective and reduce PANX1 opening during the aDP. Using whole-cell patch clamp electrophysiology and 2-photon microscopy on hippocampal slices from young 5xFAD or 5xFAD/Thy1-GCaMP6f mice, we determined that 5xFAD mice had altered aDP severity and calcium dysregulation compared to wild-type littermates, which was dependent on Aβ load. Low concentrations (pM to nM) of oligomeric Aβ attenuated the aDP, while reducing endogenous Aβ levels using a γ-secretase inhibitor increased aDP severity. Aβ potently blocked PANX1 currents in response to elevated NMDA and hypoxia, however, Aβ failed to block PANX1 currents directly (as determined in PANX1-expressing HEK cells). These findings were further explored using a novel model of photothrombotic stroke in awake and behaving mice. The molecular mechanisms of Aβ-dependent regulation of metabotropic NMDAR signaling were also investigated. These data reveal that Aβ production could be increased as a neuroprotective mechanism during hypoxia to reduce PANX1 activation, thereby attenuating the aDP and downstream cell death pathways. However, with prolonged/repeated ischemic events, Aβ could reach toxic levels and coincide with hallmark pathophysiology of AD.

Abstract: Insulin resistance, a major symptom of type-2 diabetes mellitus (T2DM), is a known risk factor for Alzheimer's disease (AD). Emerging evidence has shown that both diseases share similar pathophysiology which includes amyloidogenesis and cognitive decline. In the present study, we aimed to understand how T2DM or related conditions contribute to AD pathogenesis. We used the *App*$^{NL-F/NL-F}$ knock-in mouse model of AD, which contains a humanized Aβ region along with two pathogenic mutations, the Swedish "NL" and the Iberian "F" to express APP at wild-type levels while producing elevated pathogenic Aβ. *App*$^{NL-F/NL-F}$ mice recapitulate several AD-associated pathologies, including amyloid plaques in the cortex and hippocampus, and show signs of very mild cognitive impairment at 18 months of age, but avoid potential artifacts introduced by the *APP* transgene. For this study, 6-month-old *App*$^{NL-F/NL-F}$ and wild-type male mice were fed with a regular diet (RD) or high-fat diet (HFD) for 12 consecutive months. We then compared the effects of the diet on the AD pathogenesis and hippocampal gene expression profiles between the two mouse lines. HFD treatment successfully increased body weight and impaired glucose tolerance levels in both mouse lines at 18 months of age. However, behavioral analysis by Morris water maze revealed an impaired cognitive function only in HFD-fed *App*$^{NL-F/NL-F}$ mice, accompanied by marked increases in both Aβ deposition and microgliosis. Moreover, HFD-fed *App*$^{NL-F /NL-F}$ mice exhibited a significant decrease in the volume of the granule cell layer in the dentate gyrus and an increased accumulation of 8-oxoguanine, an oxidized guanine base in nuclei of the granule cells. Gene expression profiling by microarray revealed that populations of cell types in hippocampus were not significantly changed between the two mouse lines regardless of the diet. Interestingly, we found that HFD treatment decreased expression of the amyloid binding protein, transthyretin (TTR) mRNA, in *App*$^{NL-F/NL-F}$ but not wild-type mice. We further confirmed the decreased protein levels of TTR by western blotting and immunofluorescence microscopy suggesting that the decreased levels of TTR may be a cause of the increased amyloid deposition in the hippocampus of HFD-fed *App*$^{NL-F/NL-F}$ mice. It is likely that the chronic exposure to HFD increased oxidative stress in the brain of *App*$^{NL-F/NL-F}$ mouse, thereby aggravating the AD pathology through altered gene expression. Further studies using the HFD-fed *App*$^{NL-F/NL-F}$ mice will help us to understand the exact mechanisms underlying the effects of T2DM on the AD pathogenesis.

Abstract: Most Alzheimer's disease (AD) cases are sporadic and late-onset, yet nearly all existing mouse AD models harbor pathogenic mutations, rendering them better representations of familial autosomal-dominant forms of the disease. As a foundational step to model late-onset AD (LOAD), we generated and analyzed knock-in mice that express wildtype human amyloid beta (hAβ-KI) under control of the mouse *App* locus in exon 14 flanked by *loxP* sites (FL). Using confocal microscopy, we performed immunofluorescence stains on coronal brain slices and quantified the appearance of astrocyte-associated clusters of granules, which stained positive via Periodic Acid-Shiff (PAS) stain. To correlate the appearance of PAS granules with hAβ expression, we crossed hAβ-KI-FL mice with UBC-Cre^{ERT2} mice to enable Tamoxifen-inducible cre recombinase-mediated inactivation of hAβ expression. Finally, we generated hAβ-KI; PS1^{M146V} mice to investigate whether co-expression of familial-linked AD mutations affect the hAβ-induced presence of PAS granules. Changing 3 amino acids in the mouse Aβ sequence to its wild-type human counterpart produced age-dependent accumulation of PAS granules in the hippocampus of hAβ-KI mice by 10 months of age. Additionally, we observed impairments in cognition and synaptic plasticity in hAβ-KI mice. Remarkably, ablating hAβ expression using inducible cre reduced the formation of PAS granules and rescues cognition. Co-expression of familial-linked AD mutations with hAβ exacerbated the accumulation of PAS granules compared to homozygous hAβ-KI and WT mice. In conclusion, substituting mouse Aβ with the wild-type human isoform produces significant accumulation of PAS granules and impairments in cognition

and synaptic plasticity, highlighting the usefulness of this hAβ-KI mouse strain in investigating risk factors of LOAD.

Abstract: An oxidative mechanism for cholinergic dysfunction in neurons exposed to Aβ-oligomers
SANTOS LE[1], FERREIRA ST[1,2], DE MELLO FG[21]Instituto de Bioquímica Médica Leopoldo de Meis, [2]Instituto de Biofísica Carlos Chagas Filho, UFRJ, Rio de Janeiro, Brazil
The neurotransmitter acetylcholine is synthesized by the enzyme choline acetyltransferase (ChAT), which is also a phenotypic marker of cholinergic neurons. Defective cholinergic transmission may underlie the onset and development of several CNS pathologies, including Alzheimer's disease (AD). Previous work by our group, using the avian retina as a CNS model, showed that ChAT activity in cultured or ex vivo neurons is markedly and specifically down-regulated by excitotoxic stimuli. This effect precedes any changes in cell viability or enzyme levels and requires calcium influx and nitric oxide (NO) production. More recently, we reported similar results in a more specific pathological context, using amyloid-β peptide oligomers (AβOs). These diffusible toxins accumulate in the AD brain and may be central to the disease. Exposing cultured cholinergic neurons to AβOs inhibited ChAT activity before any detectable loss of neurons or enzyme expression. The effect was linked to excitotoxicity and reactive oxygen species production, being likely caused by oxidative damage to the enzyme. Here, we expand those observations to a mammalian model, using cultured neurons of the rat septal region, and attempt to identify oxidative modifications involved in ChAT inhibition. Using S-nitrosothiol resin-assisted capture and thiol labeling, we show that cysteine modification is not central to the mechanism of inhibition. Tyrosine nitration, however, was found to be induced in cultures exposed to glutamate, AβOs and NO donors, and correlated well with loss of ChAT

activity. Results suggest a novel mechanism of cholinergic dysfunction that precedes neuronal death and may be relevant in early-stage AD pathology.

Title: The Effects of Calmodulin Kinase IIA driven TDP-43 expression in 24 month-old APP/PSEN1 background mice.

Authors: *A. ANDERSON, S. AREZOUMANDAN, M. GITCHO, S. DAVIS;
Delaware State Univ., Dover, DE

Abstract: TDP-43 functions as a heterogeneous nuclear ribonucleoprotein involved in mRNA transport, mRNA stability, transcription, and mitochondrial metabolism. TDP-43 is the major pathological protein in frontotemporal dementia and ALS. Previously, TDP-43 pathology has been described in up to 50% of those with Alzheimer's disease. Recent evaluation of this cohort revealed a distinct pathological staging of TDP-43 proteinopathy in an aged population, which overlaps frontotemporal lobar degeneration (FTLD-TDP) and Alzheimer's disease. This overlapping pathological cohort is named limbic-predominant age-related TDP-43 encephalopathy (LATE). Through a model of cortical/hippocampal expression in an APP/PSEN1, we have extended our previously reported characterization of 9-month old mice to determine how age contributes to neurodegeneration. This TDP-43 proteinopathy is present in 20-50% of AD cases in those 80 and over. The mice characterized for this study are 24 months of age, which may be comparable to approximately 70 years of age in humans. Both human TDP-43 and nuclear localization signal defective (ΔNLS) TDP-43 in an APP/PSEN1 background were evaluated. This model shows severe neuronal loss in the hippocampus, a change in plaque deposition, aggregated tau, and a decrease in survival. This aged model of TDP-43 proteinopathy may be of use in understanding how TDP-43 contributes to neurodegeneration. **Conclusions:** hTDP-43 expression in APP background shows pathological neuronal loss with emphasis on the dentate gyrus. Further research is needed to elucidate the specific mechanisms.

Abstract: Alzheimer's disease (AD) is a complex disorder with increasing prevalence and socio-economic burden. However, majority of strategies aimed at identifying therapies for AD have been focused on targeting Aβ or TAU, which make up the plaques and tangles commonly found in people with AD. Continued failure of the drug discovery process and the accompanying trials against these targets has necessitated more and better options for therapeutic intervention. Using a multi-parametric high content phenotypic readouts with neurons derived from human differentiated iPSCs with familial AD mutations, we aim to optimize a platform for CRISPR based rescue screens for the various phenotypes associated with the mutations, such as endo-lysosomal transport, synaptic dysfunction and neuronal toxicity. The multiple-phenotypic rescue approach will enable identification novel key pathways and/or targets which could serve has drug candidates for the treatment of AD

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder affecting the elderly, but its intricate pathophysiology remains unclear. The increase of amyloid-beta peptide (Aβ) and hyperphosphorylated tau protein, and the failure of cholinergic transmission, are considered key events in AD. However, previous works have demonstrated that, in the healthy brain, low physiological concentrations of Aβ are necessary for synaptic plasticity and memory processes, acting through α7 subtype nicotinic acetylcholine receptors (α7nAChRs). Thus, we hypothesized that α7nAChRs deletion might induce a compensatory increase of Aβ production that, in turn, would trigger an AD-like pathology. To validate this hypothesis, we evaluated whether α7nAChR KO mice might develop alterations typical of AD. 3xTg models of AD and wild type animals were used as controls. We found that α7 KO mice presented an age-dependent impairment of synaptic plasticity and memory, starting at 12 months of age. In particular, we evidenced an impairment of Long Term Potentiation and Paired Pulse Facilitation at the CA3-CA1 hippocampal synapses. Furthermore, Novel Object Recognition and Location, and Fear Conditioning behavioral studies, demonstrated a reduction of recognition, spatial and contextual fear memory in α7nAChR KO mice.The onset of the impaired phenotype was paralleled by an increase of Aβ levels and Amyloid Precursor Protein (APP) expression. This was accompanied by hyperphosphorylation of tau at different residues known to be involved in AD, i.e., Thr205, Ser199 and Ser396. Consistently, α7nAChR KO showed a decrease of GSK-3β (Ser9), an important regulator of tau phosphorylation. An increase of PHF-1 immunoreactivity and the presence of paired helical filaments and neurofibrillary tangles confirmed that α7nAChR deletion induced tau pathology. In conclusion, our findings suggest that α7nAChRs malfunction might precede the increase of Aβ and tau in the cascade of events leading to AD. These results provide a different perspective to interpret the failure of previous therapeutic approaches against AD. Furthermore, α7 KO mice could represent an interesting model to study sporadic AD and revise the role of Aβ, tau and cholinergic transmission in AD pathophysiology.

Title: Alzheimer's disease pathology accelerates age-related visual changes in the 3xtg mouse model

Authors: *G. FRAME[1,2], C. M. DENGLER-CRISH[1];
[1]Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [2]Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: While Alzheimer's disease (AD) is often considered a disease of cognition, the earliest changes involve sensory systems, and thus serve as an attractive method for early diagnosis. This study aimed to temporally characterize the decline of retinal ganglion cell (RGC) function in the 3xtg AD mouse model using pattern electroretinogram (PERG) recordings. Sex and age-matched 3xtg and control C57BL6 mice were compared across three ages that represented early, emerging, and progressing disease states in 3xtg mice. Axonal transport along the retinofugal projection was also assessed in mice using cholera toxin subunit beta (CTB) which was injected into the intravitreal chamber of the eye and was then anterogradely transported to the superior colliculus. Synaptic structural markers (i.e. vesicular glutamate transporter 2 and estrogen-related receptor beta) were labeled immunohistochemically in the superior colliculus, and RGC densities in retina were labeled with RbPMS. Results indicated that while C57 mice did demonstrate age-related decreases in PERG amplitude beginning at 12 months, the 3xtg mice exhibited significant reductions in PERG amplitude earlier, beginning at 8 months of age, and a further decrease in PERG amplitude by 12 months of age. These results suggest that while age-related changes in RGC function are expected, the presence of AD-related pathologies exacerbates these deficits. Percent area fraction (PAF) analysis of the superior colliculus revealed that within 3xtg mice, females tended to have a lower PAF of CTB coverage than males, though this did not reach significance. By 12 months of age, the females exhibited a significant decrease in CTB coverage throughout the superior colliculus, indicating that axonal transport was deficient in these animals. Surprisingly, in male 3xtg mice, no age-related changes were noted. In both female and male 3xtg mice, no age-related changes for either synaptic marker (VGlut2 or ERRβ) was noted, suggesting that functional deficits precede structural changes in the 3xtg mouse model. Sections throughout the retina were sampled and the results revealed that in C57 mice, there was again an age-related decline in RGC density beginning at 12 months of age. In 3xtg, however, there was a significant decrease in RGC density at 8 months of age, with a further significant decrease at 12 months of age. The difference in RGC density between C57 and 3xtg was significantly different at 12 months of age with 3xtg having a much lower RGC density. Collectively, these results suggest that the presence of AD-related pathologies exacerbates age-related deficits in the visual system.

Abstract: Deposition of amyloid beta peptide (Aβ) in the brain is one of the major hallmarks in Alzheimer´s disease (AD) pathogenesis. The amino acid sequence of the Aβ peptide is essential for its self-assemble properties, a complex process that involves the production of soluble intermediates that lead to amyloid plaque deposition. Currently, soluble Aβ oligomers formed in early aggregation are being considered as primary neurotoxic agents and prevention of Aβ aggregation has emerged as a therapeutical target for AD. An approach in the development of peptide inhibitors of aggregation is the use of Aβ as a starting point. Previously, we generated three Aβ peptides variants by introducing the point mutations M35C, A30W or K28A in each one of two Aβ peptides of different length, 40 and 42 amino acids, respectively. All these substitutions lie in key regions that participate during the aggregation process. Cell culture assays showed a decrease in reactive oxygen species production correlated with a reduction in cytotoxicity but not with the aggregation properties of the variants. Furthermore, the 1-40 mutants were able to prevent *de novo* aggregation of the WT peptide while 1-42 mutants prevented and disorganized pre-formed WT aggregates. *Caenorhabditis elegans* is an *in vivo* model that allows for the screening of Aβ aggregation inhibitors and the evaluation of their associated effects on behavior. In this work, samples of around 30 age-synchronized worms were treated with each peptide. Lifespan and chemotaxis assays were performed in a wildtype strain to evaluate toxicity and associative memory. For chemotaxis assays, *C. elegans* was conditioned with benzaldehyde beginning at the egg stage. The conditioned worms associated the odor cue with the presence of food and were capable to remember the association, allowing the testing of memory recall in the worms. Additionally, the progression of an Aβ-dependent paralysis phenotype was assessed in transgenic worm strains expressing Aβ (CL4176 and CL2006). Only A30W mutant 1-40 variant showed a slightly reduced toxicity at 40μM with 20% of worms surviving up to 19 days, while the remaining peptides had little to non-effect in toxicity in comparison to wildtype Aβ. However, treatment with K28A peptide 1-42 variant was able to prevent loss of associative memory, while M35C and K28A mutants caused a delay of up to 48 hours of the paralysis phenotype onset. Although further studies need to be conducted to analyze the effectiveness of the peptides, these results suggest that some of the mutants could improve Aβ related phenotypes in *C. elegans* and, therefore, have a putative potential for the design of future drugs against Alzheimer's Disease.

Abstract: Alzheimer's disease (AD) is the most common form of dementia, which affects 47 million people worldwide. There are over five million AD patients over the age of 65 in the U.S. which is predicted to increase to 16 million by 2050. There are currently no approved disease-modifying therapies for AD and attempts to prevent or slow the progression of the formation of beta-amyloid plaques by targeting both the beta-secretase 1 (BACE1) and gamma-secretase enzymes have not yet achieved clinical success. Studies suggest that indirect modulation of the function of these enzymes via G-protein coupled receptors (GPCRs) may provide a novel strategy to reduce A-beta peptide production with potentially less side effects. Among GPCRs that influence amyloidogenesis, the delta opioid receptor (DOR), in particular, has been shown to play an important role in the trafficking and function of BACE1 and gamma-secretase and in the production of A-beta peptide. DOR activation increases BACE1 and gamma-secretase activity *in vitro* and in a mouse model of AD, and antagonism of DOR specifically blocks the amyloidogenic pathway and efficaciously prevents AD progression in mice. These effects were demonstrated using a known DOR antagonist, naltrindole. However, the potential of DOR antagonists as therapeutic agents for AD is yet to be explored. The aim of this project is to create novel DOR antagonists via medicinal chemistry and identify the most promising lead compound based on binding, selectivity, and functional profile *in vitro*. Further, select a small set of the most promising compounds *in vivo* and evaluate the compound's ability to mitigate AD-like pathology using APP/PS double-transgenic mice. We report here the creation of multiple selective DOR antagonists with low nanomolar affinity/potency, and we have demonstrated the ability of these antagonists to block BACE1 activity *in vitro*. Lead compounds showed systemic stability and blood brain barrier penetration using the *in vivo* tail flick assay in CD-1 mice. We will further report our progress in testing these compounds *in vivo* using APP/PS AD model double-transgenic mice.

Abstract: Decreasing amyloid beta protein (Aβ) levels using anti-amyloid compounds is a promising strategy to prevent Alzheimer's disease (AD). We and others have demonstrated that curcumin (Cur) is a potent anti-amyloid compound. Unfortunately, Cur comprises only a small percentage of the compounds comprising tumeric extract and it has limited bioavailabilty. Therefore, investigating the anti-amyloid properties of other Cur-derivatives has sparked considerable interest in AD research. In this study, we compared the anti-amyloid and neuroprotective properties of different Cur-derivatives, such as bisdemethoxycurcumin (BDMC), demethoxycurcumin (DMC) and tetrahydrocurcumin (THC) using molecular simulation, *in-silico* and *in vitro* studies. We measured binding energy, torsion angle, and hydrogen bonding capabilities of different Cur-derivatives with Aβ42. Dot blot assays, photo-induced cross linking of unmodified protein (PICUP) and transmission electron microscopy (TEM) were performed to compare the Aβ aggregation inhibition using these derivatives. Neuroprotective effects of these derivatives were evaluated in N2a and SH-SY5Y cells using Aβ42 (10 μM) as a toxin. Finally, Aβ-binding capabilites were compared in the brain tissue derived from 5xFAD, a mouse model of AD. Molecular dynamic studies revealed that THC had greater binding capability to Aβ than other Cur-derivatives. In addition, the enol form of Cur (ECur) showed stronger binding to Aβ in comparison to keto form of Cur (KCur). THC showed greater inhibition of Aβ oligomers and fibrils than other Cur-derivatives as revealed by dot blot and PICUP methods. In addition, all of these derivatives showed a similar degree of neuroprotection *in vitro,* and labeled Aβ-plaques *in vivo*. Overall, THC is much more active in binding and inhibiting Aβ aggregation *in vitro* in comparions to other Cur-derivatives. Our findings suggest that THC may provide a more potent prophylactic therapeutic for inhibiting Aβ pathologies in AD than other Cur-derivatives.

Abstract: Introduction Human brain banking is an essential examination of neurodegenerative proteinopathies, such as amyloid-β (Aβ), a primary pathologic culprit in Alzheimer's Disease (AD). Studies have demonstrated correlations between cognitive impairment and soluble Aβ (sAβ) levels. Furthermore, sAβ from frozen human brain tissue has shown threefold higher levels in AD when compared to healthy controls. However, the majority of human brain banked tissue is fixed and embedded in paraffin blocks. We have optimized and validated an efficient reproducible procedure for extraction of soluble proteins from paraformaldehyde (PFA) and neutral buffered formalin (NBF) fixed paraffin embedded human brain tissue which can then be quantified using assays for multiplexing such as Meso Scale Discovery (MSD). **Methods**: Human brains from the Northwestern University Alzheimer's Disease Center brain bank, with a range of Consortium to Establish a Registry for Alzheimer's disease (CERAD) scores, were fixed with either PFA or NBF, and blocks were embedded in paraffin. Blocks of neocortex were then cut into 3 curls, each 14 microns thick, and deparaffinized in xylene. Two different protein extraction techniques were attempted: one using the Qiagen QProteome FFPE Tissue Kit and the other using one of five homebrew extraction buffers. Homebrew extraction buffers contained 2% sodium dodecyl sulfate with increasing concentrations of tris (20mM, 100mM, 300mM, 400mM, and 500mM). BCA was used to assess total protein concentration. Samples were analyzed for total protein concentration via BCA. Western blots were performed for validation to confirm presence and amount of proteins of interest. **Results**: BCA findings revealed all extraction techniques to yield detectable protein, with the 300mM tris homebrew extraction buffer yielding the best results. Western blots confirmed extraction of soluble proteins including; Aβ, glial fibrillary acidic protein (GFAP), ionized calcium binding adaptor molecule 1 (Iba1), and human tar-DNA binding protein 43 (hTDP-43). Findings across cases with increasing CERAD scores were consistent with traditional semi-quantitative methods. Western blotting showed increasing Aβ with increasing CERAD scores. **Conclusions**: Effective extraction of soluble proteins from

PFA and NBF fixed paraffin embedded human tissue provides a useful approach for quantitative comparative studies of neurodegenerative disease associated proteins and other biomarkers.

Title: Hyperphosphorylated tau-based drug discovery for Alzheimer's disease and tauopathies

Authors: ***M.-H. KUO**[1], M. LIU[2], T. DEXHEIMER[1], D. SUI[1], S. HOVDE[1], R. KWOK[3], K.-W. WANG[1], H.-T. CHIEN[1];

Abstract: Alzheimer's disease (AD) is affecting 5.8 million Americans and more than 30 million people worldwide. There is currently no treatment or prevention for this devastating disease. AD is one of several neurodegenerative tauopathies that share a common pathology in the brain, that is, the deposition of hyperphosphorylated tau protein in selective neurons and other brain cells. AD patients suffer from progressive decline of cognitive and additional neurological functions. These clinical manifestations correlate with the spatiotemporal distribution of tau deposits. The pathological roles of abnormally phosphorylated tau have been recapitulated by intracranial injection experiments on mice. Accordingly, molecules that inhibit or enhance the pathological activities of hyperphosphorylated tau are potential therapeutics and risk factors, respectively, for AD. Identification of such molecules will likely lead to efficacious treatment or prevention. One of the formidable hurdles of tau-centric AD drug discovery has been the lack of a means to produce pathophysiologically relevant hyperphosphorylated tau for in vitro uses. We have developed the PIMAX system to synthesize hyperphosphorylated tau (p-tau) in *E. coli* that enables disease mechanism and drug discovery studies. We showed that p-tau produced by PIMAX possesses a core phosphorylation pattern highly relevant to the disease, and that the aggregates of p-tau causes cell death in vitro. Using a suite of different assays, we conducted a chemical library pilot screen from which we identified both p-tau aggregation inhibitors (apomorphine and raloxifene) and enhancers (certain benzodiazepines) that had been linked to cognitive impairments. These are active prescription drugs treating different clinical conditions, and they have previously been linked to cognitive integrity. Our discoveries suggest a molecular

mechanism underlying these prior findings, and that these drugs are excellent candidates for further development structure-activity relationship studies. Medicinal chemistry refinement of these compounds, as well as a larger-scale screen of novel compounds are ongoing.

Title: Tau-related neurodegeneration in circadian clock neurons of drosophila

Authors: ***S. WANG**, M. KELES, K. DEIBEL, I. BLUM, M. WU;
Johns Hopkins Univ., Baltimore, MD

Abstract: Tau protein aggregation is one of the neuropathological hallmarks of Alzheimer's disease (AD), one of the most prevalent form of dementia worldwide. Accumulation of tau has been shown to lead to abnormal functioning and ultimately the death of neurons. Recent research suggests that pathological tau seeds spread synaptically and recruit native tau in connected neurons, leading to the spread of abnormal tau throughout the brain. However, how pathological tau induces toxicity and spreads between neurons remains unclear. Since many AD patients suffer from multiple sleep disorders and exhibit weakened circadian rhythms and degeneration of their suprachiasmatic nuclei, we used the power of Drosophila genetics to investigate the molecular mechanisms mediating tau toxicity. The experiments conducted used a model in Drosophila expressing human pro-aggregate mutants of tau to examine its morphological and behavioral effects in circadian clock neurons. Human tau was expressed in clock neurons using the pdf-GAL4 driver. We found that the expression of human tau leads to the elongated and thinner axon terminals that exhibit extensive branching compared to the controls. This morphological phenotype was observed for different variants of tau. We then looked at the effects of tau expression on the circadian behavior. Activity monitoring of 20-day old flies expressing tau revealed circadian arrhythmicity. In contrast, 3-day old flies had intact circadian rhythms suggesting an age dependent mechanism for tau related disruption of clock neuron physiology. Using this behavioral assay, we are currently planning to conduct an unbiased large-scale RNAi screen to identify novel genes that are required for tau toxicity.

Title: Phosphorylation of microtubule-associated protein tau regulates its ability to bind and polymerize microtubules in mice brains.

Authors: *A. HAGITA[1,2], T. MIYASAKA[1,2];
[1]Dept. of Neuropathology, Fac. of Life and Med. Sci., [2]Ctr. for Res. in Neurodegenerative Dis., Doshisha Univ., Kyoto, Japan

Abstract: Tau is a microtubule-associated protein (MAP) that has abilities to bind on microtubules (MTs) and stabilize them. Tau is also identified as a framework of insoluble inclusions, formed in the affected neurons in the brains of dementia, tauopathy. Because the abnormal tau purified from NFTs is hyperphosphorylated and lost its functions, it is considered that the phosphorylation of tau may affect its functions onto MTs. However, in fact, the effects of the phosphorylation on the physiological functions of tau in vivo remain obscure. Firstly, to analyze the MT formation in mice brains, we optimized the procedure that enables us to quantify not only stable but also labile MTs and free tubulins, and evaluate the dynamics of MAPs in vivo. Using this method, we found that approximately 35% of total tubulin forms stable MTs and 51% of it forms labile MTs. About 70% and 22% of total tau bound on stable and labile MTs, respectively. Therefore, a large part of tau and tubulin are incorporated into MTs. Tau recovered in soluble-free tubulin fraction was also associated with tubulin and still had an ability to assemble to labile MTs, but not stable MTs. Secondary, to examine the dynamics of tubulin and tau in response to phosphorylation, we analyzed anesthesia-induced hypothermia model, in which tau was hyperphosphorylated. About 10% of labile MTs-bound tau became free and lost its functions of MT polymerization, although neither dissociation of tau from stable MTs nor MT disruption was induced by tau phosphorylation. This result indicates that the functions of stable MTs-bound tau was more resistant to phosphorylation than that of labile MTs-bound or MTs-unbound tau. We further analyzed the MT formation in the postnatal stages in mice brains, in which the function of tau for MTs is suppressed by phosphorylation. Tau was highly phosphorylated in MTs-unbound fraction in the first week of life, then dephosphorylated until P14. According to its dephosphorylation, tau came to assemble into MTs. Despite of unchanged proportion of free tubulin in development, stable MTs were gradually increased according to the days after birth inversely with labile MTs. Interestingly, both of these tau hyperphosphorylation models share the effective phosphorylation site of tau detected by AT8. Finally, we found that phosphorylated and MTs-unbound tau was increased in P301S mutant tau transgenic (tauopathy’s model) mouse brain. These findings suggest that phosphorylation regulates the

functions of tau on MTs in mice brains under physiological condition, and also suggest that the phosphorylation determine abnormal behavior of tau in pre-pathological step.

Title: Effects of Fyn kinase inhibition with AZD0530 on Tau pathology and Tau-induced phenotypes in mouse models of tauopathy

Authors: *S. TANG, S. NIES, H. TAKAHASHI, S. STRITTMATTER;
Program in Cell. Neuroscience, Neurodegeneration and Repair, Yale Univ., New Haven, CT

Abstract: Alzheimer's disease (AD), one of many progressive neurodegenerative tauopathies characterized by the misfolding and aggregation of hyperphosphorylated Tau, has no known cure. Recent studies demonstrate that overactivation of Fyn, a Src family tyrosine kinase that can phosphorylate Tau, causes excitotoxicity and neuronal death via Tau and Fyn mis-localization in the post-synaptic area. We aimed to assess the utility of Fyn inhibition in preventing development of tauopathy with the Fyn kinase inhibitor AZD0530. The effects of Fyn inhibition were examined in a transgenic model of tauopathy expressing human 1N4R Tau with the P301S mutation (strain PS19) and in *in vitro* and *in vivo* models of Tau spreading using human AD brain-derived Tau fibrils (AD-Tau). We first treated PS19 mice and wild-type (WT) littermates with chow formulated with either AZD0530 or a vehicle control (n=11-15 per group). Treatment (10 mg/kg of AZD0530 per day *ad libitum*) began at two months of age, prior to the onset of Tau pathology or memory impairments. At eight months old, vehicle-treated PS19 mice exhibited a spatial memory deficit in the Morris water maze that was prevented with AZD0530 treatment. Immunohistochemistry revealed a reduction in Tau hyperphosphorylation, gliosis, and synaptic loss in the hippocampus of AZD0530-treated PS19 mice, although AZD0530 had no significant effect on phosphorylation at Tyr18 of Tau. Proximity ligase assay in HEK-293T cells expressing human Fyn and Tau suggested that AZD0530 treatment also decreases the Fyn/Tau interaction. To examine whether Fyn inhibition affects Tau spreading, we next treated primary neuronal cultures with AD-Tau in the presence or absence of AZD0530. We found that AZD0530 treatment significantly suppresses mouse Tau pathology induced by AD-Tau in cultures of primary neurons. To further investigate the effects of Fyn inhibition on Tau spreading *in vivo*, we injected AD-Tau into the hippocampus and cortex of the right hemisphere of 3-month-old WT (C57BL/6) mice and then treated the mice with AZD0530 for nine months starting at fourteen

days post-injection. In this setting, we failed to observe any effect of AZD0530 treatment on formation of Tau inclusions induced by AD-Tau. These data demonstrate that the accumulation of intracellular Tau and its spreading to other cells is differentially sensitive to Fyn inhibition in different model systems. The cellular and molecular determinants of Fyn-dependence for Tau pathology require further exploration based on neuronal subpopulation, glial cell participation, and endogenous Tau substrate for accumulation to define the potential role for Fyn inhibition as a therapeutic intervention.

Title: Development of a neuronal microfluidic cell culture model for screening inhibitors of tau propagation

Authors: K. TITTERTON, N. VENKAT, K. YANAMANDRA, X. LANGLOIS, J. WU; AbbVie, Cambridge, MA

Abstract: The aggregation and propagation of the microtubule associated protein tau are key events in the pathophysiology of Alzheimer's disease (AD). Tau is a natively unfolded and soluble neuronal protein, which under pathological conditions, starts to aggregate and propagates between neurons. Recapitulating tau propagation using *in vitro* model systems has proven challenging. Here, we cultured transgenic murine neurons expressing all 6 isoforms of human tau on a mouse tau KO background in a microfluidic system. Using such devices allows neurons grown in two separate chambers to communicate between each other via axonal projections that extend through microgrooves and to establish synaptic connections between them. By seeding hTau neurons in one chamber only, we could show that tau aggregation was propagating from chamber to chamber, demonstrating unambiguously the trans-neuronal propagation of pathological forms of tau. Adding anti-tau antibodies to the receiving neuronal population(s) reduces tau propagation, suggesting that tau antibodies can stop inter-neuronal pathological tau spread. The *hTau* neuronal microfluidic platform can be used to identify anti-tau antibodies and other inhibitors of tau propagation.

Abstract: This study examined the effects of repetitive mild TBI (rmTBI) paradigm duringadolescence on the deposition of amyloid and tau and neuronal loss in dual tg AD mice at 8months of age. Alzheimer's disease (AD) is characterized by the formation of neuritic plaquescomposed of amyloid and neurofibrillary tangles composed of tau protein in the brain.Traumatic brain injury (TBI) increases the risk of developing AD. Increases in tau protein andamyloid plaques as well as neuronal degeneration are seen in TBI and may play a role in theprogression of AD, as these changes overlap with AD neuropathology. Adolescents are at anincreased risk of sustaining TBI and are then more vulnerable to a second concussive impact,with the majority of reported TBIs being mild. In this study, a dual transgenic (Tg) mouse modelthat expresses both amyloid and tau pathology (J20 hAPP bred with rtg4510 (tau) mice fromJackson Laboratories) underwent a novel rotational rmTBI paradigm to determine the effects ofrmTBI on the progression of AD pathology. Adolescent dual Tg mice sustained 5 closed-headinjuries with 48 hours between each hit, using a Controlled Cortical Impact (CCI) device on adropping platform to produce rotational effects that mimic the acceleration and decelerationforces seen in human TBI. Infralimbic (IL), cortical, and hippocampal brain regions wereassessed for tau pathology with Thioflavin-S, Congo Red, and Luxol FastBlue/Cresyl-Violetstains when mice were 8 months of age. There were significantly more tau tangles in Tg micethat sustained rmTBI compared to Tg mice who did not receive rmTBI seen in the IL (p =0.011), parietal association cortex (p = 0.002), entorhinal and perirhinal cortex (p< 0.001), visualassociation cortex (p = 0.015), mid dentate gyrus (DG) (p = 0.035), mid CA1 (p = 0.007), lateDG(p<0.001), and late CA1 (p< 0.033) In the temporal cortex, mice who sustained rmTBI hadlarger tau tangles than SHAM mice (p = 0.049). There were no significant differences in numberof amyloid plaques in any of the brain regions assessed (p> 0.05). There was significantly lower
cell density in the primary and secondary motor cortex (p = 0.044) and in the visual associationcortex (p = 0.024) in mice who received rmTBI compared to SHAM mice. There

were alsoseveral genotype effects were AD type mice had significantly lower cell density in hippocampalregions ($p< 0.001$), compared to wt mice, but AD mice also had significantly greater cell densityin the secondary somatosensory and primary and secondary motor cortical regions ($p< 0.05$)compared to wt mice. This study demonstrated that rmTBI during adolescence progresses theneuropathology of AD later in life.

Title: Understanding differential roles of stress and enrichment in pathogenesis of Alzheimer's Disease in a novel rat pre-tangle tau model

Authors: *S. TORRAVILLE, A. GHOSH, C. REINHARDT, T. OMOLUABI, C. CROSSLEY, L. MACGOWAN, Q. YUAN;
Mem. Univ. of Newfoun, St. John's, NL, Canada

Abstract: Tau pathology is a major hallmark of Alzheimer’s Disease (AD). Clinical studies have shown that tau pathology in humans is initiated in the locus coeruleus (LC), indexed by the appearance of hyperphosphorylated, pre-tangle tau. Pre-tangle tau occurs early in humans (in childhood or puberty) and evolution from pre-tangle to neurofibrillary tangles and symptomatic AD takes decades. We have established a pre-tangle tau model in rats by infusing pseudo-phosphorylated human tau in the LC, mimicking human origin of abnormal tau. This study aims to assess whether environmental stress or enrichment, either early or late in life, influences the general behaviour and cognitive functions in our pre-tangle tau model. Tyrosine hydroxylase-Cre rats were bilaterally infused in the LC with AAV9-rEF1a-DIO- htauE14-EGFP, or a control EGFP virus at 2-3 months old. Stress and enrichment paradigms were applied at either post-natal days 2-10 (early-life), or from 5-7 months old (adulthood). Cage controls did not have any behavioural interventions. Behavioural testing was carried out 7 months post-infusion, including measures of stress, anhedonia, spatial recall, and olfactory discrimination. Preliminary results show differential effects of environmental factors interacting with pre-tangle tau. While pre-tangle infused rats showed higher stress in elevated plus maze, late, but not early enrichment, reduced stress level. However, early enrichment improved spatial discrimination in the pre-tangle tau rats, while late stressed pre-tangle tau rats showed a trend of more severe deficiency in

a difficult odour discrimination learning. All together, these results suggest environmental factors may have brain region-specific effects in pre-tangle tau pathophysiology.

Abstract: Oligomeric assemblies of tau and RNA-binding proteins (RBPs), Musashi (MSI) are reported in Alzheimer's disease (AD). However, the role of MSI and tau interaction in their aggregation process and its effects are nor clearly known in neurodegenerative diseases. Here, we investigated the expression and cellular localization of MSI1 and MSI2 in the brains tissues of Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS) and Frontotemporal dementia (FTD) as well as in the wild-type, tau knock-out and P301L tau mouse models . We observed that the formation of pathologically relevant protein inclusions was driven by the aberrant interactions between MSI and tau in the nuclei associated with age-dependent extracellular depositions of tau/MSI complexes. Furthermore, tau and MSI interactions induced impairment of nuclear/cytoplasm transport, chromatin remodeling and nuclear lamina formation. Our findings provide mechanistic insight for pathological accumulation of MSI/tau aggregates providing a potential basis for therapeutic interventions in neurodegenerative proteinophaties.

Title: Pathological Tau Induces Neurodegeneration by Sequestering and Inhibiting LSD1/KDM1A

Authors: *D. J. KATZ, A. K. ENGSTROM, A. C. WALKER, R. A. MOUDGAL, D. A. MYRICK, S. M. KYLE, Y. BAI, M. A. CHRISTOPHER;
Emory Univ., Atlanta, GA

Abstract: Alzheimer's disease (AD) is an irreversible, progressive brain disorder caused by neuronal dysfunction in the cortex and hippocampus. AD is characterized by the aberrant accumulation of β-amyloid plaques and neurofibrillary tangles of hyperphosphorylated tau (NFTs). However, the molecular mechanism by which NFTs lead to neuronal cell death remains unclear. Surprisingly, we found that the histone demethylase LSD1/KDM1A is mislocalized to NFTs in AD cases and is completely depleted from the nucleus in the degenerating cortical neurons of PS19 Tauopathy mice. To determine if this interaction is functional, we deleted LSD1 in adult mice. Loss of LSD1 systemically in adult mice is sufficient to recapitulate many aspects of AD, including widespread neuronal cell death in the hippocampus and cortex, learning and memory defects, and global gene expression changes that match AD cases. This suggests that NFTs may interfere with LSD1 function by sequestering LSD1 in the cytoplasm. If Tau is functioning through the sequestration of LSD1, then reducing LSD1 in PS19 Tauopathy mice should make these mice more sensitive to pathological tau. Consistent with this, we find that reducing LSD1 in PS19 mice accelerates the depletion of LSD1 from the nucleus. This results in decreased survival, exacerbated paralysis, and increased neurodegeneration. Reducing LSD1 also exacerbates the genome-wide expression changes induced by the PS19 Tau transgene. Based on these data, we propose the following model: pathological tau leads to neuronal cell death in AD by sequestering LSD1 in the cytoplasm and interfering with the continuous requirement for LSD1 to epigenetically repress transcription associated with alternative cell fates. If this model is correct, then overexpressing LSD1 should make it more difficult for pathological tau to deplete LSD1 from the nucleus. This would be expected to delay the ability of tau to kill neurons. Strikingly, we find that viral overexpression of LSD1 in hippocampal neurons of PS19 mice at 8.5 months, when pathological tau is already present, is sufficient to suppress tau-induced neurodegeneration and block the Tau induced immune response through 11 months. In addition we find that overexpression of LSD1 specifically counteracts tau-induced gene expression changes genome-wide. This work establishes LSD1 as a major downstream effector of Tau mediated neurodegeneration and a highly promising target for therapeutic intervention in AD.

Abstract: Immune hyperactivation is a prominent feature of neurodegenerative diseases such as Alzheimer's disease (AD) and other tauopathies. Studies from our lab and others have demonstrated that immune dysregulation is not merely a bystander effect, but rather actively drives disease pathogenesis in various neurodegenerative disease models. Nonetheless, it is not completely understood what mechanisms specifically mediate these disease-enhancing effects of immune dysfunction in neurodegenerative diseases. Recently, aberrant activation of nucleotide sensing pathways has emerged as drivers of immune dysfunction and neurodegeneration in models of Parkinson's, Huntington's disease and amyotrophic lateral sclerosis. Here, we investigate the roles of cyclic GMP-AMP synthase (cGAS), a cytosolic DNA sensor implicated in antiviral interferon signaling, in disease pathogenesis in the P301S tauopathy model. To do this, we crossed P301S transgenic mice to *Cgas* knockout mice to generate transgenic and non-transgenic littermates expressing two, one or no copies of *Cgas,* and analyzed the effects of *Cgas* deletion on the molecular, cellular and behavioral changes associated with tauopathy. We utilized single nuclei RNA sequencing of aged P301S and non-transgenic hippocampi to generate robust molecular and cellular profiles of neurons and glial cells to ascertain genotype specific effects. Interestingly, our analyses revealed that *Cgas* deletion significantly reduced microglial and astrocyte transformation to interferon-enriched disease signatures, and mitigated pyramidal neuron loss in P301S mice. Further immunohistochemical analyses showed that *Cgas* deletion abolished tauopathy-associated synapse loss in CA1 neurons. Lastly, we performed Morris water maze tests to analyze spatial learning and memory. Striking, *Cgas* deletion completely rescued spatial learning, as well as short and long term memory impairments in P301S mice. Altogether, our results identify cGAS signaling as a disease enhancing mechanism that drives adverse cellular, synaptic, and cognitive changes in tauopathy.

Title: Epigenetic Treatment of Behavioral and Physiological Deficits in a Tauopathy Mouse Model

Authors: *W. WANG, C. QING, T. TAN, F. YANG, J. WILLIAMS, Z. YAN;
State Univ. of New York at Buffalo, Buffalo, NY

Abstract: Epigenetic abnormality is implicated in the cognitive decline associated with neurodegenerative diseases, such as Alzheimer's disease (AD). Accumulation of neurofibrillary tangles composed of hyperphosphorylated tau is a common feature of AD. Transgenic mice that express mutant P301S human tau protein develop AD-like progressive tau pathology and cognitive impairment. Here, we show that the euchromatic histone-lysine N-methyltransferase 2 (EHMT2) is significantly elevated in the prefrontal cortex (PFC) of P301S Tau mice (5-6 months old), leading to the increased repressive histone mark, H3K9me2, which is reversed by treatment with the selective EHMT inhibitor UNC0642. Behavioral assays show that UNC0642 treatment induces the robust rescue of spatial and recognition memory deficits in P301S Tau mice. Concomitantly, the diminished PFC neuronal excitability and glutamatergic synaptic transmission in P301S Tau mice are also normalized by UNC0642 treatment. In addition, EHMT inhibition dramatically attenuates the level of hyper-phosphorylated tau in PFC of P301S Tau mice. Transcriptomic analysis reveals that UNC0642 treatment of P301S Tau mice has normalized a number of dysregulated genes in PFC, which are enriched in cytoskeleton and extracellular matrix organization, ion channels and transporters, receptor signaling and stress responses. Together, these data suggest that targeting histone methylation enzymes to adjust gene expression could be a potential therapeutic strategy for cognitive and synaptic deficits in neurodegenerative diseases associated with tauopathies.

Title: The role of sleep in the progression and treatment of Alzheimer's Disease

Authors: *S. MARTIN, L. SHAREK, J. LORD, G. DIERING;
Univ. of North Carolina Chapel Hill, Chapel Hill, NC

Abstract: Sleep is an essential physiological behavior that supports brain health and cognitive function. In Alzheimer's disease (AD), a devastating neurodegenerative disorder, patients experience accelerated sleep loss which can be correlated with AD onset and contribute to AD

progression. Tau is an axonal microtubule stabilizing protein that forms aggregates in AD and contributes to the cognitive decline, synapse loss and neuronal death. Tau mislocalization and aggregation at synapses may impair sleep and restorative sleep-dependent homeostatic plasticity. I hypothesize that sleep disruption occurs early in AD progression and subsequently drives further tau mislocalization and aggregation, and cognitive decline. Preliminary sleep behavior data using P301S (PS19) transgenic mice shows that differences in sleep behavior arise as early as 3 months in females and 6 months in males. Accumulation of tau becomes apparent between 6-9months. These results highlight sex differences in the onset of sleep disruption and support sleep disruption as an early-stage symptom. Endocannabinoids provide an intriguing avenue for therapeutic intervention because of their role in promoting sleep and anti-inflammatory signaling. Preliminary work shows that sleep disruption in PS19 mice can be acutely reversed by increasing the endocannabinoid anandamide. The objectives of this work are to investigate the link between sleep loss and tau aggregation and to identify the therapeutic window targeting endocannabinoid signaling during sleep in advance of tau pathology and cognitive decline. These studies will provide a deeper understanding of the behavioral and molecular changes that occur during abnormal sleep in AD and highlight endocannabinoids as a suitable signaling pathway for enhancing the restorative benefits of sleep.

Title: Characterization of signaling pathways associated with neurodegeneration in skin fibroblasts from patients with familial Alzheimer's (FAD-PS1 M146L/A246E)

Authors: *G. LOPEZ-TOLEDO[1], M. SILVA-LUCERO[2], J. ARIAS-MONTAÑO[1], M. CARDENAS-AGUAYO[2];
[1]Physiology, Biophysics and Neurosciences, CINVESTAV-IPN, Mexico City, Mexico;
[2]Physiol., Sch. of Medicine, UNAM, Mexico City, Mexico

Abstract: *Introduction:* Alzheimer's disease (AD) is a neurodegenerative disorder characterized by memory loss. There are two types of AD: sporadic and familial Alzheimer's. Mutations in the genes of amyloid precursor protein (APP), presenilin1 (PS1), and presenilin 2 (PS2) cause the early onset familial AD contributing to APP processing, Amyloid Beta peptide generation and tau protein hyperphosphorylation. It is known that the identification of early biomarkers for the diagnosis of AD represents a challenge. It has been suggested that the use of peripheral cells other than neuronal cells such as mesenchymal cells from bone marrow or dental pulp, blood cells, and fibroblasts derived from patients with familial or sporadic AD represent an opportunity

to detect related molecular changes within neurodegenerative pathways that have been previously studied in the brains of Alzheimer's patients and neuronal cultures from murine Alzheimer's models that together with other diagnostic clinical criteria, could allow the early identification of AD patients. *Methods:* We cultured skin fibroblasts from patients with familial Alzheimer's disease with a Presenilin 1 mutation (M146L or A246E) and apparently healthy individuals obtained from the Coriell Institute (New Jersey) cell repository in Earl MEM salts medium with 15% non-inactivated Fetal Bovine Serum. These cells were characterized by immunodetection of the markers Vimentin and S100A4 and their chromosomal stability through karyotyping. From an in silico analysis of the data reported by Antonell's group in 2016 from brain samples from patients with FAD-PS1, we identified pathways associated with neurodegeneration, which we confirmed using Western blot techniques and a proteomics study performing 2-DE gels and mass spectrometry analysis. *Results:* We identified differences in the expression of proteins related to the autophagic-lysosomal pathway (LC3-II, LAMP2, and CATD) in affected individual´s fibroblasts. We also identified changes in kinases related to hyperphosphorylation of tau protein (ERK1/2, GSK3 and ptau231), and proteins related to cellular stress (HSP60 and HSP70), changes that have been identified in nerve tissue samples from patients with neurodegenerative diseases such as AD. *Conclusion:* In summary, our results indicate that samples derived from peripheral tissue from patients with FAD-PS1, such as fibroblasts, show altered pathways associated with neurodegeneration, giving evidence that fibroblasts can be useful in the search and modeling of pathways related to neurodegeneration as well as for identification of early biomarkers related to AD.

Title: Elovanoids (ELVs) and Neuroprotectin D1 (NPD1) counteract senescence programing by inverting the amyloidogenic pathway.

Authors: *K. V. DO, M.-A. I. KAUTZMANN, B. JUN, N. G. BAZAN;
LSU Hlth. Sci. Ctr., New Orleans, LA

Abstract: *Purpose:* Aβ42, a product of the amyloidogenic pathway, is a component of drusen in age-related macular degeneration (AMD) and of senile plaques in Alzheimer’s disease (AD). In AMD, Aβ triggers inflammation, perturbs retina function and activates senescence signaling. We showed recently that Elovanoids (ELVs) counteract Aβ-peptide-induced senescence programing (Do KV et al., PNAS, 2019). In this study, we aim to overexpress the amyloidogenic pathway.

We hypothesize that ELVs and NPD1 reverse the formation of Aβ towards the pro-survival sAPPα and downregulate the senescence signaling in primary human retinal pigment epithelial cells. *Methods:* Plasmid construct containing Swedish double mutant APP protein (APPsw), which dominantly produces sAPPβ (a precursor of amyloid beta), was transfected into primary human RPE cells. After 24h, ELVs alone, NPD1 alone were added at 500nM concentrations in sAPPβ overexpressed cells. After 24h and 48h of treatment, the medium were collected, precipitated and subjected to the Western Blots for holo-APP precursor, sAPPβ for amyloidogenic pathway, and sAPPα for non-amyloidogenic pathway. The cellular samples are also collected for α-secretase (ADAM10), β-secretase (BACE1) and γ-secretase (PS1) measurement. eGFP transfected cells were used as negative controls. The mRNA was extracted and analyzed the senescence gene expression using qPCR. *Results:* The senescence in the sAPPβ overexpressed cells was confirmed by qPCR at 24h, consistent with the activation of amyloidogenic pathway. At 24h, higher sAPPα production was observed in the ELV treatment. At 48h, higher sAPPα production was observed in the NPD1 treatment. In contrast, reverse production of sAPPβ was observed, lower level with ELV treatment 24h and with NPD1 at 48h. An equal amount of holo-APP, regarded as total of all sAPP forms, was detected in all studied conditions. The mechanisms involve the increase of α-secretase (ADAM10) and decrease of β-secretase (BACE1) by ELVs and NPD1. The senescence signaling is also inhibited by the treatment with ELVs and NPD1 in the sAPPβ overexpressed cells. *Conclusions:* ELVs and NPD1 shift the amyloidogenic pathway to the non-amyloidogenic sAPPα and protect the human RPE cells from senescence, which is activated by overexpression in Swedish double mutant APP. However, the ELVs have earlier protection, at 24h, when compared with NPD1.

Title: Review: vitamin k_2 shows promise as a novel therapy for alzheimer's disease

Authors: *A. POPESCU;
Harvard Extension Sch., Cambridge, MA

Abstract: We review the evidence for a relationship between vitamin K_2 and Alzheimer's disease, emphasizing the need for further research. Because K_2 has emerged as an essential nutrient for human health, we propose that it is of critical importance to investigate its role in Alzheimer's, a debilitating disease for which no cure has been developed. K_2, also known as menaquinone (MK), is one of two forms of vitamin K, and it has been shown to impact neuroinflammation, cardiovascular health, and cognition. K_2 is essential for activating Gla proteins such as the matrix Gla protein and growth arrest-specific protein 6 (Gas6). The matrix Gla protein is important for reducing arterial calcification, and Gas6 regulates cell growth and is

widely expressed in the nervous system. The hallmark of Alzheimer's is the extracellular deposits of neurotoxic beta-amyloid (Aβ) plaques in the brain. Two different studies used cell cultures to demonstrate that K_2 and Gas6 suppress Aβ cytotoxicity and strongly suggest the antiapoptotic effects of K_2 (Yagami et al., 2002; Hadipour et al., 2020). Two other studies that used different types of glial cells (microglia and astrocytes) and distinct forms of K_2 (MK-4 and MK-7) investigated the role of K_2 in glial activation and both found that K_2 inhibited the production of proinflammatory cytokines (Saputra et al., 2019; Yang et al., 2020). Three European population studies provide evidence that K_2 improves vascular health by reducing arterial calcification, arterial stiffness, and the risk of cardiovascular events (Geleijnse et al., 2004; Beulens et al., 2009; Knapen et al., 2015). We propose that K_2 can influence the development of Alzheimer's through its role in vascular health. Although low levels of K_2 have been associated with the progression of other neurodegenerative diseases such as Multiple Sclerosis and Parkinson's disease, there is a lack of research on the role of K_2 in Alzheimer's. We conclude that it is necessary to perform clinical studies that directly explore the role of K_2 in Alzheimer's.

Title: Three-dimensional organoid-like cultures promotes the differentiation of human dental pulp mesenchymal stem cells into neuronal phenotype

Authors: *A. I. GUTIÉRREZ-MALACARA[1], M. SILVA-LUCERO[1], G. LÓPEZ-TOLEDO[1], M. CARDENAS-AGUAYO[2], C. TORRES-ROSAS[1];
[2]Dept. of Physiology, Sch. of Med., [1]Natl. Autonomous Univ. of Mexico (UNAM), Mexico City, Mexico

Abstract: Introduction: Dental pulp stem cells (DPSCs) are capable of both self-renewal and multi-lineage differentiation, which play a positive role in dentinogenesis. Dental pulp is a vital structure present in the inner core of tooth containing mesenchymal stem cells (MSCs). Gronthos *et al*., 2000, isolated the stem cells from dental pulp and termed it as DPSCs. DPSCs are one of the widely researched tissues for its easy availability without morbidity to the human organs or tissues. It is considered as an organic waste, which can be retrieved easily from dental clinic trash bin. Teeth extracted for orthodontic purposes, and impacted third molars in young adult people constitute good source of stem cells. Various studies have proved DPSCs can differentiate into osteogenic, neurogenic myogenic, vasculogenic, chondrogenic, and adipogenic lineages. DPSCs unlike other stem cells have distinction, that is, it is derived from neural crest cells and has better lineage potential to differentiate into neural tissues than bone marrow-derived stem cells. In neurodegenerative diseases, there is an important neuronal loss, thus neuronal differentiation from DPSCs could be a suitable source of stem cells with potential to differentiate into neural cells. Methods: We isolated DPSCs from a first molar donated from a healthy female of 46 years old. We used an enzymatic mix of collagenase-dispase to disaggregated the tissue, incubated at 37o C for 45 min, shaking it every 15 min, to obtain the cellular suspension that was then seeded on a T25 culture bottle. Cells were cultured at 37oC and 5% of CO2 in an incubator. Culture medium was DMEM-F12 + 10% inactivated FBS. Cells were banked in a Nitrogen tank or further storage.Results: Cells were characterized by Western blot and RT-PCR for the detection of phenotype markers such as CD73, CD105, CD166, Oct-4, SOX-2, Nanog and BIII-Tubulin, and Nestin, and they were negative to hematopoietic markers (CD14, CD34 and CD45). To form the organoid like structures we followed Lancaster et al 2014, Natures´s protocol, in brief, cells were cultured for 24-48 h without substrate and then for 35 days in Vitro (DIV) in different surfaces and scaffolds. After 35 DIV cultured on Geltrex scaffold, DPSCS, formed organoid like structures, that were positive to BIII-Tubulin, MAP-2, tau and NeuN, indicating its neuronal differentiation.Conclusion: This 3D culture approach for DPSCs, has an important therapeutic implication for the treatment of neurodegenerative disease, such as Alzheimer´s disease, Huntington disease and Parkinson´s disease. And for modeling the neuropathologies to better understanding the molecular process involve an to test potential new drugs.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder resulting in memory loss and a reduction in the ability to perform activities of daily living. The role of caring for someone with AD in an African American (AA) family often falls on daughters, and the burden of caregiving can increase stress and depression, which are independent risk factors for AD. Furthermore, older AAs and women have an increased risk of developing AD than older whites and men. Taken together, these differences in risk suggest that AA women who are caregivers of a parent with AD are at high risk for developing AD. This phase I study compared the cognitive, motor, and psychosocial benefits of a well-established 12 week, 20-lesson adapted Argentine Tango intervention (N=24) to a no-contact control group (N=10) in middle-aged (45-65 years) AA women who are most at risk for the development of AD from parental history. Out of the thirty-four participants, some women (n=17) were familial caregivers; therefore, the impact of caregiving burden in AA women was examined in this subset. Participants were tested for inflammatory biomarkers in their blood and on their cognition, physical/motor ability, and mood before and after the intervention or control. Participants in the study were on average 60 years old, had a BMI of 30, and were highly educated. Significant effects were noted in the Tango group after the intervention, which showed reduced levels of tumor necrosis factor-alpha ($p=0.011$), interleukin-7 ($p=0.003$) , and interferon-gamma ($p=0.011$); improved performance on the maintenance of 30 s chair stand task ($p=0.018$), the Fullerton Advance Balance Scale ($p=0.023$), and inhibition of the color word interference test ($p=0.031$). Additionally, large effects were noted in Trails Making Test, as well as small-moderate effects in body position spatial task, and TOL move accuracy for the Tango group. Further studies should be conducted with this dance intervention in larger groups, as the trial resulted in substantial cognitive and motor improvements and reduction in inflammatory biomarkers through a non-pharmacologic and affordable solution that may decrease the risk of developing AD among AA familial caregivers most at risk.

Title: Assessing cell survival and immunosuppression efficacy in intracranial human neural stem cell transplantation

Authors: ***S. N. MASON**[1], O. N. KASHLAN[2], K. S. CHEN[2], A. W. STEBBINS[1], D. RIGAN[1], G. G. MURPHY[3], E. L. FELDMAN[4], L. M. MCGINLEY[1];
[1]Neurol., [2]Neurosurg., [3]Mol. & Integrative Physiol., Univ. of Michigan, Ann Arbor, MI;
[4]Neurol., The Univ. of Michigan, Ann Arbor, MI

Abstract: Highly developed and effective immunosuppression (IS) protocols to prevent graft rejection are key to clinical translation of cellular therapies for the treatment of Alzheimer's disease (AD). Although Tacrolimus is a frequently used immunosuppressive agent for xenotransplantation applications, transplanted human cell survival was unreliable in our preliminary studies, with few grafts present 6 weeks post-transplant. Graft survival is typically not evaluated until terminal histology, making it challenging to efficiently assess IS *in vivo*. Bioluminescence Imaging (BLI) is a molecular imaging tool that uses light generated from a Luciferase enzyme-substrate for signal detection specific to live cells. Integrating BLI with cell transplantation would address these technical challenges and provide crucial insight into graft survival. Therefore, we set out to establish a BLI-based method of tracking cell viability *in vivo* to simultaneously assess graft survival and compare IS regimens in real time.
Human neural stem cells (hNSCs) were modified to express dual Firefly Luciferase and green fluorescent protein reporters (hNSC-FLuc+/GFP+). hNSCs were administered to male C57BL/6J mice at 8 weeks of age (360k total cells; 3 bilateral fimbria fornix injections). IS groups included Tacrolimus (Tac, 5mg/kg IP), Tac plus monoclonal antibodies (Mab) to CD40L and CD4 (20 mg/kg IP), Mab alone, and no IS. BLI validation controls included 180k unlabeled hNSC or dead hNSC-FLuc^{+}/GFP^{+}, with contralateral 180k live hNSC-FLuc^{+}/GFP^{+}. Serial BLI was performed on postoperative day (POD) 2, 7, 10, and weekly for 8 weeks using the IVIS Spectrum *In Vivo* imaging system.
Dead and unlabeled cell controls validated that BLI signal resulted only from viable, labeled cells. BLI signal correlated histologically with viable hNSC grafts. Robust BLI signal was visible in all mice at POD2. The no-IS group lost BLI signal after POD7 and the Tac group after

POD28. However, robust signal was seen in 100% of the Tac+Mab and Mab alone groups at POD56, indicating robust hNSC graft survival. Quantification showed significantly increased total flux in both Mab-receiving groups compared to no IS and Tac groups. Therefore, Mabs enable hNSC survival for 8+ weeks in BL6 mice. Further study of Mab IS has demonstrated robust hNSC survival through 6 months post-transplant. An additional study in 5XFAD mice is ongoing to assess Mab-based IS and hNSC survival in an AD mouse model.
In conclusion, CD4 and CD40L IS without Tacrolimus is sufficient for robust graft survival. Tacrolimus is not always well-tolerated in mice nor patients, so a transition toward Mab-based IS may be advantageous in cellular therapies.

Title: Memory impairments in Tg19959 and APP/PS1 AD model mice are alleviated by eEF2K inhibitor A-484954

Authors: *N. KASICA[1], W. YANG[2], X. ZHOU[2], T. MA[2];
[1]Wake Forest Univ., Winston Salem, NC; [2]Wake Forest Univ., Winston-Salem, NC

Abstract: Mounting evidence indicates synaptic failure as an early and key event in Alzheimer's Disease (AD) pathophysiology. Maintenance of long-term memory and synaptic plasticity requires *de novo* protein synthesis. Phosphorylation of mRNA translation factor eukaryotic elongation factor 2 (eEF2) by its kinase eEF2K results in inhibition of general protein synthesis. Previous studies have shown elevated levels of eEF2 phosphorylation in *post mortem* AD human brain tissue and in AD mouse models. Here we investigated whether suppression of eEF2 phosphorylation via eEF2K inhibitor A-484954 can alleviate AD-associated synaptic failure and memory impairments. Aged Tg19959 mice (6-9 months), APP/PS1 (12-16 months) and age-matched controls were treated with a subcutaneous pellet containing A-484954 or vehicle. The pellet continuously releases treatment over 30 days. Starting two weeks after pellet placement, the mice underwent cognitive assessment via the Novel Object Recognition (NOR) and Morris Water Maze (MWM) tasks. We found that cognitive impairments displayed in aged Tg19959 and APP/PS1 mice were alleviated with treatment of A-484954. Brain tissue from these mice also underwent high performance liquid chromatography (HPLC) to assess drug concentration.

In addition, Golgi-Cox stain was done to assess dendritic spine density and morphology. Spine analysis indicates a rescue in levels of mature spines in the CA1 region of the hippocampus in APP/PS1 mice treated with A-484954. Taken together, our results suggest that treatment with a eEF2K inhibitor, A-484954, alleviates cognitive impairments and restores synaptic morphology in a mouse model of AD.

Title: Mitochondrial dysfunction by lactate dehydrogenase B deficiency causes oxidative stress and neurodegeneration via suppressing AdipoR1/PGC1-alpha signaling.

Authors: J.-S. PARK, K. SAEED, M.-G. JO, M.-H. JO, M.-W. KIM, H.-J. LEE, ***M.-O. KIM**; Gyeongsang Natl. Univ., Jinju, Korea, Republic of

Abstract: Age-dependent decrease of mitochondrial function and oxidative stress play critical role in neurodegeneration. Lactate dehydrogenase B (LDHB) is a glycolytic enzyme that catalyzes the interconversion of pyruvate and lactate in brain. Osmotin, a homolog of mammalian adiponectin is known to regulate AdipoR1/ PGC1-alpha signaling. Of note, PGC1-alpha downstream signal pathway known to regulate mitochondria biogenesis and antioxidative stress. In this study, To elucidate the role of Osmotin in mitochondrial function and to test the hypothesis that mitochondrial dysfunction induced by LDHB deficiency plays an significant role in neurodegeneration, we conducted an experiment using LDHB knockout ($LDHB^{-/-}$) mice. Depletion of LDHB proteins from the $LDHB^{-/-}$ mice, resulted in a dramatic increase oxidative stress in cortex and hippocampus and elevated the expression of apoptosis mediators such as Bax (Bcl-2-associated X protein), Caspase-3, Cytochrome C in the cortical and hippocampal regions. Moreover, we assessed the LDHB knockout-induced oxidative stress-mediated neuroinflammation, neuronal apoptosis, and cognitive deficits in $LDHB^{-/-}$ mice. Treatment with osmotin markedly attenuated LDHB knockout-induced oxidative stress, synaptic dysfunction, and learning and cognitive deficit via upregulating AdipoR1/ PGC1-alpha signaling. In briefly, these findings reveal that osmotin rescues oxidative stress-mediated neuroinflammation, neurodegeneration via upregulating AdipoR1/ PGC1-alpha signaling in $LDHB^{-/-}$ mice. This research suggests that suppression of LDHB may be closely related with the oxidative stress or progression of neurodegeneration and osmotin might be potential antioxidant and mitochondria biosynthesized agent via upregulating AdipoR1/ PGC1-alpha signaling.

Title: Effects of tart cherry extract and omega fatty acids on behavioral outcomes and amyloid beta pathology in the 5xFAD animal model of Alzheimer's disease

Authors: *Z. BOWERS[1,2], P. MAITI[3,1], L. PALADUGU[1], G. DUNBAR[3,4,1];
[1]Central Michigan Univ., Mount Pleasant, MI; [2]Saginaw Valley State Univ., Saginaw, MI; [3]Field Neurosci. Inst. Lab. for Restorative Neurol., Saginaw Michigan, MI; [4]Field Neurosciences Institute, Ascension of St. Mary's Hosp., Saginaw, MI

Abstract: Background: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder. The two cardinal protein aggregations observed in the AD brain are β-amyloid peptide (Aβ) and subsequently hyper phosphorylated tau. Multiple diseases can cause dementia, but AD is the most common accounting for nearly 70% of cases. Nutraceuticals or foods identified as giving health benefits have demonstrated progress in animal models and humans. There are currently multiple clinical trials looking at treating patients with exogenous antioxidants and omega fatty acids. This study tested TBR, a proprietary blend of tart cherry extract and omega fatty acids in the 5xFAD model of Alzheimer’s disease.
Methods: Six and 12-month, 5xFAD mice and age matched WT controls were orally treated every other day for two months. Treatment was with 60mg/kg of TBR or the equivalent dose of vehicle (.05% methylcellulose). All animals were tested pre and post treatment using the open field (OF) and novel object recognition (NOR) test. Post treatment the animals were tested using the Morris water maze (MWM). Twenty-four hours post treatment the animals were euthanized, and the tissue was collected to analyze differences in neuronal morphology, neurodegeneration, amyloid plaque load and glial activation.
Results: TBR has been demonstrated to reduce deficits in this model of AD. 5xFAD animals that were treated with TBR had reduced anxiety as measured by boli in the open field test and latency to find the escape platform during the probe and reverse trial of MWM. Additionally, GFAP was decreased in the AD+TBR vs AD+VEH when measured by western blot. It is essential to understand the separate effects by which amyloid beta and tau disturb the cognitive and the molecular functioning of the brain.**Support for this study was provided by the Field Neurosciences Institute and the John G. Kulhavi Professorship in Neuroscience at CMU*

Title: Modulating $p75^{NTR}$ signaling with the small molecule LM11A-31 prevents and reverses parvalbumin interneuron degeneration in a mouse model of Alzheimer's disease

Authors: T. L. MCHUGH[1], *D. A. SIMMONS[1], N. BELICHENKO[1], S. SEEMAN[1], S. M. MASSA[2], F. M. LONGO[3];
[1]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA; [2]Dept. of Neurol., SFVAMC & UCSF, San Francisco, CA; [3]Dept. of Neurol. and Neurolog. Sci., Stanford Univ. Med. Ctr., Stanford, CA

Abstract: Cognitive deficits prevalent in Alzheimer's disease (AD) patients and mouse models can be partially attributed to neural network hyperexcitability due to inhibitory GABAergic interneuron (IN) dysfunction. The parvalbumin (PV)-expressing sub-type of these INs is vulnerable to amyloid toxicity and shows functional deficits and degeneration early in AD progression. PV-INs are ensheathed by extracellular matrix structures termed perineuronal nets (PNN), which support their homeostasis and are depleted in AD. This depletion is driven by proNGF, which can induce degeneration via the p75 neurotrophin receptor ($p75^{NTR}$). The small molecule $p75^{NTR}$ ligand, LM11A-31 (C31) inhibits degenerative and promotes trophic signaling, ameliorating cognitive deficits and AD-related pathology in mouse models of the disease. C31 also inhibits proNGF binding to $p75^{NTR}$. Here, we examined the effects of C31 on PV-IN atrophy in the $hAPP^{Lond/Swe}$ ($APP^{L/S}$) AD mouse model. C31 (25 mg/kg) or vehicle (water) was administered by oral gavage twice daily (5 days/week) to male $APP^{L/S}$ and non-transgenic (nTg) mice for 3 months starting at either 4 - 5.5 or 10.5 - 12 months of age (*n*=6-10 mice/group). Immunostaining demonstrated $p75^{NTR}$ expression in PV-INs in hippocampus and cortex of $APP^{L/S}$ mice. There was no difference in hippocampal (CA1/2/3) PV-IN number between $APP^{L/S}$ and nTg mice at either age examined, however marked neurite degeneration was evident. At 7-8.5 months-old, area occupied by PV-containing neurites was reduced by 37% and length by 18% in $APP^{L/S}$ mice; branching complexity was also diminished. C31 prevented these deficits. At 13.5-15 months-old $APP^{L/S}$ mice had PV neurites that were 23% shorter than those in nTg mice along with reduced area and complexity. C31 treatment, initiated after degeneration was already well established, restored PV neurite area, length and complexity to nTg levels, representing an actual element of pathology reversal. Protective effects of C31 could occur, in part, by blocking proNGF-induced PNN dysfunction. Fewer PV neurons were encompassed by PNNs in $APP^{L/S}$ versus nTg hippocampus at both ages, and PV immunostaining intensity in PV/PNN-labeled cells was diminished. C31 did not prevent decreased PV-PNN number but PV

staining intensity per PV/PNN-labeled neuron was greater in treated $APP^{L/S}$ mice, suggesting that C31 may help maintain PV-IN homeostasis. In all, these results indicate that C31 can prevent and reverse PV-IN atrophy in AD mice with appreciable pathology. Most AD patients begin treatment at advanced pathological stages, thus C31's restorative effects may have particular clinical relevance.

Title: Ibuprofen induces differences in NMDA and AMPA receptor functions between males and females in 5xFAD mice

Authors: *E. P. SACKINGER[1], J. RAUENHORST[1], K. R. MAGNUSSON[2];
[2]Dept Biomed Sci, Coll Vet Med. & Linus Pauling Inst., [1]Oregon State Univ., Corvallis, OR

Abstract: Characteristics of Alzheimer's disease include memory deficits and amyloid plaques. Interactions between amyloid and N-methyl D-aspartate receptors (NMDAR) appear to contribute to declines in synaptic plasticity. Our lab discovered that the 5xFAD mouse model of amyloid overexpression showed hyperactive NMDAR responses at 4 months of age, which could lead to excitotoxicity or increased amyloid interactions. Previously, our lab determined that ibuprofen (IBU), a non-steroidal anti-inflammatory drug (NSAID) can decrease NMDAR expression in male mice, so we treated 5xFAD mice with ibuprofen for 2 months, in order to try to reduce the increased synaptic NMDAR responses and improve spatial memory. At 2 months of age, hemizygous 5xFAD or wildtype (WT) mice were fed either regular chow or chow with 375 ppm of ibuprofen. At 4 months of age, mice underwent testing in the Morris water maze (MWM) and then were used for electrophysiology. The MWM involved acclimation (2 days), place & probe trials (4 days), reversal trials (1 day) and cued trials (1 day). For electrophysiology, mice were transcardially perfused with calcium-free cold artificial cerebral spinal fluid (aCSF). Brain slices (300μm) in normal aCSF were placed on a multielectrode probe (MED64) to examine the Schaffer collateral to CA1 synapses in the hippocampus. The field

excitatory post synaptic potential (fEPSP) was analyzed in a drug study with the use of AMPA (DNQX), GluN2A (PEAQX), GluN2B (Ro25-6981) and all NMDA receptors (AP5) antagonists. Following equilibration, an input (fiber volley)/output (fEPSP) curve was generated and analyzed by comparison of linear curve fit.All groups showed improved performance across place trials (p=.04-<.0001) except female WT IBU fed mice, but there was no significant effect of treatment or genotype on long term memory or reversal trials with the hidden platform. IBU did improve performance in probe trials in hemizygous females and IBU-fed mice overall showed more perseveration in reversal probe trials. Based on curve fit differences for electrophysiology, both male and female 5xFAD showed increased I/O responses for NMDAR and GluN2A (p=.007-<.0001). IBU increased responses for NMDAR, GluN2A and AMPAR in both WT (p<.0001) and 5xFAD (p=.02-.0009) females, but decreased responses to GluN2B and AMPAR in 5xFAD males (p=.045-.0002) and had no effect on WT males (p=.35-.94). Overall, IBU improved memory in 5xFAD females, potentially by further increasing glutamatergic signaling in the hippocampus, but reduced cognitive flexibility. In addition, it appeared that IBU had opposite effects on NMDARs and AMPARs in females versus males.

Title: Early assessment of metabolic alterations under calcineurin inhibition using ^{1}H magnetic resonance spectroscopy in a canine model of preclinical Alzheimer's disease

Authors: *J. N. LINGAD[1], C. E. L. STARK[1], C. M. NORRIS[3], E. HEAD[2];
[1]Neurobio. and Behavior, [2]Pathology and Lab. Med., Univ. of California Irvine, Irvine, CA;
[3]Pharmacol. and Nutritional Sci., Univ. of Kentucky, Lexington, KY

Abstract: Background: In Alzheimer's disease, increased expression and activity of the protein phosphatase calcineurin (CN) appears at early stages of cognitive decline and has been shown to exacerbate Aβ pathology, synaptic dysfunction and chronic neuroinflammation (Norris et al., 2005). A wealth of evidence for the amelioration of these changes following CN inhibition suggests that CN inhibitors (CNI) may be a promising therapeutic for preventing or slowing AD pathogenesis (Reese & Taglialatela 2011). The current study is investigating the efficacy of chronic treatment with Tacrolimus, an FDA-approved CNI, as an anti-AD treatment in a canine model of preclinical AD, where interim findings are presented after 1 year of treatment.
Methods: Fifteen middle-aged beagles (5-8 years old) are treated with Tacrolimus (0.075 mg/kg) twice daily and are compared to age-matched beagles maintained under placebo. The dogs undergo extensive cognitive behavioral testing at baseline as well as throughout the course

of treatment for the next two years and undergo MRI scanning at 3T every year following baseline. ^{1}H magnetic resonance spectroscopy (^{1}H-MRS) was used to probe neuronal integrity and astrocyte metabolism of the hippocampus and posterior cingulate gyrus (PCG). **Results:** At baseline, dogs demonstrated an age-dependent decline of spatial memory abilities, consistent with prior evidence of spatial impairment in beagles beginning at middle age (Cotman & Head 2008). ^{1}H-MRS measures in the PCG at baseline showed levels of N-acetylaspartate (NAA), a marker of neuronal integrity, that were positively correlated with baseline spatial memory performance. Furthermore, levels of myo-inositol, an astrocyte marker, were positively correlated with age, in line with age-related increases of myo-inositol commonly observed in aging and AD (Wang et al., 2015). In the hippocampus, an increase in myo-inositol levels was found one year later only among placebo-treated dogs. **Conclusions**: Measurements of *in vivo* metabolism using ^{1}H-MRS offer novel insight into the metabolic alterations that underlie cognitive abilities in middle-aged beagles and provide early evidence for the efficacy of Tacrolimus in protecting against age-related metabolic alterations.

Title: Development of new mouse strains containing alleles of loci associated with increased risk of late-onset Alzheimer’s disease (LOAD)

Authors: *S. KAWAUCHI[1], S. FORNER[1], J. NEUMANN[2], A. WALKER[1], J. ALCANTARA[3], G. MACGREGOR[1], K. GREEN[1], F. LAFERLA[1], A. TENNER[1];

Abstract: Efforts to develop therapy for Alzheimer’s disease have consistently failed, despite success in preclinical trials in animal models. This suggests that current animal models do not recapitulate human AD in cellular mechanisms and/or physiological conditions. Development of new predictive animal models of LOAD are required to advance the field. The mission of MODEL-AD is to develop, characterize, and distribute Next-Gen preclinical models for LOAD using open science. Our approach is to engineer mouse models to express combinations of genetic variants identified as risk factors in human LOAD populations in genome-wide association studies (GWAS). To assess the role of LOAD risk alleles, homozygous mutations of GWAS-risk factors are introduced on several AD platform models (such as a 5xFAD, and a humanized Aβ allele). We have developed 10 risk models so far (ABCA7, BIN1, PICALM, ABI3, TREM2, CLU, EPHA1, SPI1). Prior to deep-phenotyping, new models are analyzed by

RNA-seq from hippocampus and cortex. This approach enables us to capture early responses to the risk factors and correlate transcription profiles in the mouse models to key human disease processes and pathways. Analysis is being performed at 4 and 12 months of age and the candidate models are analyzed for pathological phenotypes to 24 months of age. Deep phenotyping is performed using clinically relevant measures including metabolomics, biomarkers, neuropathology, electrophysiology, imaging and cognitive assays. This comprehensive approach will determine key phenotypes and the therapeutic time window for each model. All models are made available without restriction from the Jackson Laboratory, and all data will be shared via the AD Knowledge Portal. For more information see www.model-ad.org

Title: Efficacy of a small molecule tau inhibitor in young and aged htau mice

Authors: ***E. J. DAVIDOWITZ**[1], P. LOPEZ[1], H. JIMENEZ-BRAVAR[2], J. KOPPEL[2], L. ADRIEN[2], J. EUN[2], A. WOLIN[2], P. DAVIES[2], J. G. MOE[1];
[1]Oligomerix, Inc., White Plains, NY; [2]The Litwin-Zucker Res. Ctr. For The Study Of Alzheimer's Dis., The Feinstein Inst. For Med. Research, Northwell Hlth., Manhasset, NY

Abstract: The premise of this program is that tau oligomers are the acutely toxic species of tau and that their reduction will modify the course of AD. We have shown that tau oligomers cause disruption of neuronal signaling and inhibit the formation of memory in mice (Fá et al., Sci Rep. 2016 Jan 20;6:19393), and that certain forms of tau oligomers are toxic when applied to cultured neurons (Tian et al., Int J Cell Biol. 2013;2013:260787). The discovery of small molecule inhibitors was performed with assays targeting tau self-association, the initial step in the tau aggregation cascade. Preventive efficacy studies were performed in htau (Davidowitz et al., J Alzheimers Dis. 2020, 73:147-161) and JNPL3 mice that demonstrated that the lead compound reduced self-association of soluble tau and inhibited formation of insoluble tau aggregates. The

overall goal of this program is to discover and develop small molecule therapeutics targeting tau self-association for the treatment of AD and ADRD. Here, we present results from a therapeutic study comparing efficacy of the lead compound in the htau mouse model of tauopathy relative to a preventive study in htau. Measurements of therapeutic efficacy include reduction of insoluble and hyperphosphorylated tau, and amelioration of behavioral deficits. Therapeutic studies were independently performed in male htau mice. Mice were aged to 7 months (baseline) and treated for 5 months. Each study had 4 groups including baseline (n=20), vehicle (n=25), and two treatment groups (n=25, each) that were administered 40 or 80 mg/kg dose of lead compound formulated in feed. Working memory of htau mice (baseline group) was analyzed using Barnes maze. Biochemical analyses of levels of total tau, phosphorylated tau and insoluble, aggregated tau were performed by ELISA. Immunocytochemical examination was performed with 4 tau antibodies (MC1, PHF1, CP13 and RZ3), as well as with Iba1 and GFAP for microgliosis and astrocytosis, respectively, as time permitted under restricted access related to the pandemic. There were no adverse effects due to the compound during the course of the study. There was a 5.5.-fold difference in exposure between the 40 and 80 mg/kg treatment groups. There was dose dependent reduction to baseline levels of insoluble tau phosphorylated at Serine 202 in the cortex and of phospho-tau396,404 in the heat stable fractions from the forebrain and hippocampus. Results of this therapeutic study in conjunction with the results from the preventive study suggest that this small molecule may have potential for developing a drug targeting tau in ADRD.

Title: A Novel DDR1 inhibitor improves memory and reduces pathology in a model of Alzheimer’s Disease

Authors: *M. STEVENSON[1], B. KALAVU[2], A. FOWLER[1], M. HEBRON[3], W. SHI[3], C. WOLF[2], C. MOUSSA[4];

Abstract: Proteinopathies represent a subset of neurodegenerative diseases characterized by aggregated, structurally abnormal neurotoxic proteins. Despite the clear societal burden posed by proteinopathies, a complete understanding of the mechanisms by which these disorders exert their pathological effects remain elusive. A number of these diseases, such as Alzheimer’s Disease (AD), have been demonstrated to exhibit elevated expression of various tyrosine kinases (TKs) in the brains of postmortem patients. TKs such as Discoidin Domain Receptor 1 (DDR1)

are in part responsible for regulating autophagy, the cell's ability to clear waste, in healthy cells, and it is believed that overexpression of TKs may be a culprit of protein aggregation in proteinopathies. Silencing of the genes encoding tyrosine kinase receptors using shRNA constructs has been shown to alleviate levels of amyloid-beta in mice, identifying TKs as potential targets of investigation when examining the pathological mechanisms behind these conditions.Recently, we have begun investigating the use of novel tyrosine kinase inhibitors as a means of mitigating neurotoxic protein burden across animal models of disease. Following four weeks of treatment with BK40197, a potent inhibitor of DDR1, 4 month old male and female transgenic APP mice overexpressing human amyloid precursor protein scored significantly better on the novel object recognition test, a measure of memory impairment, than equal cohorts of mice treated with a vehicle (n=8). We hypothesize that this impairment is associated with early-stage accumulation of amyloid precursor protein, and that inhibition of DDR1 attenuates this process and associated neurodegeneration. We are currently performing western blot and ELISA analysis and immunohistochemistry to confirm that BK40197 treatment does in fact improve behavioral outcomes by alleviating protein burden in an DDR1-mediated manner. We will also probe for levels of amyloid-beta and phosphorylated tau, phosphorylated DDR1, and markers of autophagy such as LC3 and LAMP2A to demonstrate that activating autophagy by inhibiting DDR1 results in decreased levels of neurotoxic protein. These results will provide insight into how tyrosine kinase activity contributes to protein aggregation across disease states, elucidating a potential target for future therapeutic intervention.

Title: Effects of5α-androstane-3α,17β-diol on age-related cognitive decline in the 3xTg mouse model of Alzheimer's disease

Authors: *N. R. KUWAHARA[1], S. BHULLAR[1], K. TANG[1], K. H. JARDINE[2], B. D. WINTERS[2], N. J. MACLUSKY[1];
[1]Biomed. Sci., [2]Psychology, Univ. of Guelph, Guelph, ON, Canada

Abstract: Age-related decreases in gonadal steroid hormone levels have been associated with cognitive decline and an increased risk of developing Alzheimer's disease (AD). AD is characterized by marked sex differences, with women being more likely to develop AD, and show worsened cognitive deterioration at the same stage of the disease. This may in part, reflect the neuroprotective effects of testosterone, since men with high free testosterone levels maintained into old age have a reduced risk of developing AD. Recent studies have suggested that steroid hormone-mediated neuroprotection, may be augmented through the conversion of primary gonadal steroid hormones into metabolites that may act through distinct cellular mechanisms. Previously, we demonstrated that 5α-reduced metabolites of testosterone including 5α-androstane-3α,17β-diol (3α-diol) may play an important role in protecting the brain against AD and may contribute to the observed sex differences. Inhibiting the synthesis of testosterone-derived neurosteroids impaired object recognition memory (ORM) and exacerbated AD-like neuropathology in 6-month-old male triple transgenic AD (3xTg-AD) mice. However, the possible protective effects of 3α-diol itself *in vivo* remain unknown. To determine whether treatment of 3α-diol might protect against the development of cognitive dysfunction, male and female wildtype and 3xTg-AD mice were implanted subcutaneously with 3α-diol diproprionate-filled or empty silastic capsules at 3 months of age (n=15-16 per treatment group). After 3 months of treatment, 3α-diol differentially impaired object recognition memory (ORM) in 3xTg-AD males after short term (5 min) and in females after long-term (3h) retention delays. After 6 months of treatment, 3α-diol improved ORM in 3xTg-AD males and females after the long-term (3h) retention delay. Ongoing experiments will determine the effects of 3α-diol on cognitive performance and AD-like neuropathology as the disease progresses to 12 months of age (Supported by the Weston Brain Institute and the Ontario Veterinary College).

Title: Assessing the longitudinal benefit of two environmental enrichment methods in a triple transgenic mouse model of Alzheimer's disease

Authors: *H. A. COLLETT[1], S. E. WEBER[1], M. ODINA[1], K. M. VINT[1], A. M. TYLER[2], A. E. HUFF[1], K. KANIA[1], R. OSTERLEE[1], M. T. SULLIVAN[2], B. L. MCNAUGHTON[3], B. D. WINTERS[1];
[1]Dept. of Psychology and Collaborative Neurosci. Program, [2]Dept. of Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada; [3]Dept. of Neurosci., The Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Cognitive reserve (CR) refers to the resilience to Alzheimer's disease (AD) pathology that may be developed through complex life experiences such as higher education and mentally stimulating leisure activities. Experiences thought to create CR in humans can be modeled through environmental enrichment (EE) in rodents. However, standard home cage EE may poorly reflect the complex environments that are thought to be responsible for CR in humans. In a previous study, we validated a novel 'obstacle course' (OC) enrichment paradigm which exposed mice to daily EE over 2 mo on a running track in which they had to navigate a variety of obstacles to a receive a reward. This increased and controlled for the amount of complexity and novelty each animal experienced. The OC conferred a stronger cognitive benefit than home cage enrichment on the spontaneous object recognition task (SOR) and complex variations of the task which require feature integration, including the object category recognition task (OCR). Human AD patients display deficits in both visual recognition and feature integration. AD model mice also show visual recognition deficits with the SOR task, whereas tasks that require feature integration have not been previously evaluated in an AD mouse model. In this study, we evaluated the potential for CR-type outcomes with two different enrichment protocols in the triple transgenic mouse model (3xTG) of AD by evaluating mice longitudinally on both the SOR and OCR task after early-life exposure to EE. Post-weaning age male 3xTG transgenic (n=65) and wild-type (WT) mice (B6129SF2/J) (n=67) were divided into 4 different groups (n = 12-21/group): obstacle course (OC), home cage enrichment (EH); exercise control course (CC); or standard housing control (SH). After 2 mo of EE, all groups were longitudinally assessed at 3-4, 6, 9 and 12-mo on the SOR and OCR tasks. We found a progressive impairment on both tasks and that early-life EE was able to 'rescue' task performance. Starting at 6-mo, all non-enriched 3xTg groups were impaired on the SOR task with a 24-h retention delay and by 12-mo were also impaired with a 3-h delay. Both OC and EH enrichment ameliorated this impairment. Furthermore, we characterized a longitudinal OCR phenotype for 3xTG mice, which showed that 3xTG mice start showing task-related impairments at 9 months of age. These impairments were mitigated only by OC enrichment. Additionally, OC enriched 3xTG mice showed enhanced OCR task performance, which was observed up to 12-mo. These results emphasize the role of early-life experiences in the creation of CR and importance of individual animal control in EE methods for accurately assessing CR-type outcomes in mice.

Title: Candida rugosa lipase enhances Alzheimer's disease-like pathology in mice

Authors: *A. MENDEN[1,2], D. HALL[1], C. HAHN-TOWNSEND[1], C. A. BROEDLOW[3], F. CRAWFORD[1,2], S. CRYNEN[1,2], N. KLATT[3], M. MULLAN[1,2], G. AIT-GHEZALA[1,2]; [1]Roskamp Inst., Sarasota, FL; [2]Open Univ., Milton-Keynes, United Kingdom; [3]Univ. of Minnesota, Minneapolis, MN

Abstract: The gut microbiome is an important symbiont with functions in and beyond the gut. Diet displays the greatest impact on gut microbial composition as well as the gut metabolome. It has been determined that microbial-derived metabolites can alleviate neuroinflammation and neurodegeneration in the brain emphasizing its potential role in Alzheimer's disease (AD).Therefore, it was investigated whether *Candida rugosa* lipase (CRL) impacts AD-like pathology in APP/PS1 transgenic mice as compared to wildtype littermates by altering microbial and metabolomic gut compositions. APP/PS1 (8mo, n=12/group) and C57BL/6J (Wt) mice (8mo, n=14/group) were treated with 5000 FiP/kg CRL in their drinking water for two months and compared to littermates receiving regular drinking water. At 0, 1 and 2 months fecal samples were collected. Furthermore, behavioral testing was conducted two weeks before euthanasia. Using 16S rRNA sequencing, we investigated microbial changes, while gas-chromatography mass-spectrometry was used to quantify the gut metabolome. Additionally, peripheral changes such as cytokine levels and metabolomic profiles were analyzed. Finally, in addition to behavioral analyses, brain pathology was examined by immunohistochemistry and cortex transcriptomics performed. To show transferability of altered brain pathology due to gut-related changes, a fecal matter transplant (FMT) study was conducted from the first study into Wt mice.Our data suggested significant differences in both genotypes post CRL treatment. Furthermore, both cecal and plasma metabolites such as tryptophan could be correlated to the microbial differences. In addition, CRL treatment enhanced significantly memory and AD-like pathology. Finally, the FMT study suggested transferability of cognitive differences between treated and untreated animals into Wt animals. In conclusion, the results of this pre-clinical study highlight CRL' s and its associated metabolites' potential as new treatment agents for AD patients.

Title: Sex differences in early impairment of fear memory extinction in the TgF344AD rat model of Alzheimer's disease.

Authors: *C. M. HERNANDEZ, III, L. L. MCMAHON;
Dept Cell, Developmental, and Integrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Alzheimer's disease (AD) is accompanied by cognitive impairments affecting several memory domains. One such domain, emotional memory, is supported by a vast network of medial temporal lobe structures which are negatively impacted by AD. Human studies suggest the inability to acquire aversive emotional (fear) memories may be an early sign of AD that occurs prior to measurable cognitive impairments. In women, aversive emotional memories are associated with a greater incidence of neuropsychiatric disorders (e.g., anxiety and PTSD), and furthermore, AD is more likely to occur in women. However, whether sex interacts with fear memory as an early predictor of AD is not currently known. The transgenic Fischer344 AD (TgF344AD) rat model recapitulates many aspects of AD in humans. The current study used a behavioral approach in TgF344AD rats to better define the contributions of sex and genotype to early signs of memory impairments in AD. Prior studies have shown pathology in this rodent model is evident at 6 months of age. Young adult (6 mo.) male and female wild-type (WT) Fischer 344 and male and female TgF344AD rats were trained on a four-day contextual fear conditioning paradigm. Day 1 consisted of fear acquisition in context A in which rats were given a conditioned stimulus (CS, 20s tone) and unconditioned stimulus (US, 2s 1mA shock) pairing. Each pairing was delivered four times separated by a 20s intertrial interval (ITI). Day 2 consisted of CS extinction in a different context. Rats were placed in the conditioning chambers and given 20 CS trials with no US pairings separated by a 5s ITI. On day 3, extinction retrieval in context B was tested. Finally, on day 4, rats were placed in the same conditions as in context A to test fear renewal of the CS in the absence of US. On day 1, a mixed factor ANOVA (sex*genotype*trial) revealed all rats acquired fear (operationally defined as freezing) to the CS in context A, irrespective of sex or genotype. On day 2, there was a main effect of genotype on CS extinction such that AD rats were unable to extinguish fear expression relative to WT. On day 3, AD rats were less able than WT to retrieve extinction memory. On day 4, all rats showed continued freezing to the CS in context A, and this response was greater in AD females than other groups suggesting increased fear generalization. Furthermore, all females showed a renewal of fear to context A that was attenuated in males. Interestingly, AD females were unable to extinguish any fear expression during the post-CS period. These data suggest TgF344AD rats

show emotional memory impairments as early as 6 months of age, and these impairments may be greater in females than males.

Title: Alzheimer'S disease-inflicted microbiome alterations may be ameliorated by a ketogenic, time restricted diet in rats

Authors: *A. R. HERNANDEZ[1], S. N. BURKE[2], T. W. BUFORD[1], C. S. CARTER[1]; [1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: While the devastating effects of Alzheimer's disease (AD) on patients and their caregivers are well known, all intervention approaches thus far seeking to prevent or reverse AD have been ineffective. Furthermore, the pathology of AD reaches far beyond the central nervous system, including metabolic impairments and gut-brain-axis perturbations. Therefore, it is imperative that the scientific community broaden their approach to include those beyond the central nervous system. The gut microbiome is compositionally distinct in individuals with AD relative to age- and sex-matched controls, making it a promising avenue for potential interventions. Furthermore, age-related changes in gut microbiome composition may reciprocally interact with several physiological systems that are impaired with both age and AD. While caloric restriction has been highlighted as a strategy for increasing healthspan, time restricted feeding (TRF) and changes in dietary macronutrient composition may be more feasible alternatives with similar health outcomes and are both currently prescribed to individuals with metabolic impairment. To begin to investigate the potential utility of these interventions, fully mature young (5 mo) and older (22 mo) adult male Fischer Brown Norway Hybrid rats were placed on a TRF regimen of a ketogenic or micronutrient and calorically matched control diet for 7 months. A third group of rats was permitted to eat standard chow *ad libitum*. Fecal samples collected at the conclusion of the study were submitted for 16S microbiome analysis, which revealed significant differences across age and diet groups, as well as across feeding paradigms. Beta diversity analysis demonstrated distinct microbiome composition across the diet groups regardless of age, indicating changing caloric content and/or timing of consumption can drive changes in gut health. Furthermore, these changes are possible in aged rats at a comparable rate to the young, suggesting microbiome alterations are a feasible target in individuals with AD. Additionally, alpha-diversity was significantly lower in all TRF-fed rats, regardless of diet. At

the phylum level, diet significantly impacted relative abundance of several microbiota, including *Verrucomicrobia, Cyanobacteria, Actinobacteria* and *Patescibacteria*. Of particular note is the species *Akkermansia*, which others have shown to be lower in humans with metabolic deficits and AD mouse models. In our study, TRF-fed rats had significantly more *Akkermansia* than did ad lib fed rats. These results indicate the value of altered macronutrient composition and feeding methodology for therapeutic interventions targeting the gut microbiome.

Title: qß Virus-like particle (vlp)-based vaccine against phospho-threonine 181 tau shows robust immune response and functional efficacy in the p301s mouse model of tauopathy

Authors: *N. M. MAPHIS[1], J. PEABODY[1], S. JIANG[1], Y. YANG[2], D. N. LINSENBARDT[3], D. S. PEABODY[1], B. CHACKERIAN[1], K. BHASKAR[1];

Abstract: Background: Tauopathies are progressive neurodegenerative disorders characterized by the hyperphosphorylation of tau and development of intracellular neurofibrillary tangles, collectively referred to as pathological tau (pTau). It is becoming increasingly recognized that the development and spread of pTau accurately predicts and correlates with clinical progression in human tauopathy patients, however there are no FDA-approved drugs that target and reduce pTau. Previously, our lab has developed a virus-like particle (VLP)-based vaccine using a Qß (RNA bacteriophage) platform to multivalently display a 13-mer pTau peptide, with phospho-Threonine 181 (pT181, a well-established CSF biomarker for tauopathies). Previously, we observed that pT181-Qß generated a robust and targeted immune response against pTau in a model of tauopathy, rTg4510, resulting in reduced insoluble tau, decreased neurodegeneration and improved delay-dependent and spatial working memory. Here, we sought to expand the effects of this vaccine in an additional model of tauopathy, at a more clinically relevant intervention. **Methods:** We immunized P301S (and non-transgenic) mice twice, at 3 and 4 months of age. Next, we assessed anti-pT181 antibody titers at 1-week after the first injection and 5-months following the last injection (i.e. 9 months of age) followed by behavioral and biochemical analyses. **Results:** Anti-pT181 antibodies were significantly elevated in all mice

treated with pT181-Qß, regardless of genotype, 1 week after the first dose and remained elevated five months after the second injection. Behavioral analysis suggest that pT181-Qß-vaccinated P301S mice showed improved delay-dependent memory (as measured by novel object recognition test), and gait improvement (as assessed with Catwalk). Finally, P301S mice vaccinated with pT181-Qß had significantly downregulated transcripts involved in inflammasome activation and significantly reduced tau hyperphopsphorylation in the hippocampus, suggesting that reduction of pathological pT181-Qß can prevent pTau-driven inflammatory activation. **Conclusions:** pT181-Qß represents an efficacious and cutting-edge tool to target and reduce tau pathology in multiple animal models of tauopathy which may have substantial effects against neuroinflammation besides ameliorating tau pathology.

Abstract: Accumulating evidence from observations in mouse models and humans indicates that one of the earliest brain changes in Alzheimer's disease (AD) is an amyloid-β (Aβ)-dependent excessive neuronal activity, i.e. hyperactivity. In mouse models of AD, elevated levels of soluble Aβ but not the emergence of amyloid plaques cause neuronal hyperactivity. Conversely, the application of soluble Aβ in wild type mice is sufficient to sustain this neuronal dysfunction. As neuronal hyperactivity is implicated in brain circuit dysfunction and cognitive decline, its treatment could have beneficial effects in AD. Here, we introduced a novel approach of preventing neuronal hyperactivity in young AD mice *in vivo* by the application of an Aβ-binding Anticalin protein to the brain.We used the Aβ-specific Anticalin H1GA, a small engineered antibody-like protein, to scavenge Aβ in a mouse model of AD and evaluated its effect on neuronal activity using *in vivo* two-photon calcium imaging. We demonstrated that the

application of H1GA to the hippocampal CA1 area stopped neuronal hyperactivity in young pre-depositing APP/PS1 mice but had no effect in wild-type mice. Using size exclusion chromatography, we next determined that H1GA binds Aβ monomers but not larger aggregates. This observation is remarkable as earlier work has shown that neuronal hyperactivity and synaptic dysfunction is predominantly caused by Aβ dimers and oligomers but not monomers. To solve this conundrum, we designed a combined *in vitro-in vivo* assay. First, we verified that synthetic Aβ monomers applied to the brains of wild type mice *in vitro* and *in vivo* did not affect the neuronal activity levels. Next, we incubated Aβ monomers for 1-2 hours and confirmed the emergence of aggregates using a Thioflavin T fluorescence assay. The application these aggregates, containing Aβ dimers and oligomers, reliably induced neuronal hyperactivity *in vivo* and *in vitro*. Finally, incubation of Aβ monomers in H1GA-containing medium prevented the hyperactivating Aβ effect. In contrast, the application of synthetic Aβ dimers potently induced neuronal hyperactivity alone or in the presence of H1GA. Together, this data indicates that the removal of Aβ monomers from the brain is sufficient to prevent neuronal hyperactivity, most likely trough the prevention of Aβ aggregation. In summary, in this study we established that scavenging of functionally inert Aβ monomers can prevent early neuronal dysfunction in mouse models of AD *in vivo*, most likely through reducing the formation of toxic Aβ dimers and oligomers. These results identify Aβ monomer scavenging agents, such as the Anticalin H1GA, as promising therapeutic agents at early stages of AD.

Title: A systematic review and qualitative evidence synthesis of the role of transthyretin in Alzheimer's disease

Authors: *A. OZAIR, A. FARUQI, A. BAJAJ;
King George's Med. Univ., Lucknow, India

Abstract: Introduction: The protein prealbumin or transthyretin (TTR) is found in many organs, including the brain. Studies have found a conflicting role of TTR in Alzheimer’s Disease (AD), with some finding it protective and others reporting it as part of the pathophysiologic process. No systematic review (SR), which is the highest quality of evidence, currently exists to clarify this issue. Therefore, we aimed to clarify the role of TTR in AD through a SR.
Methods: We conducted SR as per the PRISMA guidelines (Fig. 1). We searched the PubMed database on 1st July 2020 using the function: '((transthyretin) OR (prealbumin)) AND (Alzheimer's disease)'. Duplicate removal, abstract screening, and full-text review were done.
Results: We obtained 95 eligible articles (Fig. 1). Only qualitative synthesis could be performed

due to heterogeneity in study methods, precluding a meta-analysis. Majority of studies, especially ones in last two decades, find that TTR has neuroprotective role in AD. TTR has been found to clear amyloid-beta (Aβ) and inhibit Aβ aggregation. TTR influences Aβ levels gender-specifically, its action affected by sex hormones. While previous studies were conflicted about the source of TTR in cerebrospinal fluid (CSF), there is growing evidence to suggest that CSF TTR comes from 3 sources: (1) neuronal synthesis, (2) choroid plexus synthesis; and (3) diffusion from serum. CSF studies report that TTR levels here are decreased in AD and oxidized TTR forms are detectable. Serum studies also report that TTR levels inversely correlate with AD progression. Both CSF and serum studies of TTR have found it to be a good AD biomarker. Limitations: We did not utilize SCOPUS or EMBASE for searching. There is also a lack of large observational or interventional studies in clinical practice, resulting in a lack of reporting of the true utility of TTR from our SR.
Conclusions: A rapidly accumulating, significant body of evidence for a neuroprotective role of transthyretin in AD exists. CSF and serum levels of TTR can act as good biomarkers of AD. Large clinical studies are needed to show TTR's clinical utility.

Title: Presenilin1 Familial Alzheimer's Disease mutants decrease eprhinB2-regulated angiogenic functions, ischemia-induced brain neovascularization and neuronal survival.

Authors: *A. GEORGAKOPOULOS[1], Y. YOON[1], *G. VOLOUDAKIS[1], C. DIMOVASILI[1], L. CHEN[1], Z. SHAO[1], C. TANG[2], P. R. HOF[3], N. K. ROBAKIS[1];

Abstract: Cerebral microvasculature abnormalities, such as degeneration of the capillary endothelium, are implicated in the genesis of Alzheimer's disease (AD) neuropathology. In addition, ischemic lesions that cause neuronal damage are often found in AD brains. The brain responds to ischemia by stimulating tissue neovascularization via sprouting angiogenesis; impairment of this function renders the brain vulnerable to the insult. It has been hypothesized that decreased angiogenesis in AD leads to insufficient blood flow and neuronal dysfunction in affected areas.The EphB4/ephrinB2 (efnB2) ligand-receptor system is known to regulate brain angiogenesis in response to ischemia. Using *in vitro* angiogenesis assays and co-immunoprecipitations we show that Presnilin1 (PS1), an important factor in familial AD (FAD), regulates angiogenic functions of EphB4/efnB2 including sprouting, tube formation and stimulation of VE-cadherin angiogenic complexes in brain endothelial cells (ECs) and these functions are impaired by PS1 FAD mutants. In addition, using kcnockin mice (KI) expressing PS1 FAD mutants, MCAO, spPLA, MRI and immunohistochemistry we found that ischemia stimulates formation of the same angiogenic complexes in the brain and that this function is attenuated by PS1 FAD mutants together with ischemia-induced neovascularization and cerebral blood flow while neuronal death is increased. The PS1 FAD KI mice are "humanized", the heterozygous FAD mice have the same genotype as human FAD patients, one PS1 FAD allele and one WT PS1 allele. We also found that PS1 FAD mutants decrease the γ-secretase processing of efnB2 and production of the angiogenic peptide efnB2/CTF2 thus impairing the angiogenic response of brain ECs. Finally, we found that a small peptide, which derives from efnB2/CTF2 rescues angiogenic functions of PS1 FAD ECs.Together, our data support the hypothesis that PS1 FAD mutants inhibit ischemia-induced angiogenic functions of ECs by decreasing the γ-secretase processing of efnB2 and impairing the EphB4/efnB2 signaling, thus decreasing neovascularization in the adult brain and leading to increased vulnerability to this toxic insult, cognitive decline and neuronal death (Yoon et al., 2020 Mol. Psychiatry,

doi:10.1038/s41380-020-0812-7). Furthermore, our data reveal a novel brain angiogenic mechanism targeted by PS1 FAD mutants and a potential therapeutic target for ischemia-induced neurodegeneration. Importantly, FAD mutant effects occur in absence of neuropathological hallmarks of AD, supporting such hallmarks may form downstream of mutant effects on neoangiogenesis and neuronal survival.

Title: Gamma-secretase regulates VEGF-induced angiogenic functions of brain endothelial cells : Role of presenilin1 FAD mutants

Authors: *R. PANDEY, N. K. ROBAKIS, A. GEORGAKOPOULOS;
Icahn Sch. of medicine at Mount Sinai, New York, NY

Abstract: Alzheimer’s disease (AD) is one of the major neurodegenerative disorders that leads to age-dependent cognitive impairment and death. There are currently no preventative or therapeutic agents for AD. Preclinical studies have shown cerebrovascular perturbation as well as decreased vascular density in AD, which precede and accompany cognitive dysfunction and neurodegeneration. One of the factors that could contribute to cerebrovascular pathology in AD is decreased neovascularization in the brain. Neovascularization is a process regulated by angiogenesis, the formation of new blood vessels from existing ones. Endothelial cells (EC) of the blood vessels play a crucial role in angiogenesis. Vascular Endothelial Growth factor (VEGF), is a potent angiogenic factor that regulates angiogenesis via binding to its receptor VEGFR2, a type I transmembrane protein, in EC. Presenilin 1 (PS1) is an important factor for AD as its mutants are responsible for most cases of Familial Alzheimer’s Disease (FAD). PS1 is the catalytic subunit of γ-secretase, a proteolytic complex, which regulates the processing of several type I transmembrane proteins. We hypothesize that mutants of PS1 found in FAD, may affect VEGF-induced processing of VEGFR2 and VEGF-induced angiogenesis. Using in vitro angiogenesis assays we found that inhibition of γ-secretase decreases the VEGF-induced angiogenic functions of brain EC including sprouting, tube formation and migration, all important steps of sprouting angiogenesis. Using western blot and co-immunoprecipitations we also found that VEGFR2 is processed by γ-secretase and that γ-secretase promotes VEGF-

induced angiogenic complexes, which include VE-cadherin and Rok-α kinase. Finally, we observed that VEGF-induced sprouting of ECs expressing PS1 FAD mutant M146V decreases significantly compared to induced sprouting of WT controls. EC expressing PS1 M146V mutant were prepared from brains of knockin mice (KI) expressing this mutant. These mice are "humanized", the heterozygous FAD mice have the same genotype as human FAD patients, one PS1 FAD allele and one WT PS1 allele. These data suggest that PS1/γ-secretase regulate VEGF-induced angiogenic functions of EC and that PS1 FAD mutants impede these functions. This could decrease the ability of the brain to recover from toxic insults and that might lead to increased neuronal death and cognitive decline. Targeting brain angiogenesis could have therapeutic value for neurodegenerative diseases such as AD.

Title: Tauopathies and TDP-43 proteinopathies display signature patterns of cortical layer pathology independent of clinical phenotype

Authors: *D. T. OHM[1], C. PETERSON[2], K. COUSINS[2], R. LOBROVICH[2], E. XIE[2], C. MCMILLAN[1], D. WOLK[1], V. M. VAN DEERLIN[3], L. ELMAN[2], M. SPINDLER[2], A. DEIK[2], A. SIDEROWF[2], J. Q. TROJANOWSKI[3], E. B. LEE[3], M. GROSSMAN[1], D. IRWIN[1];
[1]Neurol., [3]Dept. of Pathology and Lab. Med., [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Frontotemporal lobar degeneration (FTLD) is a group of distinct proteinopathies associated with predominant degeneration of frontotemporal networks that result in overlapping frontotemporal dementia (FTD) clinical syndromes. While tau inclusions (FTLD-tau) and transactive response DNA binding protein of 43kDa inclusions (FTLD-TDP) often accrue in the same gross anatomical regions, pathology within cytoarchitectonic subfields of gray matter is not well understood in the full FTLD spectrum due to lack of large comparative studies quantifying microstructural changes. The current study examined 152 FTLD patients with either FTLD-tau (n = 67) or FTLD-TDP (n = 85) to determine if the relative distribution of pathology across cortical layers is a distinguishing feature of FTLD groups and to identify which factors may

predict signature patterns of pathologic change. Paraffin-embedded sections from up to 10 neocortical and paralimbic regions per patient were immunostained for phosphorylated TDP-43 (1D3) and hyperphosphorylated tau (AT8). We digitally measured the % area occupied by tau and TDP-43 inclusions in upper cortical layers (I-III), lower cortical layers (IV-VI), and white matter adjacent to layer VI in all regions. A ratio of upper-to-lower layer pathology (layer ratio) calculated the relative distribution of pathologic burden. To compare proteinopathy groups, linear mixed effect models tested associations between layer ratio and proetinopathy groups, and between layer ratio and white matter pathology within groups while adjusting for demographics. We found a smaller layer ratio (greater pathology in lower layers) in FTLD-tau compared to FTLD-TDP (beta=-0.75, SE=0.08, $p<0.05$) which remained consistent when examined by clinical subgroup (i.e., dementia and motor syndromes). Post-hoc comparisons showed that a lower layer ratio was consistent among pathologic and clinical subgroups of FTLD-tau, whereas a higher layer ratio was shared among pathologic and clinical subgroups of FTLD-TDP. In FTLD-tau, not FTLD-TDP, greater white matter pathology was associated with relatively greater pathology in lower layers (beta=-0.048, SE=0.02, $p<0.05$). Our findings suggest that relatively high pathologic burden in lower layers and adjacent white matter is a common feature of FTLD-tau and distinct from more isolated upper layer pathology in TDP-43 proteinopathies. Examination of laminar architecture in FTLD provides new anatomical evidence that distinct layer pathology, and therefore changes to separate populations of neurons and/or glia, may contribute to the degeneration of similar if not identical cognitive networks associated with FTD.

Title: Isolation of Exosomes from Frozen Postmortem Human / Mouse Brain and Primary Human Microglia Culture Media

Authors: *I. A. AYALA[1], C. A. ESTRADA[2], R. SHAHIDEHPOUR[2], T. D. GEFEN[2], M. E. FLANAGAN[2], M. M. MESULAM[2], C. GEULA[2];
[1]Mesulam Ctr. for Cognitive Neurol. and Alzheimer's Dis., [2]Northwestern Univ., Chicago, IL

Abstract: Exosomes are extracellular vesicles produced in the endosomal compartment and released by most eukaryotic cells. They are the smallest extracellular vesicle and have been implicated in cell-to-cell communication under normal conditions and propagation of pathology in neurodegenerative disorders. In particular, microglia-derived exosomes have been implicated in pathologic tau propagation in Alzheimer's disease. The goal of the present experiment was to isolate exosomes from various sources and determine whether they are of microglia origin. Frozen postmortem human tissue from the middle frontal gyrus of three participants with frontotemporal dementia and two cognitively-normal controls, frozen frontal cortex from three wildtype C57/Bl6 mice, and pooled media from primary human microglia cultures were used for this purpose. Employing established high speed ultracentrifugation and fractionation protocols (Théry C et al., Curr Protoc Cell Biol, Chapter 3: Unit 3.22, 2006; Perez-Gonzalez, R et al., JBC, 287: 43108-15, 2012), we isolated exosomes from the above sources and used Western blot analysis to determine presence of known markers. 500 mg of brain tissue, and 50 ml of human microglia conditioned medium was necessary to successfully isolate and identify exosomes. Exosomes isolated from the three sources contained immunoreactivity for the exosome markers flotillin-1 and CD63. To investigate microglia as a potential origin of the isolated exosomes, we performed Western blot analysis using the microglia marker CD68. Isolated exosomes from all three sources displayed CD68 immunoreactivity. Our results demonstrate that exosomes originating in microglia can be isolated, either in a pool of exosomes from frozen brain tissue, or as pure microglia derived exosomes from cultures, and show appropriate presence of expected markers. Isolated exosomes will be useful for studies aimed at determining the role of microglia-derived exosomes in propagation of pathology in frontotemporal dementia, including FTLD-TDP-43 and FTLD-tau proteinopathies.

Title: Increased excitability and calcium influx characterize medial prefrontal cortex pyramidal neurons during early stage of Alzheimer's disease in 3xTg-AD mouse model

Authors: *N. CHOUDHURY, L. CHEN, V. T. NGUYEN, L. AL-HARTHI, X.-T. HU; Microbial Pathogens and Immunity, Rush Univ. Med. Ctr., Chicago, IL

Abstract: β-amyloid plaques and hyperphosphorylated tau tangles are hallmarks of Alzheimer's disease (AD) in several brain regions which regulate cognitive abilities, including the cortex and the hippocampus. The medial prefrontal cortex (mPFC) plays a critical role in cognition including, but not limited to, forming multisynaptic connections with the hippocampus to regulate learning/ memory-related tasks, but it is understudied in AD neuropathophysiology. We assessed the functional status of mPFC pyramidal neurons in the context of AD, using male 3xTg-AD mouse model, and electrophysiology (patch-clamp recording) in acute brain slices. We found that at the age of 3-5 months (equivalent to 20-30 years in humans), pyramidal neurons in layer 5-6 of the mPFC show abnormally increased firing followed by overactivation-induced failure to fire. These neurons are also marked by significantly more depolarized resting membrane potential, lower rheobase, higher input resistance, and lower firing threshold for evoked firing. We also assessed Ca^{2+} influx through voltage-gated Ca^{2+} channels (VGCCs) in these neurons, which was indicated by Ca^{2+} plateau potentials (spikes) evoked under blockade of voltage-gated Na^{+} and K^{+} channels. We show that evoked Ca^{2+} spikes in mPFC neurons have significantly increased duration and area as compared to non-AD mice, indicative of enhanced VGCC activity/ expression and elevated $[Ca^{2+}]_{in}$ as a result of AD neuropathology. Collectively, these findings demonstrate that hyperexcitability and excessive increase of Ca^{2+} influx via overactivated/overexpressed VGCCs occur in mPFC pyramidal neurons of 3xTg-AD mice at early stages of AD and suggest that alterations in neuronal Ca^{2+} homeostasis and neurophysiological properties may precede classical neuropathology of AD. Understanding early stages of AD and its impact on mPFC may provide early clues of pathways that mediate CNS dysregulation and inform therapeutic interventions prior to onset of neuropathology.

Title: Putative Pathologic Correlates of Neurodegeneration in an Autopsy Series of FTLD-TDP Type C

Authors: *A. KAWLES, Y. NISHIHARA, N. GILL, A. FELDMAN, H. ZHANG, M. E. FLANAGAN, M. .-M. MESULAM, C. GEULA, E. H. BIGIO, Q. MAO, T. GEFEN; Mesulam Ctr. for Cognitive Neurol. & Alzheimer's Dis., Northwestern Univ., Chicago, IL

Abstract: Background. The TDP-43 type C pathologic form of frontotemporal lobar degeneration (FTLD-TDP-C) is characterized by the presence of immunoreactive TDP-43 short and long dystrophic neurites (DNs), neuronal cytoplasmic inclusions (NCIs), and neuronal loss and gliosis (NL/G). Autopsy data show a tight correlation between FTLD-TDP-C cases and either behavioral variant frontotemporal dementia (bvFTD) or the semantic variant of primary progressive aphasia (PPA-S), offering the opportunity to study the putative correlates of neurodegeneration in clinical dementia syndromes. Here, we report regional distributions of pathologic TDP-43 and the extent of NL/G in cortical and subcortical regions in FTLD-TDP-C cases, and investigate the relationship between FTLD-TDP-C pathologic inclusions and NL/G.
Methods. Twenty-six cortical and subcortical regions were immunostained with a phosphorylated TDP-43 antibody and evaluated for long DNs, short DNs, and NCIs in ten cases with FTLD-TDP-C (PPA-S N=7; bvFTD N=3). NL/G was assessed using hematoxylin-eosin stained sections. Specimens were obtained from the Northwestern Alzheimer Disease Center. TDP pathology and NL/G were graded using a semiquantitative 5-point scale. We calculated a "neuron-to-inclusion" score (TDP-C mean score - NL/G mean score) for each region per case to assess the relationship between the extent of FTLD-TDP-C pathology vs NL/G.
Results. Distribution heat maps showed that long DNs were most abundant in the left superior temporal and inferior parietal gyri, and inferior frontal gyri bilaterally. The amygdala, caudate, and putamen were heavily affected. Interestingly, NL/G was most severe in bilateral temporal poles, amygdala, and trans/entorhinal cortices, and not necessarily the cortical regions most heavily affected by TDP-43. At both group and individual levels, linear mixed models showed that regions with the *lowest* "neuron-to-inclusion" score (little pathology and high neuronal loss) differed significantly from those with high "neuron-to-inclusion" scores (abundant pathology and preserved neuronal densities) across all three TDP markers ($p<0.01$).
Conclusion. In cases with FTLD-TDP-C, there is extensive TDP-43 pathology and NL/G in both cortical and subcortical regions. There appears to be an inverse relationship between the extent of TDP-positive inclusions and NL/G, which may reflect a process whereby inclusions disappear as their associated neurons are lost. Future studies will aim to investigate the mechanistic basis of this phenomenon to better understand the putative substrates of neurodegeneration in clinical dementia syndromes.

Title: Loss of Valosin Containing Protein (VCP) activity enhances proteopathic seeding

Authors: *J. ZHU[1], D. DHAVALE[2], R. FRENCH[3], S. PITTMANS[2], J. HAINES[2], P. KOTZBAUER[1], Y. AYALA[4], A. DAVIS[1], C. C. WEIHL[1];

Abstract: Protein inclusions such as tau, α-synuclein, and TDP-43 are considered a pathologic hallmark of many neurodegenerative diseases. These proteins are prone to misfold, aggregate, and template inclusion body formation. Accumulating evidence suggests that proteins in their oligomeric form can serve as a "seed", spread through an interconnected brain network, and induce new inclusions. This transmission correlates with disease progression. Insofar, those proteins are recognized as proteopathic seeds. We focuses on the mechanism of intracellular proteopathic seeding events. Previous studies have demonstrated that proteopathic seeds are endocytosed and damage the endolysosomal membrane. This damage facilitates seed escape from membrane-bound vesicles, subsequent templating the conversion of intracellular monomers forming new aggregates. We detected acceleration in seeding when treating cells with LLoMe—a drug that permeabilizes lysosome membranes— together with seeds. This indicates that endolysosome integrity is important for intracellular seeding event.Here, we report that the AAA ATPase, VCP, protects against proteopathic seeding by facilitating the clearance of damaged endolysosomes. VCP is a versatile protein required for protein homeostasis. We previously demonstrated that VCP is recruited to damaged endolysosome, and signals degradation by autophagy, termed as Endolysosomal damage response (ELDR). Moreover, disease mutations in VCP specifically impair ELDR. VCP disease mutations have been identified in multiple neurodegenerative diseases with proteopathic protein inclusions, including Frontotemporal dementia, ALS, and Parkinson's. This indicates that VCP may be essential for proteopathic seeding events. Using an α -synuclein FRET biosensor assay, we found both VCP inhibition and VCP disease mutations exacerbate α-synuclein seeding. A similar result was replicated in hippocampal neurons, in which both VCP knockdown and VCP mutant knock-in neurons show increasing α -synuclein aggregation following seeding. Screening different VCP cofactors, we identified that the ELDR-related cofactor, UBXD1 modifies the α-synuclein seeding similar to VCP. It suggests that VCP regulates α-synuclein seeding via ELDR. Additionally, mice carried a VCP disease mutation (n=3) exhibits significantly more α-synuclein aggregation than C57 control (n=7, p=0.015) 90 days after intrastriatal injection of α-synuclein pre-formed fibrils *in vivo*. Further, we observed the same protective effect of VCP on intracellular tau and TDP-43 seeding. Overall, our results support VCP as a gatekeeper for intracellular proteopathic seeding in general.

Title: Wnt/b-catenin canonical pathway changes in brain and bone of an amyloid-dominant mouse model of Alzheimer's disease

Authors: *K. BRETLAND[1], L. LIN[1], K. BRETLAND[2,1], C. M. DENGLER-CRISH[1]; [1]Dept. of Pharmaceut. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [2]Kent State Univ., Kent, OH

Abstract: Patients with Alzheimer's disease (AD) are at an increased risk for osteoporosis and bone fracture compared to neurotypical patients of the same age. This comorbidity negatively impacts quality of life in these patients and has been linked to increased mortality. As AD is the most common form of dementia and currently affects almost 6 million Americans, it is essential to identify mechanistic linkages between loss of bone integrity and neurodegeneration in this disease. The central and peripheral nervous systems regulate bone remodeling through complex circuitry and cell signaling pathways. One pathway of interest, canonical Wnt signaling, is shown to be disrupted in both osteoporosis as well as AD. Previously, our lab found evidence of disrupted Wnt signaling in the brain and bone of a mouse designed to model Alzheimer's-related tauopathy. In this project, we hypothesized that deficits in Wnt/β-catenin signaling would be associated with both bone loss and amyloid-β neuropathology in a rodent AD model that presents with low bone density, APP/PS1dE9 mice. Using radiographic bone densitometry, we tracked changes in bone density and body composition longitudinally across increasing pathological stages (2-13 months of age) in these mice. We then collected various brain (hippocampus, brainstem) and bone (femur, tibia) tissues for subsequent assays to measure protein and gene expression associated with the Wnt/β-catenin signaling pathway. Results were assessed with SPSS for each sex across pathological ages in comparison to sex and age-matched wildtype controls. Our preliminary results confirm evidence of a low bone density phenotype in APP/PS1 mice, as well as Wnt signaling impairments in brain and bone tissue in comparison to wildtype littermates. Interestingly, this seems to be a highly sex-dependent finding. These results could potentially support the idea of AD pathology being systemically driven. This may also provide a window for early intervention in AD, however, the sex differences must be examined further.

Title: Inducing intergenerational resilience to vascular cognitive impairment and dementia by repetitive hypoxic conditioning

Authors: *K. D. BELMONTE[1], T. WILLS[1], J. M. GIDDAY[2];
[2]Ophthalmology, [1]Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: BACKGROUND: Vascular cognitive impairment and dementia (VCID), secondary to stroke or chronic cerebral hypoperfusion, is the second leading cause of dementia following Alzheimer's disease. Although 25-30% of ischemic stroke survivors develop immediate or delayed VCID, there is no efficacious therapy. We have shown previously in mice that repetitive hypoxic preconditioning (RHC) induces a long-lasting resilience to acute stroke (PMID:21437933). More recently, we documented that untreated, first-generation adult progeny of mice exposed to RHC prior to mating are protected from retinal ischemic injury (PMID:32910134), consistent with accumulating evidence supporting the concept that long-lasting phenotypes induced by intermittent stressors may be inherited. Taken together, we hypothesized that RHC will induce resilience to VCID, and that such RHC-induced protection can also be inherited.
METHODS: Chronic cerebral hypoperfusion (CCH) was induced secondary to bilateral carotid artery stenosis with microcoils in both the parental F0 generation and their untreated F1 offspring of C57Bl/6J mice. Cohorts of F0 animals were directly exposed to either 8 wks of RHC or normoxia prior to CCH. F1-generation mice, derived from either RHC-treated animals prior to mating, or normoxic controls, never received direct RHC treatment but were properly age-matched to the F0 generation when CCH was established. Following 3 months of CCH, short-term recognition memory was assessed in vivo by novel object recognition (NOR) testing, and the following month, ex vivo measurements of hippocampal long-term potentiation (LTP) were recorded from the same animals as an electrophysiological metric of memory-associated synaptic plasticity.
RESULTS: CCH caused impairments in recognition memory in control mice from both generations. However, in F0 animals directly treated with RHC, as well as in their untreated adult F1 progeny, these CCH-induced memory impairments were prevented. Similarly, RHC treatment enhanced LTP formation in the CCH cohorts of mice directly treated with RHC, as well as in their untreated offspring, despite the latter having no direct exposure to RHC.
CONCLUSIONS: Our findings demonstrate that epigenetic-based therapeutics may hold promise for inducing resilience to VCID and raise the possibility that such a state of induced resilience may even be heritable.

Title: Cerebellar lobule volumes and neuropsychiatric symptoms in genetic frontotemporal dementia

Authors: ***A. BUSSY**, J. LEVY, M. CHAKRAVARTY, S. DUCHARME;
McGill, Montréal, QC, Canada

Abstract: Introduction: Familial frontotemporal dementia (FTD) is a neurodegenerative disorder caused by three main autosomal dominant mutations. A paucity of studies have examined the impact of these mutations on the cerebellum as a cause of neuropsychiatric symptoms. Methods: 413 participants from the Genetic Frontotemporal dementia Initiative dataset were included in this study [167 non-carriers, 246 carriers]. We used the MAGeT Brain algorithm to estimate the volumes of the cerebellar lobules from standard T1-weighted images. Partial least square (PLS) analysis was used to identify a set of latent variables (LVs), that explain patterns of covariance between "brain" and "demographic/neuropsychiatric" data with the constraint that LVs explain as much of the covariance between the two matrices as possible. Here, our "brain" data included the volume of each cerebellar lobule and total brain volume (matrix size 413x13). Our "demographic/neuropsychiatric" data contained age, sex, years of education, estimated years of onset, genetic status, and 11 behavioral scores from the Cambridge Behavioural Inventory (CBI) for each subject (matrix size 413x16). Permutation testing and bootstrap resampling were performed (at $p<0.05$ threshold) to statistically test each LV and to assess the contribution of each "demographic/neuropsychiatric" data on these LVs, respectively. Results: Two LVs were significant in each hemisphere with highly similar results (Figure). LV1 demonstrated lower overall cerebellar volumes (except lobules I-II and X) to be associated with high CBI scores, being a mutation carrier, older, closer to onset, female sex and low education. LV2 exhibited higher lobule X volumes to be related to higher CBI scores in behavior, memory and everyday skills. Discussion: Within genetic FTD individuals, subjects with larger lobule X volume seemed to be at a higher risk for neuropsychiatric symptoms. This could be explained by a dysregulation of the cholinergic system which regulates plasticity, arousal and reward, since lobule X is known to be involved in this pathway.

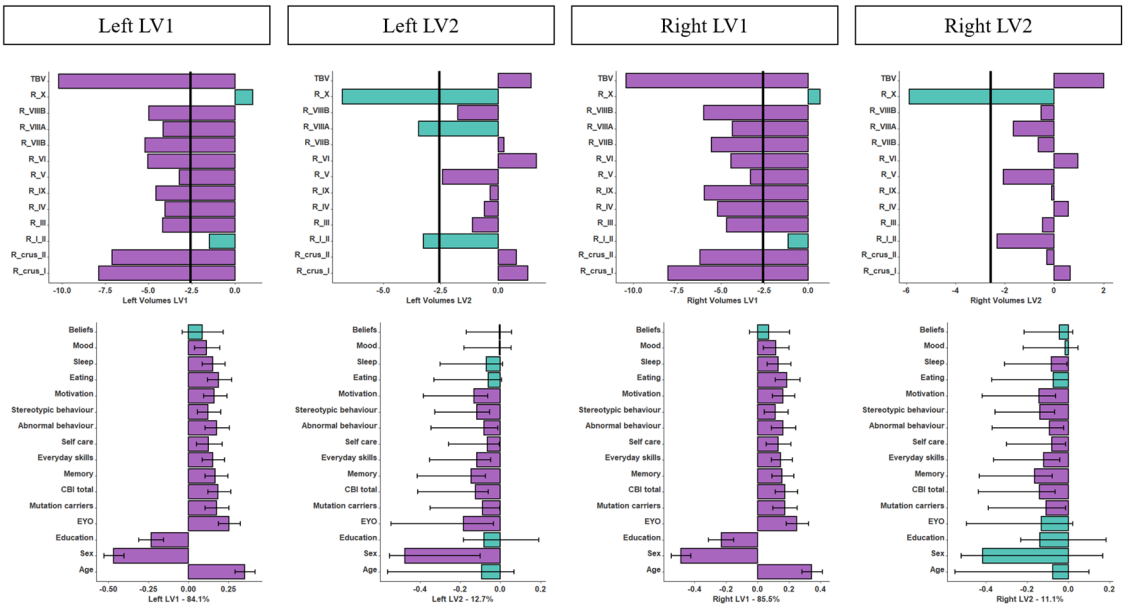

Figure : PLS between the left/right cerebellar subfield volumes and the demographic/neuropsychiatric symptoms information identified two significant LV on each hemisphere ($p<0.05$). Left LV1 explained 84.1%, left LV2 explained 12.7%, right LV1 explained 85.5% and right LV2 explained 11.1% of the covariance. **Upper row:** Bar plots describe the correlation of each subfield variable with the LV, purple color identifies variables significantly contributing to the LV, while turquoise color identifies nonsignificant variables. Black vertical line corresponds to a BSR threshold of 2.58. **Lower row:** Bar plots describe the correlation of each demographic/neuropsychiatric symptoms variable with the LV, with error bars denoting the 95% confidence interval, thus purple identifies variables significantly contributing to the LV.

Title: Chronic exposure to methamphetamine reduces excitability of pyramidal neurons associated with decreased voltage-gated calcium channel activity inthemedial prefrontal cortex of rats.

Authors: *L. CHEN, V. T. NGUYEN, S. L. CASSODAY, A. DONNER, N. CHOUDHURY, L. AL-HARTHI, X.-T. HU;
Dept. of Microbial Pathogens and Immunity, Rush Univ. Med. Ctr., Chicago, IL

Abstract: Methamphetamine (Meth) is a highly addictive and widely abused psychostimulant. There is no FDA-approved medication for the treatment of Meth addiction. Elucidating the mechanism underlying Meth-induced neuropathology is critical for the development of efficacious pharmacotherapy. The medial prefrontal cortex (mPFC) is a key regulator of cognition and addiction; but it is profoundly altered by Meth and other psychostimulants. The mechanism by which Meth induce dysfunction of glutamatergic pyramidal neurons in the mPFC is not fully undersdood. To determine the impact of chronic Meth exposure on mPFC pyramidal neurons, we assessed their functional activity using Fischer F344 male rats at different ages. Adolescent rats (4-6 weeks of age; 4-6wk) received repetitive daily injection of Meth (5mg/ml/kg, s.c.) for 5 days, while adult rats (5-6 months of age, 5-6mo) were trained to self-administer (SA) Meth at the dose of 0.01mg/kg/infusion for one week, and then switched to the dose of 0.05mg/kg/infusion for another two weeks. Saline (SAL)-pretreated, or SAL-yoked F344 rats were used as control. Brain slices containing the mPFC were prepared for whole-cell patch-clamp recording after a withdrawal period of 1-4 days from Meth-SA or SAL. We found that the firing of mPFC pyramidal neurons was significantly decreased in rats after repeated Meth exposure and withdrawal compared to those pretreated with SAL in both adolescent and adult rats. We also performed whole-cell current-clamp recordings to assess voltage-sensitive Ca^{2+} influx via voltage-gated Ca^{2+} channels (VGCCs) that was indicated by evoked Ca^{2+} plateau potentials in mPFC pyramidal neurons. During this assessment, all neurons were evaluated under blockade of synaptic activities mediated by glutamate receptors and $GABA_A$ receptors, as well as functional activity of voltage-gated Na^+ and K^+ channels. We also found that mPFC pyramidal neurons from Meth-SA rats displayed a significant reduction of Ca^{2+} potentials in both the duration and area compared to those from SAL-yoked rats. Collectively, our findings demonstrate that chronic exposure to Meth significantly decreases the functional activity of mPFC pyramidal neurons in rat mPFC during an early stage of withdrawal. And the Meth-induced decrease of mPFC neuronal excitability is mediated by dysfunctional VGCCs with decreased functional activity, which is independent of dysfunctional NMDA receptors. Such alterations may contribute to the mechanism by which chronic Meth exposure disturbs cognition and causes addiction.

Abstract: **Aims**: Alzheimer's disease (AD) is a debilitating neurodegenerative disorder that causes severe deterioration of memory, cognition, behavior, and the ability to perform daily activities. The disease is characterized by the accumulation of two proteins in fibrillar form; Amyloid-β forms fibrils that accumulate as extracellular plaques while tau fibrils form intracellular tangles. Here we aim to translate findings from a commonly used AD mouse model to AD patients. **Methods**: Here we initiate and chronically inhibit neuropathology in lateral entorhinal cortex (LEC) layer two neurons in an AD mouse model. This is achieved by over-expressing P301L tau virally and chronically activating hM4Di DREADDs intracranially using the ligand dechloroclozapine. Biomarkers in cerebrospinal fluid (CSF) is measured longitudinally in the model using microdialysis, and we use this same system to intracranially administer drugs aimed at halting AD-related neuropathology. The models are additionally tested in a novel contextual memory task. **Results:** Preliminary findings indicate that viral injections of P301L tau into LEC layer two reveal direct projections between this region and the outer molecular layer of dentate gyrus and the rest of hippocampus. Additionally, phosphorylated tau co-localize with 'starter cells' and appear to spread from the injection site. Preliminary microdialysis results suggest that the concentrations of CSF amyloid-β and tau proteins mirror changes observed along the disease cascade in patients. The disease-modifying drugs appear to halt neuropathological development in this preclincial model. **Conclusions:** These findings will lead to a novel platform for translational AD research, linking the extensive research done in rodents to clinical applications.

Title: Prospective Motion Correction Improves Effect Size for Detection of Cortical Thickness in Neurodegenerative Disease

Authors: *N. G. KINNEY, **A. TRANQUILLE**, P. R. BHARNE, F. J. NITCHIE, M. J. MARTIN, M. GROSSMAN, S. BURKE, C. A. OLM, P. A. COOK, J. C. GEE, D. W. WAKEMAN, M. D. TISDALL, C. T. MCMILLAN, J. S. PHILLIPS;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Magnetic resonance imaging (MRI) is critical for diagnostic and observational research of neurodegenerative diseases. However, subject motion can lead to reduced estimates of cortical thickness (CT, Reuter et al., 2015). Application of prospective motion correction using volumetric navigators (vNavs, Tisdall et al., 2012) has been demonstrated to reduce bias in gray matter estimates in healthy volunteers with artificial motion (Tisdall et al., 2016), but their application has not yet been studied in natural motion of neurodegenerative disease patients. In this study we investigated how prospective motion correction with vNavs influenced effect sizes for CT differences between participants clinically diagnosed with Alzheimer's Disease (AD, n=34), behavioral variant frontotemporal dementia (bvFTD, n=40), and healthy controls (n=26), recruited from the University of Pennsylvania Frontotemporal Degeneration Center. We hypothesized that group differences between AD and controls and bvFTD and controls would be larger when using vNavs than not correcting for motion. We collected two T1-weighted MRI sequences containing four echoes interspersed with vNavs on each individual, one applying motion correction, and one without. T1 images were processed using Advanced Normalization Tools (ANTs, Tustison et al., 2014). Using warps to a standardized template, a manually segmented brain atlas (Lausanne125, Daducci et al., 2012) was spatially normalized to each participant's native T1 space, and mean CT in each region of interest was calculated. CT estimates across 219 ROI were compared between patient and control groups in both MRI conditions, and effect sizes were calculated. CT comparisons in the motion corrected condition consistently demonstrated significant (false discovery rate corrected $p<0.05$) atrophy in anatomically relevant regions, while reducing spurious findings observed in the non-motion corrected condition. Effect sizes within the motion corrected condition were larger in the frontal pole and the inferior temporal lobes for both disease groups. Our results demonstrate that motion correction may allow for better discrimination between groups in biologically-plausible neuroanatomic regions.

Abstract: When a patient presents with Alzheimer's disease (AD) dementia, AD-related disease processes are already ongoing for 20 years. New methods to diagnose patients in this presymptomatic disease stage might hold the key to the development of successful AD therapies. In this light, the retina has emerged as a new target to diagnose and study AD, as it allows for the non-invasive characterization of central nervous system tissue, both in mice and patients. In this preclinical study, we aimed to gain more evidence for the early involvement of the retina in AD and for the potential of retinal examinations for follow-up of disease progression in AD mouse models. We report the results of a comprehensive phenotyping of the retina of the *App^{NL-G-F}* mouse, one of the first AD knock-in mouse models. Accumulation of amyloid beta (Aβ), one of the major hallmarks of AD, was assessed in the retina using ELISA, immunohistochemistry and *ex vivo* hyperspectral imaging. Furthermore, *in vivo* tests were applied to study the morphology and electrophysiology of the retina (optical coherence tomography and electroretinograms) and visual performance (optomotor test). We demonstrate that soluble Aβ accumulation is present in the retina of these mice early in life and progresses to Aβ plaque formation by midlife. This elevated Aβ burden, coincides with local microglia reactivity, astrogliosis, and abnormalities in retinal vein morphology. In addition, electroretinography recordings reveal subtle signs of neuronal dysfunction yet no clear neurodegeneration was observed and visual performance outcomes were unaffected in the *App^{NL-G-F}* mouse. Furthermore, we show that retinal hyperspectral imaging can be used to quantify retinal Aβ already early in life, underscoring its potential as a biomarker for AD diagnosis and monitoring. These findings suggest that the *App^{NL-G-F}* retina mimics the early, preclinical stages of AD, wherein Aβ accumulates but does not lead

to severe functional impairment yet. This model, combined with retinal imaging techniques, offers unique opportunities for drug discovery and fundamental research into preclinical AD.

Disclosures: None.

Abstract:

Background. With increasing age, there is a common and gradual decline in memory capacity. These common or “normal” declines in memory are associated with markers of Alzheimer’s

disease (AD) neuropathology, characterized by neurofibrillary tangles (NFTs) and amyloid plaques that typically appear in the entorhinal cortex (ERC). However, there is a rare group of individuals over age 80 designated as "Cognitive SuperAgers" who show exceptional memory at a level comparable to individuals 20-30 years their junior and appear to be immune to some of the deleterious effects of aging. In a recent study, we found that compared to same-aged cognitively-normal peers, SuperAgers showed significantly lower numbers of tangle-bearing neurons in the ERC. The goal of this study was to determine whether neuronal atrophy (i.e., size) in the memory-associated ERC differentiates SuperAgers from their cognitively-normal peers.
Methods. Postmortem specimens were collected from the following subject groups: SuperAgers (N=4; mean age, 89.9), cognitively-normal controls (N=6; mean age, 87.8), and individuals with amnestic Mild Cognitive Impairment (aMCI; N=5; mean age, 92.4), a prodromal stage of dementia of the AD type. ERC sections were obtained at a thickness of 40µm and stained with cresyl violet to visualize neurons. Neuronal size of cortical layers III and V were quantified using the ImageJ software (version 1.53a).
Results. One-way non-parametric ANOVAs determined no significant difference in neuronal size in the ERC between cognitively-normal controls (M=143.04µm^2; SD=77.49µm^2) and SuperAgers (M=143.48µm^2; SD=72.19µm^2); however, there was a significant difference in mean neuronal size between the aMCI group (M=130.11µm^2; SD = 44.51µm^2) and both the cognitively-normal control and the SuperAger groups (p<0.0001).
Conclusion. Despite exceptional episodic memory performance, neuronal atrophy in the ERC does not appear to be a strong discriminating factor between SuperAgers and their cognitively-normal peers. Instead, loss of neuronal integrity appears to be more closely associated with abnormal memory performance pathognomonic of aMCI, suggesting changes in neuronal size may emerge as a downstream consequence of accumulating AD neuropathology.

Abstract: Down's syndrome (DS) results from trisomy of chromosome 21, a genetic change which also confers a probable one hundred percent risk for the development of Alzheimer's disease (AD) neuropathology in later life. We aimed to assess the effectiveness of diffusion-weighted imaging and connectomic modelling for predicting brain amyloid plaque burden and longitudinal cognitive change using support vector regression. Ninety-five participants with DS successfully completed a full Pittsburgh Compound B (PiB) PET-MR protocol and memory assessment at two timepoints.

Linear regression support vector machines (SVMs) carried out on the selected features of the structural network predicted amyloid deposition via PiB binding with a root mean square error (RMSE) of 0.53 (SUVR) and an R^2 value of 0.19. The selected features of the structural network predicted longitudinal cognitive change with a RMSE of 8.8 (total score on cued recall) and an R^2 value of 0.26.

Here, we show that connection density of the structural network at baseline is a promising predictor of both current amyloid deposition and longitudinal cognitive change. Additionally, our findings indicate an important role for both network dysconnectivity and compensatory mechanisms during the trajectory of AD-development in people with DS. Taken together, these results demonstrate the integral role of the white matter during neuropathological progression and the utility of machine learning methodology for non-invasively evaluating AD prognosis.

Title: Three dimensional ultrastructural analysis of GABAergic terminals from the external globus pallidus in the subthalamic nucleus of rhesus monkeys

Authors: ***A.-C. MARTEL**[1,2], R. M. VILLALBA[1,2], T. WICHMANN[3,1,2], A. GALVAN[4,1,2], Y. SMITH[1,2,5];

Abstract: The subthalamic nucleus (STN) is part of the "indirect" pathway (striatum-external globus pallidus-STN) of the basal ganglia. Alterations of STN firing rates and patterns following nigrostriatal dopaminergic denervation are linked to the severity of parkinsonism and other diseases of basal ganglia origin (such as Huntington's disease or dystonia). Previous studies demonstrated that neuroplastic changes in the abundance, morphology and strength of GABAergic synapses from the external globus pallidus (GPe) to the STN contribute to parkinsonism. In 6-hydroxydopamine (OHDA)-treated mice with severe nigrostriatal degeneration, the increased strength of GPe-STN GABAergic synapses is associated with an increase in the number of synapses per GPe terminals (Fan et al., 2012, JNS 32:13718). This adaptation may contributes to abnormal firing patterns of STN neurons and the development of parkinsonian motor signs. Such knowledge does not exist for primate species. To enable enquires into disease-associated adaptive changes of the morphology of GPe terminals in the STN, we undertook a detailed quantitative 3D electron microscopic analysis of the morphometry of GPe terminals and their synapses in the STN in healthy monkeys. The single block facing/scanning electron microscopy (SBF/SEM) approach and the *Reconstruct* software were used to fully reconstruct 55 GABAergic pallidal terminals in the STN of 2 control rhesus monkeys. The pallidal terminals were identified either by anterograde labeling from the GPe or known ultrastructural features (large size, symmetric synapses, >3 mitochondria). We collected morphometric data for each terminal, including its volume, the flat area of synapses formed by the terminal, and the number and size of mitochondria within the terminal. Our data show that the volume of GPe terminals ranged from 1.13-26.41μm^3 (mean ± SEM= 4.02 ± 0.47). Each terminal formed large and complex fenestrated synapses with flat areas varying from 0.04-2.67μm^2 (mean ± SEM= 0.42 ± 0.05). The number of mitochondria per terminal ranged from 2-31 (mean ± SEM= 5.15 ± 0.55), while the volume of individual mitochondria varied between 0.06-0.34μm^3 (mean ± SEM=0.15 ± 0.008). Positive correlations were found between the volume of the terminal and the flat area of the synapses as well as the number and volume of mitochondria/terminal. Studies in MPTP-treated parkinsonian monkeys are in progress to compare the ultrastructural features of the GPe-STN terminals between the normal and parkinsonian states.

Title: Identification of GPR139 as an attenuator of LID through striatal interneuron transcriptional profiling

Authors: *D. R. ZUELKE[1,2], K. KENNEDY[1], P. BARKAUS[1], A. H. KOTTMANN[1,2];
[1]CUNY Sch. of Med., New York, NY; [2]The Grad. Center, CUNY, New York, NY

Abstract: Cholinergic interneurons (CINs) of the striatum have been recognized as a key mediator of L-dopa induced dyskinesia. We have previously shown that the Shh pathway attenuates L-Dopa induced dyskinesia (LID) in parkinsonian rodent and macaque models of Parkinson's disease (PD) in a mechanism that impinges on CIN activity (Malave et al., 2020, BioRX: https://doi.org/10.1101/2020.03.09.983759). The predominant source of Shh for CIN are dopaminergic neurons (DANs) located in the ventral midbrain and are the same population of neurons that degenerate in PD. The downstream transcriptional targets of Shh in CINs are not well defined. We utilized the immunoprecipitation technique, translating ribosome affinity purification (TRAP), to isolate mRNA from CINs for RNAseq in mice with and without Shh from DAN. CIN TRAP extractions were verified by qPCR and had enrichment of the CIN specific transcripts ChAT, GDNF, VAChT, M4, and M2 as well as depletion of the non-CIN transcripts M1 and Parv. The results from the RNAseq analysis identified the orphan G-coupled protein receptor GPR139 as a potential target for further investigation. First, we found that GPR139 is differentially expressed at the protein level in CIN in mice with and without Shh from DAN. GPR139 receptor agonism has been shown to block mu-opioid receptor activation by morphine and fentanyl. Interestingly, mu-opioid receptor antagonism has been shown previously to attenuate LID in animal models of PD. In a proof of principle study, we utilized the aphakia model of PD to ascertain if chronic L-dopa dosing paired with the GPR139 agonist JNJ-63533054 could attenuate the presentation and histological markers of LID. We find in preliminary results that GPR139 agonism reduces the appearance of three-paw dyskinesia in the aphakia model of PD. Histologically, the LID severity marker pERK is reduced with chronic GPR139 agonism in CIN. These results suggest that the transcriptional target of Shh, GPR139 attenuates expression of LID through a CIN resident mechanism. Further studies are needed to clarify the effects of GPR139 on CIN physiology and to determine the mechanism by which GPR139 impinges on LID formation and expression.

Title: Estrogen sensitivity and sparing of Object-in-Place performance in 6-hydroxydopamine-lesioned female, male and gonadectomized male rats

Authors: *A. PATWARDHAN[1], J. PATEL[2], M. CONNER[1], M. KRITZER[1];
[1]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY; [2]Kings Park High Sch., Kings Park, NY

Abstract: Early, pre-motor stages of Parkinson's disease (PD) are marked by treatment-resistant cognitive deficits whose underlying neurobiology is incompletely understood. However, the sex differences that characterize their type, prevalence and severity suggest key roles for sex hormones in modulating these non-motor signs (Jurado-Coronel et al., Front Neuroendocrinol, 2018). Recent work in our lab has shown striking protective effects of decreased androgen levels for deficits in spatial working and episodic memory that are induced in rats with partial bilateral neostriatal 6-OHDA lesions (Conner et al., Eur J Neurosci, 2020; Conner et al., Front in Neurol, 2020). Here we extend investigation to processes of associative memory for object identity and location using the Object in Place (OiP) task. In this task rats first explore an arena containing four distinct objects. After a delay, rats are reintroduced to the arena containing the same objects, albeit with two switched from their original locations. Driven by novelty preference, rats demonstrate associative memory by spending more time with displaced objects. We studied the effects of biological sex and sex hormones on OiP by comparing rats' discrimination index (DI) for displaced vs. stationary objects in male, female and gonadectomized male rats (GDX), and in GDX males given testosterone propionate (GDX-TP) or estrogen (GDX-E). We found robust DI that was greater in female vs. male rats, as well as striking deficits in DI in GDX rats that were partially attenuated by TP and fully rescued by E. We next evaluated impacts of sex and sex hormones in contexts of 6-OHDA lesions. Comparisons of sham and 6-OHDA-lesioned male, female, GDX, GDX-TP and GDX-E rats revealed no effects of sham surgery and profound 6-OHDA-induced DI deficits in male, GDX and, to a lesser extent, GDX-TP rats. However, in female and GDX-E rats, 6-OHDA lesions had no effect on DI. Importantly, the severity of DI deficits was unrelated to 6-OHDA lesion size and was not accompanied by obvious group differences in non-exploratory activities, e.g., grooming, rearing, ambulation. This strengthens conclusions that the memory functions tapped in OiP tasks are estrogen-sensitive and that elevated estrogen levels in the female and GDX-E groups protect these processes from harm in the 6-OHDA model. Together with our earlier data these findings also suggest that the distinct cognitive processes that are at risk in 6-OHDA rats include both estrogen- and androgen-sensitive domains that can be differentially attenuated/spared in sex- and hormone-specific ways. This in turn could help advance treatment for what are currently clinically intractable signs of PD.

Title: Unilateral dopamine denervation in the globus pallidus of rat produces changes in anxiety-like behavior, memory and aggressiveness

Authors: K. BARÓN, J. CALZADA, E. CHUC-MEZA, *M. GARCIA-RAMIREZ;
Physiol., Escuela Nacional de Ciencias Biologicas IPN, CDMX, Mexico

Abstract: External *Globus Pallidus* (GP) is a nucleus belonging to indirect pathway of basal ganglia and it is in a key position to influence processing of motor, associative and limbic information. GP receives dopaminergic innervation from Substantia Nigra pars compacta (SNc) In rodents, appetitive or aversive stimuli raise dopamine release in GP suggesting that dopaminergic innervation of GP is also involved in emotive process. Patients with globus pallidus infarctions shows acute cognitive changes, like inattention and amnesia. Besides in Parkinson`s disease patients disease it has also been observed anxiety and cognitive impairment, which are developed months or years before motor symptoms appear. The present work explores the effect of partial dopamine denervation in GP over anxiety, recognition memory, aggressiveness and motor activity in the rat. Unilateral dopaminergic lesion in GP was made with 6-OHDA (500 nL of 6-OHDA, 15 μg/μL) and 1 and 5 months after surgery, behavioral tests, were performed; Elevated plus maze (EPM), burying behavior (BB), novel object recognition test (NRT), Resident-intruder (RI) test and spontaneous motor activity (MA). Data were analyzed by one-way ANOVA followed by Student-Newman-Keuls post-hoc analysis. After a month of the surgery there were a significant decrease in time spent in open arms in EPM and increase burying time in BB, both indicative of anxiety. Recognition index was decreased in NRT revealing memory disfunction. Only 50% of lesioned rats increased aggression time in RI test. These results suggest that dopamine deficit in GP, could produce behavioral alterations resembling some of the neuropsychiatric symptoms observed in PD patients

Title: Longitudinal Assessment of Skilled Motor Function and Levodopa Treatment Efficacy in DJ-1 Knockout Rats

Authors: C. A. SANCHEZ[1], J. BROUGHER[2], D. KRISHNAN[2], *C. A. THORN[2];
[1]Dept. of Bioengineering, [2]Dept. of Neurosci., The Univ. of Texas at Dallas, Richardson, TX

Abstract: DJ-1 knockout (DJ-1) rats have been shown to exhibit a moderate parkinsonian phenotype, with ca. 50% loss of midbrain dopaminergic neurons and deficits in some gross motor behaviors appearing between 6 and 8 m.o. In the current study, we provide additional characterization of skilled motor performance of DJ-1 rats from 2 to 12 months of age, and ask whether motor deficits in these rats are responsive to standard levodopa therapy. Male DJ-1 (n = 8) and wild-type Long Evans (WT, n = 8) rats were trained on an isometric pull task previously shown to be a sensitive assay of forelimb strength and coordination. The task requires subjects to reach 1.5 cm outside a training box and pull an isometric bar with sufficient force to receive reward. Rats performed two 30-minute training sessions daily, 5 days/week, beginning at 2 m.o. During Acquisition (2-10 m.o.), rats performed a standard version of the pull task in which pull force thresholds were low (100-200 g), and adapted on each trial to the average of the strongest 5 of the last 10 pulls. Our results demonstrate that DJ-1 rats exhibit significant deficits in pull force and percent correct performance on this task compared to WT rats. Impairment was detectable at ca. 8 m.o., as DJ-1 rats' performance stabilized, while WT performance continued to improve. At 10 m.o., the upper limit of the adaptive force threshold was increased to 300 g, increasing the difficulty of the task to determine whether the deficits exhibited by DJ-1 rats were due to an inability to execute the motor demands of the task. To our surprise, during this 5-week Challenge period, DJ-1 rats were able to increase their pull force, though performance remained significantly impaired compared to WT rats. Throughout the Acquisition and Challenge periods, DJ-1 rats exhibited no differences from WT in total distance traveled or number of rearing events in an open field, suggesting that gross motor performance was not significantly impaired. To evaluate whether the forelimb deficits we observed could be rescued by standard dopamine replacement therapy, we administered levodopa/benserazide (6 mg/kg, 10 mg/kg, respectively) daily for 3 weeks. During these Treatment sessions, drugs were systemically administered once per day, 30 minutes prior to the first training session. DJ-1 rats showed a small but significant increase in pull force over the 3-week Treatment period, while performance of WT rats was impaired by L-dopa administration. Combined, our results are consistent with a mild-to-moderate dopamine-mediated motor impairment in the DJ-1 KO rats that begins to present around ca. 8 m.o., but does not significantly worsen between 8 and 12 m.o.

Title: The string-pulling task as a novel and simple behavior to test for parkinsonian deficits in unilaterally 6-OHDA-lesioned rodents

Authors: *M. J. BARTLETT[1], C. J. STOPERA[2], M. R. SEXAUER[1], A. VISHWANATH[3], G. JORDAN[4], S. L. COWEN[3], T. FALK[1];

[1]Dept. of Neurol., The Univ. of Arizona Col. of Med., Tucson, AZ; [2]Neurosci. Grad. Interdisciplinary Program, The Univ. of Arizona, Tucson, AZ; [3]Dept. of Psychology, [4]Dept. of Biomed. Engin., Univ. of Arizona, Tucson, AZ

Abstract: The unilateral 6-hydroxydopamine (6-OHDA) toxin model of Parkinson's disease (PD) has been well characterized for decades. However, many of the standardized behavioral tasks established in this model are either experimenter-led movements, tests that assess the limbs independently, or drug-induced. Moreover, two of the behavioral tests that analyze both forelimb and paw function in the 6-OHDA model, the single-pellet reaching and staircase tasks, require extensive training. The string-pulling task, which has recently been described in rodents, assesses skilled motor coordination of both forelimbs and requires minimal equipment and training for both the experimenter and animal. In this pilot study we demonstrate the first use of the string-pulling task in a 6-OHDA rodent model of PD. Male Sprague-Dawley rats were placed in a box with a transparent window allowing for video recording. A cheerio-baited string was hung at the front of the box. The rats were trained according to established literature until they successfully retrieved the reward in 8 trials across 2 consecutive days. Once complete, rats (n=3/group) received either a unilateral 6-OHDA (2 sites; 10 μg/site) lesion or sham-surgery in the medial forebrain bundle. Rats were then tested for 8 consecutive trials at 1, 3, 7, 14, and 21 days post-lesion for string pulling performance. In this pilot, we analyzed the first 3 trials at the pre-lesion and 14-day post-lesion timepoints. All statistical analyses were performed using two-way ANOVA with post-hoc Sidak's multiple comparisons tests. While we found no between-group difference in the motivation of rats to initiate the string-pulling task, there was a significant effect of both timepoint and lesion in regard to completing the task. Specifically, 6-OHDA rats took longer to complete the task compared to pre-lesion ($p<0.05$) and sham-treated rats ($p<0.01$) at 14 days post-lesion. The 6-OHDA-lesioned rats also made significantly more errors, in the form of missing the string, compared to pre-lesion ($p<0.05$) and sham-treated rats ($p<0.01$) at 14 days post-lesion. Interestingly, there were no significant differences between the use of the contralateral limb at either timepoint, regardless of lesion. However, there was a significant increase in the use of the ipsilateral limb to pull the string at 14 days post-lesion compared to pre-lesion ($p<0.05$) and a strong trend compared to sham-treated rats ($p<0.058$). We are continuing to analyze the additional timepoints post-lesion and increase our sample size to establish the string-pulling task as a novel and simple behavioral task for use in the preclinical 6-OHDA PD model.

Title: Fenofibrate promotes neuroprotection in a model of rotenone-induced Parkinson's disease

Authors: *D. C. RAMOS, J. K. BARBIERO, S. BOSCHEN, T. BASSANI, C. DA CUNHA, M. A. B. F. VITAL;
Dept. de Farmacologia, Univ. Federal do Paraná, Curitiba, PR, Brazil

Abstract: Parkinson's disease (PD) is a neurodegenerative andprogressive disease characterized by a degeneration of dopaminergic neurons in thesubstantia nigra pars compacta (SNpc) which causes a decreased in levels ofdopamine (DA) in the striatum. The etiology remains unknown but some likelycauses of PD include oxidative stress, mitochondrial dysfunction andneuroinflammation. Peroxisome proliferator-activated receptor (PPAR) agonistshave frequently been studied in models of PD and have shown protective effects inanimal models in which they were tested. In the current study, fenofibrate (100 mg/kg) (PPAR-alpha agonist) wasadministered orally for 15 days, 5 days prior to the injection of rotenone (2.5 mg / kg ip for 10 days).One, 7, 14 and 21 days after finishing the treatment with rotenone andfenofibrate the animals were subjected to the open field test. On the 21stday we performed the forced swimming test and on the 22nd a two-wayactive avoidance task. After 23 days, a subset of the animals had theirstriatum dissected to quantify DA and metabolites levels and the remaining wereperfused for quantification of tyrosine hydroxylase-immunoreactive neurons inthe SNpc. In addition, we evaluated the quantification of alpha-synuclein afterthe animals were treated for 5 days with fenofibrate treatment continuing forover 28 days with rotenone. After 29 days, the animals were perfused for immunohistochemistryanalysis of alpha synuclein in the SNpc and striatum. The results showed thatfenofibrate reduced depressive-like behavior induced by rotenone. Moreover, thePPAR-α agonist diminished the depletion of DA and protectedagainst dopaminergic neuronaldeath in the SNpc. Moreover, theadministration of fenofibrate attenuated the aggregation of α-synuclein in theSNpc and striatum in the rotenone-lesioned rats. The present study showed thatfenofibrate exerted neuroprotective effects, since rats treated before andafter the induction of parkinsonism demonstrated reduced behavioral,neurochemical and immunohistochemical changes.

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by degeneration of dopamine neurons in the substantia nigra pars compacta (SNpc). Mutations that increase kinase activity of Leucine-rich repeat kinase 2 (LRRK2), such as G2019S are a genetic cause of PD. Inhibition of LRRK2 is a current therapeutic strategy in development for PD. We investigated the interaction between LRRK2 activity and dopamine neurotoxicity in a mouse 6-hydroxydopamine (6-OHDA) injection model using LRRK2*G2019S^{GSK} knock-in mice, and pharmacological inhibition of LRRK2.
In experiment 1, we tested a range of 6-OHDA doses for inducing SNpc neurodegeneration, gait deficits, and altering locomotor response to amphetamine. In experiment 2, we compared 6-OHDA toxicity between LRRK2*G2019S^{GSK} homozygous knock in (KI) mice and wild type (WT) mice. In experiment 3, we treated 6-OHDA toxicity with administration of a LRRK2 inhibitor (MLi-2) in diet (~14 mg/kg/day). Sample size n=7-8 mice per group.
Mice were injected with 6-OHDA (2-8 µg in 1 µl PBS) in the right striatum. Mice were euthanized 4-5 weeks after injection. Brains were analyzed for nigrostriatal tyrosine hydroxylase loss and LRRK2 phosphorylation at s935.
8 µg 6-OHDA induced lasting gait impairment, reduced response to amphetamine, and TH loss in striatum and SNpc; however, the dose was not tolerated. Mice injected with 2 or 4 µg 6-OHDA showed TH loss in striatum and SNpc and developed temporary gait impairments. A dose of 6 µg 6-OHDA was chosen for subsequent experiments. Change from baseline in gait parameters "step cycle" and "stride length" was predictive of SNpc TH neuron loss. 6-OHDA produced similar TH loss in the striatum and SNpc in both WT and KI mice. 6-OHDA-WT mice showed slower gait and higher response to amphetamine compared to WT sham injection; however all KI mice sham- and 6-OHDA-injected behaved similarly to 6-OHDA-WT mice. pS935 LRRK2 was lower in KI mice compared to WT, with no effect of 6-OHDA. Daily treatment with MLi-2 inhibited pS935 LRRK2 by 41% in the brain and 61% in the lung. 6-OHDA+Veh mice displayed a gait impairment compared to Sham+Veh mice, and this impairment was not seen in 6-OHDA+MLi-2 mice. Nigrostiratal TH of 6-OHDA+Veh group was lower than that of Sham+Veh; however, TH stain in 6-OHDA+Veh did not differ from Sham+Veh.6-OHDA injection depletes dopamine in the SNpc and striatum and induces gait impairment. Mice carrying the G2019S LRRK2 mutation were not more sensitive to 6-OHDA toxicity than wild type mice. 6-OHDA-injected mice treated with MLi-2 had similar gait and TH staining to Sham-injected mice.

Title: Gtp binding inhibitor, 68 attenuates LPS-induced B-cell singling and TNF alpha secretion

Authors: T. LI[1,2], B. NING[1], L. KONG[2], A. SAWA[1], C. A. ROSS[1], ***W. SMITH**[1]; [1]John Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Univ. of Maryland Pharm. Sch., Baltimore, MD

Abstract: Mutations in the leucine-rich repeat kinase-2 (*LRRK2*) gene cause autosomal-dominant Parkinson's disease (PD) and contribute to sporadic PD. Common genetic variation in LRRK2 modifies susceptibility to immunological disorders including Crohn's disease and leprosy. Previous studies have reported that LRRK2 is expressed in B lymphocytes and macrophages, suggesting a role for LRRK2 in immunological functions. In this study, we characterized the LRRK2 protein expression and phosphorylation using human lymphoblasts. Lipopolysaccharide (LPS), a preinflammatory agent, treated human lymphoblasts resulted in increases of LRRK2 expression and kinase activities in a time dependent manner. Moreover, increase of LRRK2 protein expression by LPS appeared to be associated with activation of B cell signaling. Treatment with LRRK2 inhibitor, 68, reduced LPS-induced B-cell signaling and TNF-α secretion. These results suggested that LRRK2 is actively involved in preinflammatory responses in human lymphoblasts.

Abstract: Introduction: Parkinson's disease (PD) is the most common neurodegenerative motor disease. Mutations in the leucine rich repeat kinase 2 (*LRRK2*) gene are linked to autosomal dominant parkinsonism, and genomic variation at the *LRRK2* locus is associated with increased risk for sporadic PD. LRRK2 is a multi-phosphorylated protein and reduced phosphorylation is associated to disease. Dephosphorylation leads to alterations in LRRK2 interactions and subcellular localization. PD is characterized by impaired intracellular trafficking, however the link between LRRK2 phosphorylation and membrane trafficking is not fully understood. Interestingly, LRRK1, the closest homolog of LRRK2, interacts with VAMP7 (Vesicle Associated Membrane Protein 7) and blocks synaptic vesicle fusion. Furthermore, several vesicular Rab-GTPases are LRRK2 substrates including Rab8, Rab10, Rab29. Here we have studied how LRRK2 phospho-status affects its Rab substrates as well as the mutual regulation of LRRK2 phosphorylation sites.**Methods**: We used LRRK2 phospho-mimick and phosphor-dead mutants in a cluster of phosphorylation sites including S860-S910-S935-S955-S973-S976 to assess the phosphorylation changes on non-mutated sites induced by individual or combined phosphor-site mutations as well as the phosphorylation of the known LRRK2 substrates Rab8 and Rab10 *in cellulo*. In addition, phosphor-mutant LRRK2 was purified to assess *in vitro* kinase activity.**Results**: With analysis ongoing, our results demonstrate that the phospho-regulation of the tested phospho-sites is interdependent and that LRRK2's phospho-status affects the intensity of LRRK2's kinase activity on its Rab vesicular substrates *in cellulo*. This presents a direct link between LRRK2 phosphorylation and Rabs phosphorylation state. These results suggest that LRRK2 phosphorylation leads to the modification of its kinase activity. **Conclusions**: This study will contribute to improving our understanding of LRRK2's role in membrane perturbation in PD. We hypothesize that phosphorylation may alter LRRK2's subcellular localization thereby regulating its downstream effectors such as Rabs. The central role of LRRK2 phosphorylation and it localization is crucial to how vesicular trafficking might be defective in PD.

Title: Sustained activation of the DNA damage response and increased nuclear DNA damage in LRRK2 G2019S Parkinson's disease models

Authors: *C. P. GONZALEZ-HUNT, C. M. TOSTE, S. D. GOODSON, L. H. SANDERS; Neurol., Duke Univ. Med. Ctr., Durham, NC

Abstract: Recent studies from our laboratory demonstrated that LRRK2 G2019S-induced mitochondrial DNA (mtDNA) damage is LRRK2 kinase dependent and inhibition restores mtDNA integrity in Parkinson's disease (PD) models. However, whether or not there is also nuclear DNA damage in LRRK2 G2019S PD is unknown. We hypothesized that enhanced LRRK2 kinase activity alters signaling/repair pathways involved in genome maintenance, compromising global genome integrity. Utilizing CRISPR/Cas9-edited HEK293 cells carrying the G2019S mutation and isogenic controls, we measured nuclear DNA damage via comet assays and evaluated if the DNA damage response (DDR) was activated by western blotting. Our results show increases in nuclear DNA damage and activation of the DDR, represented by increases in phosphorylation of the kinase ataxia-telangiectasia mutated (ATM pS1981) and downstream substrates histone H2A.X (γH2A.X), CHK2 (pT68), and P53 (pS15). Next, we hypothesized that the increase in DNA damage and DDR activation would trigger cell cycle arrest; to test this we stained cells with propidium iodide and measured DNA content via flow cytometry. Our results show an increased proportion of cells in S phase, and a decreased proportion of cells in G0/G1. We also evaluated if inhibition of ATM or LRRK2 kinase activity could reverse H2A.X phosphorylation. As expected, ATM kinase inhibition was capable of reversing the γH2A.X increase we observe in LRRK2 G2019S HEK293 cells. Interestingly, LRRK2 kinase inhibition was also capable of reverting the γH2A.X increase back to baseline. In conclusion, our work shows that, in the context of the LRRK2 G2019S mutation, nuclear DNA damage is increased and the DDR is activated. We also found evidence of cell cycle arrest. Furthermore, our results show that inhibition of ATM or LRRK2 kinase activity can revert γH2A.X phosphorylation increases back to baseline, directly implicating mutant LRRK2 function in the DDR for the first time. We are currently working on further characterizing this novel signaling cascade in HEK293 lines, and evaluating DDR activation in a LRRK2 G2019S mouse model and induced pluripotent stem cell (iPSC)-derived neural progenitor cells. We are also investigating the potential impact of DDR dysregulation and DNA damage accumulation on PD pathogenesis. ATM function is critical for nervous system homeostasis, and its activation can lead to cycle arrest, DNA repair, or apoptosis. Dysregulation of the ATM signaling cascade could lead to cell death, and as such modulating ATM function has the potential to be a new strategy for therapeutic intervention in PD.

Title: Longitudinal voxel-wise mapping of alpha-synuclein-induced brain pathology in a mouse model of Parkinson's Disease

Authors: *S. TULLO[1], D. GALLINO[1], E. DEL CID-PELLITERO[2], E. A. FON[2], M. CHAKRAVARTY[1];
[1]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [2]Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: The mechanisms underlying Parkinson's Disease (PD) pathology have not been elucidated. Recent evidence suggests aggregated misfolded alpha-synuclein (a primary component of Lewy bodies, [aSyn]), may propagate in a prion-like manner, mediating the spread of pathology and contributing to PD progression. Using an aSyn propagation mouse model of PD, with a known locus of pathology, we longitudinally examined aSyn-induced changes in anatomy using magnetic resonance imaging (MRI).
11-week old wild-type (WT) and hemizygous M83 $aSyn^{A53T}$ transgenic mice received an injection of either mouse [Ms-] or human [Hu-] preformed fibrils [PFF] of aSyn, or phosphate buffered saline (PBS; control group) in the right striatum (n~10 mice/group/sex). T1-weighted MRI images (100 μm^3 voxels) were acquired at -7, 30 and 90 days post-injection. Brain atrophy was assessed using deformation-based morphometry, to measure local differences between groups.
We observed significant changes in brain anatomy over time in M83-Ms-PFF compared to WT-Ms-PFF and M83- and WT-PBS groups; specifically in regions such as the bilateral striatum, and contralateral posterior nuclei of the thalamus (FDR 15%). There is an impact of the species of PFF, such that M83-Hu-PFF mice had steeper rates of decline in the contralateral anterior olfactory nucleus, contralateral nucleus accumbens and ipsilateral field CA1, compared to M83- and WT-Ms-PFF and WT-Hu-PFF mice (FDR 20%). When examining the effect of inoculum on M83 mice, significant voxel-wise changes were observed for the bilateral striatum, contralateral primary motor cortex, ipsilateral midbrain reticular nucleus and dentate gyrus (FDR 15%). No significant differences between the PFF groups compared to the PBS group were observed in WT mice.
The inoculation of aSyn PFF in the striatum gives rise to widespread patterns of PFF-induced brain atrophy, particularly involving regions that project to or receive input from the injection

site in both M83 and WT mice. However in certain regions, the presence of the mutation appears to further modulate the observed degeneration.

Abstract: Introduction: Parkinson's Disease (PD) is a neurodegenerative disorder characterized by defects in membrane trafficking. SNCA, encoding α-synuclein (α-syn), is a major genetic determinants of PD pathogenesis involved in membrane trafficking. α-syn has recently emerged as regulator of SNARE (Soluble N-ethylmaleimide-sensitive-factor Attachment protein Receptor)-dependent vesicle fusion. Recently the vesicular SNARE protein VAMP4 emerged as novel PD-risk factor and VAMP7 as a mediator of ER-phagy secretion. Here we proposed to investigate the potential functional interactions between α-syn and VAMPs 4 and 7 as well as the aggregation profile of α-syn and its release in cell medium. **Methods**: The co-localization and interaction between α-syn and VAMPs was analyzed by immunocytochemistry and Proximity Ligation Assay. The released α-syn exocytosis was measured at different time points upon α-syn over-expression in cells. Exosomes isolation from cell culture media was performed in VAMP (2, 4, 7) KO. Pharmacological treatment with Bafilomycine A1 was performed in order to analyze the clearance of VAMPs upon lysosomal inhibition in cells. **Results**: We present preliminary results of PLA and co-localization testing the interaction between α-syn and VAMPs. Inhibition of lysosomal activity and effects on both VAMPs and α-syn levels were also tested. The α-syn release in cell medium is detectable up to 48h after transfection. We observed a reduced α-syn release in exosomes of PC12 KO for VAMP4 and VAMP7 compared to WT PC12 cells. **Conclusions**: α-syn and VAMPs are both involved in vesicular and membrane trafficking and our preliminary results may suggest an involvement of the same pathway in their clearance. In our perspectives, we will evaluate the effect of VAMPs on the α-syn aggregation and exocytosis in order to evaluate if the α-syn homeostasis could be modulated by SNARE proteins.

Title: Alterations in miR-219 expression associated with a-synuclein overexpression may contribute to impairments in oligodendrocyte maturation.

Authors: *L. E. CROMBERG, H. ROMERO, J. MOTT, P. DESPLATS;
Neurosci., UCSD, San Diego, CA

Abstract: Introduction: Multiple System Atrophy (MSA) is a neurodegenerative disorder characterized by autonomic failure and parkinsonian features. The neuropathological hallmark of MSA is the aggregation of a-synuclein (asyn) in oligodendrocytes, conforming Glial Cytoplasmic Inclusions (GCI). GCI formation leads to impairments in oligodendrocyte differentiation. MiRNAs are small non-coding RNA molecules that regulate gene expression and multiple biological processes including development and cell differentiation. Our previous studies in *postmortem* MSA human striatum samples showed dysregulation in the expression of 59 miRNAs, with miR-219-2-3p showing the largest alterations in expression in comparison to healthy controls. MiR-219 regulates oligodendrocyte differentiation by inhibiting the expression of Lingo1, Etv5, and PDGFRa. MiR-219 is expressed by 2 loci (miR-219-1 and miR-219-2) and is processed into miR-219-5p, miR-219-1-3p and miR-219-2-3p.In this work we analyzed the expression of miR-219 in cellular and transgenic mouse models of MSA to determine the involvement of this miRNA in oligodendrocyte alterations. **Methods:** miRNAs were extracted from the *striatum* of MBP29 mice, which over-express asyn under the MBP promoter, and non-transgenic (NTG) littermates (n=6/group). We compared the expression of 600 miRNAs using the nCounter® Mouse v1.5 miRNA panel. The expression of miR-219 isoforms was validated by qPCR analysis. We applied the newly developed miRNAscope technology to determine cell-specific changes in miR-219.Adult rat hippocampal neuronal progenitor cells (ARH-NPC) were differentiated into oligodendrocytes and cells were transduced with lentivirus expressing human asyn (or Lv-control) prior to differentiation. **Results:** we identified 16 miRNAs with aberrant expression in MBP29 mice compared to NTG controls, including decreased levels of miR-219-5p and miR-219-2-3p. Neuropathological analysis showed alterations in the oligodendrocyte markers MBP and CNP in MBP29 mice. MiRNAscope assays demonstrated decreased expression of miR-219-2-3p localized in MBP positive cells.The levels of miR219 change during oligodendrocyte maturation in vitro, reaching the highest levels at day 14 of differentiation in control cells. In contrast, and similar to what we observed in MBP29 mice, ARH-NPC cells over-expressing asyn showed significant reductions in miR-219-5p and miR-219-2-3p expression; as well as alterations in CNP and PDGFRa markers at differentiation day 14. **Conclusions:** we propose that dysregulation of miR-219 in response to asyn accumulation may impair oligodendrocytes maturation contributing to MSA pathology.

Title: Impaired retinal function & structure in A53T mice provide new insight into how Parkinson's disease manifests in the ageing eye

Authors: ***K. K. N. TRAN**[1], V. H. Y. WONG[1], J. K. H. LIM[1], A. SHAHANADEH[1], A. HOANG[1], D. I. FINKELSTEIN[2], B. V. BUI[1], C. T. O. NGUYEN[1];

Abstract: Purpose: Abnormal alpha-synuclein (α-syn) protein deposition within the central nervous system (CNS) has been recognised as one of Parkinson's disease's (PD) key hallmarks. As an embryological outpouching of the CNS, the retina provides an accessible means to study neurodegenerative disorders like PD. And as retinal assessments such as electroretinography (function) and optical coherence tomography (structure) are simple, non-invasive and inexpensive to conduct they may prove useful as biomarkers that can be used to streamline drug discovery from animal to human studies. For the first time, this study aims to quantify retinal biomarkers in a well-characterised murine PD model of α-syn overexpression.
Methods: Transgenic mice overexpressing human α-syn with A53T gene translocation and wildtype (WT) control littermates were assessed at 6 and 14 months of age (n=15-31/group). *In vivo* retinal function (electroretinography, ERG) and *in vivo* retinal structure (optical coherence tomography, OCT) were recorded. Dark-adapted and light-adapted ERG protocols were conducted to probe rod and cone pathways. ERG response parameters and OCT thickness profiles were analysed to assess changes to outer and inner retinal layers. Two-way ANOVA with Bonferroni correction for multiple comparisons (Prism, GraphPad) was used to compare differences between groups.
Results: Compared to WT controls, A53T mice exhibited significantly smaller and delayed ERG responses for both dark-adapted ERGs (genotype effect; photoreceptor and bipolar cell amplitude, $p<0.05$; bipolar cell timing, $p<0.0001$) and light-adapted ERGs (photoreceptor and bipolar cell amplitude, $p<0.001$; bipolar cell timing, $p<0.0001$). An interaction effect was also found in photoreceptor timing (dark- and light-adapted ERG, $p<0.05$). Light-adapted ERGs had a larger effect size than dark-adapted ERGs (Cohen's $d = -2.16$, effect size $r = -0.73$). OCT retinal thinning was also found in the outer retinal layers of A53T mice (outer plexiform layer, outer

nuclear layer, p<0.0001) but no changes were found in inner retinal layers (retinal nerve fibre layer, ganglion cell inner plexiform layer, inner nuclear layer, p = 0.06 to 0.37).
Conclusion: Accumulation of α-syn leads to outer retinal thinning and visual dysfunction in A53T transgenic mice at timepoints that model mid to advanced stages of PD. These retinal changes in function and structure provide a high throughput means to longitudinally study α-syn induced neurodegeneration and ultimately triage *in vivo* biomarker endpoints for PD drug discovery. Characterising retinal changes in PD models may also pave the way for a deeper understanding of vision loss in PD.

Title: Using the proportionator to assess neuronal loss in an MPTP-treated mouse model of Parkinson's Disease

Authors: *M. A. STAUP[1], R. PUSSINEN[2], T. HUHTALA[2], J. BAILY[3];
[1]Charles River, Durham, NC; [2]Charles River, Kuopio, Finland; [3]Charles River, Edinburgh, United Kingdom

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by motor and non-motor symptoms, including rigidity, tremor, and impaired walking and gait. The main pathological feature of PD is the cell death of striatofugal dopaminergic (DA) neurons located primarily in the substantia nigra pars compacta (SNc). The toxin-induced PD mouse model, in which 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) administration results in catecholamine depletion in the SNc, is commonly used to test novel therapeutics. This model reproduces many of the behavioral and physiological characteristics of the disease, including the selective vulnerability of striatofugal DA cells of the SNc, while DA cells of the neighboring ventral tegmental area (VTA) remain comparatively protected from the neurotoxin. However, the regions within which this neurodegeneration occurs varies somewhat across species, and even between strains. Some of this variability may be attributed to differences in expression of calbindin, a calcium-binding molecule, among DA cells of the ventral mesencephalic DA complex.
The present study undertook to demonstrate that restricting our sampling and analysis of neuronal loss to DA neurons that do not express calbindin, within a broader region of the ventral mesencephalic DA complex than just the SNc is a more sensitive assay of MPTP-induced neurodegeneration than counting all of the DA neurons within the same region.
This study uses advanced stereological analysis to accurately evaluate neuronal changes in the MPTP mouse model. The tyrosine kinase inhibitor, Nilotonib, was used as an agent of rescue.

Immunofluorescent (IF) methods were used to generate a duplex stain for tyrosine hydroxylase (TH) and calbindin. The proportionator method of area sampling was used to unbiasedly sample from this subpopulation of neurons in mounted sections that were captured from the ventral mesencephalic DA complex using a systematic uniform random sampling (SURS) method. The increased sensitivity and specificity of molecular phenotyping combined with the proportionator technique enables us to capture drug effects more efficiently compared to traditional approaches.

Title: Tip60 HAT activity prevents locomotor defects and short term memory loss in multiple neurodegenerative conditions

Authors: ***A. BHATNAGAR**, M. BEAVER, P. PANIKKER, H. ZHANG, R. SNOOK, F. ELEFANT;
Drexel Univ., Philadelphia, PA

Abstract: Epigenetic mechanisms, such as histone acetylation, regulate dynamic gene expression that is critical for several neural functions including learning and memory. Consequently, loss of neural histone acetylation has been implicated in multiple neurodegenerative conditions, yet the mechanisms underlying such alterations remain unclear. Our lab has previously shown that imbalance in Tip60 histone acetyltransferase (HAT) and histone deacetylase 2 (HDAC2) in a well characterized *Drosophila* AD model results in epigenetic repression of critical synaptic plasticity genes and functional cognitive deficits. Interestingly, these phenotypes are restored by increasing Tip60 HAT levels in the AD brain, supporting a neuroprotective role for Tip60 in AD linked neurodegeneration. Here we show that similar to AD, disruption of Tip60 HAT/HDAC2 balance and repression of synaptic plasticity genes is a shared early event in Parkinson's Disease (PD), Huntington's Disease (HD) and Amyotrophic Lateral Sclerosis (ALS). Further, chromatin immunoprecipitation (ChIP) studies reveal that repressed neuroplasticity genes show reduced Tip60 enrichment and reduced histone acetylation at all gene loci examined with certain genes also showing inappropriate HDAC2 enrichment. Functional neuronal consequences of each of these disease conditions are reminiscent of human pathology and include locomotion, synapse morphology, and short term memory deficits. Since Tip60 overexpression is neuroprotective in AD linked neurodegeneration, we wanted to further explore if Tip60 plays a general neuroprotective role in multiple neurodegenerative conditions. Remarkably, increasing Tip60 HAT levels specifically in the learning and memory center of the *Drosophila* brain protects against locomotion and short-

term memory function deficits. Together, our results support a model by which Tip60 protects against neurological impairments in different neurodegenerative diseases *via* similar modes of action, giving hope for a unified therapeutic approach.

Title: Behavioral analysis in the progressive unilateral 6-OHDA-lesion rat model indicates a neuroprotective effect of sub-anesthetic ketamine-treatment

Authors: *C. J. STOPERA[1], M. J. BARTLETT[3], K. BERNARD[2], M. R. SEXAUER[3], A. ESQUEDA[3], S. J. SHERMAN[3], H. MORRISON[4], T. FALK[3];
[1]Neurosci. Grad. Interdisciplinary Program, [2]Grad. Interdisciplinary Program in Physiological Sci., The Univ. of Arizona, Tucson, AZ; [3]Dept. of Neurol., The Univ. of Arizona Col. of Med., Tucson, AZ; [4]Col. of Nursing, Univ. of Arizona, Tucson, AZ

Abstract: Low-dose, sub-anesthetic ketamine has been shown to be neuroprotective in rodent models of cerebral ischemia and traumatic brain injury. Additionally, a recent publication from our lab demonstrated that treatment with sub-anesthetic ketamine (10-hr infusion; 5 x 20 mg/kg; *i.p.*; 2-hrs apart) can reduce levodopa (L-DOPA)-induced dyskinesia (LID) in a rat model of 6-hydroxydopamine (6-OHDA), while also providing acute anti-parkinsonian activity. Specifically, we have shown that increased brain-derived neurotrophic factor (BDNF) release underlies the long-term anti-dyskinetic activity of 10-hr sub-anesthetic ketamine treatment in LID rats. There is also evidence in the literature for ketamine having anti-inflammatory effects via activation of both microglia and astrocytes. Therefore, we hypothesized that sub-anesthetic ketamine may exhibit neuroprotective effects in the progressive 6-OHDA rat model of Parkinson's disease (PD). To test this, male Sprague-Dawley rats were administered either ketamine or vehicle via a treatment protocol (6-hr treatment; 3 x 20 mg/kg; *i.p.*; 2-hrs apart) that began 6-hrs prior to a unilateral intrastriatal (2 sites; 13.75 µg/site) lesion. Animals were then treated daily with the 6-hr treatment protocol for 7 days post-lesion. Baseline behavioral activity was established prior to the lesion and animals were retested at 14 and 28-days post-lesion. We have completed the analysis of the amphetamine-induced rotation test, which provides an estimate of the extent of the parkinsonian lesion, at the 28-days post-lesion timepoint. Rats were injected with D-amphetamine (5 mg/kg; *i.p.*) and rotational asymmetry was assessed by counting the net ipsilateral rotations (mean ± SEM) over 90-minutes. Ketamine (211 ± 116) treated

animals showed a significantly decreased number of net ipsilateral rotations compared to the vehicle (666 ± 187) treated group (Two-tailed t-test; *p < 0.05; n=15), suggesting a neuroprotective effect of ketamine. Currently we are performing unbiased stereology on dopaminergic neurons in the substantia nigra to further evaluate ketamine's neuroprotective effects. To investigate anti-inflammatory activity, we are staining for the microglia and astrocyte markers IBA1 and GFAP, and conducting a morphometric analysis to identify changes in activation of these cell types post-ketamine. In addition, video analysis of other behavioral tests, including the cylinder, vibrissae-elicited forelimb placing, and the forelimb adjusting steps tests, are ongoing to further analyze the effects of ketamine treatment in the progressive unilateral 6-OHDA model of PD.

Title: Motor learning of novel choreography investigated with mobile eeg

Authors: R. E. BARNSTAPLE[1], L. JAUFMANN[2], S. JEUNG[2], J. PROTZAK[2], K. GRAMANN[2], ***J. F. X. DESOUZA**[3];
[1]Dance, York Univ., Toronto, ON, Canada; [2]TU Berlin, TU Berlin, Germany; [3]Psych, York Ctr. For Vision Res., Toronto, ON, Canada

Abstract: We are investigating dance-related learning in an ecologically valid setting using Mobile Brain/Body Imaging (MoBI) to better understand potential therapeutic applications for neurorehabilitation. Previous studies from members of our group have shown that dance-based learning over 8-months produced BOLD signal changes in SMA using fMRI (Bar & DeSouza 2016) and resting state alpha power increases in frontal cortex post-dance in people with Parkinson's disease (PwPD) compared to controls (Levkov et al 2014). PwPD who dance weekly over 3-yrs show a slowdown in disease progression (DeSouza & Bearss, 2018). Our current project uses mobile neuroimaging (MoBI) to assess the impact of motor learning while subjects (n=17) learn a 30-sec choreography (Barnstaple et al 2020) with the aim of examining brain and motor dynamics involved. The choreography was specifically designed to include elements common to many dance forms without referencing a specific dance style, image, or affect, and synthesized music unfamiliar to all participants was the training stimulus. Recordings used motion capture data synced with continuous recording of wireless mobile EEG (Brain Products ActiCap; 128 electrodes) in a dedicated 150 m^2 lab space. Movements through space were recorded using 10 HTC Vive trackers running on Steam VR. 30-sec trials included (i) watching VIDEO (4 times), (ii) LIVE performances of the choreography (6 times), (iii) moving with the

teacher RB (LEARN; 3 to 20 times until 80% criteria was reached rated by experimenter LJ), (iv) imagining performing from a first-person perspective (IMAGINE; 6 times), and (v) finally performing in space (PERFORM; 6 times). Music was rated for affective valence pre/post motor learning. All participants reached our target of 80% or higher accuracy in reproducing the movement sequence within 20 LEARN trials, with expertise in dance resulting in 10.13 trials to reach criteria. Subjects also reported the degree to which they felt as though they were "dancing" over 6 PERFORM trials; scores consistently increased, corresponding to a subjective sense of self-expression in the knowledge of the dance.

Title: Systemic MC1R activation modulates immune response and protects the nigrostriatal dopaminergic system in MPTP+LPS model of PD

Authors: *P. SRIVASTAVA, W. KAI, T. STIMPSON, M. SCHWARZSCHILD, X. CHEN; Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Objective: We previously identified a role of Melanocortin receptor 1 (MC1R) in dopaminergic neuron survival. MC1R is present on immune cells and can regulate the immune system. The present study explores effects of systemically-administered NDP-MSH, an MC1R agonist and existing drug that does not cross BBB, in modifying the immune response and protecting nigrostriatal dopaminergic system in the MPTP+LPS mouse model of PD. **Methods:** Male C57BL/6 mice were treated i.p. with MPTP (17 mg/kg) and LPS (1 mg/kg) from day 1 to day 4 and NDP-MSH (400 μg/kg) or vehicle from day 1 to day 12 following which the mice were sacrificed. Immune cells in the blood, striatal dopamine, and nigral TH+ neurons and glia, and expression of occludin, a marker for BBB integrity were accessed. **Result:** NDP-MSH treatment significantly attenuated striatal dopamine depletion (by 37%, $p<0.001$) and nigral TH+ neuron loss (by 33%, $p<0.01$) induced by MPTP+LPS. NDP-MSH reduced microglia activation and IBA1+ cells in the nigral region. No significant difference in occludin expression was observed in NDP-MSH treated mice vs controls in the striatum. NDP-MSH treatment in MPTP+LPS mice significantly reduced blood $CD4^+$ T cells ($p=0.006$) and B cells ($p=0.04$). NDP-MSH did not show any protective effect in MC1R mutant mice following MPTP+LPS. **Conclusion:** A peripherally acting MC1R agonist confers protection on dopaminergic nigrostriatal neurons and reduces hyperactivate states of microglia. Whether the neuroprotection

by NDP-MSH results, at least in part, from its immune-modulating effects remains to be determined.

Title: Sars-cov-2 infects neural cell types in developing human cortex

Authors: ***M. ANDREWS**, T. MUKHTAR, A. KRIEGSTEIN;
Univ. of California, San Francisco (UCSF), San Francisco, CA

Abstract: The novel coronavirus, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), causes the life-threatening illness, COVID-19, and is responsible for the current global pandemic and over one million deaths world-wide. Although SARS-CoV-2 infection most notably impairs respiratory and cardiac function, the capacity to infect other cell types and organ systems is currently being elucidated. Strikingly, many patients suffering with or having recovered from COVID-19, can present with a range of neurological symptoms including seizures, encephalopathy, stroke, headaches, dizziness, loss of smell and taste and a general inability to focus. In order to investigate the biological origin of COVID-19 related neurological insults, we sought to test whether neural tissue could be directly infected by SARS-Cov2. We utilized adult cortical surgical samples, primary developing human cortical tissue, and cortical organoid models to evaluate the capacity for coronavirus infection and replication in the human brain. In cortical tissue cultures treated with SARS-Cov-2, we observed significant infection in vascular cells innervating the brain, as well as in some neural cell types. In developing tissue, we observed modest infection in radial glial cells, the stem cells of the developing cortex, and there was minimal infection in dividing cells. Importantly, the neuronal domain of the developing cortex, the cortical plate, was devoid of infected neurons. However, we identified a population of glial precursors that had consistent SARS-CoV-2 infection and robust viral replication. In contrast, organoids of comparative stages did not demonstrate infection of any cell types present, perhaps due to lack of glial diversity or maturation in these models. Despite minimal expression of the SAR-COV-2 receptor, ACE2, in cell types present in primary cortical tissue, glial cells were preferentially infected. Possibly an alternative entry factor may meditate infection in these cells. Our study provides evidence of direct infection of specific human neural cell types with implications for the vulnerability of the developing brain and the potential for neural infection after SARS-CoV-2 exposure in postnatal life.

Title: Neural dynamics of parkinsonian tremor onset and maintenance

Authors: *P. M. LAURO[1], S. LEE[1], W. F. ASAAD[2];
[1]Neurosci., [2]Neurosurg., Brown Univ., Providence, RI

Abstract: Parkinsonian tremor, a common symptom of Parkinson's disease (PD), is characterized by oscillatory (4-6 Hz) motor output in distal limbs. Deep brain stimulation (DBS) of the subthalamic nucleus (STN) alleviates tremor in patients, suggesting the STN is involved in tremor. To precisely understand the STN's role in tremor dynamics, we obtained microelectrode STN recordings and electrocorticography (ECoG) recordings from sensorimotor cortex from 10 patients with PD undergoing DBS implantation surgery (9M, 1F; 65.2 ± 7.4 years). To capture tremor dynamics, patients performed a motor performance task where they followed a moving onscreen target with a joystick-controlled cursor. Tremor was captured from the 3-8 Hz bandpassed joystick trace, and was scaled to that of age-matched healthy control subjects (3M, 11F; 62.4 ± 10.0 years). Based on population-based tremor thresholds, behavioral and neural data from patients were split into 4 second epochs to measure separate components of tremor: absence, onset, and sustained tremor.

Tremor onset epochs were characterized by increased tremor frequency power (~ 5 Hz) and decreased high-beta frequency power (20-30 Hz) in STN, motor cortex, and somatosensory cortex relative to tremor absence epochs. At the same time, alpha-low beta frequency power (10-20 Hz) increased in premotor and parietal cortices. Each of these spectral power changes remained during tremor maintenance episodes.

While both low- and high-beta frequencies exhibited phase-locking across motor and somatosensory cortices during tremor absence epochs, this phase-locking decreased during onset and sustained tremor epochs. Simultaneously, premotor and parietal cortices exhibit increased phase-locking at beta frequencies during onset and sustained tremor epochs. The STN exhibited increased tremor frequency phase-locking and beta frequency phase-locking with premotor and parietal cortices, with tremor frequencies dominant during onset epochs and beta frequencies during sustained tremor epochs.

Taken together, these results suggest that changes in tremor are reflected by dynamic changes in cortical connectivity. While motor-somatosensory cortices may be coupled during volitional movement, premotor-parietal cortices become more coupled during Parkinsonian tremor.

Preliminary evidence suggests that the STN preferentially phase-locks with premotor and parietal cortices, acting as a subcortical node for this transition.

Title: Compensatory Cortical Oscillatory Activity During Movement Activation and Inhibition in Parkinson's Disease

Authors: *N. GLASSY[1], L. HINKLEY[2], E. DISBROW[1];
[1]Neurology, Ctr. for Brain Hlth., LSUHSC, Shreveport, LA; [2]Radiology and Biomed. Imaging, Univ. of California, San Francisco, San Francisco, CA

Abstract: Background: Response activation and inhibition are functions fundamental to executive control that are disrupted in Parkinson disease (PD). Impairments in movement activation and inhibition likely underlie the common motor signs observed in PD. Brain network reorganization observed after dopamine depletion in the nigrostriatal pathway may be associated with preservation of similar task performance in early to moderate PD. **Methods:** We examined oscillatory power amplitude, peak latency and frequency in cortical networks subserving motor activation and inhibition using magnetoencephalography (MEG) to identify abnormalities associated with PD. We used a whole-head biomagnetometer (CTF MEG, Coquitlam, Canada) with 275 first-order axial gradiometers and 27 reference sensors. MEG data was reconstructed in source space using a structural MRI (1.5 T GE Signa scanner) collected with a multiplanar rapidly acquired gradient echo imaging sequence and repetition time, 7.87 s; echo time, 2.69 ms; flip angle, 8 degrees; slices, 200; field of view, 256 mm; resolution, 1x1x1.2 mm). Participants (N=18 PD, 18 age-matched controls) performed a cue/target task requiring initiation of an un-cued movement or inhibition of a cued movement, with 120 trials during a 70-minute scan. Data were stimulus-locked (target onset=0 ms) followed by 25 ms time windows until 1112.5 ms post-target onset. Data were passed through a filter and partitioned into time windows at 100, 150, 200, and 300 ms to capture spectral peaks in the MEG signal. Twenty-five ms steps were estimated in alpha (8-12 Hz), beta (12-30 Hz) and gamma (30-55 Hz). Behavioral and latency data were evaluated using repeated measures ANOVA with t-test post-hoc analysis and an alpha threshold of 0.05. **Results:** We found decreased power and delayed peak latency in the beta band in medial frontal gyrus and in alpha band in pre-supplementary motor area at 387.5 ms during activation of an un-cued movement in PD patients, but reaction time was not statistically different from controls ($F(1,70)=2.25$, $p=0.14$). **Conclusions:** Abnormal alpha activity and relatively normal response activation reaction times in the PD group could be related to

compensation for failing dopaminergic neurons (up to 80% of substantia nigra neurons by symptom onset). This interpretation is supported by fMRI/genomics studies reporting asymptomatic Parkin or LRRK2 mutation carriers who had altered brain network activity and connectivity compared to healthy non-carriers with similar performance of internal movement selection. Disentangling compensatory changes from pathological disinhibition will advance our understanding of the pathophysiology of PD.

Title: Internodal analysis reveals multiple beta oscillations within the basal ganglia in patients with Parkinson's disease.

Authors: ***S. L. SCHMIDT**[1], J. J. PETERS[1], K. PALOPOLI-TROJANI[1], K. T. MITCHELL[2], W. M. GRILL[1], D. A. TURNER[3];
[1]Duke Univ., Durham, NC; [3]Neurosurg., [2]Duke Univ. Med. Ctr., Durham, NC

Abstract: Deep brain stimulation (DBS) is the primary surgical intervention for treatment of tremor and/or fluctuations of levodopa-responsive motor symptoms in Parkinson's disease (PD). Leads are implanted into either the subthalamic nucleus (STN) or globus pallidus (GP: GPi/e). The 16-channel RC+S (Medtronic, PLC), allows connection of four standard DBS leads, and we tested combined STN + GPi DBS in a cohort of 3 participants with PD. The RC+S allows simultaneous sensing of local field potentials (LFP) of four leads. Beta oscillatory activity (13-30 Hz) has been suggested as a biomarker which correlates with severity of rigidity and bradykinesia. Beta spectral power is enhanced in the untreated state and reduced with levodopa or DBS. Conversely, STN - GPi coherence in the narrowband gamma range (~ 60 - 90 Hz) has been found to increase after administration of levodopa or therapeutic DBS, particularly in patients with dyskinesia. Given the communication through coherence hypothesis and the information block model of DBS, we probed internodal interactions between the STN and GP. We recorded LFP from 3 awake participants in a series of experiments initiated ≥ 3 mo after implantation of DBS leads. With DBS off, we observed prominent beta oscillations throughout the motor circuit and significant interactions between nodes as measured by magnitude-squared coherence (MSCoh) and phase-locking value (PLV). Indeed, multiple frequency-distinct beta-oscillations appeared across the nodes. The MSCoh profiles varied by participant but were relatively consistent within each participant over time. In general, a band of coherence occurred within the low beta band (< ~20 Hz) between most regions. Conversely, MSCoh in the high beta band (> ~20 Hz) was broader in frequency range but observed only between the STN and GP of

the same hemisphere. MSCoh in both the low and high beta bands was decreased substantially during DBS. The lag time determined by PLV confirmed that the coherence was not simply volume conduction between regions. We analyzed the MSCoh between nuclei in narrowband gamma at multiple points during the participants' levodopa cycles. We did not observe dyskinesia, a narrowband gamma spectral power peak, or gamma coherence in any participant at any point, even though the participants demonstrated dyskinesia pre-operatively. Together these results suggest that inter-nodal analyses including MScoh and PLV in beta frequency oscillatory activity may be a useful tool for assessing the presence of Parkinsonian symptoms and as control signals for adaptive DBS. Clinical studies were approved by the IRB of Duke University Health System and participants provided informed consent.

Title: Temporal variability in the firing of external globus pallidus neurons in normal and parkinsonian monkeys

Authors: ***A. GALVAN**, X. HU, K. HEFFERNAN, A. DEVERGNAS, T. WICHMANN; Emory Univ., Atlanta, GA

Abstract: Based on extracellular recordings obtained *in vivo* in monkeys, most neurons in the external segment of the globus pallidus (GPe) show high frequency firing interspersed by pauses while a smaller proportion of neurons fire at low frequency and generate bursts. Traditionally, these two patterns of firing have been considered to arise from distinct subpopulations of GPe neurons, but it is possible that the heterogeneity of firing patterns originates, instead, from temporal variations in the firing behavior of individual neurons. In rodents, GPe neurons show significant temporal variations in firing rates (Diester et al, 2013). In monkeys that have been treated with the neurotoxin MPTP to induce parkinsonism, GPe neurons show a reduction in the firing rate and an increase in the proportion of firing in bursts. Most of the available studies, however, are based on seconds or, at most, a few minutes of recording of neuronal activity. To examine the temporal stability of GPe neuronal firing in normal and parkinsonian monkeys, we obtained long duration (7-60 min) recordings of well-isolated GPe neurons. Four young adult monkeys (one male, three females) received chronic recording chambers aimed at the GPe.

Extracellular electrophysiologic recordings were then conducted using tungsten electrodes and standard recording procedures, while the monkeys were sitting on a primate chair. In two of the monkeys, recordings were conducted before and after induction of stable parkinsonism with MPTP. All recordings were conducted while the animals were awake. The data was collected to computer disk and spikes sorted. Timings of spikes were converted to inter-spike intervals (ISIs) for further analysis. The data were binned in one-minute bins, and for each bin we obtained several firing parameters (firing rate, ISI-coefficient of variability (ISI-CV), bursting parameters). In most of the recorded GPe neurons, substantial changes in firing parameters were seen across the recorded time in both normal and MPTP-treated monkeys. However, the temporal variability in firing rates, as well as in other parameters of firing, was larger in normal than in parkinsonian conditions. For example, in the normal monkeys, GPe neurons firing rates varied from 80 to 35 spikes/sec, while GPe cells in the parkinsonian state the range was from 54 to 28 spikes/sec. Our results suggest that the firing of individual GPe neurons shows very high temporal variability, this could explain the heterogeneous firing patterns that have been ascribed to GPe neurons in *in vivo* monkey recordings. Our results also indicate that the temporal variability in firing of GPe neurons is reduced in the parkinsonian state.

Title: Phosphodiesterase 10A inhibitor for Parkinson's Disease therapy

Authors: ***B. KOCHOIAN**[1,3], C. G. SINON[1,3], K. PENDERGRAST[1,3], S. M. PAPA[2,3]; [2]Neurol., [1]Emory Univ., Atlanta, GA; [3]Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: BACKGROUND: L-Dopa improves mobility in Parkinson’s disease (PD), but long-term therapy is associated with efficacy decline and abnormal involuntary movements, called L-Dopa-induced dyskinesias (LID). Previous work has revealed decreased striatal expression levels of the cyclic nucleotides, cAMP and/or cGMP, second messengers that play a major role in dopaminergic signaling cascades of striatal projection neurons (SPNs). Restoring cyclic nucleotide levels with inhibition of phosphodiesterases (PDEs), enzymes that catabolize cAMP and cGMP, may help regulate DA signaling in SPNs. PDE10A is highly expressed in the striatum and has substrate affinity for both cAMP and cGMP. To understand the impact of PDE10A function on striatal SPN responses to DA, we assessed the effect of PDE10A inhibition directly on the SPN activity in the primate model of PD. METHODS: An MPTP-treated macaque with advanced parkinsonism and reproducible LID was used for striatal single-cell

recordings with local microinjection of a selective PDE10A inhibitor (PDE10A-I). Our approach was to analyze firing changes of SPNs with continuous recordings from the OFF state, to 1 min and 5 min after local PDE-I injection, and to 20 min following a systemic L-Dopa administration, ON state, and to the point of peak-dose dyskinesias. RESULTS: SPNs displayed a variable response in firing to local injection of PDE10A-I. Among SPNs that increased firing rate following PDE10A-I injection, there was a synergistic effect of L-Dopa sustaining the frequency increase. At the point of dyskinetic response, however, we observed an inversion of the initial firing rate changes induced by L-Dopa (ON state onset). This unstable frequency increases induced by L-Dopa are consistent with the expression of LID and expressed the D1 receptor (D1R) expressing SPN response to dopaminergic stimulation. DISCUSSION: Our previous work has demonstrated that systemic administration of PDE10A-I decreases dyskinesias. Our present analysis of the SPN response to PDE10A inhibition revealed synergistic action of PDE10A-I with L-Dopa on positive modulation of D1R-like SPNs. However, persistence of inversion of firing rate changes in the ON state suggests that PDE10A-I does not stabilize DA responses of D1R-like SPNs, and that opposite effects can be expected on D2R-like SPNs. Our results support further investigation into the mechanisms underlying the anti-dyskinetic effect of PDE10A-I.

Title: Temporally non-regular patterns to improve the efficacy of deep brain stimulation (DBS) for Parkinson's disease (PD)

Authors: *K. PALOPOLI-TROJANI[1], S. L. SCHMIDT[1], J. J. PETERS[1], D. A. TURNER[2], W. M. GRILL[1];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Neurosurg., Duke Univ. Med. Ctr., Durham, NC

Abstract: DBS is an effective treatment for movement disorders such as PD for individuals who are refractory to pharmacological intervention alone. The dependency of DBS efficacy on stimulation frequency is well established, with only high frequencies (greater than ~100 Hz) providing symptom relief and low frequencies potentially exacerbating symptoms. We previously demonstrated that the effects of DBS are also dependent on the temporal pattern of stimulation. This novel parameter space provides opportunity to improve the efficacy of DBS by suppressing oscillatory activity in the basal ganglia. Here, we tested in intraoperative experiments the effects of two temporally non-regular patterns of stimulation on both oscillatory

activity in the basal ganglia and motor symptoms in participants with PD. The Institutional Review Boards at Duke University and Emory University approved the study protocol. Individuals undergoing DBS implantation or implantable pulse generator replacement surgeries were recruited and gave written informed consent. We simultaneously delivered DBS and recorded oscillatory activity from the subthalamic nucleus (STN) in each participant (n = 17). Motor symptoms were also recorded before and during DBS according to each participant's dominant symptom (bradykinesia or tremor). Bradykinesia (n = 11) was evaluated using an alternating finger tapping task, and tremor power (n = 6) was measured with a hand-mounted accelerometer. Five stimulation conditions were tested: *Off*, *Low* (regular 10 Hz), *High* (regular 185 Hz), and two temporally non-regular stimulation patterns with geometric mean of 185 Hz (named *Absence* and *Presence*). The absence and presence stimulation patterns were both periodic and characterized by the absence or presence of short bursts of pulses, respectively. Analysis consisted of paired signed rank tests between *Off* and *On*. In the tremor cohort, *High* ($p = 0.031$) and *Presence* ($p = 0.031$) reduced tremor power compared to *Off*, while *Absence* and *Low* did not. Reduction in tremor was not correlated with a reduction in beta power in this cohort. In the bradykinesia cohort, *High* ($p = 0.0078$) and *Absence* ($p = 0.014$) improved the performance on the alternating finger tapping task compared to *Off*, while *Presence* and *Low* did not. Additionally, *High* ($p = 0.0078$), *Absence* ($p = 0.0098$) and *Presence* ($p = 0.039$) reduced beta power compared to *Off*, while *Low* did not. Temporally non-regular DBS patterns were as effective as traditional high frequency stimulation in treating the motor symptoms of PD and suppressing pathological beta activity.

Title: Ketamine disrupts 80-Hz gamma oscillations in parkinsonian rats with L-DOPA-induced dyskinesia

Authors: A. VISHWANATH[1], M. J. BARTLETT[2], G. JORDAN[3], V. BOUDREAU[4], S. J. SHERMAN[2], T. FALK[5], *S. L. COWEN[4];
[1]Psychology, Univ. of Arizona, TUCSON, AZ; [2]Neurol., [3]Biomed. Engin., [4]Psychology, Univ. of Arizona, Tucson, AZ; [5]Dept. Of Neurol., Univ. of Arizona Col. of Med., Tucson, AZ

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, and symptoms include debilitating motor and cognitive deficits. While levodopa (L-DOPA) is the leading treatment for PD, long-term administration leads to L-DOPA-Induced Dyskinesias (LID), which are uncontrollable involuntary movements. A common neurophysiological feature of LID is the emergence of 80-Hz oscillations in the motor cortex (M1) following administration of L-DOPA. Ketamine, an N-methyl-D-aspartate (NMDA) receptor antagonist, can be effective in treating depression, chronic pain, and post-traumatic stress disorder. Sub-anesthetic infusion of ketamine has recently been shown to reduce LID in preclinical studies and in human case studies. In M1, ketamine administration produces narrowband low-gamma oscillations in control animals that are notably distinct from 80-Hz gamma in LID. Given ketamine's capacity to reduce LID and generate 'competing' low-gamma oscillations, we hypothesized that ketamine would reduce the 80-Hz signature in LID. We induced LID in 6-hydroxydopamine-lesioned (6-OHDA) rats by treating animals regularly with L-DOPA (12 mg/kg for ≥10 days). During each experimental session, control and LID-expressing rats were injected with saline or L-DOPA (L-DOPA: 12 mg/kg, i.p.; subjects: n=1 control, n=1 6-OHDA, n=8 total sessions). L-DOPA or saline injections were followed 1-hour later by a ketamine injection (20 mg/kg, i.p.). Single-unit and local-field responses were measured from each hemisphere through a dual-bundle 16-tetrode hyperdrive (AP: 1.5, ML: ±2.2mm). Preliminary data indicated that LID-associated 80-Hz oscillations and dyskinetic movements were suppressed within 5 minutes following ketamine injection, with the 80-Hz oscillations being replaced by robust low-gamma (~50 Hz). Action potentials of neurons in M1 were also phase-locked to changes in 80-Hz power but not 80-Hz phase during LID. These preliminary data support the hypothesis that ketamine reduces LID through the disruption of 80-Hz gamma in M1.

Engin., Case Western Univ., Cleveland, OH; [3]Dept. of Neurologic Surgery, [4]Dept. of Psychiatry & Psychology, [5]Dept. of Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN; [6]Dept. of Psychology, Western Michigan Univ., Kalamazoo, MI; [7]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Deep brain stimulation (DBS) is a treatment option for people suffering from severe Parkinson's disease (PD). A popular clinical target associated with relief of Parkinsonian symptoms is the subthalamic nucleus (STN), which is responsible for integrating signals associated with control of voluntary movement and control of emotions. While the characteristic result of DBS is a decrease in motor symptoms (e.g., tremor), undesired psychiatric side effects can also occur during treatment. Currently, there is a lack of understanding of the mechanisms by which DBS evokes motor-symptom relief and their implications in emotion and cognition during stimulation. Tractography-based modeling of patient-specific pathways activated by STN DBS can offer insight into the underlying circuitry responsible for the cognitive and psychiatric effects of stimulation.

This study examines a cohort of 15 PD patients who underwent bilateral STN-DBS (Medtronic quadripolar electrode 3387) and experienced transient non-motor side effects during optimization of stimulation parameters. These transient non-motor symptoms (TNMS) presented at specific combinations of contact location and stimulus amplitude (i.e., voltage), and manifested as confusion, crying, a sense of euphoria, feeling anxious, or feeling relaxed.

The aim of this study is to determine if there is a correlation between these TNMS, the stimulation parameters, and engagement of specific neural pathways. Pathway activation modeling, which is used to determine engagement of neural pathways, involves modeling of white matter pathways in the brain as well as the electric field produced by specific stimulation parameters used both during their TNMS events and the relief of their motor symptoms. Electric field models are combined with multi-compartment cable models of axons along the reconstructed white matter pathway models to simulate axonal activation in response to the presence of specific electric fields. The findings of axonal activation modeling are then correlated with the TNMS observed. We expect to find similar pathway activation in individuals experiencing similar TNMS symptoms. We also expect to observe differences between DBS parameters that resulted in therapeutic benefits and DBS parameters that evoked TNMS. The knowledge gained from this study will further our understanding of which pathways are associated with psychiatric side effects related to STN DBS and will represent the first step toward improved targeting for improved therapeutic efficacy of STN DBS for movement and psychiatric disorders.

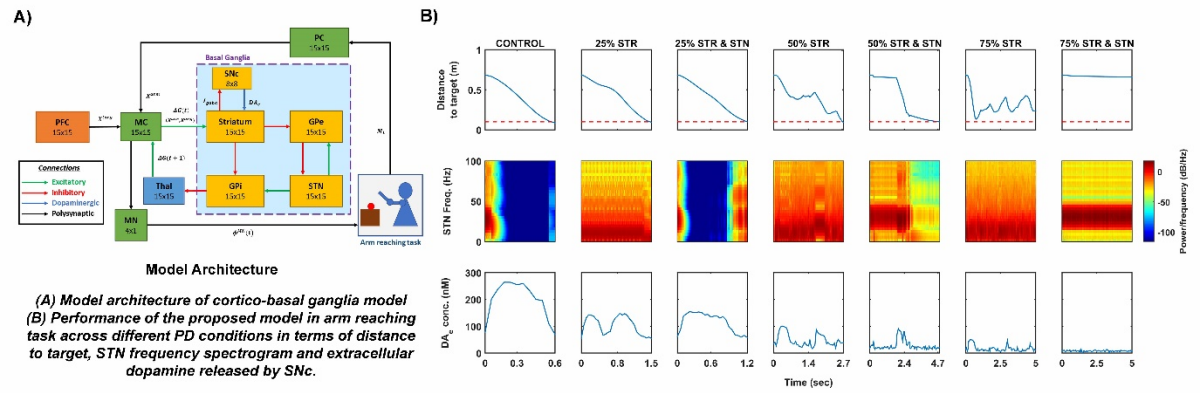
Title: Differential dopaminergic axonal degeneration manifest into tremor-like and rigidity-like Parkinsonian symptoms: A computational investigation

Authors: *S. S. NAIR, V. R. MUDDAPU, V. CHAKRAVARTHY;
Biotech., Indian Inst. of Technol. Madras, Chennai, India

Abstract: A major underlying cause of Parkinson's disease (PD) is the idiopathic loss of dopaminergic neurons in Substantia Nigra pars compacta (SNc). Dopamine (DA) deficiency due to the loss of SNc neurons manifests in cardinal symptoms of PD, including tremor, rigidity, bradykinesia, and postural imbalance. To investigate the PD condition in detail and manage its symptoms, it is important to have an integrated multiscale computational model that can replicate the symptoms at the behavioral level by evoking the key cellular and molecular underlying mechanisms that contribute to the pathology. A realistic simulation of various symptoms of PD can go a long way toward achieving this goal. In line with this approach, we developed a multiscale integrated model of cortico-basal ganglia motor circuitry for arm reaching task incorporating a detailed biophysical model of SNc dopaminergic neuron. Computational models of the basal ganglia tend to take a dichotomous approach, describing exclusively at a detailed biophysical level or at abstract information processing level using concepts from Reinforcement Learning (RL), without working out the relationship between the two levels. In our model, we replace the abstract representations of reward with the realistic variable of extracellular DA released by a network of SNc cells and incorporate it with the RL-based behavioral model, which simulates the reaching task. The phasic DA release from the SNc subsystem is analogous to the reward prediction error in RL terminology. In this model, we introduce the pathological PD condition by modulating the number of surviving SNc neurons, which affects the amount of DA released extracellularly. Differential degeneration of dopaminergic axonal projections to two regions of the basal ganglia viz., striatum and subthalamic nucleus exhibits a differential manifestation of symptoms of PD such as tremor on one hand and bradykinesia and rigidity on the other. The model explores the cellular and anatomical basis to the two key PD patient categories viz., tremor-dominant and rigidity-dominant.



(A) Model architecture of cortico-basal ganglia model (B) Performance of the proposed model in arm reaching task across different PD conditions in terms of distance to target, STN frequency spectrogram and extracellular dopamine released by SNc.

Title: 3D Human Midbrain-like Organoid (hMLO) Model Using Patient-Derived Induced Pluripotent Stem Cells (iPSCs) For The Exploration Of Parkinson's Disease (PD) Pathology

Authors: *L. A. STRUZYNA, N. G. HATCHER, L. YAO, M. J. MARINO, M. E. HOFMANN, M. L. WATT;
Merck, Kenilworth, NJ

Abstract: PD is the second most common neurodegenerative disease, affecting 2% of people over the age of 65. Despite significant research efforts, the vast majority of neuroprotective treatment strategies for PD fail in clinical trials - in part due to inadequate disease models. Recent studies have suggested organoid models recapitulate complex functions that make them superior to conventional 2D cultures for the interrogation of human disease. Therefore, we have generated hMLOs from human PD patient iPSCs in an attempt to establish a more physiologically-relevant model in which to assess PD pathology. In a protocol adapted from Jo et al. (2016), human PD patient-derived iPSCs were aggregated into embryoid bodies, after which they were exposed to a series of growth factors and small molecules in order to differentiate them towards a midbrain neuronal lineage. The embryoid bodies were embedded in matrigel and placed on an orbital shaker, after which they matured into midbrain organoids over months *in vitro*. The organoids were characterized using a variety of histological, cell biological, and biochemical techniques. As anticipated, the hMLOs demonstrated an organized 3D cytoarchitecture with ventricle-like structures that contain discrete cell layers. Young organoids (<25 days *in vitro*) exhibited midbrain progenitor markers, while mature organoids revealed the presence of the dopamine transporter and tyrosine hydroxylase-positive dopaminergic neurons that produced neuromelanin. Patch-clamp electrophysiology studies with hMLO slices demonstrated a neuronal phenotype with the firing of repetitive action potentials. Furthermore,

LC-MS analyses demonstrated the ability to evaluate glycosphingolipid content. Ongoing work is evaluating organelle function, alpha synuclein aggregation, and gene expression within the organoids. Human midbrain-like organoids have the potential to provide an improved *in vitro* discovery platform in which to examine mechanisms of PD pathology and interrogate neuroprotective treatments for PD. However, such analyses require a deep understanding of these complex models. Toward that end, we are extending the work of previous groups in order to provide novel insight into lipid content, organelle function, and alpha synuclein accumulation within these PD patient iPSC-derived hMLOs. This extended panel of characterization metrics will hopefully enable refined detection and interrogation of PD pathophysiologically-relevant perturbations, aiding in our understanding of the mechanisms involved in PD onset and identification of therapeutics.

Title: Activation of D2 receptor on cholinergic interneurons is critical for the induction of L-Dopa induced dyskinesia

Authors: *S. URIBE-CANO[1,2], K. LIU[1], L. MALAVE[3], A. H. KOTTMANN[1,2];
[1]Dept. of Molecular, Cell. and Biomed. Sci., City Univ. of New York Sch. of Med. (CSOM), New York, NY; [2]Neurosci. Collaborative, The Grad. Center, CUNY, New York, NY; [3]New York State Psychiatric Inst., Columbia Univ., New York, NY

Abstract: Dopamine neuron (DAN) loss is a hallmark sign of Parkinson's Disease (PD). L-Dopa therapy, the gold-standard treatment for PD, attenuates bradykinesia and akinesia in patients. Unfortunately, prolonged L-Dopa use eventually produces a debilitating side-effect called L-Dopa induced dyskinesia (LID) in ~90% of medicated PD patients. The mechanistic underpinnings of LID remain obscure and are of interest for the purpose of improving PD therapies. Cholinergic interneurons of the striatum (CIN) are projection targets of DAN and undergo pathophysiological changes in response to DAN degeneration. These changes to CIN physiology have been suggested key for LID formation, a contention supported by studies demonstrating that manipulations of CIN activity in animal models of LID can impact LID expression. While a link between aberrant CIN function and LID is increasingly clear, the nature of this relationship remains disputed. Namely, both increased and decreased CIN activity have been implicated in LID. Therefore, to reconcile these results, the changes to CIN physiology

following DAN loss and subsequent L-Dopa treatment, as well as the mechanisms responsible for those changes, warrant closer examination.
DAN are known to signal CIN via numerous signaling factors, all of which are lost as DAN degenerate in PD. L-Dopa therapy restores dopamine (DA) signaling but fails to restore the additional signaling factors released by DAN to CIN. We recently found that release of the signaling peptide sonic hedgehog (Shh) from DAN to CIN is crucial in the prevention of aberrant CIN physiology and LID induction. Additionally, loss of Shh signaling on CIN reduces levels of neuronal activity marker p-rpS6 among dorsolateral CIN. These observations suggest that hypo-active CIN physiology may be a key driver of LID in the striatum. CIN express both inhibitory D2 receptors and facilitatory D5 receptors. Here, we further probe the degree to which CIN hypo-activity, specifically through activation of D2 following L-Dopa administration, may be responsible for LID induction. We hypothesize that reducing inhibition from D2 signaling on CIN can help maintain normal CIN physiology during L-Dopa therapy and confer LID resistance. To test this, we utilized CIN specific ablation of the D2 receptor in 6-OHDA animals treated with L-Dopa. Behavioral scoring of abnormal involuntary movements was used to quantify LID in D2 knockout and heterozygous mice. Additionally, we report differences in CIN p-rpS6 levels as well as the LID cytochemical marker p-ERK. Our initial results suggest that ablation of D2 signaling from CIN prevents the induction of LID behavior and associated changes in CIN physiology.

Abstract: Four Salvage NAD^+ Biosynthetic Pathway Enzymes Moonlight as Molecular Chaperones to Protect Against Proteotoxic Stress
Authors: Meredith Pinkerton1, Andrea Ruetenik1, Viktoriia Bazylianska1, Eva Nyvltova1, and Antoni Barrientos1,2*
Neurodegenerative proteinopathies involve the misfolding and aggregation of disease-specific proteins in the brain. Searches for neuronal maintenance factors have identified the NAD+

salvage biosynthetic pathway enzyme NMNAT (nicotinamide mononucleotide (NMN) adenylyltransferase) as an effective suppressor of proteotoxicity. Although there has been some controversy regarding whether the neuroprotective effect of NMNAT is mediated by increased NAD+ levels or a non-catalytic chaperone role of NMNAT, it is now accepted that both may contribute. Screens in yeast models of HD and PD in our lab have allowed us to identify not only the NMNAT homologs Nma1/2 but three additional enzymes of the NAD+ salvage pathway that achieve similar protection against extended polyglutamine- and a-synuclein-induced proteotoxic stress: Npt1, Pnc1, and Qns1. Under proteotoxic stress, the four proteins are recruited to promote the clearance of misfolded and oligomerized proteins. We have shown that the suppression mechanism by NAD+ proteins is independent of their catalytic activity. In vitro and in vivo studies have indicated that the four proteins have the ability to act as molecular chaperones. Our data suggest that they perform holdase and foldase chaperone activities to contribute to the reduction of misfolded toxic proteins, while promoting their refolding. The proteotoxicity suppression mechanism requires the presence of the HSP90 chaperones HSP82/HSC82. In the case of Nma1, structure-function relationship studies have shown that the C-terminus of the protein is essential for its chaperone activity and presumably for interaction with HSP90. Our data illustrates the existence of an evolutionarily conserved strategy of repurposing housekeeping enzymes under stress conditions, such as age-associated neurodegenerative proteotoxicities.

Title: Phospho-serine 276 of nuclear factor kappa b is involved in the genesis of l-dopa-induced dyskinesia

Authors: *R. MORIGAKI[1], M. OGAWA[1], S. OKITA[2], T. MATSUDA[1], Y. TAKAGI[1], S. GOTO[1];

Abstract: Nuclear factor kappa B (p65/RelA) is ubiquitously distributed in the body and regulates various genes involved in inflammation, stress, and immune responses, and cell

survival and proliferation. In this study, we observed that phosphorylation of the serine 276 residue of p65 (p65-pS276) was regulated by dopamine signaling in mouse striatum. Differential dopaminergic modulation across naïve and 6-hydroxydopamine-induced parkinsonian mice resulted in an increase or decrease in the expression of p65-pS276 in the dorsal striatum. The expression pattern of p65-pS276 induced by dopamine D1/D2 synergy was strikingly similar to that of c-fos, and over 80% of c-fos mRNA-positive cells induced by high-dose apomorphine were also p65-pS276 positive. Administration of a small-molecular p65-pS276 inhibitor prevented striatal c-fos expression and motor stereotypy induced by dopamine D1/D2 synergy. Moreover, continuous administration of this agent in a mice model of LDOPA-induced dyskinesia decreased ΔfosB expression in the dorsal striatum and dyskinetic movements as well. These results indicated that p65-pS276 could be a molecular target for the treatment of motor stereotypy and L-DOPA-induced dyskinesia.

Title: Mesdopetam suppresses sensitization and AIMs in the rodent unilateral 6-OHDA lesion model of Parkinson's disease

Authors: P. SVENNINGSSON[1], Y. YANG[1], *S. HJORTH[2,3], **S. WATERS**[3], N. WATERS[3], P. SVENSSON[3], J. TEDROFF[1];
[1]Dept. of Clin. Neurosci., Karolinska Inst., Stockholm, Sweden; [2]Pharmacilitator AB (inc.), Vallda, Sweden; [3]Integrative Res. Labs. (IRL) AB, Gothenburg, Sweden

Abstract: Introduction
Mesdopetam is a dopamine D3 antagonist, displaying an agonist-like binding mode at the orthosteric receptor site but devoid of intrinsic activity. It is currently in Phase II clinical development for the treatment of L-DOPA induced dyskinesias (LIDs) in advanced Parkinson's disease. It has been shown to reduce bad ON-time (time with troublesome dyskinesias) with 4-5 hours, in a well-tolerated dose range. In the 6-OHDA lesioned hemiparkinsonian rat model, mesdopetam has previously been reported to dose-dependently reduce established LIDs. In this study, the effect of co-administering mesdopetam with L-DOPA in hemilesioned rats was explored.

Methods
Female rats with unilateral 6-OHDA lesions in the MFB (post-mortem verified by DA

transporter autoradiography) were used. Two weeks after surgery, proper lesioning was confirmed by an acute apomorphine challenge rotation test. Then chronic treatment was started with either: Saline (N=6); L-DOPA/benserazide (10/7.5mg/kg, i.p.; N=6); mesdopetam (3 or 10mg/kg, s.c; N=6); amantadine (40mg/kg, i.p.; N=7); L-DOPA/benserazide combined with mesdopetam (N=6); L-DOPA/benserazide combined with amantadine (N=7). Behavioural assessments were performed on Day 1, 7, and 14 of the chronic treatment regime. Contralateral rotations were measured by RotoRat® over 2.5 hours post-drug administration. Rat abnormal involuntary movements (AIMs) were scored from 5-min video recordings captured at 90 min post-injection. The experiments were approved by the local ethical committee at Karolinska Institute and conducted in accordance with the European Communities Council Directive (86/609/EEC).

Results

Rats treated with L-DOPA alone displayed increasing rotational behaviour over the 14 Days of repeated dosing, along with increased AIMs scores. Co-treatment with mesdopetam or amantadine suppressed AIMs to a similar degree. In contrast, only co-treatment with mesdopetam countered the L-DOPA-induced increase in contralateral turns over the 2-week period of repeated dosing.

Conclusions

Co-treatment with mesdopetam, at 3 or 10 mg/kg, suppressed L-DOPA-induced AIMs over 14 days. Furthermore, the sensitization (reflected by increased rotational behaviour) in rats receiving repeated doses of L-DOPA was clearly suppressed, especially at the 3 mg/kg dose. This effect was not seen with the comparator amantadine, which reduced AIMs but did not affect the L-DOPA sensitization. It is concluded that mesdopetam, in addition to its previously described acute antidyskinetic effects, may prevent the development of dyskinesias by blocking L-DOPA sensitization.

Title: Intranasal carnosine mitigates alpha-synuclein pathology and motor dysfunction in the Thy1-aSyn mouse model of Parkinson's disease

Authors: J. M. BROWN[1], L. S. BAKER[1], ***K. B. SEROOGY**[2], M. GENTER[1];
[1]Envrn. Hlth., [2]Neurol., Univ. of Cincinnati, Cincinnati, OH

Abstract: Parkinson's disease (PD) is a common and debilitating neurodegenerative disorder. Early symptoms of PD include motor dysfunction and impaired olfaction (hyposmia). Toxic aggregation of alpha-synuclein (aSyn) is a hallmark of PD neuropathology and includes aSyn accumulation in the olfactory bulb (OB) and substantia nigra pars compacta (SNpc). Thy1-aSyn transgenic mice exhibit many features of PD, including olfactory and sensorimotor impairment, making these mice a useful model for studying drug intervention in PD. Carnosine is an endogenous dipeptide with antioxidant and anti-aggregating properties. Previously, we showed that treatment with 2.0 mg/d intranasal (IN) carnosine for two months improved motor behavior in Thy1-aSyn mice. Here, we tested whether an elevated dose of the dipeptide would provide greater benefit for mitigation of motor and olfactory deficits in the transgenic mice. In addition, neuronal expression of aSyn in the OB mitral cell layer (MCL) and of aSyn and tyrosine hydroxylase (TH) in the SNpc were assessed in both the Thy1-aSyn and wild-type mice after IN carnosine treatment. After baseline behavioral testing, two-month-old male wild-type and Thy1-aSyn mice were randomly assigned to treatment groups (n=25-46/group) and received daily IN vehicle, 2.0 or 4.0 mg/d carnosine treatment for eight weeks. Mice were then reassessed for motor and olfactory function in the challenging beam traversal (CBT), spontaneous activity and buried pellet tests. Animals were then sacrificed and the brains processed for aSyn and TH immunohistochemistry, and labeled cells were counted in the SNpc and OB MCL using design-based stereology. Intranasal carnosine dose-dependently mitigated progressive gait deficits in Thy1-aSyn mice in the CBT. There were no effects of IN carnosine treatment on olfactory function. Thy1-aSyn mice treated with IN carnosine exhibited fewer aSyn+ somata in the SNpc vs. vehicle-treated transgenic mice. Carnosine treatment did not affect the number of aSyn+ somata in the MCL, nor the number of TH+ cells in the SNpc of either genotype. Overall, these results demonstrate that IN administration of carnosine decreases somatic aSyn accumulation in the SNpc, which may underlie its mitigation of motor deficits in Thy1-aSyn mice.

Title: Levodopa and celecoxib interact synergistically to alleviate allodynia in hemiparkinsonian rats

Authors: ***B. GODÍNEZ-CHAPARRO**[1], C. RODRIGUEZ-RAMOS[1], M. BENÍTEZ-DÍAZ MIRÓN[2], G. GARZA-MOURIÑO[2];
[1]Sistemas Biológicos, [2]Hombre y su Ambiente, Univ. Autónoma Metropolitana Unidad Xochimil, Mexico City, Mexico

Abstract: Pain is a common non-motor symptom of Parkinson's disease patients, with a prevalence between 29-82%. Consequently, it´s vital to find pharmacological treatments for the management of PD-associated pain symptoms, in order to improve patients' quality of life. This study tested the degree of interaction between levodopa and celecoxib combination in allodynia induced by unilateral 6-OHDA injection into the SNpc in rats. Allodynia was evaluated using von Frey filament with up-down method. For acute treatment, at 20 days' post-lesion with 6-OHDA. The animals were administrated with levodopa (3, 6, 10, 25 mg / kg, i.p., n = 6), or CXB (2.5, 5, 10, 20 mg / kg, ip, n = 6) allodynia was evaluated for 8 h. For sub-acute treatment (10 days), the same group of animals used for acute treatment received levodopa (3, 6, 10, 25 mg / Kg, ip, per day, every 24 h, n = 6), celecoxib (2.5 , 5, 10, 20 mg / Kg, ip, per day, every 24 h, n = 6), tactile allodynia was evaluated. Isobolographic analysis was employed to define the nature of the drug interaction using a dose ratio (0.5:0.5). The ED_{50} calculated from Levodopa or celecoxib was considered as a theoretical dose for each drug. The experimental ED_{50} of the L-DOPA + CXB combination was calculated by the following scheme: 1) L-DOPA ED_{50} + CXB ED_{50}; 2) ½ (L-DOPA ED_{50} + CXB ED_{50}); 3) ¼ (L-DOPA ED_{50} + CXB ED_{50}); 4) 1/8 (L-DOPA ED_{50} + CXB ED_{50}). For acute or sub-acute (10 days) treatment, the animals received an intraperitoneal injection with the dosing scheme before indicated and allodynia was evaluated. Acute and sub-acute (10 days) treatment with a single dose of levodopa (3-25 mg / Kg, i.p.) or celecoxib (2.5-20 mg/kg, i.p.) induced dose-dependent antiallodynic effect in hemiparkinsonian rats. For acute treatment, the theoretical ED_{50} of the combination was 13.5 mg/kg, this value was higher than the experimental ED_{50} value 3.9 mg/kg. Moreover, for sub-acute treatment (10 days), the theoretical ED_{50} to the combination was 11.2 mg/kg. while the experimental ED_{50} was 3.1 mg/kg. These data suggest that levodopa and celecoxib combination produces an antiallodynic synergistic interaction at the systemic level. Therefore, the combination of levodopa and CXB may use as an analgesic strategy in Parkinson's patients

Title: The Cortical Evoked Potential as a Biomarker for Deep Brain Stimulation Efficacy

Authors: ***I. R. CASSAR**, A. CZEISZPERGER, K. HANCOCK, W. M. GRILL;
Duke Univ., Durham, NC

Abstract: Deep brain stimulation (DBS) applied at a fixed amplitude and frequency is effective at alleviating the motor symptoms of Parkinson's disease (PD), but efficacy may be improved by using customized temporal patterns of stimulation or closed-loop control. A necessary element in the development of these techniques is an electrophysiological biomarker that can serve as a proxy for DBS-mediated changes in symptoms. Many such biomarkers have been proposed, with nearly all quantifying some type of spectral feature in the cortico-basal ganglia-thalamic network. However, these spectral biomarkers have high inter-patient variability, and the mechanisms by which DBS alters them is uncertain. We assessed the utility of an alternative, non-spectral biomarker: the cortical evoked potential (cEP) following DBS in the subthalamic nucleus (STN), in the 6-OHDA lesioned rat model of parkinsonism. We hypothesized that changes in the cEP magnitude and latency between effective and ineffective DBS settings would have a stronger correlation with symptom reduction than conventional, spectral biomarkers. For the conventional biomarkers, we quantified the M1 ECoG beta band power, beta band bursting, and phase-amplitude coupling (PAC). We obtained within-animal correlations of each biomarker with symptom reduction by applying stimulation frequencies that spanned a range of efficacies (13 - 200 Hz) and yielded a spectrum of symptom changes for each animal that were correlated with each biomarker. To quantify symptom reduction, we used methamphetamine-induced circling (N=9) and an adjusting steps task (N=6). High stimulation frequencies decreased the cEP magnitude, increased the cEP latency, and reduced the cortical beta band power, beta band bursting, and PAC. However, the cEP features exhibited a stronger correlation with symptom reduction across stimulation frequencies than the spectral biomarkers, for both behavioral tasks. The cEP magnitude and latency had r2 values of 0.73 ± 0.05 (mean ± SEM) and 0.74 ± 0.05 for the adjusting steps task and 0.64 ± 0.04 and 0.63 ± 0.07 for the circling task, respectively. Alternatively, the highest average r2 values for the spectral biomarkers were 0.46 ± 0.07 for the adjusting steps task (beta band power) and 0.54 ± 0.11 for the circling task (beta band bursting). The cEP features exhibited stronger correlations with symptom reduction from STN DBS than conventional cortical spectral biomarkers. This strong correlation may be indicative of a mechanistic link between the observed changes in cEP magnitude and latency at high stimulation

frequencies and the cortical mechanism by which STN DBS alleviates parkinsonian motor symptoms.

Inst., Toronto, ON, Canada

Abstract: Introduction: The underlying mechanisms of deep brain stimulation (DBS) of the subthalamic nucleus (STN), a well-established treatment for Parkinson's disease (PD), remains largely unknown. STN-DBS induces anti-inflammatory mechanisms[1], and considering the importance of glial modulating for synapse regulation, here we aimed to understand the striatal release of dopamine (DA), glutamate (GLU), and GABA before, during, and after the first and fifth session of STN-DBS in a rat model of PD. **Methods:** Male Wistar rats were injected with 6-OHDA neurotoxin and implanted with guidance cannula in the left striatum, and implanted or not with stainless steel electrodes in the left STN. After 7 days, the nigrostriatal lesion was assessed by apomorphine-induced rotation. On the 8th day, 6-OHDA+DBS ON animals were stimulated 2 h/day/5 days (130 Hz, 60 μs, 0.1 mA). Striatal microdialysis samples were collected before, during, and after the 1st and 5th session of DBS in the 6-OHDA+DBS ON and 8 and 12 days after the surgeries in the 6-OHDA and 6-OHDA+DBS OFF animals. Statistical analyses: 2-way-ANOVA and Bonferroni post-hoc test. **Results:** Rat model of PD was validated by increase on rotational behavior, related with inhibition of striatal DA fibers[2]. On the 12th day, 6-OHDA

animals showed reduction of 20% of DA ($p < 0.0001$) and increase of 40% of GLU release in the striatum. Six-OHDA+DBS OFF animals showed a DA reduction of 40% ($p < 0.0001$) and GLU inhibition of 30% ($p < 0.05$), comparing the 8th and 12th day after neurotoxin. No change in the striatal GABA release was observed. In 6-OHDA+DBS ON rats, the 1st stimulation induced a transitional increase of DA and GLU initially; but as the stimulation continues, DA decreases consistently. Before the last stimulation, striatal DA release was 20% decreased when compared to 8th day and decreased consistently in 40% during and after the last stimulation. Striatal GLU levels of 6-OHDA+DBS ON maintain below 6-OHDA levels, and above 6-OHDA+DBS OFF, while GABAergic release accompanies the transition and stability of GLU. **Conclusion:** Our findings may suggest that STN ablation induced by the electrode implantation elicits an initial but not sustainable protection. The increase of striatal GLU release may suggest excitotoxicity that contributes to the extensive inflammation in PD. Additionally, DBS inhibits the striatal DA release probably by regulating the motor pathways downstream circuitry from the striatum and induces an optimal balance between GLU and GABA release which may contribute to the improvement of symptoms. Hence, by decreasing inflammation, STN-DBS regulates the synaptic plasticity, thus improving the neuronal circuitry impairment.

Title: Aerobic exercise increases CD68+ M2 microglia and TH+ levels in rotenone-induced parkinsonian rats quantified rapidly in fresh-frozen tissue using a computer-based infrared immunohistochemistry imaging method

Authors: *J. W. SONNE[1], C. FROSTI[2], C. M. SEAVEY[2], C. LEMIEUX[2], A. BUNEA[2], J. S. GROSHONG[2];
[1]Univ. of South Carolina Sch. of Med. Gr, Greenville, SC; [2]Univ. of Central Florida, Orlando, FL

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by reduced tyrosine hydroxylase (TH) dopamine neurons and progressive motor impairment. Using a 14-day systemic (IP) rotenone injection in rats, we show that M1 microglial markers (CD11b+IBA-1+) are increased, while therapeutic treadmill exercise increases microglial M2 markers (CD11b+CD68+) coincident with high TH levels and increased rotarod latency-to-fall. Rotenone-treated (RO) Sprague Dawley rats exhibited a 57.1% lower latency-to-fall than vehicle-injected controls (CTRL) (56.3±4.9 v 131.3±18.2 s, n=5, $p<0.0001$), while the RO-with-exercise group (RE) exhibited performance similar to controls (127.5±11.1 s), concurrent with

TH levels (CTRL v RO: $p<0.0001$). M2 markers were significantly lower in RO compared with CTRL (8.4±1.1 v 17.0±1.7 counts, $p<0.0001$), while RE M2 levels were higher than RO (12.2±1.4, $p=0.0013$). Levels of pAkt observed by Western blot in RE sample suggest trophic factor modulation.
Furthermore, we present a rapid, robust, fresh-frozen approach to IHC, without committing the tissue to IHC via fixation and cryopreservation while maintaining long-term storage. We used a sensitive LiCor-based infrared quantification of TH in midbrain sections that can be directly compared across studies. In fresh-frozen tissue that was stored for up to 1 year prior to IHC reaction, this method was highly sensitive to rotenone treatment in 3-month-old Sprague-Dawley rats, correlating with a significant loss decrease in latency-to-fall by approximately 2.5 fold. Using the in situ method presented here, the measured RO midbrain showed 31% lower TH signal than CTRL ($p<0.01$, $n=5$). TH infrared counts versus rotarod latency-to-fall indicates a positive slope and significant correlation of $R^2=0.68$ ($p<0.05$, $n=10$). This rapid, instrument-based quantification method by in situ infrared detection may have minimal bias and good power to quantify TH levels in brain tissue. This approach also allows for the identification of multiple targets by IHC with the simultaneous performance of downstream molecular analysis in the same tissue, allowing for reduced animal use per study.

Title: Engineered intrabodies regulate levels of pathogenic alpha-synuclein in Parkinson's Disease models

Authors: *D. CHATTERJEE[1], L. D'BRANT[3], A. MESSER[3], D. BUTLER[3], J. H. KORDOWER[2];
[2]Dept Neurol Sci., [1]Rush Univ. Med. Ctr., Chicago, IL; [3]Regenerative Res. Fdn, Neural Stem Cell Inst., Rensselaer, NY

Abstract: Preventing the intracellular pathological aggregation of the protein alpha-synuclein (α-syn) may be an effective strategy in modifying the progression of synucleinopathies, such as Parkinson's Disease (PD). We have generated nanobody constructs with affinity for aggregation-critical α-syn target epitopes that can be delivered intracellularly (intrabody) as genes via viral vectors. Upon fusion with a negatively-charged proteasomal targeting motif (PEST) that enhances nanobody solubility, anti-α-syn nanobodies function by 1) interfering with target

aggregation regions and 2) mediating α-syn clearance via proteasomal degradation. Here, we report the development of a family of our lead, humanized intrabody construct, VH14-hPEST, for the therapeutic targeting of intracellular α-syn. Using point-mutations at conserved residues critical for PEST interaction with the 19S proteasome cap, we engineered several variants of PEST that modify the efficiency of proteasomal clearance activity. We have generated a family of VH14-hPEST constructs that can reduce total α-syn levels to 60% (VhP), 20-30% (VhP-mid), or <10% (VhP-Low) of control levels. We also generated the VhP-OFF construct that retains α-syn engagement but abolishes intrabody proteasomal interaction. VhP and VhP-Low intrabodies significantly decreased the level of endogenous α-syn expression compared to VhP-OFF when delivered to 3D forebrain organoids generated with iPSCs derived from PD patients with triplications of the α-syn gene (SNCA) ($p=0.0002$), validating engagement in human cells. We aimed to evaluate whether intrabody therapy would protect against neurodegeneration in a progressive rat model of PD. To achieve the broadest CNS distribution of AAV-intrabody therapy, we compared the transduction efficiencies of the engineered viral vector, AAV.PHP.eB (PHP), and its parent serotype, AAV9, when delivered into the cisterna magna of adult rats. PHP achieved vastly superior biodistribution throughout the neuraxis, warranting its use for in vivo experiments. We induced synucleinopathy using injections of α-syn pre-formed fibrils into the striatum of aged rats and delivered intrathecal PHP-VhP and PHP-VhP-Low one month post-lesion. Animals treated with both VhP and VhP-low significantly reduced the number of pathological aggregates in the substantia nigra compared to control-treated animals, confirming effective target engagement in vivo ($p=0.0003$). These data demonstrate the utility of intrabody-mediated regulation of protein levels and highlight the use of this strategy for potential clinical application across numerous neurodegenerative proteinopathies.

Title: Low intensity repetitive transcranial magnetic stimulation in a rodent model of Parkinson`s

Authors: *E. CHUC-MEZA[1], **A. NAZARIO-PALLARES**[2], E. GUARNEROS-BAÑUELOS[2], M. GARCIA-RAMIREZ[1];

Abstract: Repetitive transcranial magnetic stimulation (TMSr) is a cortical stimulation technique that takes advantage of electromagnetic induction to cause neuronal depolarizations. It has been used in the therapy of various psychiatric and neurological conditions, as depression and Parkinson's, respectively. The instruments and protocols reported make use of magnetic field intensities of the order of 2 to 3 Teslas and stimulation frequencies of 4 to 25 Hz. Although these parameters have shown positive effects in the aforementioned conditions, they also have collateral effects such as seizure induction epileptic, hypomania, headaches, neck pain and paresthesia. An alternative is offered by the low intensity TMSr (0.2 to .5 mT and frequencies from 8 to 560 Hz). To evaluate the effect of such a technique on an experimental Parkinson's model, a daily stimulation protocol was tested for 2 months in hemilesioned rats with 6-hydroxydopamine in the medial forebrain bundle. The results demonstrated a significant reduction in the number of turns induced by amphetamine, as well as a reduction in anxiogenesis evaluated with the defensive burial test and a lower number of dead neurons. There were no effects on motor activity or induction of seizures either during or in the treatment-free intervals. Thus, these results would support the use of this type of technique, especially to reduce the non-motor symptoms observed in Parkinson's.

Title: Ketone ester-enriched diet protects against progressive motor dysfunction in MitoPark mice

Authors: *A. G. SALINAS, J. A. NADEL, V. MAHAJAN, M. T. KING, R. L. VEECH, D. M. LOVINGER;
Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD

Abstract: Parkinson’s disease (PD) is a progressive, neurodegenerative disease characterized by motor and non-motor dysfunctions. Its pathology involves a progressive loss of midbrain dopamine neurons (DANs) and converging lines of evidence suggest a central role for mitochondrial dysfunction, and subsequent increases in oxidative stress, in PD etiology. The MitoPark (MP) mouse is a model of PD in which the mitochondrial *tfam* gene is knocked out of DANs. This model recapitulates several aspects of PD, such as the gradual development of motor deficits, responsiveness to L-DOPA, and protein inclusions. Thus, in contrast to other PD models with rapid loss of DANs, the gradual onset of motor dysfunction and DAN degeneration in MP

mice enables the study of potential therapeutic interventions on the preservation of motor function and neurodegeneration. One such strategy involves decreasing the metabolic load on mitochondria by inducing a state of ketosis and thereby providing an alternative energy source for neurons which could decrease neuronal oxidative stress and enhance monoamine synthesis (by increasing tetrahydrobiopterin levels, a critical cofactor for monoamine synthesis). To test this hypothesis, we administered a β-Hydroxybutyrate ketone ester-enriched (KEE) diet or standard rodent chow to control and MP mice beginning at four weeks. At six weeks, we began weekly testing of spontaneous and challenged locomotor activity with open field and rotarod, respectively. We found that MP mice fed standard rodent chow had impaired spontaneous and challenged motor function beginning at 14 weeks, relative to control mice fed either the standard diet or KEE diet. In contrast, MP mice fed the KEE diet did not develop significant motor deficits in either task up to our endpoint of 20 weeks. We also examined ex vivo striatal dopamine release with fast-scan cyclic voltammetry in all groups. Similar to rotarod and open field tests, we found that standard chow-fed MP mice had significantly reduced dopamine release relative to control groups at 20 weeks, and that this reduction was partially ameliorated in MP mice fed the KEE diet. Finally, we assessed the loss of midbrain DANs and striatal dopamine axons via tyrosine hydroxylase immunoreactivity and found that DAN numbers and striatal dopamine axon immunoreactivity were decreased in MP mice relative to WT mice, regardless of which diet they were fed. The most parsimonious explanation of our behavioral, voltammetric, and histological results is that the KEE diet enhances monoamine synthesis in remaining DANs in MP mice. We therefore believe that a ketone ester dietary supplement may be a promising adjunct therapeutic treatment for PD.

Title: Evaluation of Anti-Parkinson’s activity of herbomineral (Abhrak bhasma) on MPTP induced Parkinson’s disease in mice model

Authors: *A. SHANKAR;
Seth GS Med. Col. & KEM Hosp., Mumbai, India

Abstract: Background: The study was designed to validate the claims in Ayurveda regarding the efficacy of Ayurvedic drugs in neurodegenerative disorders. It was decided to conduct an efficacy study of a herbomineral drug (*Abhrak bhasma*) on Parkinson’s disease induced in C57BL/6 mice. Parkinson’s disease has symptom descriptions in Ayurveda and modern medicine. The latter offers only the symptomatic therapy by replacing dopamine, the neurotransmitter involved, but does not slowdown or reverse the loss of dopaminergic neurons.

Method: 8 weeks old male C57BL/6 mice were used for the study. Parkinsons disease was induced by MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine). The dose selected for inducing Parkinsons disease was 20 mg/kg, i.p., twice a day at an interval of 12 hours for four consecutive days. The positive control used was l-Dopa. The test drug used was a herbomineral (*Abhrak bhasma*). The groups in the study were- Healthy normal group, Disease group, Positive control group and Test drug group. The model was for a period of 15 days and MPTP was injected between 07th day to 11th day. L-Dopa and test dug were fed on all 15 days. The disease group was fed with saline. Behaviour tests- Rotarod test, Photoactometer, Paw stride length and Open field test was carried on the 16th day. After carrying out the tests, the mice were sacrificed and striatum was dissected out. One set of striatum were used for Neurotransmitter (Dopamine) and its metabolites (Homovanillic acid and 3,4-Dihydroxyphenylacetic acid) and the other set were used for Immunohistochemistry of Tyrosine hydroxylase neurons. **Result:** Bahaviour studies showed that the test group had a significant improvement in Rotarod test, Open field test, Paw stride length and Open field test. Neurotrasmitter (Dopamine) and its metabolites (Homovanillic acid and 3,4-Dihydroxyphenylacetic acid) levels were improved in the test drug when compared to the disease group. Immunohistochemistry of Tyrosine hydroxylase neurons in Striatum showed a significant protection of neurons in the group fed with the test drug. **Conclusion:** The drug (*Abhrak bhasma*) was found to be effective in reducing the inflammation in the brain of the mice indicating its anti-inflammatory properties. There was a significant improvement in the neurotransmitter levels and immunohistochemistry suggesting that the drug plays a protective role against the MPTP agent.

Title: Evaluation of a neuroprotective PACAP glycopeptide as systemically delivered CNS active drug to treat Parkinson's disease

Authors: K. BERNARD[1], M. J. BARTLETT[1], C. LIU[1], G. MOLNAR[1], C. APOSTOL[1], L. SZABÒ[1], S. J. SHERMAN[1], L. MADHAVAN[2], J. M. STREICHER[3], R. POLT[1], M. L. HEIEN[1], T. FALK[4];
[2]Neurol., [3]Pharmacol., [1]Univ. of Arizona, Tucson, AZ; [4]Dept. Of Neurol., Univ. of Arizona Col. of Med., Tucson, AZ

Abstract: Pituitary adenylate cyclase-activating peptide (PACAP), is an endogenous neuropeptide hormone that has been extensively studied as a protective therapeutic in a variety of

neurodegenerative settings due to its potential for initiating cellular processes that promote survival and inhibit potentially harmful processes such as inflammation. This multi-faceted response to PACAP is due to interactions with PAC1, VPAC1 and VPAC2 receptors. However, despite PACAP's trophic and anti-inflammatory properties, it has not realized its translational potential due to its poor pharmacokinetic profile (non-linear PK/PD), and limited blood-brain barrier (BBB) permeability. We have designed and synthesized a glycosylated PACAP analog ($PACAP_{1\text{-}27}$S-Lac) that is able to stimulate cAMP production *in vitro* using individual CHO cell lines expressing either PAC1, VPAC1, and VPAC2 receptors. Glycosylation stabilizes a peptide normally susceptible to peptidase activity and enhances BBB penetration by favoring the alpha helical conformation of the peptide to increase the probability of membrane interaction, which along with negative membrane curvature promoted by the presence of the sugar residue facilitates transcytosis at endothelial tissues at the BBB. Using *in vivo* microdialysis in rats coupled with LC-MS^3 we show $PACAP_{1\text{-}27}$S-Lac (n=3, 15 mg/kg, *i.v.*) is able to penetrate the BBB. $PACAP_{1\text{-}27}$S-Lac is detected in the striatum at ~376 nM at 60 min, compared to native PACAP with estimated ~41 nM at 60 min. To test for protective ability of the $PACAP_{1\text{-}27}$S-Lac, we began a study using a mild progressive unilateral 6-hydroxydopamine (6-OHDA; 2 x 27.5 µg) rat PD model (n=16/group). In the treatment group rats were injected (*i.p.*) with 15 mg/kg of $PACAP_{1\text{-}27}$S-Lac 6-hrs prior, 48-hrs and 72-hrs post 6-OHDA injection. Analysis of a subset of animals at 4 weeks post-6-OHDA lesion shows that PACAP-treated rats exhibit a trend towards reduced ipsilateral turning behavior (n = 6/group, 27.5 mean turns/100 min in vehicle-treated, compared to -75.53 in PACAP-treated, p=0.0678) in response to the indirect dopamine agonist amphetamine, consistent with reductions in overall parkinsonian lesion size. Unbiased stereology of dopaminergic neurons in the substantia nigra is underway (n=8/group) to evaluate the extent of neuroprotection. Preliminary analysis of a subset of these rats indicates a lesion size of 20% in the PACAP-treated compared to 30% in the vehicle-treated groups. Further video analysis, including the cylinder, vibrissae-elicited forelimb placing, and forelimb adjusting steps tests, will be done to determine the exact extent of neuroprotective activity, if any, that PACAP has.

Title: Striatal GluN2B gene silencing improves motor responses to L-Dopa in hemiparkinsonian rats

Authors: *C. SINON[1], B. KOCHOIAN[1], J. DOOYEMA[1], K. I. PENDERGRAST[1], Y. LI[1], R. HALVERSON[1], S. M. PAPA[2];
[2]Neurol., [1]Emory Univ., Atlanta, GA

Abstract: Introduction: Dopamine (DA) denervation of the striatum in Parkinson's disease (PD) results in profound alterations in striatal projection neuron (SPN) activity. Studies of SPN dysregulation demonstrate a role for glutamate signaling in SPN hyperactivity following DA depletion. DA substitution therapies are associated with long-term efficacy decline and side effects including L-DOPA-induced dyskinesias (LID). Antagonism of NMDAR signaling has shown anti-LID effects, but pharmacological approaches lack specificity for the striatum. We undertook a gene therapy approach to silence the expression of GluN2B subunit gene in SPNs to explore a potential new treatment for PD.
Methods: Rats received nigrostriatal 6-OHDA lesions and injections of rAAV-GluN2B shRNA (n=8) or scrambled shRNA control virus (n=6) in the ipsilateral striatum. Motor deficits were assessed at baseline and 30-minutes after L-DOPA injection. Rats were then given daily injections of L-DOPA/benserazide (8/8 mg/kg i.p.) for 15 days. Abnormal involuntary movement (AIMs) scoring and rotation tests were performed on days 1, 4, 8, 12, & 15.
Results: Rats with 6-OHDA lesion demonstrated a decrease in forehand and backhand adjusting steps, and increased latency to initiate stepping with the contralateral forepaw. On day 16 of chronic L-DOPA treatment, adjusting step test and initiation step test performance was equivalent in both forepaws after LDOPA injection. Additionally, rats that received rAAV-GluN2B shRNA injection in striatum performed more overall steps with the contralateral paw after LDOPA injection than those receiving scrambled shRNA injection. Silencing of GluN2B gene expression in the striatum resulted in an increase in total rotations and significantly reduced AIMs in response to L-Dopa from day 8 to the end of chronic treatment.
Discussion: Our results demonstrate that striatal NMDAR/GluN2B gene silencing in hemiparkinsonian rats effectively reduced AIMs while increasing the antiparkinsonian action of L-Dopa. Therefore, these rodent tests of GluN2B gene therapy showed efficacy for improving motor responses to L-Dopa over long-term treatment, and thereby support further investigation into the potential clinical application of this gene therapy for PD.

Title: Directional basal ganglia evoked potentials for a guided objective deep brain stimulation programming

Authors: *E. OPRI[1], F. ISBAINE[2], N. AU YONG[2], J. T. WILLIE[3], R. E. GROSS[2], S. MIOCINOVIC[1];
[1]Neurol., [2]Neurosurg., Emory Univ. Sch. of Med., Atlanta, GA; [3]Neurosurgery, Neurology, Psychiatry, Neuroscience, and Biomed. Engin., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Deep brain stimulation (DBS) devices require postoperative programming to realize the therapeutic benefit, determining which parameters (e.g. contact combination) provide the best symptomatic benefit and the fewest side effects. This process relies on the skills of the clinician and the patient exam, requiring a time consuming trial and error approach, which has been further exacerbated by the recent introduction of higher contact-density electrodes known as segmented DBS leads. In this study, we provide a proof of concept platform that could be used to objectively guide programming and placement of leads by using DBS local evoked potentials (DLEP) in an intraoperative setup. We have explored DLEP in the subthalamic nucleus (STN) and ventral intermediate nucleus (VIM), using low-frequency (10 Hz) and therapeutic high-frequency (130 Hz) stimulation, and their relationship to the electrode location. We enrolled 14 patients affected by either Parkinson's disease (PD) or essential tremor (ET), implanted with segmented DBS leads. We have developed post processing tools to reliably recover EP activity from commercially available clinical amplifiers (e.g. Neuro Omega), facilitating the deployment in the current surgical process. DLEP activity was recovered after each stimulation pulse by subtracting the modeled DBS artifact. DLEP is a strongly stereotyped oscillatory activity (typical amplitude range of 50-550 μV) with a high signal-to-noise ratio (SNR), which allows single-trial DLEP detection without relying on multi-epoch averages. Our initial results show that DLEP had a consistent difference between STN and VIM targets (absent in the latter). We demonstrate that our post-processing pipeline is sufficient to reliably recover DLEP from noisy recordings which follow a brief saturation recovery of the amplifier. In addition, the recorded DLEP could evaluate the accuracy of STN targeting, as contacts nearer to the motor STN (based on imaging and microelectrode recordings) typically manifested higher DLEPs amplitudes while leads off target showed no DLEPs. Consistently with previous work, we found that DLEP in the STN had a better SNR compared to spontaneous beta band activity. Furthermore, we believe that DLEP can address a few pitfalls of STN beta based lead localization, such as its relative time-domain instability (as the underlying STN beta bursts are not strongly stereotyped) and the difficulty of defining a priori pathological beta amplitude thresholds, center frequency, and bandwidth. In conclusion, we show how this method can be implemented in a data-driven approach to help guide the placement and the initial programming of DBS segmented leads.

Title: TPS (transcranial pulse stimulation) significantly reduces Parkinson's disease symptoms

Authors: *P. NOVAK[1], H. LOHSE-BUSCH[2];
[1]Storz Med. AG, Tägerwilen, Switzerland; [2]Rheintal Klinik, Bad Krotzingen, Germany

Abstract: Background Shockwaves are used in medicine since 1980. First application was for extracorporeal kidney stone disintegration. Meanwhile, low intensity shock waves proofed to be efficient for the treatment of non-unions, tendon and muscular pain, wound healing, heart insufficiency, erectile dysfunction, aesthetics and finally also neurological indications like Alzheimer's disease. The working principle is the mechanical stimulation of biological processes called mechanotransduction resulting in increased cell metabolism, release of nitric oxide (eNO) and of numerous growth factors like VEGF, BMP, TGF-β, GABA, BDNF and GDNF. There is also an anti-inflammatory effect, stimulation of stem cells and of the innate immune system. **Materials and Methods** Transcranial Pulse Stimulation (TPS), former under the term TESWT (Transcranial Extracorporeal Shockwave Therapy) uses shockwave pulses for mechanical stimulation of the brain tissue. Due to the application through the scull, the intensity is significantly reduced: pressure amplitude down to 35% and energy intensity accordingly to approximately 15%. The average power density is less than 0.1W/cm^2. There is no heating effect, no microlesions. Four patients with Parkinson's disease have been treated with TPS in a feasibility study. The treatment was performed with the Neurolith (Storz Medical AG, CE marked) and consisted of 6 approximately 30 minutes sessions within two weeks. 6000 pulses/session and energy flux density of 0.2mJ/mm^2 at 5Hz were applied during each session. Additionally, a maintenance treatment (one session) was applied once per month. **Results** UPDRS, motoric part decreased by more than 50% within the treatment period. UPDRS, all 3 items was reduce by 44%. This positive outcome was maintained by monthly treatment over the time period of over 3 years. There are no negative side effects. Placebo controlled, randomized trial is ongoing. **Conclusions** Parkinson's disease treatment with TPS is safe and effective. Nevertheless, a regular maintenance treatment is necessary in order to maintain the positive outcome of the initial treatment. Further clinical trials with larger number of patients are necessary. The broad scope of shockwave stimulated biological effects in the brain seems to be an interesting and promising extension of the traditional treatment. The Neurolith is fitted with IR based documentation and navigation system using patient's MRI or CT brain images allowing further optimization of the Parkinson's disease treatment.

Title: Optimization of high-cadence cycling parameters to improve motor function in people with Parkinson's disease

Authors: *P. GATES[1], R. MELCZAK[2], A. L. RIDGEL[1];
[1]Exercise Science, Biomed. Sci., [2]Exercise Sci., Kent State Univ., Kent, OH

Abstract: Previous research has shown that dynamic high-cadence cycling can improve motor symptoms of Parkinson's disease (PD) such as tremor and bradykinesia. However, these improvements were not homogenous, with some participants experiencing greater benefits than others. To gain insight into how individual characteristics, bike settings and cycling performance affects functional changes, data from a previous study where individuals with PD rode the dynamic cycle with different resistance settings was used to build several preliminary predictive models. PURPOSE: To examine which variables contribute to greater improvement in symptom scores after one dynamic bike session. We hypothesized that participants who had higher body mass index (BMI), increased age, more severe symptoms, and higher PD medication dosages were less likely to contribute effort during the study. METHODS: Thirteen participants completed three sessions of dynamic biking under three different resistance settings. UPDRS-III was assessed before and after each session and bike settings (cadence, power) were recorded every second. Entropy of cadence was calculated using Matlab and data were analyzed using repeated measures ANOVA and multiple linear regression. RESULTS: There were no significant differences in cadence, entropy of cadence, average power, effort defined as >65% of positive power, or change in UPDRS-III score between the three bike settings. However, there was a high correlation (r^2=-0.62, p=0.01) between effort and BMI, which remained significant (r^2=-0.85, p<0.005) for participants who completed all three sessions within 10 days but not for those who took longer to complete the sessions (r^2=-0.59, p=0.1). There was also a significant difference in the change in UPDRS-III scores between upper and lower body regions (p<0.03), where high effort mitigated positive changes. These findings were used to create a preliminary model explaining variance in effort (R^2 adjusted=0.62, p=0.04). CONCLUSION: Participants characteristics such as pre-UPDRS, age, BMI, and daily medication play a role in the amount of exerted effort during bouts of dynamic cycling. This study suggests that effort during dynamic cycling is significantly affected by intrinsic participant characteristics. Future studies will test and improve on the preliminary model, and will examine techniques to increase effort during a cycling session.

Title: Platform for online neuropsychological testing (PONT)

Authors: ***W. SABAN**[1], R. IVRY[2];
[1]Univ. of California Berkeley, Berkeley, CA; [2]Univ. California, Berkeley, CA

Abstract: A major challenge for neuropsychological research arises from the fact that we are dealing with a precious and limited resource: The patients. Not only is it frequently difficult to identify and recruit individuals appropriate for the question at hand, but their ability to participate in research projects can be limited. As a result, neuropsychological studies typically include small sample sizes (e.g., n=8) and it can take quite a bit of time to complete a single study (e.g., 2 years), let alone a package of studies that might make for a comprehensive story with appropriate controls. As a step towards addressing these issues, we have developed a platform for online neuropsychological testing (PONT). PONT is an online neuropsychological testing protocol that includes five primary steps: 1) Contacting support group leaders to help advertise the project; 2) Having interested individuals initiate contact with us given IRB contact rules; 3) Conducting interactive, remote neuropsychological assessments; 4) Automated administration of the experimental tasks; 5) Obtaining feedback and providing payment. The platform uses a Gorilla interface and is designed to handle a range of experimental protocols (e.g., surveys, reaction time tasks) that can be run on different devices (computer, phone, tablet). To date, we have developed PONT as a tool to accelerate our research program on subcortical contributions to action and cognition, reaching out to Parkinson and ataxia support groups. By contacting approximately 600 support group coordinators, we have recruited around 150 individuals with spinocerebellar ataxia (SCA) and 135 individuals with Parkinson's disease (PD) over the past nine months. We have also completed four experiments testing motor (sequence learning) and cognitive (arithmetic) abilities, with an average of 20 SCA, 20 PD, and 25 matched controls in each experiment. The results demonstrate the feasibility and efficiency of conducting online experiments on people with different neurological disorders. Participants like PONT because they can complete the experiments at home and at a time that fits into their personal schedule. We have encountered some limitations with this approach; for example, it is difficult to handle problems that come up when a participant finds a task too difficult or doesn't understand the instructions. Nonetheless, PONT has great potential to significantly increase the sample size in neuropsychological studies, make data collection much more efficient, and increase the impact

of neuropsychological research. And, of course, this type of research can thrive during the pandemic.

Title: Deep Learning for Differentiating Parameter Configurations of Deep Brain Stimulation for Treating Parkinson's Disease Incorporating Conformal Wearable and Wireless Inertial Sensors as an Evolution for Network Centric Therapy

Authors: *R. C. LEMOYNE[1], T. J. MASTROIANNI[2];
[1]Independent, Running Springs, CA; [2]Cognition Engin., Pittsburgh, PA

Abstract: The application of deep learning offers an advanced opportunity for evolving Network Centric Therapy for the treatment of movement disorders, such as Parkinson's disease. Network Centric Therapy consists of the application of wearable and wireless inertial sensor systems with Internet connectivity to Cloud computing resources. In particular, deep learning is uniquely equipped to differentiate between various parameter configurations for deep brain stimulation. Utilizing a conformal wearable and wireless inertial sensor system with a profile on the order of a bandage, the tremor response to an assortment of deep brain stimulation parameter configuration settings is objectively quantified for a subject with Parkinson's disease. The acquired inertial signal data enables deep learning to achieve considerable classification accuracy with respect to the assortment of deep brain stimulation parameter configuration settings. The results implicate the utility of advanced concept synergy of conformal wearable and wireless inertial sensor systems, Cloud computing, and deep learning for attaining considerable classification accuracy that further realize the potential of Network Centric Therapy. These achievements further evolve the objective of optimizing deep brain stimulation parameter configurations in a real-time and closed-loop context.

Title: Functional correlates of response inhibition in impulse control disorders in Parkinson's disease

Authors: *T. ESTEBAN-PEÑALBA[1], P. M. PAZ-ALONSO[1], I. NAVALPOTRO-GÓMEZ[2], M. C. RODRÍGUEZ-OROZ[3];
[1]BCBL, Donostia-San Sebastián, Spain; [2]Biodonostia, Donostia-San Sebastián, Spain; [3]Clínica Universitaria de Navarra, Pamplona, Spain

Abstract: Background: Impulse control disorder is prevalent in Parkinson's disease (PD) and has a strong negative impact on the quality of life of those affected. Although impulsivity has classically been associated with response inhibition deficits, previous evidence from PD patients with impulse control disorder has not revealed behavioral dysfunction in response inhibition. Here, our objective was to investigate the neural underpinnings of two aspects of inhibitory control: *proactive inhibition,* inhibition that has been prepared beforehand, and *restrained inhibition*, inhibition of an impulse to inhibit.**Methods**: Eighteen PD patients with impulse control disorders, 17 PD patients without the complication, and 15 healthy controls performed a version of the conditional Stop Signal Task during functional magnetic resonance imaging. Whole-brain contrasts, regions of interest, and whole-brain functional connectivity analyses were conducted.**Results**: PD patients with impulse control disorder exhibited bilateral hyperactivation of two areas of the stopping network - inferior frontal gyrus (IFG) and presupplementary motor area - while performing proactive inhibition. When engaged in restrained inhibition, they showed hyperactivation of the left IFG, an area linked to action monitoring. Additionally, restrained inhibition showed changes in the functional coactivation of inhibitory regions with left inferior parietal cortex and the right supramarginal gyrus.**Conclusions**: PD patients with impulse control disorder completed the inhibition task correctly, while showing altered engagement of inhibitory and attentional areas. During proactive inhibition they showed bilateral hyperactivation of two inhibitory regions, while during restrained inhibition they showed additional involvement of attentional areas responsible for alerting and orienting, suggesting PD patients with impulse control disorder deploy additional mechanisms to maintain an adequate inhibitory performance.

Title: AMP PD: Collaborating in the discovery of biomarkers to accelerate the development of therapies for Parkinson's disease

Authors: *C. R. SWANSON-FISCHER[1], E. APPELMANS[2], S. BISWAS[3], M. BOOKMAN[4], D. ALONSO[5], C. WONDERS[1], J. M. WARD[1], D. BABCOCK[1], A. SINGLETON[6,7], H. IWAKI[8], .. AND AMP PD CONSORTIUM[2];
[1]Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD; [2]Fndn. for the Natl. Inst. of Hlth., Bethesda, MD; [3]Bristol Myers Squibb, Seattle, WA; [4]Verily Life Sci., South San Francisco, CA; [5]The Michael J. Fox Fndn. for Parkinson's Res., New York, NY; [6]Lab. of Neurogenetics, [7]Ctr. for Alzheimer's and Related Dementias, Natl. Inst. on Aging, Bethesda, MD; [8]Data Tecnica Intl., Glen Echo, MD

Abstract: Aims: The Accelerating Medicines Partnership in Parkinson's Disease (AMP PD; https://amp-pd.org/) is a public-private partnership between the National Institutes of Health (NIH), the U.S. Food and Drug Administration (FDA), with industry (Celgene, GSK, Pfizer, Sanofi and Verily), non-profit (the Michael J. Fox Foundation; MJFF) organizations and managed by the Foundation of the National Institutes of Health (FNIH). AMP PD aims to identify and validate diagnostic, prognostic, and progression biomarkers to improve clinical trial design and identify pathways for therapeutic development.

Method: The AMP PD research plan encompasses a deep molecular characterization and longitudinal clinical profiling of PD patient data and biosamples with the goal of identifying and validating diagnostic, prognostic and/or disease progression biomarkers for Parkinson's disease (PD). The program includes open sharing of harmonized molecular (e.g. whole genome sequencing and transcriptomics) and clinical data to enable dissection of new targets, disease subtypes, and identification of predictive markers for disease progression and disease prognosis. AMP PD utilizes well-characterized cohorts with existing biosamples and clinical data that are collected under comparable protocols using common data elements. The core cohorts include the MJFF and NINDS BioFIND Study, the Harvard Biomarkers Study (HBS), the NINDS Parkinson's Disease Biomarkers Program (PDBP), and the MJFF Parkinson's Progression Marker Initiative (PPMI). Data from new cohorts, including the International Lewy Body Dementia Genetics Consortium Genome Sequencing in Lewy body dementia case-control cohort, the MJFF LRRK2 Cohort Consortium (LCC), and the Study of Isradipine as a Disease Modifying Agent in Subjects With Early Parkinson Disease, Phase 3 (STEADY-PD3), will be in the AMP PD platform by end of 2020.

Results: The AMP PD Knowledge Platform provides a controlled access mechanism to analyze data for PD biomarker discovery. The clinical diagnosis of participants in Release 1.0 includes 2,005 idiopathic PD patients, 963 healthy controls, 64 prodromal subjects, 62 clinically diagnosed PD subjects without evidence of dopamine deficit, and 705 participants of genetically enriched cohorts with GBA or LRRK2 variants in which 304 were affected (details to be made available on bioRxiv).

Conclusions: The AMP PD cloud-based infrastructure fosters the sharing of tools and data, supports nimble data analysis, decreases storage and compute costs, and facilitates collaboration with the over-arching goal of enabling the discovery of biomarkers for clinical trial design and therapeutic development.

Title: Decreased Dorsal Attention Network grey matter volume associated with persistent working memory impairment in early stage Parkinson's Disease

Authors: *R. ALSAKAJI[1], S. JONES[2,1], N. CHAUDHRY[3,1], O. IBIK[1], K. COLLETTA[1], S. LIVENGOOD[4,1], S. KLETZEL[1];
[1]Edward Hines Jr. VA Hosp., Hines, IL; [2]Adler Univ., Chicago, IL; [3]Biol. Sci., Univ. of Illinois At Chicago, Orland Park, IL; [4]Northwestern Univ., Chicago, IL

Abstract: Background: On average, 1 in 4 individuals diagnosed with Parkinson's disease (PD) will also have mild cognitive impairment (PD-MCI). PD-MCI is a risk factor to dementia. Identifying early biomarkers is essential to advancing treatments to prevent progression of dementia. Cross-sectional studies have identified decrease grey matter volume relative to impairment in various cognitive domains affected in PD. However, performance on cognitive tests can fluctuate overtime in PD patients, questioning whether cognitive impairment is a stable trait of the individual. Identifying grey matter differences in PD patients with persistent, non-fluctuating cognitive impairment may be a better approach to identifying biomarkers of progressive cognitive decline.
Methods: To further explore the relationship between grey matter volume and persistent attention/working memory (WM) impairment, we analyzed anatomical images and cognitive data from the Parkinson's Progressive Marker Initiative (PPMI; www.ppmi-info.org/). PPMI provides longitudinal data collected from early, drug naïve PD patients. This allows for the

characterization of individuals who show persistent or fluctuating cognitive changes over several years. WM was measured using the Letter Number Sequencing (LNS) test. Participants with persistent WM impairment (n= 10) were defined by an LNS standardized test score of 8 or less for 4 consecutive years since baseline imaging. Persistent unimpaired WM (n=10) was defined by an LNS standardized test score of 10 or more for 4 consecutive years since baseline imaging. The two groups were matched on sex, age, years of education, and disease duration. Grey matter volume was measured using voxel-based morphometry (VBM) through SPM12 and CAT12. Region of interest (ROI) analysis, focusing on the dorsal attention network (DAN; Schaeffer et al., 2018 100-parcel atlas), was conducted.
Results: Compared to PD patients with persistent unimpaired WM, those with persistent impaired WM had decreased grey matter density/volume in the bilateral visuomotor cortex (p=0.005), bilateral intraparietal sulcus (p=0.04), and right superior parietal lobule (p=0.021).
Significance: Our results demonstrated a loss of grey matter volume in key regions of the DAN related to persistent impairment in WM performance. The DAN is a critical cognitive network that supports encoding and maintenance of external information. This promising preliminary study warrants further investigation into brain regions that could potentially support targets for cognitive rehabilitation therapies.

Title: Discoidin Domain Receptor 1 alters brain angiogenesis and autophagy: a microRNA sequencing analysis

Authors: *A. J. FOWLER[1], J. AHN[2], F. PAGAN[3], Y. TORRES-YAGHI[3], C. MOUSSA[2]; [1]Georgetown Univ. Med. Ctr., Washington, DC; [2]Georgetown Univ., Washington, DC; [3]MedStar Georgetown Univ. Hosp., Washington, DC

Abstract: We used an adaptive-design clinical trial to evaluate the effects of DDR1 inhibition via Nilotinib on microRNAs in the cerebrospinal fluid Parkinson's patients. Nilotinib is a tyrosine kinase inhibitor that potently and preferentially inhibits (IC_{50} 1nM) Discoidin domain receptors (DDRs) and is FDA-approved for the treatment of chronic myelogenous leukemia (CML) as an inhibitor of c-Abelson (IC_{50} >20nM). We conducted a phase 2 study that enrolled 75 moderately severe Parkinson's patients, who were randomized into a single dose of 100mg,

200mg, 300mg and 400mg nilotinib versus placebo (n=15 per group). These participants were re-randomized into multiple dose of nilotinib, 150mg and 300mg, versus placebo for 12 months (n=25 per group). Following 3 months wash-out, participants were randomized into an open label treatment of nilotinib, 150mg and 300mg for 12 months (n=30-33 per group). Lumbar punctures were performed after a single dose (baseline) and multiple dose at 12 months and the CSF was analyzed using next generation miRNA sequencing. Approximately 2500 miRNA were detected in the CSF. A cross-sectional analysis between treatment groups after a single dose show no differences in miRNA expression. The multiple dose study showed that nilotinib was measured in the CSF in a dose-dependent manner up to (C_{max}) 1.8 nM and 3.4 nM in nilotinib, 150mg and 300mg, respectively, achieving a pharmacologically adequate CSF concentration that would inhibit DDRs. Analysis of longitudinal expression changes between 12-months and baseline detected approximately 140 significantly differentially expressed miRNAs. Gene ontology analysis of the miRNAs in the Nilotinib treated participants show strong regulation of inflammation, blood brain barrier (angiogenesis) and protein clearance via ubiquitination and autophagy. Several miRNA highly correlate with the sum of Unified Parkinson's Disease Rating Scales (UPDRS) II and III at 12 months and can predict clinical outcomes progression at 27 months. These data are in agreement with pre-clinical evidence and suggest that miRNA sequencing in human CSF provides an alternative approach to determine biomarkers based on regulation of pathways that are relevant to neuropathology. Furthermore, this study suggests that data from smaller Phase 2 studies can be used to predict biomarker and clinical outcomes in larger Phase 3 trials.

Title: Linking TBI secondary injuries to FTLD- and ALS-like neurodegeneration

Authors: *G. R. BJORKLUND, J. C. WONG, S. E. STABENFELDT;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: In the United States, approximately 2.8 million traumatic brain injury (TBI) related emergencies were reported annually. These injuries resulted in approximately 2.5 million emergency room visits, 282,000 hospitalizations, and 56,000 deaths placing a tremendous burden on the public health system. A traumatic brain injury (TBI) initiates primary and secondary

damage that may lead to a significantly increased risk for the development of neurodegenerative disorders such as frontotemporal lobar dementia (FTLD) and motor neuron diseases like amyotrophic lateral sclerosis (ALS). Currently there are no standard treatments or cures for TBIs or associated neurodegenerative disorders other than symptomatic treatment and supportive therapies. In this study, our aim is to determine the impact of a unilateral TBI located within the motor cortex on neuronal degeneration spatially distant (forebrain and cervical spinal cord) from the site of injury. Adult male C57BL/6J mice with no genetic predisposition to either ALS or FTLD were subjected to a unilateral controlled cortical impact (CCI) in the primary motor cortex. Tissue sections from the forebrain, hindbrain, and cervical spinal cord were then examined for clinically relevant biomarkers of FTLD and ALS via immunohistochemistry. Specifically, neuronal cells were examined to determine the extent to which TAR DNA Binding Protein 43 (TDP-43) exhibited translocation from the nucleus accompanied by cytosolic accumulation with or without abnormal levels of ubiquitination. These cellular pathologies of TDP-43 are strongly associated with neurodegenerative diseases in humans that include both ALS and FTLD. Time points for the analysis include 7, 14, and 28 days post injury (DPI). Current preliminary results indicate the widespread loss of neuronal nuclear TDP-43 accompanied by an apparent cytosolic aggregation primarily on the ipsilateral side of the injury in both the forebrain and cervical spinal cord. This observation is accompanied by heavy patterns of ubiquitination and is most prominent at 7 DPI. By 28 DPI, a number of neurons appear to have recovered nuclear TDP-43 although cytosolic aggregations of TDP-43 were persistent as compared to uninjured control samples. As TDP-43 aggregation is considered a cornerstone of ALS and is present in the majority of FTLD cases, these early results have shown a possible link between TBIs and the development of FTLD- and ALS-like neurodegenerative diseases.

Title: Basal forebrain cholinergic system resilience to tauopathy in corticobasal degeneration

Authors: *S. R. DUNLOP[1], Y. NISHIHIRA[3], I. AYALA[1], E. BIGIO[2], T. GEFEN[1], M. E. FLANAGAN[2], M. MESULAM[1], C. GEULA[1];

[1]Mesulam Ctr. for Cognitive Neurol. and Alzheimer's Dis. Ctr., [2]Pathology, Northwestern Univ., Chicago, IL; [3]Neurol., Natl. Hosp. Organization Okinawa Hosp., Okinawa, Japan

Abstract: The basal forebrain cholinergic neurons (BFCN) provide the only source of cortical cholinergic innervation and are involved in memory and attention. The BFCN display neurofibrillary tangle (NFT) pathology early in the pathologic cascade of AD. Cholinergic system degeneration in AD is associated with extensive loss of cortical cholinergic axons. There is also a correlation between the NFT in the BFCN and memory scores in aging, MCI and dementia. These features serve as the foundation for cholinergic therapy in AD. The aim of the present study was to investigate the vulnerability of the cholinergic basal forebrain to another tauopathy known as corticobasal degeneration (CBD), which is characterized by accumulation of 4-repeat tau. In a cohort of five autopsied participants, ranging in age at death between 54-71 years (80% male), we quantified BFCN, AT8 phosphorylated tau pathology, and number of cholinergic axons in five cortical regions. BFCN were quantified using hemotoxylin stained histological sections, hyperphosphorylated tau via AT8 immunoreactivity, and cholinergic axons were assessed using acetylcholinesterase histochemical reactivity. Density of cortical cholinergic axons in CBD patricipants was compared with published data from a cohort of cognitively normal and AD participants (Geula et al., Cerebral Cortex, 6:165-177, 1996). The percentage of cholinergic basal forebrain neurons with CBD-related tauopathy ranged from 30 to 71% and was qualitatively ranked as moderate in 4 and severe in 1. Numbers of BFCN remained relatively constant across particpants and showed no correlation with CBD-related AT8 immunoreactivity ($p>0.05$). In fact, we observed the second greatest number of BFCN in the participant with the highest AT8 immunoreactivity in BFCN. The density of cholinergic axons in CBD was not significantly different from normal controls ($p>0.05$). In contrast, the density of these axons was significantly reduced in AD participants when compared with controls ($p<0.005$) or CBD participants ($p<0.03$). The results of the present study demonstrate that different tauopathies have dramatically different effects on the cellular integrity of BCFN. The paired helical filaments of the AD-related tauopathy contain a mixture of 3-repeat and 4-repeat tau and have a profound degenerative effect on the BFCN. In contrast, the CBD-related tauopathy, comprised of 4-repeat tau species, has no such effect. These findings stand to provide new insights into the neurotoxicity of tauopathies and also suggest that, unlike AD, cholinergic therapy is not indicated in CBD.

Title: An in-silico study to identify new biomarkers and therapeutic targets for Progressive Supranuclear Palsy disease

Authors: *J. RIVERA-OSORIO[1], V. MULEY[2], M. CARDENAS-AGUAYO[1];
[1]Physiol., UNAM, Fac. of Med., Ciudad de México, Mexico; [2]Developmental neurobiology and neurophysiology, UNAM, Neurobio. Inst., Juriquilla, Queretaro, Mexico

Abstract: *IIntroduction:* Progressive supranuclear palsy (PSP) is a sporadic, uncommon neurological disorder. It is considered the second most frequent form of atypical parkinsonism. It is characterized by the presence of neurofibrillary tangles in the brainstem, basal ganglia, and cerebellum. Currently, there has not be identified an apparent trigger of this disease, many MAPT mutations related to the inclusion of exon 10 and environmental factors have been reported as significant risk factors, but the molecular mechanisms involved in this disease remains elusive. Approximately 40% of the diagnosed patients are misled with related neurodegenerative diseases, and no specific biomarkers has been discovered. A wide range of bioinformatics tools, and available databases could be used to identify possible diagnostic biomarkers; these tools could help us study dysregulated cellular and molecular processes that could lead us to find new therapeutic targets and possible drug targets. *Methods:* In the present work we used online available transcriptomic profile data of confirmed PSP patients: a GEO2R microarray datasets from blood tissue (GSE34287, GSE6613, and GSE99039); and a microarray dataset from medial temporal lobe (MTL)(E-MEXP-2280). Raw data were processed and normalized in R system packages; differential expression analysis was performed with limma package, differentially expressed genes (DEGs) were selected, and further functional enrichment analysis and KEGGp analysis were conducted with topGO and limma packages. *Results*: In blood data sets enrichment analysis showed an increased dysregulation in gene ontologies and KEGGp related to mRNA processing, metabolic process, apoptosis, inflammatory response, and synaptic process. Besides, in MTL we observed an increased dysregulation expression of genes related to mRNA processing, metabolic process, ROS regulation and synaptic process. *Conclusions*: Our results correlate with the dysregulation of genes related to neuropathophysiological processes, like mitochondrial metabolic genes and apoptosis-related genes. Furthermore, we observe the marked dysregulation of genes involved in mRNA processing in both blood and brain tissue, this agrees with previous reports were RNA splicing and RNA binding proteins could be playing an essential physiopathological role in the progression of some tauopathies. We propose the possibility to evaluate some of these DEGs that changed in the same direction (Upregulated or Downregulated) in blood and brain tissue data sets as a possible diagnostic biomarkers and new therapeutic targets for PSP.

Title: Clinicopathological associations for psychiatric phenotypes across brain regions in chronic traumatic encephalopathy

Authors: *I. MAHAR[1], S. E. CHANCELLOR[1], B. R. HUBER[1], T. D. STEIN[1], V. ALVAREZ[2], A. C. MCKEE[1];
[1]Boston Univ., Boston, MA; [2]Dept. of Veterans Affairs, Boston, MA

Abstract: BACKGROUND
Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease with cognitive, behavioral, and psychiatric symptoms, with depression and suicidality present in a large proportion of pathologically validated CTE cases to date. Pathologically it is defined by a distinctive accumulation of hyperphophorylated tau (pTau) in the frontal and temporal cortex, medial temporal lobe and brainstem. However, the association between pathology in particular brain regions and psychiatric phenotypes in CTE is currently unknown.
METHODS AND RESULTS
Human postmortem brains from CTE cases and controls were obtained from the Veterans Affairs - Boston University - Concussion Legacy Foundation (VA-BU-CLF) Brain Bank (N=320). A team of trained neuropathologists examined each brain (blinded to identity) for gross and microscopic pathology, and provided semi-quantitative assessments. Brain regions of interest were isolated and sectioned as reported previously (Mez et al. 2015 Alzheimers Res Ther 7:62), including frontal, temporal, limbic, and brainstem structures. Sections were stained for pathological markers of interest (e.g. pTau, β-amyloid, α-synuclein, pTDP43, etc). Stained slides were scanned and traced digitally, with staining quantified using a Leica Aperio system. Preliminary analyses suggest that alterations in specific limbic, midbrain, and white matter structures may associate with specific depressive and suicidal phenotypes in CTE. In particular, we have found white matter loss and hippocampal and nigral pathology were increased in depressed cases. We have also found myelination-, gliosis-, and inflammation-associated changes for white matter in the anterior cingulate cortex of depressed CTE cases.
CONCLUSIONS
This ongoing investigation is the first to explore the association between neuropathology in particular brain regions and specific psychiatric phenotypes in CTE. Preliminary results suggest that increased neurodegenerative pathology, loss of white matter, and neuroinflammation could underlie depressive symptoms in CTE. We are currently adding additional cases and markers in order to validate and extend our initial analyses and findings.

Title: Spatio-temporal mapping of 3R and 4R Tau isoforms during mouse brain development using BaseScope™ in situ hybridization technology

Authors: J. SHELDON[1], E. DOOLITTLE[1], H. JARNAGIN[1], N. ZHAVERI[1], B. NYUGEN[1], W. WEI[1], A. DIKSHIT[1], M. QUTAISH[1], B. ZHANG[1], *K. C. BRADLEY[2], X.-J. MA[1]; [1]Bio-Techne, Newark, CA; [2]Bio-Techne, Minneapolis, MN

Abstract: The microtubule-associated protein tau (MAPT) gene encodes a multifunctional protein that is predominantly expressed in neurons where it has a role in microtubule assembly and stability, axonal transport and neurite outgrowth. Neurodegenerative diseases such as Alzheimer's disease are a result of toxic tau aggregates often referred to as tauopathies. Alternative splicing of exon 10 that encodes for the microtubule-binding repeat sequence gives rise to two protein isoforms with either three or four microtubule-binding repeats in the 3R Tau (exon 10 exclusion) and 4R Tau (exon 10 inclusion) splice variant, respectively. The expression of both isoforms is developmentally regulated with each of these isoforms likely to have distinct physiological roles. While both isoforms are balanced in the normal adult brain, this balance or 3R:4R ratio can be skewed in diseased brains like Frontotemporal dementia (FTD). Also, the isoform content of Tau aggregates differs amongst various tauopathies. In order to elucidate the regulatory mechanisms and functional intricacies of Tau isoforms and develop effective Tau-based therapies, there is a critical need to map the spatial and temporal expression patterns of Tau isoforms at a single-cell resolution with the morphological context during brain development and disease progression. Here we report the development of an *in situ* hybridization (ISH) assay for the isoform-specific detection of 3R and 4R Tau mRNA isoforms and their profiles during mouse brain development. The BaseScope ISH technology was employed in this study to detect the alternative splicing of MAPT exon 10 at the single cell level. BaseScope probes were designed to target the exon 9 and exon 10 junction and the exon 9 and exon 11 junction to specifically detect 4R and 3R Tau, respectively. We used transfected cells as a model system to optimize the probe designs to achieve highly specific detection of these highly homologous isoform-specific junctions. These probes were then used to evaluate the neuroanatomic expression of 3R and 4R Tau variants during mouse brain development in postnatal ages P1, P10, P30, and P56 of adult C57Bl/6J mouse. Combining these probes with an antibody for NeuN in an ISH/IHC dual assay, our results revealed a clear opposing dynamic between these two isoforms over the course of development in the cortex and hippocampus regions. To conclude,

the unique BaseScope probe designs used in this study provide a powerful approach to study the spatial and temporal expression patterns of various Tau splice variants in various cell-based and animal models.

Title: Comprehensive gene expression and transcript analysis in post-mortem autopsy-validated progressive supranuclear palsy

Authors: ***H. A. WALSH**[1], R. VIALLE[2], K. FARRELL[1], M. A. IIDA[1], A. CASELLA[1], T. RAJ[1], J. F. CRARY[1];
[1]Pathology and Neurosci., [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Progressive supranuclear palsy (PSP) is a neurodegenerative disease characterized by movement disorder, cognitive impairment, and other symptoms. Neuropathologically, PSP patients display neurofibrillary and gliofibrillary tangles prominently in the substantia nigra, subthalamic nucleus, globus pallidus, neocortex, and other brain regions. Prior studies have demonstrated that sporadic PSP is associated with the 17q21.31 *MAPT* H1 haplotype, but the impact of this complex genetic locus on gene expression remains unclear. Here we examine the transcriptomic changes in post-mortem brain tissue in a novel cohort of PSP cases compared to controls. Next-generation RNA sequencing (RNA-seq) of the transcriptome was performed using the frontal cortex from a cohort of sporadic PSP cases (n = 16) and controls (n = 24) using Illumina HiSeq. These data were aligned using STAR, with library sizes > 30M reads per sample. Transcript quantification was performed using RSEM. Differential gene expression was analyzed using R Bioconductor Package, and visualized with ggplot2. Differential splice junction analysis using Leafcutter, differential transcript usage, and differential transcript expression were performed. Differential expression analysis was repeated in an independent publicly available dataset of PSP cases (n = 84) and controls (n = 80) from two different brain regions. We obtained an average of 38.6 million surviving reads across 40 samples with an average read length of 134 bp. There were 1,576 differentially expressed genes between PSP and control samples ($p < 0.05$, unadjusted). We identified 34 genes differentially spliced between cases and controls, and 10 transcripts were differentially expressed with genome-wide significance ($p < 0.05$, adjusted). Expression analysis was repeated in a publicly available RNA-seq dataset from the cerebellum and temporal cortex. 11 genes were differentially expressed

across all cohorts and brain regions. This included *PANK2*, the gene that causes pantothenate kinase-associated neurodegeneration (PKAN), a progressive neurodegenerative disease affecting regions that are also highly vulnerable in PSP, including the globus pallidus and substantia nigra. Pending further validation, these findings highlight a set of genes that may help elucidate the mechanisms underlying disease risk in PSP and other neurodegenerative disorders.

Title: Clinical features of limbic and subcortical Pick body distribution in behavioral variant Frontotemporal Dementia (bvFTD)

Authors: *R. M. KESZYCKI[1,2], A. KAWLES[1], G. MINOGUE[1], S. JUTHAPAN[1], M. RILEY[1], C. SPENCER[1], J. LILEK[1], I. AYALA[1], R. SHEPARD[1], K. AJROUD[3], A. FELDMAN[3], Q. MAO[3], M. E. FLANAGAN[3], S. WEINTRAUB[1,2], M. M. MESULAM[3], E. BIGIO[3], C. GEULA[1], T. GEFEN[1,2];
[1]Mesulam Ctr. for Cognitive Neurol. & Alzheimer's Dis., Northwestern Univ., Chicago, IL; [2]Dept. of Psychiatry, [3]Dept. of Pathology, Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Introduction: Behavioral variant frontotemporal dementia (bvFTD) is an early-onset dementia syndrome characterized by progressive decline in executive functioning and comportment. Several pathologies may underlie the pattern of bilateral, frontotemporal cortical atrophy typically observed in this syndrome, including Pick's disease ("PiD"), a 3R tauopathy. This study examined the clinical features of bvFTD with PiD. Unbiased stereological counting permitted clinicopathologic correlations between Pick bodies and antemortem features in cortical, limbic, and subcortical brain regions.
Methods: Six right-handed participants with antemortem clinical diagnoses of bvFTD and autopsy confirmed PiD were selected from the Northwestern University Alzheimer's Disease Center brain bank. Twelve neuropsychiatric symptoms (NPS) were assessed longitudinally

(M=1.10 years between visits) with the Neuropsychiatric Inventory—Questionnaire (NPI-Q), an informant-based screener. AT-8 immunostaining identified Pick bodies, which were quantified via unbiased stereological analysis across bilateral middle frontal gyrus (MFG), inferior parietal lobule (IPL), superior temporal gyrus (STG), dentate gyrus (DG) and CA1 region of the hippocampal complex, and unilateral caudate, amygdala, and anterior cingulate cortex (ACC). **Results:** Average age of disease onset was 59.5 years (range, 46-70 years). Mean disease duration was 11.5 years (range, 8-14 years), with average age of death at 71 years (range, 58-82 years). Wilcoxon signed-rank test revealed a significant increase in total NPS from initial visit to final visit before death (p<0.05). Pick body density was highest in DG (M=~71652 per mm^3), followed by caudate (M=~58951per mm^3), then CA1 (M=~42994 per mm^3). Pearson correlations showed a significant, positive correlation between age of onset and Pick bodies in ACC (r = 0.94, p<0.01). Interestingly, densities of Pick bodies in caudate were positively associated with disease duration (r = 0.98, p<0.01); and, though this did not reach statistical significance, Pick body densities in the caudate were also positively related to total NPS observed at final visit prior to death (Kendall's τ = 0.77, p=0.08).
Conclusions: Later disease onset seems to be associated with greater Pick bodies in the ACC. The vulnerability of the caudate to pathology appears to be related to disease duration and the emergence of NPS over time. While frontotemporal cortical atrophy is typically associated with clinical symptoms in bvFTD, this study demonstrates that at the cellular level, Pick bodies in limbic and subcortical brain regions also have significant clinical relevance.

Title: OKN-007 slows down disease progression in the G93A ALS mouse model

Authors: *K. M. PIEKARZ[1,2], D. SAUNDERS[2], R. GULEJ[1], M. ZALLES[2,1], R. TOWNER[2,1], H. VAN REMMEN[2,1,3];
[1]OUHSC, Oklahoma City, OK; [2]OMRF, Oklahoma City, OK; [3]VA, Oklahoma City, OK

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that leads to death of motor neurons (MNs) in the brain and the spinal cord. There are currently four FDA-approved treatments for ALS, however there is still no cure for the disease. In our study, we investigated if treatment with OKN-007, a compound with antioxidant and anti-inflammatory

properties, can modulate ALS onset and progression. We treated female Sod1 G93A mutant mice and wildtype mice with OKN-007 in drinking water starting at 60 days of age and the mice were sacrificed at day 145, before disease end stage. Disease progression was monitored and scored based on hindlimb tremor and progressing hindlimb dysfunction leading to paralysis. Although the treatment did not delay the disease onset (treated G93A mice became symptomatic on day 97 (median), while the untreated G93A mice reach disease onset on day 96 (Mantel-Cox test, $p = 0.19$)), the treatment significantly slowed disease progression. The treated G93A mice reached a score of 2 on day 127.5, while untreated G93A mice progressed to stage 2 on day 113.5 ($p = 0.015$). Strikingly, by 145 days, the treated group had not progressed beyond the score of 2, whereas G93A mice in the untreated group had reached as high as a score of 4 at this age. OKN-007 also prevented α-motor neuron loss. Untreated G93A mice had 10.7 ± 1.9 α-MNs per ventral horn, while the OKN-007-treated G93A mice had 19 ± 4.6 α-MNs, which is comparable to the α-MN counts in WT mice (untreated: 15.9 ± 2.2, treated: 20.2 ± 6.2). OKN-007 treatment did not affect astrocyte proliferation, but significantly reduced microglia proliferation and activation. Moreover, treatment with OKN-007 changed the tissue structure, as the apparent diffusion coefficient (ADC) measured using diffusion-weighted MRI (DWI) was lower in the lumbar spinal cord in OKN-007-treated G93A mice comparing to untreated G93A, indicating higher tissue cellularity, which is consistent with higher α-motor neuron count. Perfusion MRI revealed that the relative tissue blood flow in the spinal cord is lower in control G93A mice than in WT mice, suggesting a decreased vascularization, and the OKN-007 treatment significantly increased the blood flow in the G93A mice. Moreover, the MR spectroscopy data indicates that the level of myo-inositol decreases in control G93A mice, which is indicative of neuroinflammation, and OKN-007 treatment increases the level of this metabolite. Overall, our results suggest that, due to its neuroprotective and anti-inflammatory effect, OKN-007 may be a potential treatment for slowing down ALS progression.

Abstract: Although several genes have been implicated in the pathogenesis of Amyotrophic Lateral Sclerosis (ALS), mutations in these genes account only for a minority of cases, and the etiology of the disease remains to be elucidated. Therefore, understanding the exact pathogenic mechanisms leading to motor neuron loss is crucial for the development of new therapeutic approaches. Several studies demonstrate that alterations in mitochondrial morphology, dynamics and function, a common and early pathogenetic event in neurodegeneration, are also involved in ALS pathogenesis. Accordingly, deficits in bioenergetics and mitochondrial dysfunctions have been described in ALS patient samples as well as in animal and cellular models of the disease. Here, we hypothesized that the accumulation of dynamin-related protein 1 (DRP1), the GTPase involved in mitochondrial fission, and the microtubule binding protein tau may lead to mitochondrial fragmentation and dysfunction. Our findings using a large cohort of post-mortem samples demonstrated a significant decrease in both mitochondria number and length in ALS post-mortem motor cortex (mCTX) as measured by electron microscopy. Furthermore, there was a significant increase in DRP1 and phosphorylated-tau (pTau) in synaptoneuronsomes (SNs) derived from ALS mCTX and co-IP experiments demonstrated that DRP1 interacts with pTau in these samples. Lastly, the treatment of SH-SY5Y cells with ALS SNs, enriched in both pTau and DRP1, induced a significant decrease in mitochondrial length, volume, and networks. Importantly, knocking down DRP1 using a siRNA approach or reducing tau levels by the specific tau degrader, QC-01-175, significantly mitigated alterations in mitochondrial length, volume and networks induced by ALS SNs. Collectively, our results suggest that increases in DRP1 and pTau may cause mitochondria fragmentation in ALS, leading to an unfavorable energetic state. Importantly, targeting this molecular pathway reverses mitochondrial deficits in vitro. ***Acknowledgements.*** *T.P. was supported by an award from the Judith and Jean Pape Adams Charitable Foundation and Byrne Family Endowed Fellowship in ALS Research. Title: Rapid reprogramming method differentiates CuATSM responders/nonresponders from ALS patient population.

Authors: *C. N. DENNYS[1], F. ROUSSEL[1], R. RODRIGO[1], X. ZHANG[1], A. SIERRA DELGADO[1], A. HARTLAUB[1], S. KOLB[2], J. BECKMAN[3], M. FRANCO[3], K. MEYER[1]; [1]Nationwide Children's Hosp., Columbus, OH; [2]Ohio State Univ., Columbus, OH; [3]Oregon State Univ., Corvallis, OR

Abstract: Patient diversity and unknown disease cause are major challenges for drug development and clinical trial design for neurodegenerative diseases. Moreover, the heterogeneity of the Amyotrophic Lateral Sclerosis (ALS) patient population is not reflected in currently available transgenic animal models. Hence, the direct translation of potential therapeutics tested in such models to the clinic has proven difficult. To address this, we utilize direct conversion technology to transform skin biopsies from ALS patients into neuronal progenitor cells (NPC). Using induced astrocytes (iAs) differentiated from these NPCs in co-culture with mouse embryonic motor neurons, we developed an *in vitro* ALS model to screen potential therapeutics. We have screened numerous compounds on multiple sporadic (sALS) and familial (fALS) iAs. Our data indicate a diverse patient response to different therapeutic agents, suggesting shared pathways of interest between patient subgroups. Here we utilize the compound CuATSM, in clinical trial for the treatment of ALS, to investigated its effects on iAstrocyte mediated motor neuron toxicity in both sALS and fALS (mtSOD1 and C9ORF72 patients) lines. We identified responders and nonresponders in co-culture assay for each patient subpopulations. We then performed a detailed analysis of the effects of CuATSM on known ALS disease markers (oxidative stress, mitochondrial dysfunction, elevation of stress response systems). We identified one shared parameter in mitochondrial activity present in all ALS patient CuATSM responders, that was nonexistent in nonresponders. Treatment of iAs with CuATSM restored this activity to healthy control levels. Together these findings suggest that patient iAstrocytes can be used to identify disease modifiers influencing therapeutic response and be sub-grouped based on targetable dysregulated pathways. Moreover, shared pathways amongst patient responders implicated CuATSM as a potential therapeutic strategy for additional disorders. Thus, these results indicate that enhanced understanding of cellular profiles could aid clinicians in determining the best treatment approach for patients in the future.

Title: Dynamic analysis of huntingtin interactomes, normal and diseased, in response to proteotoxic stress

Authors: *J. WEI[1], H. XU[1], E. CAPOBIANCO[2], M. LU[1];
[1]Florida Atlantic Univ., Boca Raton, FL; [2]Univ. of Miami, Miami, FL

Abstract: Huntingtin protein (Htt) is a large protein (~350KDa) whose exact function is unknown. It is generally recognized that Htt is a scaffold protein that forms protein complexes under various physiological conditions. In Huntington's disease (HD), mutant huntingtin (muHtt) is implicated in perturbing protein-protein interactions (PPI) in association with normal Htt. Neurons are selectively venerable to lowered stressor-thresholds in neurodegenerative diseases. We and others have shown that HD cells are more susceptible to cellular stresses. To identify the dynamic interacting partners, for both normal and mutant Htt, in response to cellular stresses, we established an ascorbate peroxidase (APEX2)-based proximity labeling platform to spatiotemporally label Htt-interacting proteins in live cells in order to map the dynamic Htt/muHtt interactome in response to proteotoxic stress by unbiased quantitative proteomic and bioinformatic analyses. Using the human neuroblastoma SH-SY5Y cells line, we first generated stable cell lines expressing Flag-APEX2-Htt23Q, Flag-APEX2-Htt145Q and NES (nucleus export sequence)-APEX2. NES-APEX2 randomly labels cytosolic proteins that are in close proximity with APEX2, thus serves as the reference probe for background proteins identified in Htt samples. The clones were verified for Htt and Flag epitope expression by Western blot and immunostaining using specific antibodies against Htt and Flag, respectively. *In vivo* biotinylation was performed to demonstrate that APEX2-Htt can successfully label Htt-interacting proteins. A known Htt-interacting protein p62 was used for assay validation. Biotinylated proteins were pulled down by streptavidin beads, trypsin-digested and concentrated using ZiptipC18. The resulting samples were subjected to further characterization and analysis using LC-MS/MS. We have identified ~500 proteins from each group without stress treatment. We used the spectral count, defined as the total number of spectra identified for a protein, to semi-quantitively measure protein abundance in different samples. For common proteins present in all three groups, Foldchange was calculated as the ratio of total spectral counts of proteins identified from Flag-APEX2-Htt23Q and Flag-APEX2-Htt145Q to those of NES-APEX2. Proteins with a foldchange above 2 and unique proteins identified in Flag-APEX2-Htt23Q and Flag-APEX2-

Htt145Q samples were selected for further analysis. We will build dynamic interaction networks of Htt/muHtt under various stress conditions which could be the key to understand the molecular pathogenesis of HD.

Abstract: Several modalities aimed at lowering levels of pathogenic mutant HTT (mHTT) are currently in development for the treatment of Huntington's disease. Positive HTT lowering results have been recently shown in clinical trials with the use of antisense oligonucleotides (ASO) targeting HTT mRNA.
Recently, small molecules have been identified targeting HTT mRNA splicing, that result in nonsense mediated decay (NMD) decreasing HTT mRNA and thus lowering HTT protein production. The use of orally bioavailable, brain penetrant small molecules for therapeutic intervention represents a potential advantage over modalities currently in development.
Here we describe the *in vitro* and *in vivo* profile of one such splicing modulator, Compound X. Compound potency was assessed and mutant HTT protein lowering, splicing modulation, mRNA lowering and window over cell toxicity demonstrated. Moreover, Compound X exhibited acceptable ADME properties making it potentially suitable for *in vivo* evaluation. Indeed, *in vivo* PK studies in mice confirmed that Compound X is orally bioavailable and highly brain penetrant, reaching levels in brain tissue that would be expected to generate splicing modulation and HTT lowering.
Sub-chronic oral dosing of Compound X was carried out in the BACHD mouse model, with once daily dosing given for 21 days. After 7-, 14-, and 21-day dosing, tissues and plasma samples were collected at 8 hrs post-dose for assessment of compound concentration, splicing modulation of HTT mRNA and mHTT protein levels. Compound X showed a significant time- and dose-dependent HTT protein reduction in brain, muscle, and liver. In this study, mHTT lowering was

observed to be greater in peripheral tissues compared to brain tissue at all doses and time points. Additionally, detectable level of mHTT protein in plasma was also significantly reduced upon compound treatment.
These data demonstrate that orally dosed splicing modulators targeting HTT mRNA is a feasible therapeutic approach to lowering mHTT protein systemically *in vivo*.

Title: Use of novel cell-based delivery platform for the evaluation of dxCas9 for allele-specific silencing in Huntington's disease

Authors: ***J. J. WALDO**[1], P. DENG[1], J. A. N. M. HALMAI[1], I. VILLEGAS[1], F. K. BUCHANAN[1], J. CARTER[1], C. E. GONZALEZ[1], D. L. CAMERON[1], D. SEGAL[2], J. NOLTA[3], K. FINK[1];

Abstract: Huntington's disease (HD) is a rare, autosomal dominant neurodegenerative disorder caused by a trinucleotide expansion in exon 1 of the Huntingtin gene (HTT), which leads to neuronal dysfunction and cell death. Healthy huntingtin is implicated in axonal trafficking and trophic factor regulation, making targeted allele-specific reduction important. This study aimed to target single nucleotide polymorphisms (SNPs) in HD patient-derived cells to reduce expression of mutant HTT using dxCas9 fused to repressive domains. This study also evaluated a

novel delivery modality harnessing mesenchymal stem cells (MSCs).Heterozygous SNPs near regulatory regions of the Huntingtin promoter were confirmed in HD patient cells, allowing for the design of allele-specific gRNAs. Our novel vector (dxiCas9) containing repressive effector domains allowed for broader PAM site coverage and higher binding specificity compared to spdCas9. dxiCas9 and gRNA plasmids were introduced to an HD patient fibroblast line and knockdown of total HTT transcript levels was assessed to screen for gRNA selection. Knockdown was assessed at multiple loci in the HTT gene and significant downregulation was achieved using several of our gRNAs that were designed to be allele specific. Targeting of rs762855 or rs3856973 resulted in significant downregulation compared to a non-treated control. Interestingly, synergy between multiplexed gRNAs was not observed. A gRNA targeting rs762855 also showed significant downregulation in primary cortical neurons derived from YAC128 mice.Delivery of large proteins into the CNS continues to be a barrier to success when using these gene editing tools. By harnessing the packaging mechanism of a lentivirus, cells can be engineered to secrete large proteins into extracellular vesicles to deliver the protein of interest into recipient cells. MSCs have a strong clinical safety profile and are easily engineered, making them a top candidate for cell-based therapies. This technology has been termed Cell based Nanoengineered X Therapies (Cell NeXT). MSCs were transduced with packaging components and GFP fused to a packaging signal. These MSCs successfully produced NeXT particles containing GFP that were able to infect recipient cells. HEK293T production of NeXT particles containing dxiCas9-KRAB has also shown successful recipient cell infection as a proof of principle. Our current efforts are to assess knockdown of HTT using the Cell NeXT delivery platform as well as assessing the allele-specificity of our gRNAs.These studies support the potential of targeted allele-specific strategies paired with the Cell NeXT non-invasive delivery platforms for CNS disorders.

Abstract: Progressive transcriptional dysregulation in brain is an early and central feature of Huntington's disease (HD) pathogenesis. Using cell and mouse models, we and others have previously demonstrated genome-wide changes in transcription, DNA methylation and histone modification patterns that may underlie transcriptional dysregulation in HD. Thus, targeting epigenetic mechanisms for rescue of aberrant gene expression is a promising therapeutic strategy for HD. Here, we investigate potential therapeutic effects of a histone deacetylase inhibitor (HDACi) targeting selectively HDAC1 and HDAC3 in a mouse model of HD. Using transcriptional profiling and behavioral testing, we found that selective inhibition of HDAC1 and HDAC3 repaired the expression of a number of genes and about half of the gene sets that were dysregulated by mutant Huntingtin expression in the striatum and improved motor skill learning deficit in the R6/1 mice. We also found, by volumetric MRI, a widespread brain atrophy in the R6/1 mice at the symptomatic disease stage, on which the selective HDACi treatment showed a modest effect. Collectively, our combined work presents new evidence for specific HDAC 1 and 3 inhibition as a therapeutic strategy for alleviating the phenotypic and molecular features of HD.

Title: Microglia response to polarizing agents in Huntington's disease and modulatory effects of ganglioside GM1

Authors: *N. STEINBERG[1,2], D. GALLEGUILLOS[1,2], A. ZAIDI[2], S. SIPIONE[1,2];

Abstract: Huntington disease (HD) is a neurodegenerative disease caused by mutation of the *huntingtin* (*HTT*) gene, which results in the production of a protein, mutant HTT, that misfolds and aggregates within brain cells. In addition to the loss of neurons, growing evidence suggests that non-neuronal cells are also affected in HD. Microglia are the immune cells of the brain, that not solely fight pathogens but also play homeostatic roles in brain health. In HD, microglia activation was proposed to occur from early disease stages. However, a broader characterization of HD microglia phenotype is still missing, and the overall extent of microglia dysfunction in the disease onset and progression remains controversial. The aim of our study was to investigate the

response of Q140 primary microglia and human HD macrophages to polarizing agents, including LPS and necrotic cells (M1-like polarization) and IL4/IL13 (M2-like polarization). We also tested whether GM1 - a ganglioside with neuroprotective activity in HD models - affects polarization of HD microglia and macrophages. Measurement of RNA and protein levels for pro-inflammatory cytokines showed that Q140 primary microglia respond to pro-inflammatory stimuli in a similar manner as wild-type (WT) cells. In human HD macrophages, stimulation with IFNγ and LPS resulted in higher transcription of pro-inflammatory genes, but the levels of the corresponding proteins were not significantly different from control cells. Polarization toward M2 state resulted in the transcription of anti-inflammatory cytokines to a similar extent in cells (microglia and macrophages) of both genotypes. In Q140 microglia, however, transcription of the M2 marker Ym-1 was higher than in WT cells. Finally, Q140 and WT microglia showed a similar inflammatory profile upon uptake of necrotic cells. Treatment with GM1 decreased inflammatory responses in HD microglia and macrophages. In the latter, it also increased transcription of M2 markers upon polarization with IL-4. Overall, our studies suggest that the HD mutation does not significantly affect the magnitude of microglia and macrophage response to polarizing factors. This is in contrast with previous studies that have shown increased inflammatory response to LPS. We speculate that the reasons for this discrepancy may rely on differences in experimental conditions and/or initial microglia state. Our data show that GM1 has anti-inflammatory activity and promotes the transcription of anti-inflammatory molecules, at least in HD macrophages. These beneficial effects exerted by GM1 directly on HD microglia might contribute to the neuroprotective activity of the ganglioside in HD models.

Abstract: Gangliosides are glycosphingolipids that participate in cell signaling, cell-cell interactions and modulate immune cell signaling. In Huntington's disease (HD), a protein misfolding neurodegenerative disease caused by the expansion of an N-terminal polyglutamine stretch in the protein huntingtin, levels of ganglioside GM1 are reduced. In mouse models of HD, administration of GM1 is a disease-modifying treatment: it significantly reduces levels of both soluble and aggregated mutant huntingtin (mHTT) in the striatum and cortex of HD mice, and corrects all disease symptoms. We have shown that mHTT-lowering effects of GM1 are independent of *Htt* gene transcription. To uncover neuroprotective pathways elicited by GM1 treatment, we performed an unbiased label-free proteomics screen. Wild-type (WT) or knock-in Q140 HD mice were administered artificial CSF (vehicle) or GM1 for 42 days, by intraventricular infusion. Proteomics analysis of lysates from striata and cortices was performed by Gel-LC-MS/MS. We then performed pairwise comparisons of WT mice treated with CSF (n=9) or GM1 (n=8) and HD mice treated with CSF (n=7) or GM1 (n=11) to identify significant changes in protein levels in the striatum and cortex. In line with the disease-modifying effects observed in GM1-treated mice, a significant proportion of the proteins affected by GM1 was represented by known HTT interactors and/or proteins previously found to be affected in HD. In addition, Gene Ontology cell compartment analysis revealed the extracellular vesicle (EV) compartment was significantly enriched in our datasets, regardless of genotype and tissue. EVs are membrane-enclosed nanoparticles that play roles in cell-cell communication and proteostasis. Using a combination of imaging flow cytometry, fluorometry and immunoblotting, we confirmed that GM1 treatment significantly increases EV secretion from both WT and mHTT-expressing cells. Importantly, GM1 increases the secretion of mHTT via EVs, potentially explaining the mHTT-clearing effect of GM1 treatment *in vivo* and *in vitro*. Altogether, our data suggest that GM1-mediated potentiation of EV secretion may underlie the mHTT-lowering effects we observe in HD mice. Furthermore, our data provide insights into a novel role of ganglioside GM1 in proteostasis and EV secretion with important potential implications for other misfolded protein diseases.

Abstract: Huntington's disease (HD) is a genetically inherited progressive neurodegenerative disease caused by a mutation in the trinucleotide repeats of cytosine, adenine, and guanine (CAG) of the *huntingtin* (*HTT*) gene. The mutation in the *HTT* gene increases the number of CAG repeats, leading to increased production of the huntingtin protein. Healthy individuals typically exhibit 16 to 20 CAG repeats on the *HTT* gene, while those with HD exhibit 35 or greater CAG repeats, with an increase in CAG repeats corresponding to increased severity in HD symptoms, including motor and cognitive declines, personality changes, involuntary movements, weight loss, muscle loss, and a shorter lifespan. The R6/2 mouse model of HD has a mutated gene that exhibits 160 CAG repeats, serving as a severe model of patients with HD. R6/2 mice display similar symptoms to HD patients, such as severe weight loss, muscle loss, deficits in motor function, and reduced lifespan. Individuals with HD show a decrease in GM1 ganglioside levels, severely impacting neurons, and ultimately leading to a shorter lifespan in the affected individual. Treatment of mouse models of HD with bovine-sourced GM1 gangliosides leads to a decrease in disease symptoms. Ovine-sourced GM1 gangliosides are one-fourth the cost and thus may serve as a cost-efficient alternative to bovine-sourced GM1 gangliosides. The aim of this project was to determine the effectiveness of ovine-sourced GM1 ganglioside treatment on R6/2 mouse models by studying survivability and quality of life of the mouse model. The results of our study indicated that HD mice treated with ovine-sourced GM1 ganglioside showed a significant increase in weight over their lifespan, compared to bovine-sourced GM1 ganglioside treated HD mice and the vehicle-treated HD group. Ovine-sourced GM1-treated HD mice had a prolonged lifespan of ten days compared to HD mice treated with bovine-sourced GM1 ganglioside and vehicle-treated HD mice.

Abstract: Huntington's disease (HD) is a genetic autosomal dominant neurodegenerative disease caused by mutations in the *HTT* gene containing a long polyglutamine (CAG) stretch. This leads to excessive production and accumulation of mutant huntingtin protein (mHTT) in the brain. This excessive mHTT protein accumulation causes motor, psychiatric, cognitive impairments and, ultimately, neuronal death. Currently, no effective treatment has been approved for HD. However, a promising line of research in therapeutics for HD, involves the use of GM1 ganglioside, as levels of GM1 are reduced in HD patients, which is thought to contribute to the disease progression. GM1 ganglioside is a sialic acid-containing glycosphingolipid that is found abundantly in the outer leaflet of the neuronal membrane in the brain. The initial source for GM1 came from bovine brains, but new sources, including synthetic as well as those obtained from the bovine brain, have been developed subsequently. Treatments with synthetic- and bovine- sourced gangliosides have been shown to reduce motor dysfunction in HD rodent models. However, the efficacy of treatment using ovine-sourced GM1, which is much more economical, has yet to be tested. The goal of this study was to compare the efficacy of ovine-sourced GM1 with that obtained from bovine sources on the motor and cognitive dysfunctions in the R6/2 mouse model of HD. In the current study, we used intraventricular osmotic pumps to deliver the different-sourced GM1 gangliosides for four weeks in five-weeks-old R6/2 mice. Rotarod-, open field-, catwalk-, Barnes maze- and novel-object-recognition- tasks were used to measure motor and cognitive abilities in the treated and non-treated mice. Results indicated that ovine-sourced GM1 gangliosides significantly reduced behavioral deficits in R6/2 mice on the rotarod-, open field-, catwalk-, but not on Barnes maze-, and novel-object-recognition- tasks, compared to vehicle-treated and bovine-sourced-GM1-treated R6/2mice.

Abstract:
Huntington's disease (HD) is neurodegenerative disease with progressive motor and cognitive impairment caused by a mutation in the HTT gene. The mutation causes abnormal elongation of the polyglutamine (CAG) repeats. This leads to over-production and accumulation of huntingtin protein (mHTT) in the brain. Furthermore, the excessive mHTT protein accumulation causes various impairments in sleep, activity levels, and circadian rhythms, all of which would further impact behavior and quality of life. Currently, no treatment has been approved to help with sleep and activity problems in HD. GM1 ganglioside has significant promise as a potential therapeutic for HD, given that its levels are reduced in HD patients. Treatments with synthetic- and bovine-sourced gangliosides have been conducted with these types of GM1 gangliosides, and no studies have been conducted with the less expensive, ovine-sourced GM1 on the reduction of motor deficits, activity levels, and circadian rhythms in rodent models of HD. The goal of this study was to examine the effect of both ovine-sourced and bovine-sourced GM1 on activity and circadian rhythms in R6/2 and YAC128 mice models of HD. We used intraventricular osmotic pumps for the delivery both sources of GM1 gangliosides for six weeks in 15-month-old YAC128 mice and four weeks treatment for five-week-old R6/2 mice. We monitored the GM1- and vehicle-treated activity levels and circadian rhythms of the mice in an open-field apparatus equipped with infrared light beams. Although no treatments affected the YAC128 mice, the R6/2

mice who were treated with ovine-sourced GM1 tended to be less hypoactive and maintain a more normal circadian rhythmicity than their vehicle-treated and bovine-sourced-GM1-treated counterparts.

Abstract: Huntington's Disease (HD) is a devastating neurodegenerative disorder that clinically manifests as motor dysfunction, cognitive impairment, and psychiatric symptoms. The disease is caused by an expansion of cytosine-adenine-guanine trinucleotide repeats in exon 1 of the huntingtin (HTT) gene. The mutation of HTT forms abnormal aggregates, which affect cellular proteostasis, axonal transport, transcription, translation, as well as mitochondrial and synaptic functions. Medium spiny neurons of the striatum are selectively vulnerable to the HTT gene mutation. Gangliosides are cell membrane components that are important for the survival and functioning of cells. GM1 ganglioside expression is decreased in HD cells and exogenous treatment of GM1 can reduce cell death. However, the effects of GM1 exposure in brain development, such as neural progenitor cell proliferation and differentiation, remains to be elucidated. Here we show that ovine- or bovine-sourced GM1 exposure can modulate proliferation and differentiation in neural progenitor cells (NPCs). Primary cultures of NPCs were obtained at embryonic day 18 from individual embryonic cortices dissected from timed-pregnant YAC 128 mice, which carry the HD transgene. Based on the genetic characteristics, cells were divided into wild and HD groups, which were exposed to ovine- or bovine-sourced GM1 (100, 200, and 400 ng/ml) for 8 days. We found upregulation of differentiating markers, Tuj1 and GFAP in NPCs given bovine or ovine-sourced GM1. Our findings suggest that ovine- or bovine-sourced GM1 may alter cell proliferation and differentiation, and further investigation may provide new insights into the molecular mechanisms of GM1-induced effects on NPCs.

Abstract: Huntington's disease (HD) is an inherited autosomal dominant disease that is caused by a mutation on the huntingtin gene (*HTT*) which is located on the short arm of chromosome 4. Multiple polyglutamine (CAG) repeats lead to the overproduction of mutant huntingtin protein (mHTT). The overproduced mHTT protein accumulates in the nuclei of neuronal cell bodies which causes cell dysfunction and death in the affected brain region(s), most heavily in the caudate nucleus and putamen. HD symptoms are progressive and are characterized by behavioral, cognitive, and motor deficits, especially chorea. Over 50% of HD patients develop type-2 diabetes, which is a metabolic disease that is caused by defective insulin receptor substrate (IRS) proteins. The function of IRS proteins is to monitor glucose levels and signal to/activate beta pancreatic cells to release insulin; but these defective IRS proteins are unable to effectively send signals to the beta pancreatic cells which release the insulin needed to restabilize blood glucose levels. It is hypothesized that the overproduction of mHTT impairs the cells that are responsible for insulin signaling and eventually causes apoptosis of neurons in the affected region of the cortex. The YAC128 mouse model was used to conduct this study. This specific mouse model was used because they show significant striatal degeneration, and increased insulin resistance which mimics the diseased human condition. Liraglutide and HM15211 are GLP-1 analogues, both of which have been proven to restore insulin sensitivity in IRS proteins and demonstrate neuroprotective effects in previous studies. Liraglutide (25 nmol/kg/day) and HM15211 (10 nmol/kg/day) were administered intraperitoneally for 12 weeks in 12-month-old

YAC128 mice. Blood glucose levels were measured once every two weeks throughout the study. It was found that the glucose levels of the liraglutide- and HM15211-treated groups were unaffected. Behavioral assessments using rotarod-, open field-, and water-T-maze -tasks indicated that both liraglutide and HM15211 treatments did not reduce motor behavioral deficits in YAC128 mice on the rotarod or open fields- tasks. However, Liraglutide- and HM15211-treated YAC128 mice showed trends of marginal improvements in cognitive deficits in learning and memory during water-T-maze testing.

Title: In vivo striatal neural activity during motor learning and spontaneous behaviour in Huntington's disease mice

Authors: *E. T. KOCH, M. D. SEPERS, R. YEUNG, L. A. RAYMOND;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Huntington’s disease (HD) is an autosomal dominant neurodegenerative disorder characterized by motor, cognitive and psychiatric deficits. The dorsal striatum is the major site of neurodegeneration in HD, particularly the spiny projection neurons, along with atrophy of other areas including the cortex. The YAC128 and zQ175 mouse models of HD both show progressive deficits in the accelerating rotarod motor learning task as well as changes to locomotor activity in the open field. *In vitro* studies have revealed that YAC128 mice display aberrant cortico-striatal signalling, including changes to glutamate release and deficits in cortico-striatal plasticity. Although there has been extensive research on changes to cortico-striatal signalling *in vitro* in HD models, there has been relatively little research on how these changes to signalling correlate with behavioural deficits *in vivo*. Here, we have combined the accelerating rotarod and open field tasks with GCaMP7f imaging using fiber photometry to correlate activity in striatal neural populations with task performance and motor learning. We are also using machine learning software to analyze behaviour on the rotarod and open field in detailed ways, such as looking at the positioning and kinetics of the paws during rotarod and open field, and identifying the frequency of different behaviours in the open field. In our wild-type mice, we found that as mice learn the rotarod task, the mean GCAMP7f activity in the striatum decreases, as well as mean

peak amplitude of Ca2+ events. Mean GCAMP7f activity was thus negatively correlated with latency to fall on the rotarod task. Early stage 2-3 month old YAC128 mice did not have a deficit on the accelerating rotarod, however the correlation between mean GCAMP7f activity and performance on the rotarod was disrupted in these mice. Overall, early stage YAC128 HD mice show changes to GCAMP7f activity including reduced mean activity levels, and changes to peak kinetics such as frequency, amplitude, and width, during open field and rotarod. This research contributes to our understanding of the changes to striatal signalling that may contribute to motor and cognitive symptoms in HD.

Title: Effects of circadian intervention on sleep and EEG in the BACHD mouse model of Huntington’s disease

Authors: *E. CHIEM, C. GHIANI, C. COLWELL, K. PAUL;
UCLA, Los Angeles, CA

Abstract: Sleep and circadian disturbances are common features of neurodegenerative diseases, such as Huntington’s disease (HD). Since sleep disruptions manifest early in the disease pathogenesis, we examined whether these can serve as early biomarkers for disease. In this study, EEG was used to characterize sleep-wake states and spectral power in the BACHD mouse model of HD. Our findings show that temporal patterning of the sleep-wake cycle is disrupted in BACHD mice. They exhibit more wake during the light phase, and less wake during the dark phase than wildtypes ($F(11,187)=4.374$, $p<0.001$). The diurnal rhythm of NREM sleep was also significantly disrupted ($F(11,187)=4.273$, $p<0.001$). In order to examine sleep homeostatic regulation, mice underwent 6 hrs of sleep deprivation by gentle-handling. There were no significant differences in wake amount ($F(11,154)=1.8$, $p=0.0583$), NREM ($F(11,176)=1.613$, $p=0.0986$), or REM sleep amount ($F(11,176)=1.459$, $p=0.1506$) during recovery from sleep loss. This suggests that the homeostatic regulation of sleep may be preserved in BACHD mice. Next we sought to determine if the BACHD mutation alters EEG spectral power. Examination of the 24-hr rhythm of delta power (0.5-4 Hz) revealed that BACHD mice are unable to dissipate delta power during NREM sleep in the dark phase ($F(11,176=1.854$, $p=0.0484$) at rates similar to wildtype controls. Additionally, BACHD mice exhibit a distinct phase difference and a reduction in the amplitude of gamma (20-40 Hz) power during the 24-hr recording period ($F(11,88)=1.723$, $p=0.0811$). These results suggest that the BACHD mutation is sufficient to cause impairments in the sleep-wake cycle early in disease pathogenesis, and prior to the onset of more severe

behavioral phenotypes. They also suggest that EEG may be a valuable diagnostic tool in revealing and monitoring progression of HD. To explore the therapeutic potential of a circadian-based treatment, we implemented a time-restricted feeding (TRF) protocol (6-hr feeding/18-hr fasting). TRF improved the temporal patterning of wake ($F(11,66)=2.949$, $p=0.0031$), and NREM ($F(11,66)=2.633$, $p=0.0075$) in BACHD mice. Thus, a circadian-based treatment, such as scheduled feeding, may be an effective therapeutic tool to alter the trajectory of disease progression.

Abstract: Huntington’s disease (HD) is a devastating, progressive, neurodegenerative disorder caused by a CAG expansion in the *Huntingtin (HTT)* gene which encodes the widely expressed protein huntingtin. Neuropathologically, HD causes brain atrophy with overt degeneration of medium spiny neurons and to lesser extent cortical pyramidal neurons. We have shown that reduction of mHTT in astrocytes of BACHD mice results in a significant improvement in behavioral phenotypes, brain weight, striatal volume and the expression of synaptic proteins thus suggesting that mHTT expression in astrocytes is critical in HD. In primary astrocyte cultures, we observed increased extracellular glutamate levels after evoking SNARE-dependent exocytosis. An increase in extracellular glutamate levels could lead to excitotoxicity and contribute to behavioral abnormalities. In order to determine whether SNARE-dependent exocytosis from astrocytes contributed to neuropathological changes *in vivo*, we crossed BACHD mice to dominant negative SNARE (dnSNARE) mice and performed behavioral analyses. We observed an improvement in motor coordination, worsening of the anxiety-like phenotype but found no effect on the depressive-like phenotype when astrocytic SNARE-

dependent exocytosis was reduced. In the study presented here, we determined whether SNARE-dependent exocytosis from astrocytes contributes to the neuropathological changes observed in BACHD mice. We analyzed mice at 13-15 months of age when neuropathological changes are present. We did not observe a significant increase in the total brain weight in the BACHD/dnSNARE mice. However, we observed a significant increase in the striatal volume with no significant change observed in the cortical volume when compared to BACHD mice. Our analyses of post-synaptic proteins in the striatum shows that reducing astrocytic SNARE-dependent exocytosis had no effect on the expression of these post-synaptic proteins. Although astrocyte morphology is altered in HD patients and some mHTT expressing mouse models, we did not observe any overt changes in the BACHD mice or BACHD/dnSNARE mice. Thus, the modulation of astrocyte SNARE-dependent exocytosis in BACHD mice is beneficial for striatal volume while not causing overt changes in astrocyte number or morphology. Along with our previous behavioral data, we can conclude that modulating SNARE-dependent exocytosis globally has benefits in motor coordination and striatal volume as well as adverse effects in the anxiety-like phenotype. This work reveals that broadly targeting this cell type is not the most appropriate approach for alleviation of disease relevant phenotypes.

Title: The role of adrenergic transmission in stress-induced cerebellar dysfunction

Authors: ***H. D. SNELL**[1], A. VITENZON[2], J. BRYEN[1], K. KHODAKHAH[3];
[1]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Dept. of Neurol., Duke Univ., Durham, NC; [3]Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. Med., Bronx, NY

Abstract: Stress is the most common trigger among episodic channelopathies, such as periodic paralyses, and Episodic Ataxia. In fact, in some cerebellar disorders, such as many ataxias, dystonias, and tremors, motor symptoms are either triggered, or worsen with stress. The mechanism by which stress elicits or exacerbates these symptoms remains unknown. Episodic ataxia type 2 (EA2) is a channelopathy that arises from mutations in the *CACNA1A* gene encoding for the α1 pore forming subunit of P/Q-type voltage-gated calcium channels. Patients with this disorder exhibit baseline ataxia, and motor attacks in the form of ataxia and dyskinesia, which are brought about by physical or emotional stress, or consumption of caffeine or alcohol.

We used the *tottering* mouse, a faithful animal model of Episodic Ataxia Type 2, to dissect the mechanisms underlying stress-induced motor attacks. Previously, our lab showed a decrease in calcium activated potassium (SK) channel activity in Purkinje cells is the underlying mechanism for the baseline ataxia. Cerebellar Purkinje cells (PCs) are required for the expression of attacks in *tottering* mice. Pharmacologically activating α1 adrenergic receptors in the cerebellum was sufficient to induce attacks, and was required for stress-induced attacks. This receptor can regulate SK channel activity through casein kinase II (CK2), which phosphorylates SK channels decreasing its activity. Using slice electrophysiology, we show that bath application of norepinephrine (NE) increased PCs irregularity from *tottering* and wild type slices. Knock down of casein kinase II (CK2) using shRNAs prevented stress-induced attacks and NE- induced irregularity of *tottering* PCs. Additionally, pharmacologically blocking CK2 with CX-4945, an FDA approved blocker of CK2, prevented stress-induced attacks and NE induced irregularity in PCs. In *tottering* and wild type PC, block of α1 adrenergic receptors attenuated but failed to abolish NE-induced irregularity, suggesting involvement of an additional adrenergic receptor. While the mechanism of action remains unknown, β-adrenergic receptor blockers, such as propranolol, are used to treat stress/anxiety-induced tremor and Essential tremor. Bath application of the β-adrenergic agonist isoproterenol caused an increase in the irregularity of firing of wild type PC that was prevented by blockers of fast synaptic transmission. These data suggest irregular firing of PC could contribute to stress-induced motor disorders through the modulation of cerebellar adrenergic receptors, and offers insight into the mechanism of stress-induced attacks in EA2 and potentially other stress-induced motor disorders.

Abstract: Non-selective antagonists of muscarinic acetylcholine receptors (mAChRs) that broadly inhibit all five mAChR subtypes provide an efficacious treatment for some movement disorders, including Parkinson's disease and dystonia. Despite their efficacy in these and other central nervous system disorders, anti-muscarinic therapy has limited utility due to severe adverse effects that often limit their tolerability by patients. Recent advances in understanding the roles that each mAChR subtype plays in disease pathology suggest that highly selective ligands for individual subtypes may underlie the anti-parkinsonian and anti-dystonic efficacy observed with the use of non-selective anti-muscarinic therapeutics. Our recent work has indicated that the M_4 muscarinic acetylcholine receptor has several important roles in opposing aberrant neurotransmitter release, intracellular signaling pathways, and brain circuits associated with movement disorders. This raises the possibility that selective antagonists of M_4 may recapitulate the efficacy of non-selective anti-muscarinic therapeutics and may decrease or eliminate the adverse effects associated with these non-selective drugs. However, this hypothesis has not been directly tested due to lack of selective antagonists of M_4. Here we utilize genetic mAChR knockout animals in combination with non-selective mAChR antagonists to confirm that the M_4 receptor underlies the locomotor-stimulating and anti-parkinsonian efficacy in rodent models. We also report the synthesis, discovery, and characterization of the first-in-class selective M_4 antagonists VU6013720, VU6021302, and VU6021625. These novel compounds have ideal pharmacokinetic properties for in vivo evaluations, and we have confirmed that these optimized compounds have anti-parkinsonian and anti-dystonic efficacy in pharmacological and genetic models of movement disorders. These data provide critical pre-clinical rationale for the development of M_4 antagonists and represent a potential novel treatment mechanism to meet the unmet clinical need across several movement disorders.

Abstract: The most common form of inherited dystonia is DYT1 dystonia, a form of generalized dystonia caused by a GAG deletion (ΔE) in the *TOR1A* gene. Mouse models of DYT1 dystonia exhibit a profound decrease in striatal dopamine (DA) release. Although dysregulation of vesicular function/trafficking has been suggested, the underlying substrate(s) of reduced striatal DA release in DYT1 dystonia remain unknown. To study potential ultrastructural changes of nigrostriatal DA terminals that could contribute to this reduced striatal DA release in DYT1 dystonia, we used serial electron microscope images generated with a Serial-Block Face/Scanning Electron Microscope (SBF/SEM) and the 3D reconstruction software *Reconstruct* (NIH) to analyze the ultrastructure of striatal tyrosine hydroxylase-immunoreactive (TH+) terminals and their synapses in one wild type (WT) and one DYT1(ΔE) knock-in (KI) mouse. Furthermore, to study possible changes in vesicle packaging capacity of DA, we used transmission electron microscope (TEM) to assess changes in the surface area of synaptic vesicles in striatal DAT-immunoreactive (DAT+) terminals between the WT and the DYT1 KI mouse. Quantitative analysis of 100 fully reconstructed TH+ terminals in the WT (n=50) and DYT1 KI (n=50) mice indicate: 1) The volume of TH+ terminals ranged from 0.1 to 0.8 μm^3 without any major difference in the average terminal volume between WT (0.41+/-0.04 μm^3) and DYT1 KI (0.48 +/-0.03 μm^3) mice. 2) However, when pooled into small-sized (0.1-0.4 μm^3) and large-sized (>0.5μm^3) terminals, the relative proportion of large-sized TH+ terminals were higher in the DYT1 KI mouse than in the WT animal (36% vs 16% of total TH+ terminals, respectively). 3) No major change was found in the proportion of axo-spinous (50% in WT vs 40% in DYT1 KI) vs axo-dendritic (39% in WT vs 38% in DYT1 KI) synapses formed by TH+ terminals between the two mice, but the number (46 in WT vs 26 in DYT1 KI) and surface area (0.014+/-0.002μm^2 in WT vs 0.0084+/-0.002 μm^2 in DYT1 KI) of the postsynaptic densities of axo-spinous synapses were smaller in the DYT1 KI mouse than in control. 4) No significant difference was found in the surface area of synaptic vesicles (250 in WT and 250 in KI mice) in dopaminergic (DAT+) terminals between WT and DYT1 KI mice (487.43 +/- 16.1 nm^2 in WT vs 499.31 +/- 13.7 nm^2 in DYT1 KI) . These ultrastructural data provide a solid foundation for further studies of the synaptic mechanisms that underlie decreased striatal DA release in DYT1 dystonia. Further analyses of a larger sample of terminals from additional animals are needed to confirm these preliminary data.

Title: Exercise acts via BDNF-TrkB signaling to rescue deficits in a mouse model of spinocerebellar ataxia type 6

Authors: *A. A. COOK[1], S. JAYABAL[1,2], K. C. J. SHENG[1], A. J. WATT[1];
[1]Dept. of Biol., McGill Univ., Montreal, QC, Canada; [2]Stanford Univ., Stanford, CA

Abstract: Spinocerebellar ataxia type 6 (SCA6) is a hereditary, progressive ataxia, presenting with mid-life onset of motor coordination difficulties and eventual cerebellar degeneration. We used a knock-in mouse model ($SCA6^{84Q/84Q}$) that carries a CAG expansion mutation in the *CACNA1A* gene to characterise the pathophysiology of SCA6 and identify potential treatments. We have previously shown that at 7 months these mice display deficits in motor coordination, as well as abnormalities in the intrinsic firing patterns of the Purkinje cells in the cerebellum. A 1 month program of voluntary exercise was able to rescue both motor coordination deficits and the frequency of intrinsic Purkinje cell firing. In order to identify the mechanism by which exercise acts therapeutically in the $SCA6^{84Q/84Q}$ model, we investigated brain-derived neurotrophic factor (BDNF) since BDNF levels are reduced in post-mortem brain tissue from SCA6 patients[1] and BDNF administration has been found to delay disease onset in a model of SCA1[2]. We found that $SCA6^{84Q/84Q}$ mice had reduced levels of cerebellar BDNF, but this could be reversed by exercise. To determine whether exercise acts therapeutically in this model via BDNF-TrkB signaling, we administered 7,8-dihydroxyflavone, a small molecule that mimics BDNF as an agonist of the TrkB receptor. Chronic oral administration of 7,8-DHF rescued both motor coordination and Purkinje cell firing frequency deficits in the $SCA6^{84Q/84Q}$ mouse. The beneficial effect on motor coordination was sustained over several months of administration, demonstrating its potential as a long term treatment for SCA6. By identifying a pathway by which exercise exerts its positive effect on cerebellar function, we have identified novel therapeutic strategies for SCA6.

Title: Impaired vestibular reflexes response and vestibulo ocular reflex adaptation in a mouse model of spinocerebellar ataxia type 6

Authors: *H. V. CHANG[1], A. J. WATT[2], K. E. CULLEN[3];
[2]Biol., [1]McGill Univ., Montreal, QC, Canada; [3]Dept. of Biomed. Engin., The Johns Hopkins Univ., Baltimore, MD

Abstract: Spinocerebellar Ataxia Type 6 (SCA6) is a mid-life onset neurodegenerative disease that affects motor coordination. This autosomal dominant disease is caused by the expansion of a CAG repeat tract in a CACNA1A gene that encodes the α1A subunit of the P/Q type voltage-gated Ca^{2+} channel. A hyper-expanded polyglutamine (84Q) mouse model of SCA6 ($SCA6^{84Q/84Q}$), is characterized by impaired locomotive function. Using both *in vitro* and *in vivo* recordings, we have previously shown that, in this same mouse model, the firing precision of cerebellar Purkinje cells in lobule 3, areas of the cerebellum generally associated with locomotion, is significantly reduced (Jayabal et al., 2016). In addition, $SCA6^{84Q/84Q}$ mice showed reduction in complex spike firing rate and increase in the duration of pause after the appearance of complex spikes. Previous studies have demonstrated cell death across the entire cerebellar cortex in SCA6 patients. Given the involvement of cerebellum in generation of and motor learning in the vestibulo ocular reflex (VOR) and optokinetic reflex (OKR), we hypothesized that $SCA6^{84Q/84Q}$ mice would likely show deficits during these oculomotor behaviors. To test this hypothesis and to understand the pathophysiology of SCA6 mice in more detail, we quantified their eye movements to characterize their VOR, OKR, and VOR adaptation. Vestibular rotational stimuli were delivered to a head-restrained mouse at frequencies and velocities spanning the range of those comprising natural behaviors (0.2-2 Hz and 16 deg/s). VOR eye movement responses were measured in both dark and light conditions. OKR were evoked by rotation of visual stimulus at the same frequencies and velocities. For VOR adaptation, gain decrease was induced by presenting visual and vestibular stimuli (2Hz and peak velocity of 16 deg/s) that were at the same speed and exactly in phase. The gain-down training lasted for 30 minutes. Our preliminary data show that $SCA6^{84Q/84Q}$ mice had a significant reduction of VOR gain at 0.8, 1 and 2 Hz and a ~35% reduction of OKR gain without a change in phase compared to litter-matched control WT mice. Additionally, during VOR motor learning, $SCA6^{84Q/84Q}$ mice only showed 16% decrease in VOR gain whereases WT mice showed over 40% VOR gain decrease. Finally, we found that $SCA6^{4Q/84Q}$ mice also generated slower saccades than the control mice. Taken together, our results confirm our original hypothesis that neuronal responses are altered in the floccular lobe of $SCA6^{84Q/84Q}$ mice, a region of the cerebellum known to play a vital role in the calibration of the VOR pathway as well as generation of the optokinetic responses.
